Welcome! This is the documentation for Python 3.3.3rc2, last updated Nov 11, 2013.

Parts of the documentation:

**What's new in Python 3.3?** or all "What's new" documents since 2.0

**Extending and Embedding**

tutorial for C/C++ programmers

**Tutorial**

start here

**Python/C API**

reference for C/C++ programmers

**Library Reference**

keep this under your pillow

**Language Reference**

describes syntax and language elements

**Python Setup and Usage**

how to use Python on different platforms

**Installing Python Modules**

information for installers & sys-admins

**Distributing Python Modules**

sharing modules with others

**FAQs**

frequently asked questions (with answers!)

**Python HOWTOs**

in-depth documents on specific topics

**Indices and tables:**
# Python Module Index

| __future__                  | Future statement definitions |
| __main__                    | The environment where the top-level script is run. |
| _dummy_thread              | Drop-in replacement for the _thread module. |
| _thread                     | Low-level threading API. |

### a
- **abc**: Abstract base classes according to PEP 3119.
- **aifc**: Read and write audio files in AIFF or AIFC format.
- **argparse**: Command-line option and argument parsing library.
- **array**: Space efficient arrays of uniformly typed numeric values.
- **ast**: Abstract Syntax Tree classes and manipulation.
- **asynchat**: Support for asynchronous command/response protocols.
asyncore

A base class for developing asynchronous socket handling services.

atexit

Register and execute cleanup functions.

audioop

Manipulate raw audio data.

---

b

base64

RFC 3548: Base16, Base32, Base64 Data Encodings

bdb

Debugger framework.

binascii

Tools for converting between binary and various ASCII-encoded binary representations.

binhex

Encode and decode files in binhex4 format.

bisect

Array bisection algorithms for binary searching.

builtins

The module that provides the built-in namespace.

bz2

Interfaces for bzip2 compression and decompression.

---

c

calendar

Functions for working with calendars, including some emulation of the Unix cal program.
<table>
<thead>
<tr>
<th>Module</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>cgi</td>
<td>Helpers for running Python scripts via the Common Gateway Interface.</td>

<tr>
<td>dbm.dumb</td>
<td>Portable implementation of the simple DBM interface.</td>
</tr>
<tr>
<td>dbm.gnu (Unix)</td>
<td>GNU's reinterpretation</td>
</tr>
</tbody>
</table>
dbm.ndbm (Unix)  
The standard "database" interface, based on ndbm.

decimal  

difflib  
Helpers for computing differences between objects.

dis  
Disassembler for Python bytecode.

distutils  
Support for building and installing Python modules into an existing Python installation.

distutils.archive_util  
Utility functions for creating archive files (tarballs, zip files, ...)

distutils.bcppcompiler

distutils.ccompiler  
Abstract CCompiler class

distutils.cmd  
This module provides the abstract base class Command. This class is subclassed by the modules in the distutils.command subpackage.

distutils.command  
This subpackage contains one module for each standard Distutils command.

distutils.command.bdist  
Build a binary installer for a package
Build a "dumb" installer
distutils.command.bdist_dumb - a simple archive of files

distutils.command.bdist_msi Build a binary distribution as a Windows MSI file

Abstract base class for packagers

distutils.command.bdist_packager

distutils.command.bdist_rpm Build a binary distribution as a Redhat RPM and SRPM

Build a Windows installer

distutils.command.bdist_wininst

Build all files of a package

distutils.command.build

Build any C libraries in a package

distutils.command.build_clib

Build any extensions in a package

distutils.command.build_ext

Build the .py/.pyc files of a package

distutils.command.build_py

Build the scripts of a package

distutils.command.build_scripts

Check the metadata of a package

distutils.command.check

Clean a package build area

distutils.command.clean

Perform package configuration

distutils.command.config

Install a package

distutils.command.install

Install data files from a package

Install C/C++ header files from a package

distutils.command.install_data

Install library files from a package

distutils.command.install_lib
distutils.command.install_scripts
- Install script files from a package

distutils.command.register
- Register a module with the Python Package Index

distutils.command.sdist
- Build a source distribution

distutils.core
- The core Distutils functionality

distutils.cygwinccompiler
- Provides the debug flag for distutils

distutils.debug
- Utility functions for simple dependency checking

distutils.dep_util
- Utility functions for operating on directories and directory trees

distutils.dir_util
- Provides the Distribution class, which represents the module distribution being built/installed/distributed

distutils.dist
- OS/2 EMX Compiler support

distutils.emxccompiler
- Provides standard exceptions

distutils.errors
- Provides the Extension class, used to describe C/C++ extension modules in setup scripts

distutils.extension
- Additional getopt functionality

distutils.fancy_getopt
- Utility functions for operating on single files

distutils.file_util
distutils.filelist

The FileList class, used for poking about the file system and building lists of files.

distutils.log

A simple logging mechanism, 282-style

distutils.msvccompiler

Microsoft Compiler

distutils.spawn

Provides the spawn() function

distutils.sysconfig

Low-level access to configuration information of the Python interpreter.

distutils.text_file

provides the TextFile class, a simple interface to text files

distutils.unixccompiler

UNIX C Compiler

distutils.util

Miscellaneous other utility functions

distutils.version

implements classes that represent module version numbers.

doctest

Test pieces of code within docstrings.

dummy_threading

Drop-in replacement for the threading module.

e

email

Package supporting the parsing, manipulating, and generating email messages, including MIME documents.

email.charset

Character Sets

e.email.encoders

Encoders for email message payloads.
email.errors

The exception classes used by the email package.

e-mail.generator

Generate flat text email messages from a message structure.

e-mail.header

Representing non-ASCII headers

e-mail.headerregistry

Automatic Parsing of headers based on the field name

e-mail.iterators

Iterate over a message object tree.

e-mail.message

The base class representing email messages.

e-mail.mime

Build MIME messages.

e-mail.parser

Parse flat text email messages to produce a message object structure.

e-mail.policy

Controlling the parsing and generating of messages

e-mail.utils

Miscellaneous email package utilities.

encodings

encodings.idna

Internationalized Domain Names implementation

codings.mbcsc

Windows ANSI codepage

codings.utf_8_sig

UTF-8 codec with BOM signature

errno

Standard errno system symbols.

math

Mathematical functions (sin() etc.).

mimetypes

Mapping of filename extensions to MIME types.

mmap

Interface to memory-mapped files for Unix and Windows.

modulefinder

Find modules used by a script.

msilib (Windows)

Creation of Microsoft Installer files, and CAB files.

msvcrt (Windows)

Miscellaneous useful routines from the MS VC++ runtime.

multiprocessing

Process-based parallelism.

multiprocessing.connection

API for dealing with sockets.

multiprocessing.dummy

Dumb wrapper around threading.

multiprocessing.managers

Share data between process with shared objects.

multiprocessing.pool

Create pools of processes.

multiprocessing.sharedctypes

Allocate ctypes objects from shared memory.

netrc

Loading of .netrc files.

nis (Unix)

Interface to Sun's NIS (Yellow Pages) library.

ntplib

NNTP protocol client

stringprep

**Deprecated:** String preparation, as per RFC 3453

struct

*Interpret bytes as packed binary data.*

subprocess

*Subprocess management.*

sunau

*Provide an interface to the Sun AU sound format.*

symbol

*Constants representing internal nodes of the parse tree.*

symtable

*Interface to the compiler's internal symbol tables.*

sys

*Access system-specific parameters and functions.*

sysconfig

*Python's configuration information*

syslog *(Unix)*

*An interface to the Unix syslog library routines.*

tabnanny

*Tool for detecting white space related problems in Python source files in a directory tree.*

tarfile

*Read and write tar-format archive files.*

telnetlib

*Telnet client class.*

tempfile

*Generate temporary files and directories.*

termios *(Unix)*

*POSIX style tty control.*

test

*Regression tests*
test.support
Support for Python's regression test suite.

textwrap
Text wrapping and filling

threading
Thread-based parallelism.

time
Time access and conversions.

timeit
Measure the execution time of small code snippets.

tkinter
Interface to Tcl/Tk for graphical user interfaces

tkinter.scrolledtext (Tk)
Text widget with a vertical scroll bar.

tkinter.tix
Tk Extension Widgets for Tkinter

tkinter.ttk
Tk themed widget set

token
Constants representing terminal nodes of the parse tree.

tokenize
Lexical scanner for Python source code.

trace
Trace or track Python statement execution.

traceback
Print or retrieve a stack traceback.

tty (Unix)
Utility functions that perform common terminal control operations.

turtle
An educational framework for simple graphics applications

Low-level interface to compression and decompression routines compatible with gzip.
What’s New In Python 3.3

This article explains the new features in Python 3.3, compared to 3.2. Python 3.3 was released on September 29, 2012. For full details, see the changelog.

See also:  PEP 398 - Python 3.3 Release Schedule
Summary – Release highlights

New syntax features:

- New `yield from` expression for *generator delegation*.
- The `u'unicode'` syntax is accepted again for `str` objects.

New library modules:

- `faulthandler` (helps debugging low-level crashes)
- `ipaddress` (high-level objects representing IP addresses and masks)
- `lzma` (compress data using the XZ / LZMA algorithm)
- `unittest.mock` (replace parts of your system under test with mock objects)
- `venv` (Python virtual environments, as in the popular `virtualenv` package)

New built-in features:

- Reworked *I/O exception hierarchy*.

Implementation improvements:

- Rewritten `import machinery` based on `importlib`.
- More compact `unicode strings`.
- More compact `attribute dictionaries`.

Significantly Improved Library Modules:

- C Accelerator for the `decimal` module.
- Better unicode handling in the `email` module *(provisional)*.

Security improvements:
• Hash randomization is switched on by default.

Please read on for a comprehensive list of user-facing changes.
PEP 405: Virtual Environments

Virtual environments help create separate Python setups while sharing a system-wide base install, for ease of maintenance. Virtual environments have their own set of private site packages (i.e. locally-installed libraries), and are optionally segregated from the system-wide site packages. Their concept and implementation are inspired by the popular virtualenv third-party package, but benefit from tighter integration with the interpreter core.

This PEP adds the venv module for programmatic access, and the pyvenv script for command-line access and administration. The Python interpreter checks for a pyvenv.cfg, file whose existence signals the base of a virtual environment’s directory tree.

See also:

PEP 405 - Python Virtual Environments
PEP written by Carl Meyer; implementation by Carl Meyer and Vinay Sajip
PEP 420: Implicit Namespace Packages

Native support for package directories that don't require __init__.py marker files and can automatically span multiple path segments (inspired by various third party approaches to namespace packages, as described in PEP 420)

See also:

PEP 420 - Implicit Namespace Packages
    PEP written by Eric V. Smith; implementation by Eric V. Smith and Barry Warsaw
PEP 3118: New memoryview implementation and buffer protocol documentation

The implementation of PEP 3118 has been significantly improved.

The new memoryview implementation comprehensively fixes all ownership and lifetime issues of dynamically allocated fields in the Py_buffer struct that led to multiple crash reports. Additionally, several functions that crashed or returned incorrect results for non-contiguous or multi-dimensional input have been fixed.

The memoryview object now has a PEP-3118 compliant getbufferproc() that checks the consumer’s request type. Many new features have been added, most of them work in full generality for non-contiguous arrays and arrays with suboffsets.

The documentation has been updated, clearly spelling out responsibilities for both exporters and consumers. Buffer request flags are grouped into basic and compound flags. The memory layout of non-contiguous and multi-dimensional NumPy-style arrays is explained.

Features

- All native single character format specifiers in struct module syntax (optionally prefixed with ‘@’) are now supported.
- With some restrictions, the cast() method allows changing of format and shape of C-contiguous arrays.
- Multi-dimensional list representations are supported for any array type.
Multi-dimensional comparisons are supported for any array type.
One-dimensional memoryviews of hashable (read-only) types with formats B, b or c are now hashable. (Contributed by Antoine Pitrou in issue 13411)
Arbitrary slicing of any 1-D arrays type is supported. For example, it is now possible to reverse a memoryview in O(1) by using a negative step.

API changes

- The maximum number of dimensions is officially limited to 64.
- The representation of empty shape, strides and suboffsets is now an empty tuple instead of None.
- Accessing a memoryview element with format ‘B’ (unsigned bytes) now returns an integer (in accordance with the struct module syntax). For returning a bytes object the view must be cast to ‘c’ first.
- memoryview comparisons now use the logical structure of the operands and compare all array elements by value. All format strings in struct module syntax are supported. Views with unrecognised format strings are still permitted, but will always compare as unequal, regardless of view contents.
- For further changes see Build and C API Changes and Porting C code.

(Contributed by Stefan Krah in issue 10181)

See also: PEP 3118 - Revising the Buffer Protocol
PEP 393: Flexible String Representation

The Unicode string type is changed to support multiple internal representations, depending on the character with the largest Unicode ordinal (1, 2, or 4 bytes) in the represented string. This allows a space-efficient representation in common cases, but gives access to full UCS-4 on all systems. For compatibility with existing APIs, several representations may exist in parallel; over time, this compatibility should be phased out.

On the Python side, there should be no downside to this change.

On the C API side, PEP 393 is fully backward compatible. The legacy API should remain available at least five years. Applications using the legacy API will not fully benefit of the memory reduction, or - worse - may use a bit more memory, because Python may have to maintain two versions of each string (in the legacy format and in the new efficient storage).

Functionality

Changes introduced by PEP 393 are the following:

- Python now always supports the full range of Unicode codepoints, including non-BMP ones (i.e. from U+0000 to U+10FFFF). The distinction between narrow and wide builds no longer exists and Python now behaves like a wide build, even under Windows.
- With the death of narrow builds, the problems specific to narrow builds have also been fixed, for example:
  - `len()` now always returns 1 for non-BMP characters, so `len('\U0010FFFF') == 1`;
  - surrogate pairs are not recombined in string literals, so
indexing or slicing non-BMP characters returns the expected value, so '\U0010FFFF'[0] now returns '\U0010FFFF' and not '\uDBFF';

all other functions in the standard library now correctly handle non-BMP codepoints.

- The value of `sys.maxunicode` is now always 1114111 (0x10FFFF in hexadecimal). The `PyUnicode_GetMax()` function still returns either 0xFFFF or 0x10FFFF for backward compatibility, and it should not be used with the new Unicode API (see issue 13054).
- The `./configure` flag `--with-wide-unicode` has been removed.

Performance and resource usage

The storage of Unicode strings now depends on the highest codepoint in the string:

- pure ASCII and Latin1 strings (U+0000-U+00FF) use 1 byte per codepoint;
- BMP strings (U+0000-U+FFFF) use 2 bytes per codepoint;
- non-BMP strings (U+10000-U+10FFFF) use 4 bytes per codepoint.

The net effect is that for most applications, memory usage of string storage should decrease significantly - especially compared to former wide unicode builds - as, in many cases, strings will be pure ASCII even in international contexts (because many strings store non-human language data, such as XML fragments, HTTP headers, JSON-encoded data, etc.). We also hope that it will, for the same reasons, increase CPU cache efficiency on non-trivial applications. The memory usage of Python 3.3 is two to three times smaller than Python 3.2, and
a little bit better than Python 2.7, on a Django benchmark (see the PEP for details).

**PEP 393 - Flexible String Representation**

PEP written by Martin von Löwis; implementation by Torsten Becker and Martin von Löwis.
PEP 397: Python Launcher for Windows

The Python 3.3 Windows installer now includes a py launcher application that can be used to launch Python applications in a version independent fashion.

This launcher is invoked implicitly when double-clicking *.py files. If only a single Python version is installed on the system, that version will be used to run the file. If multiple versions are installed, the most recent version is used by default, but this can be overridden by including a Unix-style “shebang line” in the Python script.

The launcher can also be used explicitly from the command line as the py application. Running py follows the same version selection rules as implicitly launching scripts, but a more specific version can be selected by passing appropriate arguments (such as -3 to request Python 3 when Python 2 is also installed, or -2.6 to specifically request an earlier Python version when a more recent version is installed).

In addition to the launcher, the Windows installer now includes an option to add the newly installed Python to the system PATH (contributed by Brian Curtin in issue 3561).

PEP written by Mark Hammond and Martin v. Löwis; implementation by Vinay Sajip.

Launcher documentation: *Python Launcher for Windows*

Installer PATH modification: *Finding the Python executable*
PEP 3151: Reworking the OS and IO exception hierarchy

The hierarchy of exceptions raised by operating system errors is now both simplified and finer-grained.

You don't have to worry anymore about choosing the appropriate exception type between OSError, IOError, EnvironmentError, WindowsError, mmap.error, socket.error or select.error. All these exception types are now only one: OSError. The other names are kept as aliases for compatibility reasons.

Also, it is now easier to catch a specific error condition. Instead of inspecting the errno attribute (or args[0]) for a particular constant from the errno module, you can catch the adequate OSError subclass. The available subclasses are the following:

- BlockingIOError
- ChildProcessError
- ConnectionError
- FileExistsError
- FileNotFoundError
- InterruptedError
- IsADirectoryError
- NotADirectoryError
- PermissionError
- ProcessLookupError
- TimeoutError

And the ConnectionError itself has finer-grained subclasses:
• BrokenPipeError
• ConnectionAbortedError
• ConnectionRefusedError
• ConnectionResetError

Thanks to the new exceptions, common usages of the errno can now be avoided. For example, the following code written for Python 3.2:

```python
from errno import ENOENT, EACCES, EPERM

try:
    with open("document.txt") as f:
        content = f.read()
except IOError as err:
    if err.errno == ENOENT:
        print("document.txt file is missing")
    elif err.errno in (EACCES, EPERM):
        print("You are not allowed to read document.
    else:
        raise
```

can now be written without the errno import and without manual inspection of exception attributes:

```python
try:
    with open("document.txt") as f:
        content = f.read()
except FileNotFoundError:
    print("document.txt file is missing")
except PermissionError:
    print("You are not allowed to read document.txt"
```

PEP 3151 - Reworking the OS and IO Exception Hierarchy

PEP written and implemented by Antoine Pitrou
PEP 380: Syntax for Delegating to a Subgenerator

PEP 380 adds the `yield from` expression, allowing a generator to delegate part of its operations to another generator. This allows a section of code containing `yield` to be factored out and placed in another generator. Additionally, the subgenerator is allowed to return with a value, and the value is made available to the delegating generator.

While designed primarily for use in delegating to a subgenerator, the `yield from` expression actually allows delegation to arbitrary subiterators.

For simple iterators, `yield from iterable` is essentially just a shortened form of `for item in iterable: yield item`:

```python
>>> def g(x):
...     yield from range(x, 0, -1)
...     yield from range(x)
...
>>> list(g(5))
[5, 4, 3, 2, 1, 0, 1, 2, 3, 4]
```

However, unlike an ordinary loop, `yield from` allows subgenerators to receive sent and thrown values directly from the calling scope, and return a final value to the outer generator:

```python
>>> def accumulate():
...     tally = 0
...     while 1:
...         next = yield
```
```python
...     if next is None:
...         return tally
...     tally += next
...

>>> def gather_tallies(tallies):
...     while 1:
...         tally = yield from accumulate()
...         tallies.append(tally)
...

>>> tallies = []
>>> acc = gather_tallies(tallies)
>>> next(acc)  # Ensure the accumulator is ready to accept values
>>> for i in range(4):
...     acc.send(i)
...
>>> acc.send(None)  # Finish the first tally
>>> for i in range(5):
...     acc.send(i)
...
>>> acc.send(None)  # Finish the second tally
>>> tallies
[6, 10]
```

The main principle driving this change is to allow even generators that are designed to be used with the `send` and `throw` methods to be split into multiple subgenerators as easily as a single large function can be split into multiple subfunctions.

**PEP 380 - Syntax for Delegating to a Subgenerator**

PEP written by Greg Ewing; implementation by Greg Ewing, integrated into 3.3 by Renaud Blanch, Ryan Kelly and Nick Coghlan; documentation by Zbigniew Jędrzejewski-Szmek and Nick Coghlan
PEP 409: Suppressing exception context

PEP 409 introduces new syntax that allows the display of the chained exception context to be disabled. This allows cleaner error messages in applications that convert between exception types:

```python
>>> class D:
...     def __init__(self, extra):
...         self._extra_attributes = extra
...     def __getattr__(self, attr):
...         try:
...             return self._extra_attributes[attr]
...         except KeyError:
...             raise AttributeError(attr) from None

D({}).x
```

Traceback (most recent call last):
  File "<stdin>", line 1, in <module>
  File "<stdin>", line 8, in __getattr__
AttributeError: x

Without the `from None` suffix to suppress the cause, the original exception would be displayed by default:

```python
>>> class C:
...     def __init__(self, extra):
...         self._extra_attributes = extra
...     def __getattr__(self, attr):
...         try:
...             return self._extra_attributes[attr]
...         except KeyError:
...             raise AttributeError(attr)

C({}).x
```
Traceback (most recent call last):
  File "<stdin>", line 6, in __getattr__
  KeyError: 'x'

During handling of the above exception, another exception occurred:

Traceback (most recent call last):
  File "<stdin>", line 1, in <module>
  File "<stdin>", line 8, in __getattr__
  AttributeError: x

No debugging capability is lost, as the original exception context remains available if needed (for example, if an intervening library has incorrectly suppressed valuable underlying details):

```python
>>> try:
...     D({}).x
... except AttributeError as exc:
...     print(repr(exc.__context__))
...  
KeyError('x',)
```

See also:

**PEP 409 - Suppressing exception context**
  
  PEP written by Ethan Furman; implemented by Ethan Furman and Nick Coghlan.
PEP 414: Explicit Unicode literals

To ease the transition from Python 2 for Unicode aware Python applications that make heavy use of Unicode literals, Python 3.3 once again supports the “u” prefix for string literals. This prefix has no semantic significance in Python 3, it is provided solely to reduce the number of purely mechanical changes in migrating to Python 3, making it easier for developers to focus on the more significant semantic changes (such as the stricter default separation of binary and text data).

See also:

PEP 414 - Explicit Unicode literals
PEP written by Armin Ronacher.
PEP 3155: Qualified name for classes and functions

Functions and class objects have a new \_
___qualname\_
___ attribute representing the “path” from the module top-level to their definition. For global functions and classes, this is the same as \_
___name\_
___. For other functions and classes, it provides better information about where they were actually defined, and how they might be accessible from the global scope.

Example with (non-bound) methods:

```
>>> class C:
...    def meth(self):
...        pass

>>> C.meth.__name__
'meth'
>>> C.meth.__qualname__
'C.meth'
```

Example with nested classes:

```
>>> class C:
...    class D:
...        def meth(self):
...            pass
...

>>> C.D.__name__
'D'
>>> C.D.__qualname__
'C.D'
>>> C.D.meth.__name__
'meth'
>>> C.D.meth.__qualname__
```
Example with nested functions:

```python
>>> def outer():
...     def inner():
...         pass
...     return inner
...
>>> outer().__name__
'inner'
>>> outer().__qualname__
'outer.<locals>.inner'
```

The string representation of those objects is also changed to include the new, more precise information:

```python
>>> str(C.D)
"<class '__main__.C.D'>"
>>> str(C.D.meth)
'<function C.D.meth at 0x7f46b9fe31e0>'
```

See also:

**PEP 3155 - Qualified name for classes and functions**

PEP written and implemented by Antoine Pitrou.
PEP 412: Key-Sharing Dictionary

Dictionaries used for the storage of objects’ attributes are now able to share part of their internal storage between each other (namely, the part which stores the keys and their respective hashes). This reduces the memory consumption of programs creating many instances of non-built-in types.

See also:

PEP 412 - Key-Sharing Dictionary
  PEP written and implemented by Mark Shannon.
PEP 362: Function Signature Object

A new function `inspect.signature()` makes introspection of python callables easy and straightforward. A broad range of callables is supported: python functions, decorated or not, classes, and `functools.partial()` objects. New classes `inspect.Signature`, `inspect.Parameter` and `inspect.BoundArguments` hold information about the call signatures, such as, annotations, default values, parameters kinds, and bound arguments, which considerably simplifies writing decorators and any code that validates or amends calling signatures or arguments.

See also:

PEP 362: - Function Signature Object

PEP written by Brett Cannon, Yury Selivanov, Larry Hastings, Jiwon Seo; implemented by Yury Selivanov.
PEP 421: Adding sys.implementation

A new attribute on the `sys` module exposes details specific to the implementation of the currently running interpreter. The initial set of attributes on `sys.implementation` are `name`, `version`, `hexversion`, and `cache_tag`.

The intention of `sys.implementation` is to consolidate into one namespace the implementation-specific data used by the standard library. This allows different Python implementations to share a single standard library code base much more easily. In its initial state, `sys.implementation` holds only a small portion of the implementation-specific data. Over time that ratio will shift in order to make the standard library more portable.

One example of improved standard library portability is `cache_tag`. As of Python 3.3, `sys.implementation.cache_tag` is used by `importlib` to support PEP 3147 compliance. Any Python implementation that uses `importlib` for its built-in import system may use `cache_tag` to control the caching behavior for modules.

SimpleNamespace

The implementation of `sys.implementation` also introduces a new type to Python: `types.SimpleNamespace`. In contrast to a mapping-based namespace, like `dict`, `SimpleNamespace` is attribute-based, like `object`. However, unlike `object`, `SimpleNamespace` instances are writable. This means that you can add, remove, and modify the namespace through normal attribute access.
See also:

**PEP 421** - Adding `sys.implementation`

PEP written and implemented by Eric Snow.
Using importlib as the Implementation of Import

issue 2377 - Replace __import__ w/ importlib.__import__ issue 13959
- Re-implement parts of imp in pure Python issue 14605 - Make import machinery explicit issue 14646 - Require loaders set __loader__ and __package__

The __import__() function is now powered by importlib.__import__(). This work leads to the completion of “phase 2” of PEP 302. There are multiple benefits to this change. First, it has allowed for more of the machinery powering import to be exposed instead of being implicit and hidden within the C code. It also provides a single implementation for all Python VMs supporting Python 3.3 to use, helping to end any VM-specific deviations in import semantics. And finally it eases the maintenance of import, allowing for future growth to occur.

For the common user, there should be no visible change in semantics. For those whose code currently manipulates import or calls import programmatically, the code changes that might possibly be required are covered in the Porting Python code section of this document.

New APIs

One of the large benefits of this work is the exposure of what goes into making the import statement work. That means the various importers that were once implicit are now fully exposed as part of the importlib package.

The abstract base classes defined in importlib.abc have been
expanded to properly delineate between *meta path finders* and *path entry finders* by introducing `importlib.abc.MetaPathFinder` and `importlib.abc.PathEntryFinder`, respectively. The old ABC of `importlib.abc.Finder` is now only provided for backwards-compatibility and does not enforce any method requirements.

In terms of finders, `importlib.machinery.FileFinder` exposes the mechanism used to search for source and bytecode files of a module. Previously this class was an implicit member of `sys.path_hooks`.

For loaders, the new abstract base class `importlib.abc.FileLoader` helps write a loader that uses the file system as the storage mechanism for a module's code. The loader for source files (`importlib.machinery.SourceFileLoader`), sourceless bytecode files (`importlib.machinery.SourcelessFileLoader`), and extension modules (`importlib.machinery.ExtensionFileLoader`) are now available for direct use.

`ImportError` now has `name` and `path` attributes which are set when there is relevant data to provide. The message for failed imports will also provide the full name of the module now instead of just the tail end of the module's name.

The `importlib.invalidate_caches()` function will now call the method with the same name on all finders cached in `sys.path_importer_cache` to help clean up any stored state as necessary.

**Visible Changes**
For potential required changes to code, see the Porting Python code section.

Beyond the expanse of what `importlib` now exposes, there are other visible changes to import. The biggest is that `sys.meta_path` and `sys.path_hooks` now store all of the meta path finders and path entry hooks used by import. Previously the finders were implicit and hidden within the C code of import instead of being directly exposed. This means that one can now easily remove or change the order of the various finders to fit one’s needs.

Another change is that all modules have a `__loader__` attribute, storing the loader used to create the module. PEP 302 has been updated to make this attribute mandatory for loaders to implement, so in the future once 3rd-party loaders have been updated people will be able to rely on the existence of the attribute. Until such time, though, import is setting the module post-load.

Loaders are also now expected to set the `__package__` attribute from PEP 366. Once again, import itself is already setting this on all loaders from `importlib` and import itself is setting the attribute post-load.

None is now inserted into `sys.path_importer_cache` when no finder can be found on `sys.path_hooks`. Since `imp.NullImporter` is not directly exposed on `sys.path_hooks` it could no longer be relied upon to always be available to use as a value representing no finder found.

All other changes relate to semantic changes which should be taken into consideration when updating code for Python 3.3, and thus should be read about in the Porting Python code section of this document.
Other Language Changes

Some smaller changes made to the core Python language are:

- Added support for Unicode name aliases and named sequences. Both `unicodedata.lookup()` and `\N{...}` now resolve name aliases, and `unicodedata.lookup()` resolves named sequences too.

  (Contributed by Ezio Melotti in issue 12753)

- Unicode database updated to UCD version 6.1.0

- Equality comparisons on `range()` objects now return a result reflecting the equality of the underlying sequences generated by those range objects. (issue 13201)

- The `count()`, `find()`, `rfind()`, `index()`, and `rindex()` methods of `bytes` and `bytearray` objects now accept an integer between 0 and 255 as their first argument.

  (Contributed by Petri Lehtinen in issue 12170)

- The `rjust()`, `ljust()`, and `center()` methods of `bytes` and `bytearray` now accept a `bytearray` for the `fill` argument. (Contributed by Petri Lehtinen in issue 12380.)

- New methods have been added to `list` and `bytearray`: `copy()` and `clear()` (issue 10516). Consequently, `MutableSequence` now also defines a `clear()` method (issue 11388).

- Raw bytes literals can now be written `rb"..."` as well as
dict.setdefault() now does only one lookup for the given key, making it atomic when used with built-in types.

(Contributed by Filip Gruszczynski in issue 13521.)

The error messages produced when a function call does not match the function signature have been significantly improved.

(Contributed by Benjamin Peterson.)
A Finer-Grained Import Lock

Previous versions of CPython have always relied on a global import lock. This led to unexpected annoyances, such as deadlocks when importing a module would trigger code execution in a different thread as a side-effect. Clumsy workarounds were sometimes employed, such as the `PyImport_ImportModuleNoBlock()` C API function.

In Python 3.3, importing a module takes a per-module lock. This correctly serializes importation of a given module from multiple threads (preventing the exposure of incompletely initialized modules), while eliminating the aforementioned annoyances.

(Contributed by Antoine Pitrou in issue 9260.)
Built-in functions and types

- **open()**: gets a new *opener* parameter: the underlying file descriptor for the file object is then obtained by calling *opener* with *(file, flags)*. It can be used to use custom flags like *os.O_CLOEXEC* for example. The "x" mode was added: open for exclusive creation, failing if the file already exists.

- **print()**: added the *flush* keyword argument. If the *flush* keyword argument is true, the stream is forcibly flushed.

- **hash()**: hash randomization is enabled by default, see *object.__hash__()* and *PYTHONHASHSEED*.

- The *str* type gets a new *casefold()* method: return a casefolded copy of the string, casefolded strings may be used for caseless matching. For example, "ß".casefold() returns "ss".

- The sequence documentation has been substantially rewritten to better explain the binary/text sequence distinction and to provide specific documentation sections for the individual built-in sequence types (*issue 4966*)
New Modules

faulthandler

This new debug module faulthandler contains functions to dump Python tracebacks explicitly, on a fault (a crash like a segmentation fault), after a timeout, or on a user signal. Call faulthandler.enable() to install fault handlers for the SIGSEGV, SIGFPE, SIGABRT, SIGBUS, and SIGILL signals. You can also enable them at startup by setting the PYTHONFAULTHANDLER environment variable or by using -X faulthandler command line option.

Example of a segmentation fault on Linux:

$ python -q -X faulthandler
>>> import ctypes
>>> ctypes.string_at(0)
Fatal Python error: Segmentation fault

Current thread 0x00007fb899f39700:
  File "/home/python/cpython/Lib/ctypes/__init__.py", line 486 in string_at
  File "<stdin>", line 1 in <module>
Segmentation fault

ipaddress

The new ipaddress module provides tools for creating and manipulating objects representing IPv4 and IPv6 addresses, networks and interfaces (i.e. an IP address associated with a specific IP subnet).

(Contributed by Google and Peter Moody in PEP 3144)
lzma

The newly-added **lzma** module provides data compression and decompression using the LZMA algorithm, including support for the `.xz` and `.lzma` file formats.

(Contributed by Nadeem Vawda and Per Øyvind Karlsen in issue 6715)
Improved Modules

abc

Improved support for abstract base classes containing descriptors composed with abstract methods. The recommended approach to declaring abstract descriptors is now to provide `__isabstractmethod__` as a dynamically updated property. The built-in descriptors have been updated accordingly.

- `abc.abstractproperty` has been deprecated, use `property` with `abc.abstractmethod()` instead.
- `abc.abstractclassmethod` has been deprecated, use `classmethod` with `abc.abstractmethod()` instead.
- `abc.abstractstaticmethod` has been deprecated, use `staticmethod` with `abc.abstractmethod()` instead.

(Contributed by Darren Dale in issue 11610)

`abc.ABCMeta.register()` now returns the registered subclass, which means it can now be used as a class decorator (issue 10868).

array

The `array` module supports the `long` `long` type using `Q` and `Q` type codes.

(Contributed by Oren Tirosh and Hirokazu Yamamoto in issue 1172711)

base64
ASCII-only Unicode strings are now accepted by the decoding functions of the `base64` modern interface. For example, `base64.b64decode('YWJj')` returns `b'abc'`. (Contributed by Catalin Iacob in issue 13641.)

**binascii**

In addition to the binary objects they normally accept, the `a2b_` functions now all also accept ASCII-only strings as input. (Contributed by Antoine Pitrou in issue 13637.)

**bz2**

The `bz2` module has been rewritten from scratch. In the process, several new features have been added:

- New `bz2.open()` function: open a bzip2-compressed file in binary or text mode.

- `bz2.BZ2File` can now read from and write to arbitrary file-like objects, by means of its constructor's `fileobj` argument.

  (Contributed by Nadeem Vawda in issue 5863)

- `bz2.BZ2File` and `bz2.decompress()` can now decompress multi-stream inputs (such as those produced by the `pbzip2` tool). `bz2.BZ2File` can now also be used to create this type of file, using the `'a'` (append) mode.

  (Contributed by Nir Aides in issue 1625)

- `bz2.BZ2File` now implements all of the `io.BufferedIOBase`
API, except for the detach() and truncate() methods.

codecs

The mbcs codec has been rewritten to handle correctly replace and ignore error handlers on all Windows versions. The mbcs codec now supports all error handlers, instead of only replace to encode and ignore to decode.

A new Windows-only codec has been added: cp65001 (issue 13216). It is the Windows code page 65001 (Windows UTF-8, CP_UTF8). For example, it is used by sys.stdout if the console output code page is set to cp65001 (e.g., using chcp 65001 command).

Multibyte CJK decoders now resynchronize faster. They only ignore the first byte of an invalid byte sequence. For example, b'\xff\n'.decode('gb2312', 'replace') now returns a \n after the replacement character.

(issue 12016)

Incremental CJK codec encoders are no longer reset at each call to their encode() methods. For example:

```
$ ./python -q
>>> import codecs
>>> encoder = codecs.getincrementalencoder('hz')('strict')
>>> b''.join(encoder.encode(x) for x in '\u52ff\u65bd\u65bc\u4eba\nBye."

Bye.{'NpJ}~{J}~{16}~{HK}~{!#}'} with older Python versions.
```
The `unicode_internal` codec has been deprecated.

**collections**

Addition of a new `ChainMap` class to allow treating a number of mappings as a single unit. (Written by Raymond Hettinger for issue 11089, made public in issue 11297)

The abstract base classes have been moved in a new `collections.abc` module, to better differentiate between the abstract and the concrete collections classes. Aliases for ABCs are still present in the `collections` module to preserve existing imports. (issue 11085)

The `Counter` class now supports the unary `+` and `-` operators, as well as the in-place operators `+=`, `-=``, `|=`, and `&=`. (Contributed by Raymond Hettinger in issue 13121.)

**contextlib**

`ExitStack` now provides a solid foundation for programmatic manipulation of context managers and similar cleanup functionality. Unlike the previous `contextlib.nested` API (which was deprecated and removed), the new API is designed to work correctly regardless of whether context managers acquire their resources in their `__init__` method (for example, file objects) or in their `__enter__` method (for example, synchronisation objects from the `threading` module).

(issue 13585)
crypt

Addition of salt and modular crypt format (hashing method) and the `mksalt()` function to the `crypt` module.

(issue 10924)

curses

- If the `curses` module is linked to the ncursesw library, use Unicode functions when Unicode strings or characters are passed (e.g. `waddwstr()`), and bytes functions otherwise (e.g. `waddstr()`).
- Use the locale encoding instead of `utf-8` to encode Unicode strings.
- `curses.window` has a new `curses.window.encoding` attribute.
- The `curses.window` class has a new `get_wch()` method to get a wide character
- The `curses` module has a new `unget_wch()` function to push a wide character so the next `get_wch()` will return it

(Contributed by Iñigo Serna in issue 6755)

datetime

- Equality comparisons between naive and aware `datetime` instances now return `False` instead of raising `TypeError` (issue 15006).
- New `datetime.datetime.timestamp()` method: Return POSIX timestamp corresponding to the `datetime` instance.
- The `datetime.datetime.strftime()` method supports
The `datetime.datetime.astimezone()` method can now be called without arguments to convert datetime instance to the system timezone.

**decimal**

**issue 7652** - integrate fast native decimal arithmetic. C-module and libmpdec written by Stefan Krah.

The new C version of the decimal module integrates the high speed libmpdec library for arbitrary precision correctly-rounded decimal floating point arithmetic. libmpdec conforms to IBM's General Decimal Arithmetic Specification.

Performance gains range from 10x for database applications to 100x for numerically intensive applications. These numbers are expected gains for standard precisions used in decimal floating point arithmetic. Since the precision is user configurable, the exact figures may vary. For example, in integer bignum arithmetic the differences can be significantly higher.

The following table is meant as an illustration. Benchmarks are available at [http://www.bytereef.org/mpdecimal/quickstart.html](http://www.bytereef.org/mpdecimal/quickstart.html).

Features
- The **FloatOperation** signal optionally enables stricter semantics for mixing floats and Decimals.
- If Python is compiled without threads, the C version automatically disables the expensive thread local context machinery. In this case, the variable **HAVE_THREADS** is set to False.

**API changes**

- The C module has the following context limits, depending on the machine architecture:

<table>
<thead>
<tr>
<th></th>
<th>32-bit</th>
<th>64-bit</th>
</tr>
</thead>
<tbody>
<tr>
<td>MAX_PREC</td>
<td>4250000000</td>
<td>999999999999999999</td>
</tr>
<tr>
<td>MAX_EMAX</td>
<td>4250000000</td>
<td>999999999999999999</td>
</tr>
<tr>
<td>MIN_EMIN</td>
<td>-4250000000</td>
<td>-999999999999999999</td>
</tr>
</tbody>
</table>

- In the context templates (**DefaultContext**, **BasicContext** and **ExtendedContext**) the magnitude of Emax and Emin has changed to 999999.

- The **Decimal** constructor in decimal.py does not observe the context limits and converts values with arbitrary exponents or precision exactly. Since the C version has internal limits, the following scheme is used: If possible, values are converted exactly, otherwise **InvalidOperation** is raised and the result is NaN. In the latter case it is always possible to use **create_decimal()** in order to obtain a rounded or inexact value.

- The power function in decimal.py is always correctly-rounded. In the C version, it is defined in terms of the correctly-rounded
exp() and ln() functions, but the final result is only “almost always correctly rounded”.

- In the C version, the context dictionary containing the signals is a `MutableMapping`. For speed reasons, flags and traps always refer to the same `MutableMapping` that the context was initialized with. If a new signal dictionary is assigned, flags and traps are updated with the new values, but they do not reference the RHS dictionary.

- Pickling a `Context` produces a different output in order to have a common interchange format for the Python and C versions.

- The order of arguments in the `Context` constructor has been changed to match the order displayed by `repr()`.

- The `watchexp` parameter in the `quantize()` method is deprecated.

email

Policy Framework

The email package now has a `policy` framework. A `Policy` is an object with several methods and properties that control how the email package behaves. The primary policy for Python 3.3 is the `Compat32` policy, which provides backward compatibility with the email package in Python 3.2. A `policy` can be specified when an email message is parsed by a `parser`, or when a `Message` object is created, or when an email is serialized using a `generator`. Unless overridden, a policy passed to a `parser` is inherited by all the `Message` object and sub-objects created by the `parser`. By default a `generator` will use the
policy of the Message object it is serializing. The default policy is compat32.

The minimum set of controls implemented by all policy objects are:

<table>
<thead>
<tr>
<th>Control</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>max_line_length</td>
<td>The maximum length, excluding the linesep character(s), individual lines may have when a Message is serialized. Defaults to 78.</td>
</tr>
<tr>
<td>linesep</td>
<td>The character used to separate individual lines when a Message is serialized. Defaults to \n.</td>
</tr>
<tr>
<td>cte_type</td>
<td>7bit or 8bit. 8bit applies only to a Bytes generator, and means that non-ASCII may be used where allowed by the protocol (or where it exists in the original input).</td>
</tr>
<tr>
<td>raise_on_defect</td>
<td>Causes a parser to raise error when defects are encountered instead of adding them to the Message object's defects list.</td>
</tr>
</tbody>
</table>

A new policy instance, with new settings, is created using the clone() method of policy objects. clone takes any of the above controls as keyword arguments. Any control not specified in the call retains its default value. Thus you can create a policy that uses \r\n linesep characters like this:

```python
cmypolicy = compat32.clone(linesep='\r\n')
```

Policies can be used to make the generation of messages in the format needed by your application simpler. Instead of having to remember to specify linesep='\r\n' in all the places you call a generator, you can specify it once, when you set the policy used by the parser or the Message, whichever your program uses to create
Message objects. On the other hand, if you need to generate messages in multiple forms, you can still specify the parameters in the appropriate generator call. Or you can have custom policy instances for your different cases, and pass those in when you create the generator.

Provisional Policy with New Header API

While the policy framework is worthwhile all by itself, the main motivation for introducing it is to allow the creation of new policies that implement new features for the email package in a way that maintains backward compatibility for those who do not use the new policies. Because the new policies introduce a new API, we are releasing them in Python 3.3 as a provisional policy. Backwards incompatible changes (up to and including removal of the code) may occur if deemed necessary by the core developers.

The new policies are instances of EmailPolicy, and add the following additional controls:

<table>
<thead>
<tr>
<th>refold_source</th>
<th>Controls whether or not headers parsed by a parser are refolded by the generator. It can be none, long, or all. The default is long, which means that source headers with a line longer than max_line_length get refolded. none means no line get refolded, and all means that all lines get refolded.</th>
</tr>
</thead>
<tbody>
<tr>
<td>header_factory</td>
<td>A callable that take a name and value and produces a custom header object.</td>
</tr>
</tbody>
</table>

The header_factory is the key to the new features provided by the new policies. When one of the new policies is used, any header retrieved from a Message object is an object produced by the
header_factory, and any time you set a header on a Message it becomes an object produced by header_factory. All such header objects have a name attribute equal to the header name. Address and Date headers have additional attributes that give you access to the parsed data of the header. This means you can now do things like this:

```python
>>> m = Message(policy=SMTP)
>>> m['To'] = 'Éric <foo@example.com>'
>>> m['to']
'Éric <foo@example.com>'
>>> m['to'].addresses
(Address(display_name='Éric', username='foo', domain='example.com'),)
>>> m['to'].addresses[0].username
'foo'
>>> m['to'].addresses[0].display_name
'Éric'
>>> m['Date'] = email.utils.localtime()
>>> m['Date'].datetime
datetime.datetime(2012, 5, 25, 21, 39, 24, 465484, tzinfo=datetime.timezone(datetime.timedelta(-1, 72000), 'EDT'))
>>> m['Date']
'Fri, 25 May 2012 21:44:27 -0400'
>>> print(m)
To: =?utf-8?q?=C3=89ric?= <foo@example.com>
Date: Fri, 25 May 2012 21:44:27 -0400
```

You will note that the unicode display name is automatically encoded as utf-8 when the message is serialized, but that when the header is accessed directly, you get the unicode version. This eliminates any need to deal with the email.header decode_header() or make_header() functions.

You can also create addresses from parts:

```python
>>> m['cc'] = [Group('pals', [Address('Bob', 'bob',
```
Decoding to unicode is done automatically:

```python
>>> m2 = message_from_string(str(m))
>>> m2['to']
'Éric <foo@example.com>'
```

When you parse a message, you can use the `addresses` and `groups` attributes of the header objects to access the groups and individual addresses:

```python
>>> m2['cc'].addresses
(Address(display_name='Bob', username='bob', domain='example.com'),
 Address(display_name='Sally', username='sally', domain='example.com'),
 Address(display_name='Bonzo', username='bonz', domain='laugh.com'))
```

In summary, if you use one of the new policies, header manipulation works the way it ought to: your application works with unicode strings, and the email package transparently encodes and decodes the unicode to and from the RFC standard Content Transfer Encodings.

**Other API Changes**

New `BytesHeaderParser`, added to the `parser` module to complement `HeaderParser` and complete the Bytes API.

New utility functions:
• `format_datetime()`: given a `datetime`, produce a string formatted for use in an email header.
• `parsedate_to_datetime()`: given a date string from an email header, convert it into an aware `datetime`, or a naive `datetime` if the offset is `-0000`.
• `localtime()`: With no argument, returns the current local time as an aware `datetime` using the local `timezone`. Given an aware `datetime`, converts it into an aware `datetime` using the local `timezone`.

ftplib

• `ftplib.FTP` now accepts a `source_address` keyword argument to specify the `(host, port)` to use as the source address in the bind call when creating the outgoing socket. (Contributed by Giampaolo Rodolà in issue 8594.)
• The `FTP_TLS` class now provides a new `ccc()` function to revert control channel back to plaintext. This can be useful to take advantage of firewalls that know how to handle NAT with non-secure FTP without opening fixed ports. (Contributed by Giampaolo Rodolà in issue 12139)
• Added `ftplib.FTP.mlsd()` method which provides a parsable directory listing format and deprecates `ftplib.FTP.nlst()` and `ftplib.FTP.dir()`. (Contributed by Giampaolo Rodolà in issue 11072)

functools

The `functools.lru_cache()` decorator now accepts a `typed` keyword argument (that defaults to `False` to ensure that it caches values of different types that compare equal in separate cache slots. (Contributed by Raymond Hettinger in issue 13227.)
It is now possible to register callbacks invoked by the garbage collector before and after collection using the new `callbacks` list.

A new `compare_digest()` function has been added to prevent side channel attacks on digests through timing analysis. (Contributed by Nick Coghlan and Christian Heimes in issue 15061)

`http.server.BaseHTTPRequestHandler` now buffers the headers and writes them all at once when `end_headers()` is called. A new method `flush_headers()` can be used to directly manage when the accumulated headers are sent. (Contributed by Andrew Schaaf in issue 3709.)

`http.server` now produces valid HTML 4.01 strict output. (Contributed by Ezio Melotti in issue 13295.)

`http.client.HTTPResponse` now has a `readinto()` method, which means it can be used as a `io.RawIOBase` class. (Contributed by John Kuhn in issue 13464.)

`html.parser.HTMLParser` is now able to parse broken markup without raising errors, therefore the `strict` argument of the constructor
and the **HTMLParseError** exception are now deprecated. The ability to parse broken markup is the result of a number of bug fixes that are also available on the latest bug fix releases of Python 2.7/3.2. (Contributed by Ezio Melotti in issue 15114, and issue 14538, issue 13993, issue 13960, issue 13358, issue 1745761, issue 755670, issue 13357, issue 12629, issue 1200313, issue 670664, issue 13273, issue 12888, issue 7311)

A new **html5** dictionary that maps HTML5 named character references to the equivalent Unicode character(s) (e.g. `html5['gt;'] == '>'`) has been added to the **html.entities** module. The dictionary is now also used by **HTMLParser**. (Contributed by Ezio Melotti in issue 11113 and issue 15156)

**imaplib**

The **IMAP4_SSL** constructor now accepts an SSLContext parameter to control parameters of the secure channel.

(Contributed by Sijin Joseph in issue 8808)

**inspect**

A new **getclosurevars()** function has been added. This function reports the current binding of all names referenced from the function body and where those names were resolved, making it easier to verify correct internal state when testing code that relies on stateful closures.

(Contributed by Meador Inge and Nick Coghlan in issue 13062)

A new **getgeneratorlocals()** function has been added. This function reports the current binding of local variables in the generator's
stack frame, making it easier to verify correct internal state when testing generators.

(Contributed by Meador Inge in issue 15153)

io

The \texttt{open()} function has a new 'x' mode that can be used to exclusively create a new file, and raise a \texttt{FileExistsError} if the file already exists. It is based on the C11 'x' mode to fopen().

(Contributed by David Townshend in issue 12760)

The constructor of the \texttt{TextIOWrapper} class has a new \texttt{write_through} optional argument. If \texttt{write_through} is True, calls to \texttt{write()} are guaranteed not to be buffered: any data written on the \texttt{TextIOWrapper} object is immediately handled to its underlying binary buffer.

itertools

\texttt{accumulate()} now takes an optional \texttt{func} argument for providing a user-supplied binary function.

logging

The \texttt{basicConfig()} function now supports an optional \texttt{handlers} argument taking an iterable of handlers to be added to the root logger.

A class level attribute \texttt{append_nul} has been added to \texttt{SysLogHandler} to allow control of the appending of the NUL (\texttt{	extbackslash 000})
byte to syslog records, since for some deamons it is required while for others it is passed through to the log.

**math**

The **math** module has a new function, **log2()**, which returns the base-2 logarithm of \( x \).

(Written by Mark Dickinson in **issue 11888**).

**mmap**

The **read()** method is now more compatible with other file-like objects: if the argument is omitted or specified as None, it returns the bytes from the current file position to the end of the mapping. (Contributed by Petri Lehtinen in **issue 12021**.)

**multiprocessing**

The new **multiprocessing.connection.wait()** function allows to poll multiple objects (such as connections, sockets and pipes) with a timeout. (Contributed by Richard Oudkerk in **issue 12328**.)

**multiprocessing.Connection** objects can now be transferred over multiprocessing connections. (Contributed by Richard Oudkerk in **issue 4892**.)

**multiprocessing.Process** now accepts a **daemon** keyword argument to override the default behavior of inheriting the daemon flag from the parent process (**issue 6064**).

New attribute attribute **multiprocessing.Process.sentinel**
allows a program to wait on multiple `Process` objects at one time using the appropriate OS primitives (for example, `select` on posix systems).

New methods `multiprocessing.pool.Pool.starmap()` and `starmap_async()` provide `itertools.starmap()` equivalents to the existing `multiprocessing.pool.Pool.map()` and `map_async()` functions. (Contributed by Hynek Schlawack in issue 12708.)

**nntplib**

The `nntplib.NNTP` class now supports the context manager protocol to unconditionally consume `socket.error` exceptions and to close the NNTP connection when done:

```python
>>> from nntplib import NNTP
>>> with NNTP('news.gmane.org') as n:
...    n.group('gmane.comp.python.committers')
... ('211 1755 1 1755 gmane.comp.python.committers', 1755,
>>>```

(Contributed by Giampaolo Rodolà in issue 9795)

**OS**

- The `os` module has a new `pipe2()` function that makes it possible to create a pipe with `O_CLOEXEC` or `O_NONBLOCK` flags set atomically. This is especially useful to avoid race conditions in multi-threaded programs.
The **os** module has a new **sendfile()** function which provides an efficient “zero-copy” way for copying data from one file (or socket) descriptor to another. The phrase “zero-copy” refers to the fact that all of the copying of data between the two descriptors is done entirely by the kernel, with no copying of data into userspace buffers. **sendfile()** can be used to efficiently copy data from a file on disk to a network socket, e.g. for downloading a file.

(Patch submitted by Ross Lagerwall and Giampaolo Rodolà in issue 10882.)

To avoid race conditions like symlink attacks and issues with temporary files and directories, it is more reliable (and also faster) to manipulate file descriptors instead of file names. Python 3.3 enhances existing functions and introduces new functions to work on file descriptors (issue 4761, issue 10755 and issue 14626).

- The **os** module has a new **fwalk()** function similar to **walk()** except that it also yields file descriptors referring to the directories visited. This is especially useful to avoid symlink races.
- The following functions get new optional **dir_fd** (**paths relative to directory descriptors**) and/or **follow_symlinks** (**not following symlinks**): **access()**, **chflags()**, **chmod()**, **chown()**, **link()**, **lstat()**, **mkdir()**, **mkfifo()**, **mknod()**, **open()**, **readlink()**, **remove()**, **rename()**, **replace()**, **rmdir()**, **stat()**, **symlink()**, **unlink()**, **utime()**. Platform support for using these parameters can be checked via the sets **os.supports_dir_fd** and **os.supports_follows_symlinks**.
- The following functions now support a file descriptor for their path argument: **chdir()**, **chmod()**, **chown()**, **execve()**, **listdir()**, **pathconf()**, **exists()**, **stat()**, **readlink()**.
statvfs(), utime(). Platform support for this can be checked via the os.supports_fd set.

- access() accepts an effective_ids keyword argument to turn on using the effective uid/gid rather than the real uid/gid in the access check. Platform support for this can be checked via the supports_effective_ids set.

- The os module has two new functions: getpriority() and setpriority(). They can be used to get or set process niceness/priority in a fashion similar to os.nice() but extended to all processes instead of just the current one.

  (Patch submitted by Giampaolo Rodolà in issue 10784.)

- The new os.replace() function allows cross-platform renaming of a file with overwriting the destination. With os.rename(), an existing destination file is overwritten under POSIX, but raises an error under Windows. (Contributed by Antoine Pitrou in issue 8828.)

- The stat family of functions (stat(), fstat(), and lstat()) now support reading a file's timestamps with nanosecond precision. Symmetrically, utime() can now write file timestamps with nanosecond precision. (Contributed by Larry Hastings in issue 14127.)

- The new os.get_terminal_size() function queries the size of the terminal attached to a file descriptor. See also shutil.get_terminal_size(). (Contributed by Zbigniew Jędrzejewski-Szmek in issue 13609.)

- New functions to support Linux extended attributes (issue 12720): getxattr(), listxattr(), removexattr(), setxattr().
• New interface to the scheduler. These functions control how a process is allocated CPU time by the operating system. New functions:

- sched_get_priority_max()
- sched_get_priority_min()
- sched_getaffinity()
- sched_getparam()
- sched_getscheduler()
- sched_rr_get_interval()
- sched_setaffinity()
- sched_setparam()
- sched_setscheduler()
- sched_yield()

• New functions to control the file system:
  - posix_fadvise(): Announces an intention to access data in a specific pattern thus allowing the kernel to make optimizations.
  - posix_fallocate(): Ensures that enough disk space is allocated for a file.
  - sync(): Force write of everything to disk.

• Additional new posix functions:
  - lockf(): Apply, test or remove a POSIX lock on an open file descriptor.
  - pread(): Read from a file descriptor at an offset, the file offset remains unchanged.
  - pwrite(): Write to a file descriptor from an offset, leaving the file offset unchanged.
  - readv(): Read from a file descriptor into a number of writable buffers.
  - truncate(): Truncate the file corresponding to path, so that it is at most length bytes in size.
  - waitid(): Wait for the completion of one or more child processes.
  - writev(): Write the contents of buffers to a file descriptor, where buffers is an arbitrary sequence of buffers.
  - getgrouplist() (issue 9344): Return list of group ids that specified user belongs to.

• times() and uname(): Return type changed from a tuple to a
tuple-like object with named attributes.

- Some platforms now support additional constants for the `lseek()` function, such as `os.SEEK_HOLE` and `os.SEEK_DATA`.
- New constants `RTLD_LAZY`, `RTLD_NOW`, `RTLD_GLOBAL`, `RTLD_LOCAL`, `RTLD_NODELETE`, `RTLD_NOLOAD`, and `RTLD_DEEPBIND` are available on platforms that support them. These are for use with the `sys.setdlopenflags()` function, and supersede the similar constants defined in `ctypes` and `DLFCN`. (Contributed by Victor Stinner in issue 13226.)
- `os.symlink()` now accepts (and ignores) the `target_is_directory` keyword argument on non-Windows platforms, to ease cross-platform support.

**pdb**

Tab-completion is now available not only for command names, but also their arguments. For example, for the `break` command, function and file names are completed.

(Contributed by Georg Brandl in issue 14210)

**pickle**

`pickle.Pickler` objects now have an optional `dispatch_table` attribute allowing to set per-pickler reduction functions.

(Contributed by Richard Oudkerk in issue 14166.)

**pydoc**

The Tk GUI and the `serve()` function have been removed from the
pydoc module: `pydoc -g` and `serve()` have been deprecated in Python 3.2.

re

`str` regular expressions now support `\u` and `\U` escapes.

(Contributed by Serhiy Storchaka in issue 3665.)

sched

- `run()` now accepts a `blocking` parameter which when set to False makes the method execute the scheduled events due to expire soonest (if any) and then return immediately. This is useful in case you want to use the `scheduler` in non-blocking applications. (Contributed by Giampaolo Rodolà in issue 13449)
- `scheduler` class can now be safely used in multi-threaded environments. (Contributed by Josiah Carlson and Giampaolo Rodolà in issue 8684)
- `timefunc` and `delayfunc` parameters of `scheduler` class constructor are now optional and defaults to `time.time()` and `time.sleep()` respectively. (Contributed by Chris Clark in issue 13245)
- `enter()` and `enterabs()` `argument` parameter is now optional. (Contributed by Chris Clark in issue 13245)
- `enter()` and `enterabs()` now accept a `kwargs` parameter. (Contributed by Chris Clark in issue 13245)

select

Solaris and derivatives platforms have a new class `select.devpoll` for high performance asynchronous sockets via `/dev/poll`. 
shlex

The previously undocumented helper function \texttt{quote} from the \texttt{pipes} modules has been moved to the \texttt{shlex} module and documented. \texttt{quote()} properly escapes all characters in a string that might be otherwise given special meaning by the shell.

shutil

- New functions:
  - \texttt{disk_usage()}: provides total, used and free disk space statistics. (Contributed by Giampaolo Rodolà in issue 12442)
  - \texttt{chown()}: allows one to change user and/or group of the given path also specifying the user/group names and not only their numeric ids. (Contributed by Sandro Tosi in issue 12191)
  - \texttt{shutil.get_terminal_size()}: returns the size of the terminal window to which the interpreter is attached. (Contributed by Zbigniew Jędrzejewski-Szmek in issue 13609.)
- \texttt{copy2()} and \texttt{copystat()} now preserve file timestamps with nanosecond precision on platforms that support it. They also preserve file “extended attributes” on Linux. (Contributed by Larry Hastings in issue 14127 and issue 15238.)
- Several functions now take an optional \texttt{symlinks} argument: when that parameter is true, symlinks aren’t dereferenced and the operation instead acts on the symlink itself (or creates one, if relevant). (Contributed by Hynek Schlawack in issue 12715.)
- When copying files to a different file system, \texttt{move()} now handles symlinks the way the posix \texttt{mv} command does, recreating
the symlink rather than copying the target file contents. (Contributed by Jonathan Niehof in issue 9993.) move() now also returns the dst argument as its result.

- rmtree() is now resistant to symlink attacks on platforms which support the new dir_fd parameter in os.open() and os.unlink(). (Contributed by Martin von Löwis and Hynek Schlawack in issue 4489.)

**signal**

- The signal module has new functions:
  - pthread_sigmask(): fetch and/or change the signal mask of the calling thread (Contributed by Jean-Paul Calderone in issue 8407);
  - pthread_kill(): send a signal to a thread;
  - sigpending(): examine pending functions;
  - sigwait(): wait a signal.
  - sigwaitinfo(): wait for a signal, returning detailed information about it.
  - sigtimedwait(): like sigwaitinfo() but with a timeout.
- The signal handler writes the signal number as a single byte instead of a nul byte into the wakeup file descriptor. So it is possible to wait more than one signal and know which signals were raised.
- signal.signal() and signal.siginterrupt() raise an OSError, instead of a RuntimeError: OSError has an errno attribute.

**smtpd**

The smtpd module now supports RFC 5321 (extended SMTP) and RFC 1870 (size extension). Per the standard, these extensions are
enabled if and only if the client initiates the session with an EHLO command.

(Initial ELHO support by Alberto Trevino. Size extension by Juhana Jauhiainen. Substantial additional work on the patch contributed by Michele Orrù and Dan Boswell. issue 8739)

smtplib

The SMTP, SMTP_SSL, and LMTP classes now accept a source_address keyword argument to specify the (host, port) to use as the source address in the bind call when creating the outgoing socket. (Contributed by Paulo Scardine in issue 11281.)

SMTP now supports the context manager protocol, allowing an SMTP instance to be used in a with statement. (Contributed by Giampaolo Rodolà in issue 11289.)

The SMTP_SSL constructor and the starttls() method now accept an SSLContext parameter to control parameters of the secure channel. (Contributed by Kasun Herath in issue 8809)

socket

- The socket class now exposes additional methods to process ancillary data when supported by the underlying platform:
  - sendmsg()
  - recvmsg()
  - recvmsg_into()

(Contributed by David Watson in issue 6560, based on an earlier
patch by Heiko Wundram)

- The `socket` class now supports the PF_CAN protocol family ([http://en.wikipedia.org/wiki/Socketcan](http://en.wikipedia.org/wiki/Socketcan)), on Linux ([http://lwn.net/Articles/253425](http://lwn.net/Articles/253425)).

  (Contributed by Matthias Fuchs, updated by Tiago Gonçalves in issue 10141)

- The `socket` class now supports the PF_SYSTEM protocol family on OS X. (Contributed by Michael Goderbauer in issue 13777.)

- New function `sethostname()` allows the hostname to be set on unix systems if the calling process has sufficient privileges. (Contributed by Ross Lagerwall in issue 10866.)

**socketserver**

`BaseServer` now has an overridable method `service_actions()` that is called by the `serve_forever()` method in the service loop. `ForkingMixIn` now uses this to clean up zombie child processes. (Contributed by Justin Warkentin in issue 11109.)

**sqlite3**

New `sqlite3.Connection` method `set_trace_callback()` can be used to capture a trace of all sql commands processed by sqlite. (Contributed by Torsten Landschoff in issue 11688.)
The `ssl` module has two new random generation functions:

- `RAND_bytes()`: generate cryptographically strong pseudo-random bytes.
- `RAND_pseudo_bytes()`: generate pseudo-random bytes.

(Contributed by Victor Stinner in issue 12049)

The `ssl` module now exposes a finer-grained exception hierarchy in order to make it easier to inspect the various kinds of errors. (Contributed by Antoine Pitrou in issue 11183)

`load_cert_chain()` now accepts a `password` argument to be used if the private key is encrypted. (Contributed by Adam Simpkins in issue 12803)

Diffie-Hellman key exchange, both regular and Elliptic Curve-based, is now supported through the `load_dh_params()` and `set_ecdh_curve()` methods. (Contributed by Antoine Pitrou in issue 13626 and issue 13627)

SSL sockets have a new `get_channel_binding()` method allowing the implementation of certain authentication mechanisms such as SCRAM-SHA-1-PLUS. (Contributed by Jacek Konieczny in issue 12551)

You can query the SSL compression algorithm used by an SSL socket, thanks to its new `compression()` method. The new attribute `OP_NO_COMPRESSION` can be used to disable compression. (Contributed by Antoine Pitrou in issue 13634)
Support has been added for the Next Protocol Negotiation extension using the `ssl.SSLContext.set_npn_protocols()` method. (Contributed by Colin Marc in issue 14204)

SSL errors can now be introspected more easily thanks to the `library` and `reason` attributes. (Contributed by Antoine Pitrou in issue 14837)

The `get_server_certificate()` function now supports IPv6. (Contributed by Charles-François Natali in issue 11811.)

New attribute `OP_CIPHER_SERVER_PREFERENCE` allows setting SSLv3 server sockets to use the server’s cipher ordering preference rather than the client’s (issue 13635).

**stat**

The undocumented `tarfile.filemode` function has been moved to `stat.filemode()`. It can be used to convert a file’s mode to a string of the form ‘-rwxrwxrwx’.

(Contributed by Giampaolo Rodolà in issue 14807)

**struct**

The `struct` module now supports `ssize_t` and `size_t` via the new codes `n` and `N`, respectively. (Contributed by Antoine Pitrou in issue 3163.)

**subprocess**
Command strings can now be bytes objects on posix platforms. (Contributed by Victor Stinner in issue 8513.)

A new constant `DEVNULL` allows suppressing output in a platform-independent fashion. (Contributed by Ross Lagerwall in issue 5870.)

**sys**

The `sys` module has a new `thread_info struct sequence` holding informations about the thread implementation (issue 11223).

**tarfile**

tarfile now supports `lzma` encoding via the `lzma` module. (Contributed by Lars Gustäbel in issue 5689.)

**tempfile**

tempfile.SpooledTemporaryFile's `truncate()` method now accepts a `size` parameter. (Contributed by Ryan Kelly in issue 9957.)

**textwrap**

The `textwrap` module has a new `indent()` that makes it straightforward to add a common prefix to selected lines in a block of text (issue 13857).

**threading**

`threading.Condition`, `threading.Semaphore`,
threading.BoundedSemaphore, threading.Event, and threading.Timer, all of which used to be factory functions returning a class instance, are now classes and may be subclassed. (Contributed by Éric Araujo in issue 10968).

The threading.Thread constructor now accepts a daemon keyword argument to override the default behavior of inheriting the daemon flag value from the parent thread (issue 6064).

The formerly private function _thread.get_ident is now available as the public function threading.get_ident(). This eliminates several cases of direct access to the _thread module in the stdlib. Third party code that used _thread.get_ident should likewise be changed to use the new public interface.

time

The PEP 418 added new functions to the time module:

- get_clock_info(): Get information on a clock.
- monotonic(): Monotonic clock (cannot go backward), not affected by system clock updates.
- perf_counter(): Performance counter with the highest available resolution to measure a short duration.
- process_time(): Sum of the system and user CPU time of the current process.

Other new functions:

- clock_getres(), clock_gettime() and clock_settime() functions with CLOCK_XXX constants. (Contributed by Victor Stinner in issue 10278)
To improve cross platform consistency, `sleep()` now raises a `ValueError` when passed a negative sleep value. Previously this was an error on posix, but produced an infinite sleep on Windows.

**types**

Add a new `types.MappingProxyType` class: Read-only proxy of a mapping. ([issue 14386](#))

The new functions `types.new_class` and `types.prepare_class` provide support for PEP 3115 compliant dynamic type creation. ([issue 14588](#))

**unittest**

`assertRaises()`, `assertRaisesRegex()`, `assertWarns()`, and `assertWarnsRegex()` now accept a keyword argument `msg` when used as context managers. (Contributed by Ezio Melotti and Winston Ewert in [issue 10775](#))

`unittest.TestCase.run()` now returns the `TestResult` object.

**urllib**

The `Request` class, now accepts a `method` argument used by `get_method()` to determine what HTTP method should be used. For example, this will send a 'HEAD' request:

```python
>>> urlopen(Request('http://www.python.org', method='HEAD'))
```

([issue 1673007](#))
webbrowser

The `webbrowser` module supports more “browsers”: Google Chrome (named `chrome`, `chromium`, `chrome-browser` or `chromium-browser` depending on the version and operating system), and the generic launchers `xdg-open`, from the FreeDesktop.org project, and `gvfs-open`, which is the default URI handler for GNOME 3. (The former contributed by Arnaud Calmettes in issue 13620, the latter by Matthias Klose in issue 14493)

xml.etree.ElementTree

The `xml.etree.ElementTree` module now imports its C accelerator by default; there is no longer a need to explicitly import `xml.etree.cElementTree` (this module stays for backwards compatibility, but is now deprecated). In addition, the `iter` family of methods of `Element` has been optimized (rewritten in C). The module’s documentation has also been greatly improved with added examples and a more detailed reference.

zlib

New attribute `zlib.Decompress.eof` makes it possible to distinguish between a properly-formed compressed stream and an incomplete or truncated one. (Contributed by Nadeem Vawda in issue 12646.)

New attribute `zlib.ZLIB_RUNTIME_VERSION` reports the version string of the underlying `zlib` library that is loaded at runtime. (Contributed by Torsten Landschoff in issue 12306.)
Optimizations

Major performance enhancements have been added:

- Thanks to PEP 393, some operations on Unicode strings have been optimized:
  - the memory footprint is divided by 2 to 4 depending on the text
  - encode an ASCII string to UTF-8 doesn’t need to encode characters anymore, the UTF-8 representation is shared with the ASCII representation
  - the UTF-8 encoder has been optimized
  - repeating a single ASCII letter and getting a substring of a ASCII strings is 4 times faster
- UTF-8 is now 2x to 4x faster. UTF-16 encoding is now up to 10x faster.

(contributed by Serhiy Storchaka, issue 14624, issue 14738 and issue 15026.)
Build and C API Changes

Changes to Python's build process and to the C API include:

- New **PEP 3118** related function:
  - `PyMemoryView_FromMemory()`
- **PEP 393** added new Unicode types, macros and functions:
  - High-level API:
    - `PyUnicode_CopyCharacters()`
    - `PyUnicode_FindChar()`
    - `PyUnicode_GetLength()`, `PyUnicode_GET_LENGTH`
    - `PyUnicode_New()`
    - `PyUnicode_Substring()`
    - `PyUnicode_ReadChar()`, `PyUnicode_WriteChar()`
  - Low-level API:
    - `Py_UCS1`, `Py_UCS2`, `Py_UCS4` types
    - `PyASCIIObject` and `PyCompactUnicodeObject` structures
    - `PyUnicode_READY`
    - `PyUnicode_FromKindAndData()`
    - `PyUnicode_AsUCS4()`, `PyUnicode_AsUCS4Copy()`
    - `PyUnicode_DATA`, `PyUnicode_1BYTE_DATA`, `PyUnicode_2BYTE_DATA`, `PyUnicode_4BYTE_DATA`
    - `PyUnicode_KIND` with `PyUnicode_Kind` enum:
      - `PyUnicode_WCHAR_KIND`, `PyUnicode_1BYTE_KIND`, `PyUnicode_2BYTE_KIND`, `PyUnicode_4BYTE_KIND`
    - `PyUnicode_READ`, `PyUnicode_READ_CHAR`, `PyUnicode_WRITE`
    - `PyUnicode_MAX_CHAR_VALUE`
• PyArg_ParseTuple now accepts a bytearray for the c format (issue 12380).
Deprecated

Unsupported Operating Systems

OS/2 and VMS are no longer supported due to the lack of a maintainer.

Windows 2000 and Windows platforms which set COMSPEC to command.com are no longer supported due to maintenance burden.

OSF support, which was deprecated in 3.2, has been completely removed.

Deprecated Python modules, functions and methods

- Passing a non-empty string to object.__format__() is deprecated, and will produce a TypeError in Python 3.4 (issue 9856).
- The unicode_internal codec has been deprecated because of the PEP 393, use UTF-8, UTF-16 (utf-16-le or utf-16-be), or UTF-32 (utf-32-le or utf-32-be)
- ftplib.FTP.nlst() and ftplib.FTP.dir(): use ftplib.FTP.mlsd()
- platform.popen(): use the subprocess module. Check especially the Replacing Older Functions with the subprocess Module section (issue 11377).
- issue 13374: The Windows bytes API has been deprecated in the os module. Use Unicode filenames, instead of bytes filenames, to not depend on the ANSI code page anymore and to support any filename.
- issue 13988: The xml.etree.cElementTree module is
Deprecated. The accelerator is used automatically whenever available.

- The behaviour of `time.clock()` depends on the platform: use the new `time.perf_counter()` or `time.process_time()` function instead, depending on your requirements, to have a well defined behaviour.
- The `os.stat_float_times()` function is deprecated.
- `abc` module:
  - `abc.abstractproperty` has been deprecated, use `property` with `abc.abstractmethod()` instead.
  - `abc.abstractclassmethod` has been deprecated, use `classmethod` with `abc.abstractmethod()` instead.
  - `abc.abstractstaticmethod` has been deprecated, use `staticmethod` with `abc.abstractmethod()` instead.
- `importlib` package:
  - `importlib.abc.SourceLoader.path_mtime()` is now deprecated in favour of `importlib.abc.SourceLoader.path_stats()` as bytecode files now store both the modification time and size of the source file the bytecode file was compiled from.

### Deprecated functions and types of the C API

The `Py_UNICODE` has been deprecated by PEP 393 and will be removed in Python 4. All functions using this type are deprecated:

**Unicode functions and methods using `Py_UNICODE` and `Py_UNICODE*` types:**

- `PyUnicode_FromUnicode`: use `PyUnicode_FromWideChar()` or `PyUnicode_FromKindAndData()`
- `PyUnicode_AS_UNICODE`, `PyUnicode_AsUnicode()`, `PyUnicode_AsUnicodeAndSize()`:
  use `PyUnicode_AsWideCharString()`
- `PyUnicode_AS_DATA`: use `PyUnicode_DATA` with `PyUnicode_READ` and `PyUnicode_WRITE`
- `PyUnicode_GET_SIZE`, `PyUnicode_GetSize()`:
  use `PyUnicode_GET_LENGTH` or `PyUnicode_GetLength()`
- `PyUnicode_GET_DATA_SIZE`:
  use `PyUnicode_GET_LENGTH(str) * PyUnicode_KIND(str)` (only work on ready strings)
- `PyUnicode_AsUnicodeCopy()`:
  use `PyUnicode_AsUCS4Copy()` or `PyUnicode_AsWideCharString()`
- `PyUnicode_GetMax()`

Functions and macros manipulating `Py_UNICODE*` strings:

- `Py_UNICODE_strlen`: use `PyUnicode_GetLength()` or `PyUnicode_GET_LENGTH`
- `Py_UNICODE_strcat`: use `PyUnicode_CopyCharacters()` or `PyUnicode_FromFormat()`
- `Py_UNICODE_strcpy`, `Py_UNICODE_strncpy`, `Py_UNICODE_COPY`:
  use `PyUnicode_CopyCharacters()` or `PyUnicode_Substring()`
- `Py_UNICODE_strcmp`: use `PyUnicode_Compare()`
- `Py_UNICODE_strncmp`: use `PyUnicode_Tailmatch()`
- `Py_UNICODE strchr`, `Py_UNICODE strrchr`:
  use `PyUnicode_FindChar()`
- `Py_UNICODE_FILL`: use `PyUnicode_Fill()`
- `Py_UNICODE_MATCH`
- `PyUnicode_Encode()`: use `PyUnicode_AsEncodedObject()``
- `PyUnicode_EncodeUTF7()``
- `PyUnicode_EncodeUTF8()`: use `PyUnicode_AsUTF8()`, or `PyUnicode_AsUTF8String()``
- `PyUnicode_EncodeUTF32()``
- `PyUnicode_EncodeUTF16()``
- `PyUnicode_EncodeUnicodeEscape()`: use `PyUnicode_AsUnicodeEscapeString()``
- `PyUnicode_EncodeRawUnicodeEscape()`: use `PyUnicode_AsRawUnicodeEscapeString()``
- `PyUnicode_EncodeLatin1()`: use `PyUnicode_AsLatin1String()``
- `PyUnicode_EncodeASCII()`: use `PyUnicode_AsASCIIString()``
- `PyUnicode_TranslateCharmap()``
- `PyUnicode_EncodeMBCS()`: use `PyUnicode_AsMBCSString()`, or `PyUnicode_EncodeCodePage()`, (with `CP_ACP` code_page)``
- `PyUnicode_EncodeDecimal()`,
- `PyUnicode_TransformDecimalToASCII()``

**Deprecated features**

The `array` module's `u` format code is now deprecated and will be removed in Python 4 together with the rest of the `(Py_UNICODE)` API.
Porting to Python 3.3

This section lists previously described changes and other bugfixes that may require changes to your code.

Porting Python code

- Hash randomization is enabled by default. Set the PYTHONHASHSEED environment variable to 0 to disable hash randomization. See also the `object.__hash__() method.

- **issue 12326**: On Linux, sys.platform doesn’t contain the major version anymore. It is now always ‘linux’, instead of ‘linux2’ or ‘linux3’ depending on the Linux version used to build Python. Replace `sys.platform == 'linux2'` with `sys.platform.startswith('linux')`, or directly `sys.platform == 'linux'` if you don’t need to support older Python versions.

- **issue 13847, issue 14180**: `time` and `datetime`: `OverflowError` is now raised instead of `ValueError` if a timestamp is out of range. `OSError` is now raised if C functions `gmtime()` or `localtime()` failed.

- The default finders used by import now utilize a cache of what is contained within a specific directory. If you create a Python source file or sourceless bytecode file, make sure to call `importlib.invalidate_caches()` to clear out the cache for the finders to notice the new file.

- `ImportError` now uses the full name of the module that was attempted to be imported. Doctests that check ImportErrors’ message will need to be updated to use the full name of the module instead of just the tail of the name.

- The `index` argument to `__import__() now defaults to 0 instead of -1 and no longer support negative values. It was an oversight when **PEP 328** was implemented that the default value remained
-1. If you need to continue to perform a relative import followed by an absolute import, then perform the relative import using an index of 1, followed by another import using an index of 0. It is preferred, though, that you use `importlib.import_module()` rather than call `__import__()` directly.

- `__import__()` no longer allows one to use an index value other than 0 for top-level modules. E.g. `__import__('sys', level=1)` is now an error.

- Because `sys.meta_path` and `sys.path_hooks` now have finders on them by default, you will most likely want to use `list.insert()` instead of `list.append()` to add to those lists.

- Because None is now inserted into `sys.path_importer_cache`, if you are clearing out entries in the dictionary of paths that do not have a finder, you will need to remove keys paired with values of None and `imp.NullImporter` to be backwards-compatible. This will lead to extra overhead on older versions of Python that re-insert None into `sys.path_importer_cache` where it represents the use of implicit finders, but semantically it should not change anything.

- `importlib.abc.Finder` no longer specifies a `find_module()` abstract method that must be implemented. If you were relying on subclasses to implement that method, make sure to check for the method’s existence first. You will probably want to check for `find_loader()` first, though, in the case of working with path entry finders.

- `pkgutil` has been converted to use `importlib` internally. This eliminates many edge cases where the old behaviour of the PEP 302 import emulation failed to match the behaviour of the real import system. The import emulation itself is still present, but is now deprecated. The `pkgutil.iter_importers()` and `pkgutil.walk_packages()` functions special case the standard import hooks so they are still supported even though
they do not provide the non-standard `iter_modules()` method.

- A longstanding RFC-compliance bug (issue 1079) in the parsing done by `email.header.decode_header()` has been fixed. Code that uses the standard idiom to convert encoded headers into unicode (`str(make_header(decode_header(h)))`) will see no change, but code that looks at the individual tuples returned by `decode_header` will see that whitespace that precedes or follows ASCII sections is now included in the ASCII section. Code that builds headers using `make_header` should also continue to work without change, since `make_header` continues to add whitespace between ASCII and non-ASCII sections if it is not already present in the input strings.

  - `email.utils.formataddr()` now does the correct content transfer encoding when passed non-ASCII display names. Any code that depended on the previous buggy behavior that preserved the non-ASCII unicode in the formatted output string will need to be changed (issue 1690608).

  - `poplib.POP3.quit()` may now raise protocol errors like all other `poplib` methods. Code that assumes `quit` does not raise `poplib.error_proto` errors may need to be changed if errors on `quit` are encountered by a particular application (issue 11291).

- The `strict` argument to `email.parser.Parser`, deprecated since Python 2.4, has finally been removed.

- The deprecated method `unittest.TestCase.assertSameElements` has been removed.

- The deprecated variable `time.accept2dyear` has been removed.

- The deprecated `Context._clamp` attribute has been removed from the `decimal` module. It was previously replaced by the public attribute `clamp`. (See issue 8540.)

- The undocumented internal helper class `SSLFakeFile` has been
removed from smtplib, since its functionality has long been provided directly by socket.socket.makefile().

- Passing a negative value to time.sleep() on Windows now raises an error instead of sleeping forever. It has always raised an error on posix.
- The ast.__version__ constant has been removed. If you need to make decisions affected by the AST version, use sys.version_info to make the decision.
- Code that used to work around the fact that the threading module used factory functions by subclassing the private classes will need to change to subclass the now-public classes.
- The undocumented debugging machinery in the threading module has been removed, simplifying the code. This should have no effect on production code, but is mentioned here in case any application debug frameworks were interacting with it (issue 13550).

Porting C code

- In the course of changes to the buffer API the undocumented smalltable member of the Py_buffer structure has been removed and the layout of the PyMemoryViewObject has changed.

    All extensions relying on the relevant parts in memoryobject.h or object.h must be rebuilt.

- Due to PEP 393, the Py_UNICODE type and all functions using this type are deprecated (but will stay available for at least five years). If you were using low-level Unicode APIs to construct and access unicode objects and you want to benefit of the memory footprint reduction provided by PEP 393, you have to convert your
code to the new *Unicode API*.

However, if you only have been using high-level functions such as `PyUnicodeConcat()`, `PyUnicodeJoin()` or `PyUnicodeFromFormat()`, your code will automatically take advantage of the new unicode representations.

- `PyImport_GetMagicNumber()` now returns -1 upon failure.

- As a negative value for the *level* argument to `__import__() is no longer valid, the same now holds for `PyImport_ImportModuleLevel()`. This also means that the value of *level* used by `PyImport_ImportModuleEx()` is now 0 instead of -1.

**Building C extensions**

- The range of possible file names for C extensions has been narrowed. Very rarely used spellings have been suppressed: under POSIX, files named `xxxmodule.so`, `xxxmodule.abi3.so` and `xxxmodule.cpython-*.so` are no longer recognized as implementing the `xxx` module. If you had been generating such files, you have to switch to the other spellings (i.e., remove the module string from the file names).

  (implemented in issue 14040.)

**Command Line Switch Changes**

- The -Q command-line flag and related artifacts have been removed. Code checking `sys.flags.division_warning` will need updating.
(issue 10998, contributed by Éric Araujo.)

- When **python** is started with `-S`, `import site` will no longer add site-specific paths to the module search paths. In previous versions, it did.

(issue 11591, contributed by Carl Meyer with editions by Éric Araujo.)
What’s New In Python 3.2

Author: Raymond Hettinger

This article explains the new features in Python 3.2 as compared to 3.1. It focuses on a few highlights and gives a few examples. For full details, see the Misc/NEWS file.

See also: PEP 392 - Python 3.2 Release Schedule
PEP 384: Defining a Stable ABI

In the past, extension modules built for one Python version were often not usable with other Python versions. Particularly on Windows, every feature release of Python required rebuilding all extension modules that one wanted to use. This requirement was the result of the free access to Python interpreter internals that extension modules could use.

With Python 3.2, an alternative approach becomes available: extension modules which restrict themselves to a limited API (by defining Py_LIMITED_API) cannot use many of the internals, but are constrained to a set of API functions that are promised to be stable for several releases. As a consequence, extension modules built for 3.2 in that mode will also work with 3.3, 3.4, and so on. Extension modules that make use of details of memory structures can still be built, but will need to be recompiled for every feature release.

PEP 384 - Defining a Stable ABI
PEP written by Martin von Löwis.
PEP 389: Argparse Command Line Parsing Module

A new module for command line parsing, argparse, was introduced to overcome the limitations of optparse which did not provide support for positional arguments (not just options), subcommands, required options and other common patterns of specifying and validating options.

This module has already had widespread success in the community as a third-party module. Being more fully featured than its predecessor, the argparse module is now the preferred module for command-line processing. The older module is still being kept available because of the substantial amount of legacy code that depends on it.

Here's an annotated example parser showing features like limiting results to a set of choices, specifying a metavar in the help screen, validating that one or more positional arguments is present, and making a required option:

```python
import argparse

parser = argparse.ArgumentParser(
    description = 'Manage servers',
    epilog = 'Tested on Solaris and Linux')

parser.add_argument('action',
    choices = ['deploy', 'start', 'stop'],
    help = 'action on each target')

parser.add_argument('targets',
    metavar = 'HOSTNAME',
    nargs = '+',
    help = 'url for target machines')

parser.add_argument('-u', '--user',
    required = True,
    help = 'username for login')
```
help = 'login as user')

Example of calling the parser on a command string:

```python
>>> cmd = 'deploy sneezy.example.com sleepy.example.com -u skycaptain
>>> result = parser.parse_args(cmd.split())
>>> result.action
'deploy'
>>> result.targets
['sneezy.example.com', 'sleepy.example.com']
>>> result.user
'skycaptain'
```

Example of the parser's automatically generated help:

```python
>>> parser.parse_args('-h'.split())

usage: manage_cloud.py [-h] -u USER {deploy,start,stop} HOSTNAME

Manage servers

positional arguments:
  {deploy,start,stop} action on each target
  HOSTNAME url for target machines

optional arguments:
  -h, --help          show this help message and exit
  -u USER, --user USER login as user

Tested on Solaris and Linux
```

An especially nice `argparse` feature is the ability to define subparsers, each with their own argument patterns and help displays:
import argparse
parser = argparse.ArgumentParser(prog='HELM')
subparsers = parser.add_subparsers()

parser_l = subparsers.add_parser('launch', help='Launch Control')
    # first subgroup
parser_l.add_argument('-m', '--missiles', action='store_true')
parser_l.add_argument('-t', '--torpedos', action='store_true')

parser_m = subparsers.add_parser('move', help='Move Vessel',
    aliases=('steer', 'turn'))
    # second subgroup
parser_m.add_argument('-c', '--course', type=int, required=True)
parser_m.add_argument('-s', '--speed', type=int, default=0)

$ ./helm.py --help
$ ./helm.py launch --help
$ ./helm.py launch --missiles
$ ./helm.py steer --course 180 --speed 5

PEP 389 - New Command Line Parsing Module
    PEP written by Steven Bethard.

Upgrading optparse code for details on the differences from optparse.
PEP 391: Dictionary Based Configuration for Logging

The `logging` module provided two kinds of configuration, one style with function calls for each option or another style driven by an external file saved in a ConfigParser format. Those options did not provide the flexibility to create configurations from JSON or YAML files, nor did they support incremental configuration, which is needed for specifying logger options from a command line.

To support a more flexible style, the module now offers `logging.config.dictConfig()` for specifying logging configuration with plain Python dictionaries. The configuration options include formatters, handlers, filters, and loggers. Here's a working example of a configuration dictionary:

```json
{
    "version": 1,
    "formatters": {
        "brief": {
            "format": "%(levelname)-8s:%(name)-15s:%(message)s"
        },
        "full": {
            "format": "%(asctime)s %(name)-15s %(levelname)-8s %(message)s"
        }
    },
    "handlers": {
        "console": {
            "class": "logging.StreamHandler",
            "formatter": "brief",
            "level": "INFO",
            "stream": "ext://sys.stdout"
        },
        "console_priority": {
            "class": "logging.StreamHandler",
            "formatter": "full",
            "level": "ERROR",
            "stream": "ext://sys.stderr"
        }
    },
    "root": {
        "level": "DEBUG",
        "handlers": ["console",
```
```
If that dictionary is stored in a file called `conf.json`, it can be loaded and called with code like this:

```python
>>> import json, logging.config
>>> with open('conf.json') as f:
    conf = json.load(f)
>>> logging.config.dictConfig(conf)
>>> logging.info("Transaction completed normally")
INFO : root : Transaction completed normally
>>> logging.critical("Abnormal termination")
2011-02-17 11:14:36,694 root CRITICAL Abnormal termination
```

See also:

**PEP 391 - Dictionary Based Configuration for Logging**

PEP written by Vinay Sajip.
PEP 3148: The concurrent.futures module

Code for creating and managing concurrency is being collected in a new top-level namespace, `concurrent`. Its first member is a `futures` package which provides a uniform high-level interface for managing threads and processes.

The design for `concurrent.futures` was inspired by the `java.util.concurrent` package. In that model, a running call and its result are represented by a `Future` object that abstracts features common to threads, processes, and remote procedure calls. That object supports status checks (running or done), timeouts, cancellations, adding callbacks, and access to results or exceptions.

The primary offering of the new module is a pair of executor classes for launching and managing calls. The goal of the executors is to make it easier to use existing tools for making parallel calls. They save the effort needed to setup a pool of resources, launch the calls, create a results queue, add time-out handling, and limit the total number of threads, processes, or remote procedure calls.

Ideally, each application should share a single executor across multiple components so that process and thread limits can be centrally managed. This solves the design challenge that arises when each component has its own competing strategy for resource management.

Both classes share a common interface with three methods: `submit()` for scheduling a callable and returning a `Future` object; `map()` for scheduling many asynchronous calls at a time, and `shutdown()` for freeing resources. The class is a `context manager`
and can be used in a `with` statement to assure that resources are automatically released when currently pending futures are done executing.

A simple example of `ThreadPoolExecutor` is a launch of four parallel threads for copying files:

```python
import concurrent.futures, shutil
with concurrent.futures.ThreadPoolExecutor(max_workers=4) as e:
    e.submit(shutil.copy, 'src1.txt', 'dest1.txt')
    e.submit(shutil.copy, 'src2.txt', 'dest2.txt')
    e.submit(shutil.copy, 'src3.txt', 'dest3.txt')
    e.submit(shutil.copy, 'src4.txt', 'dest4.txt')
```

**PEP 3148 - Futures – Execute Computations Asynchronously**

PEP written by Brian Quinlan.

*Code for Threaded Parallel URL reads*, an example using threads to fetch multiple web pages in parallel.

PEP 3147: PYC Repository Directories

Python’s scheme for caching bytecode in .pyc files did not work well in environments with multiple Python interpreters. If one interpreter encountered a cached file created by another interpreter, it would recompile the source and overwrite the cached file, thus losing the benefits of caching.

The issue of “pyc fights” has become more pronounced as it has become commonplace for Linux distributions to ship with multiple versions of Python. These conflicts also arise with CPython alternatives such as Unladen Swallow.

To solve this problem, Python’s import machinery has been extended to use distinct filenames for each interpreter. Instead of Python 3.2 and Python 3.3 and Unladen Swallow each competing for a file called “mymodule.pyc”, they will now look for “mymodule.cpython-32.pyc”, “mymodule.cpython-33.pyc”, and “mymodule.unladen10.pyc”. And to prevent all of these new files from cluttering source directories, the pyc files are now collected in a “__pycache__” directory stored under the package directory.

Aside from the filenames and target directories, the new scheme has a few aspects that are visible to the programmer:

- Imported modules now have a __cached__ attribute which stores the name of the actual file that was imported:

```python
>>> import collections
>>> collections.__cached__
'c:/py32/lib/__pycache__/collections.cpython-32.pyc'
```
• The tag that is unique to each interpreter is accessible from the \texttt{imp} module:

```python
>>> import imp
>>> imp.get_tag()
'cpython-32'
```

• Scripts that try to deduce source filename from the imported file now need to be smarter. It is no longer sufficient to simply strip the “c” from a ”.pyc” filename. Instead, use the new functions in the \texttt{imp} module:

```python
>>> imp.source_from_cache('c:/py32/lib/__pycache__/collections.cpython-32.pyc', 'c:/py32/lib/collections.py')
>>> imp.cache_from_source('c:/py32/lib/collections.py', 'c:/py32/lib/__pycache__/collections.cpython-32.pyc')
```

• The \texttt{py_compile} and \texttt{compileall} modules have been updated to reflect the new naming convention and target directory. The command-line invocation of \texttt{compileall} has new options: \texttt{-i} for specifying a list of files and directories to compile and \texttt{-b} which causes bytecode files to be written to their legacy location rather than \texttt{__pycache__}.

• The \texttt{importlib.abc} module has been updated with new \textit{abstract base classes} for loading bytecode files. The obsolete ABCs, \texttt{PyLoader} and \texttt{PyPycLoader}, have been deprecated (instructions on how to stay Python 3.1 compatible are included with the documentation).

\textbf{See also:}

\texttt{PEP 3147 - PYC Repository Directories}
PEP written by Barry Warsaw.
PEP 3149: ABI Version Tagged .so Files

The PYC repository directory allows multiple bytecode cache files to be co-located. This PEP implements a similar mechanism for shared object files by giving them a common directory and distinct names for each version.

The common directory is “pyshared” and the file names are made distinct by identifying the Python implementation (such as CPython, PyPy, Jython, etc.), the major and minor version numbers, and optional build flags (such as “d” for debug, “m” for pymalloc, “u” for wide-unicode). For an arbitrary package “foo”, you may see these files when the distribution package is installed:

```
/usr/share/pyshared/foo.cpython-32m.so
/usr/share/pyshared/foo.cpython-33md.so
```

In Python itself, the tags are accessible from functions in the `sysconfig` module:

```
>>> import sysconfig
>>> sysconfig.get_config_var('SOABI')  # find the version tag
'cpython-32mu'
>>> sysconfig.get_config_var('EXT_SUFFIX')  # find the full filename extension
'.cpython-32mu.so'
```

See also:

**PEP 3149 - ABI Version Tagged .so Files**
PEP written by Barry Warsaw.
PEP 3333: Python Web Server Gateway Interface v1.0.1

This informational PEP clarifies how bytes/text issues are to be handled by the WSGI protocol. The challenge is that string handling in Python 3 is most conveniently handled with the `str` type even though the HTTP protocol is itself bytes oriented.

The PEP differentiates so-called *native strings* that are used for request/response headers and metadata versus *byte strings* which are used for the bodies of requests and responses.

The *native strings* are always of type `str` but are restricted to code points between $U+0000$ through $U+00FF$ which are translatable to bytes using *Latin-1* encoding. These strings are used for the keys and values in the environment dictionary and for response headers and statuses in the `start_response()` function. They must follow RFC 2616 with respect to encoding. That is, they must either be *ISO-8859-1* characters or use RFC 2047 MIME encoding.

For developers porting WSGI applications from Python 2, here are the salient points:

- If the app already used strings for headers in Python 2, no change is needed.
- If instead, the app encoded output headers or decoded input headers, then the headers will need to be re-encoded to Latin-1. For example, an output header encoded in utf-8 was using `h.encode('utf-8')` now needs to convert from bytes to native strings using `h.encode('utf-8').decode('latin-1')`.
- Values yielded by an application or sent using the `write()` method must be byte strings. The `start_response()` function
and environ must use native strings. The two cannot be mixed.

For server implementers writing CGI-to-WSGI pathways or other CGI-style protocols, the users must to be able access the environment using native strings even though the underlying platform may have a different convention. To bridge this gap, the wsgiref module has a new function, wsgiref.handlers.read_environ() for transcoding CGI variables from os.environ into native strings and returning a new dictionary.

**PEP 3333** - Python Web Server Gateway Interface v1.0.1

PEP written by Phillip Eby.
Other Language Changes

Some smaller changes made to the core Python language are:

- String formatting for `format()` and `str.format()` gained new capabilities for the format character `#`. Previously, for integers in binary, octal, or hexadecimal, it caused the output to be prefixed with ‘0b’, ‘0o’, or ‘0x’ respectively. Now it can also handle floats, complex, and Decimal, causing the output to always have a decimal point even when no digits follow it.

```python
>>> format(20, '#o')
'0o24'
>>> format(12.34, '#5.0f')
'12.'
```

(Suggested by Mark Dickinson and implemented by Eric Smith in issue 7094.)

- There is also a new `str.format_map()` method that extends the capabilities of the existing `str.format()` method by accepting arbitrary `mapping` objects. This new method makes it possible to use string formatting with any of Python’s many dictionary-like objects such as `defaultdict`, `Shelf`, `ConfigParser`, or `dbm`. It is also useful with custom `dict` subclasses that normalize keys before look-up or that supply a `__missing__()` method for unknown keys:

```python
>>> import shelve
>>> d = shelve.open('tmp.shl')
>>> 'The {project_name} status is {status} as of {date}'.format_map(d)
'The testing project status is green as of February 15, 2011'
```
```python
>>> class LowerCasedDict(dict):
    def __getitem__(self, key):
        return dict.__getitem__(self, key.lower())
>>> lcd = LowerCasedDict(part='widgets', quantity=10)
>>> 'There are {QUANTITY} {Part} in stock'.format_map(lcd)
'There are 10 widgets in stock'

>>> class PlaceholderDict(dict):
    def __missing__(self, key):
        return '<{}>'.format(key)
>>> 'Hello {name}, welcome to {location}'.format_map(PlaceholderDict(name='Alice', location='New York'))
'Hello <name>, welcome to <location>'
```

(Suggested by Raymond Hettinger and implemented by Eric Smith in issue 6081.)

- The interpreter can now be started with a quiet option, `-q`, to prevent the copyright and version information from being displayed in the interactive mode. The option can be introspected using the `sys.flags` attribute:

```
$ python -q
>>> sys.flags
sys.flags(debug=0, division_warning=0, inspect=0, optimize=0, dont_write_bytecode=0, no_user_site=0, ignore_environment=0, verbose=0, bytes_warning=0, quiet=1)
```

(Contributed by Marcin Wojdyr in issue 1772833).

- The `hasattr()` function works by calling `getattr()` and detecting whether an exception is raised. This technique allows it to detect methods created dynamically by `__getattr__()` or `__getattribute__()` which would otherwise be absent from
the class dictionary. Formerly, `hasattr` would catch any exception, possibly masking genuine errors. Now, `hasattr` has been tightened to only catch `AttributeError` and let other exceptions pass through:

```python
>>> class A:
    @property
def f(self):
        return 1 // 0

>>> a = A()
>>> hasattr(a, 'f')
Traceback (most recent call last):
  ...ZeroDivisionError: integer division or modulo by zero
```

(Discovered by Yury Selivanov and fixed by Benjamin Peterson; issue 9666.)

- The `str()` of a float or complex number is now the same as its `repr()`. Previously, the `str()` form was shorter but that just caused confusion and is no longer needed now that the shortest possible `repr()` is displayed by default:

```python
>>> import math
>>> repr(math.pi)
'3.141592653589793'
>>> str(math.pi)
'3.141592653589793'
```

(Proposed and implemented by Mark Dickinson; issue 9337.)

- `memoryview` objects now have a `release()` method and they also now support the context manager protocol. This allows timely
release of any resources that were acquired when requesting a buffer from the original object.

```python
>>> with memoryview(b'abcdefgh') as v:
    print(v.tolist())
[97, 98, 99, 100, 101, 102, 103, 104]
```

(Added by Antoine Pitrou; issue 9757.)

- Previously it was illegal to delete a name from the local namespace if it occurs as a free variable in a nested block:

```python
def outer(x):
    def inner():
        return x
    inner()
    del x
```

This is now allowed. Remember that the target of an `except` clause is cleared, so this code which used to work with Python 2.6, raised a `SyntaxError` with Python 3.1 and now works again:

```python
def f():
    def print_error():
        print(e)
    try:
        something
    except Exception as e:
        print_error()
        # implicit "del e" here
```

(See issue 4617.)

- The internal structsequence tool now creates subclasses of
tuple. This means that C structures like those returned by `os.stat()`, `time.gmtime()`, and `sys.version_info` now work like a named tuple and now work with functions and methods that expect a tuple as an argument. This is a big step forward in making the C structures as flexible as their pure Python counterparts:

```python
>>> isinstance(sys.version_info, tuple)
True
>>> 'Version %d.%d.%d %s(%d)'
'Version 3.2.0 final(0)'
```

(Suggested by Arfrever Frehtes Taifersar Arahesis and implemented by Benjamin Peterson in issue 8413.)

- Warnings are now easier to control using the `PYTHONWARNINGS` environment variable as an alternative to using `-W` at the command line:

```bash
$ export PYTHONWARNINGS='ignore::RuntimeWarning::,once::UnicodeWarning::'
```

(Suggested by Barry Warsaw and implemented by Philip Jenvey in issue 7301.)

- A new warning category, `ResourceWarning`, has been added. It is emitted when potential issues with resource consumption or cleanup are detected. It is silenced by default in normal release builds but can be enabled through the means provided by the `warnings` module, or on the command line.

A `ResourceWarning` is issued at interpreter shutdown if the `gc.garbage` list isn't empty, and if `gc.DEBUG_UNCOLLECTABLE`
is set, all uncollectable objects are printed. This is meant to make the programmer aware that their code contains object finalization issues.

A ResourceWarning is also issued when a file object is destroyed without having been explicitly closed. While the deallocator for such object ensures it closes the underlying operating system resource (usually, a file descriptor), the delay in deallocating the object could produce various issues, especially under Windows. Here is an example of enabling the warning from the command line:

```
$ python -q -Wdefault
>>> f = open("foo", "wb")
>>> del f
__main__:1: ResourceWarning: unclosed file <_io.BufferedWriter name='foo'>
```

(Added by Antoine Pitrou and Georg Brandl in issue 10093 and issue 477863.)

- range objects now support index and count methods. This is part of an effort to make more objects fully implement the collections.Sequence abstract base class. As a result, the language will have a more uniform API. In addition, range objects now support slicing and negative indices, even with values larger than sys.maxsize. This makes range more interoperable with lists:

```
>>> range(0, 100, 2).count(10)
1
>>> range(0, 100, 2).index(10)
5
>>> range(0, 100, 2)[5]
```
The callable() built-in function from Py2.x was resurrected. It provides a concise, readable alternative to using an abstract base class in an expression like `isinstance(x, collections.Callable):

```python
>>> callable(max)
True
>>> callable(20)
False
```

Python’s import mechanism can now load modules installed in directories with non-ASCII characters in the path name. This solved an aggravating problem with home directories for users with non-ASCII characters in their usernames.

(Contributed by Daniel Stutzbach in issue 9213, by Alexander Belopolsky in issue 2690, and by Nick Coghlan in issue 10889.)

(See issue 10518.)

(Required extensive work by Victor Stinner in issue 9425.)
New, Improved, and Deprecated Modules

Python’s standard library has undergone significant maintenance efforts and quality improvements.

The biggest news for Python 3.2 is that the email package, mailbox module, and nntplib modules now work correctly with the bytes/text model in Python 3. For the first time, there is correct handling of messages with mixed encodings.

Throughout the standard library, there has been more careful attention to encodings and text versus bytes issues. In particular, interactions with the operating system are now better able to exchange non-ASCII data using the Windows MBCS encoding, locale-aware encodings, or UTF-8.

Another significant win is the addition of substantially better support for SSL connections and security certificates.

In addition, more classes now implement a context manager to support convenient and reliable resource clean-up using a with statement.

email

The usability of the email package in Python 3 has been mostly fixed by the extensive efforts of R. David Murray. The problem was that emails are typically read and stored in the form of bytes rather than str text, and they may contain multiple encodings within a single email. So, the email package had to be extended to parse and generate email messages in bytes format.
• New functions `message_from_bytes()` and `message_from_binary_file()`, and new classes `BytesFeedParser` and `BytesParser` allow binary message data to be parsed into model objects.

• Given bytes input to the model, `get_payload()` will by default decode a message body that has a `Content-Transfer-Encoding` of 8bit using the charset specified in the MIME headers and return the resulting string.

• Given bytes input to the model, `Generator` will convert message bodies that have a `Content-Transfer-Encoding` of 8bit to instead have a 7bit `Content-Transfer-Encoding`.

Headers with unencoded non-ASCII bytes are deemed to be RFC 2047-encoded using the `unknown-8bit` character set.

• A new class `BytesGenerator` produces bytes as output, preserving any unchanged non-ASCII data that was present in the input used to build the model, including message bodies with a `Content-Transfer-Encoding` of 8bit.

• The `smtplib` `SMTP` class now accepts a byte string for the `msg` argument to the `sendmail()` method, and a new method, `send_message()` accepts a `Message` object and can optionally obtain the `from_addr` and `to_addr` addresses directly from the object.

(Proposed and implemented by R. David Murray, issue 4661 and issue 10321.)

`elementtree`
The *xml.etree.ElementTree* package and its *xml.etree.cElementTree* counterpart have been updated to version 1.3.

Several new and useful functions and methods have been added:

- *xml.etree.ElementTree.fromstringlist()* which builds an XML document from a sequence of fragments
- *xml.etree.ElementTree.register_namespace()* for registering a global namespace prefix
- *xml.etree.ElementTree.tostringlist()* for string representation including all sublists
- *xml.etree.ElementTree.Element.extend()* for appending a sequence of zero or more elements
- *xml.etree.ElementTree.Element.iterfind()* searches an element and subelements
- *xml.etree.ElementTree.Element.itertext()* creates a text iterator over an element and its subelements
- *xml.etree.ElementTree.TreeBuilder.end()* closes the current element
- *xml.etree.ElementTree.TreeBuilder.doctype()* handles a doctype declaration

Two methods have been deprecated:

- *xml.etree.ElementTree.getchildren()* use `list(elem)` instead.
- *xml.etree.ElementTree.getiterator()* use `Element.iter` instead.

For details of the update, see *Introducing ElementTree* on Fredrik Lundh’s website.

(Contributed by Florent Xicluna and Fredrik Lundh, *issue 6472.*)
functools

- The `functools` module includes a new decorator for caching function calls. `functools.lru_cache()` can save repeated queries to an external resource whenever the results are expected to be the same.

For example, adding a caching decorator to a database query function can save database accesses for popular searches:

```python
>>> import functools

>>> @functools.lru_cache(maxsize=300)

>>> def get_phone_number(name):
    c = conn.cursor()
    c.execute('SELECT phonenumber FROM phonelist WHERE name=?', (name,))
    return c.fetchone()[0]

>>> for name in user_requests:    # cached lookup
    get_phone_number(name)

To help with choosing an effective cache size, the wrapped function is instrumented for tracking cache statistics:

```python
>>> get_phone_number.cache_info()
CacheInfo(hits=4805, misses=980, maxsize=300, currsize=300)
```

If the phonelist table gets updated, the outdated contents of the cache can be cleared with:

```python
>>> get_phone_number.cache_clear()
```
(Contributed by Raymond Hettinger and incorporating design ideas from Jim Baker, Miki Tebeka, and Nick Coghlan; see recipe 498245, recipe 577479, issue 10586, and issue 10593.)

- The `functools.wraps()` decorator now adds a `__wrapped__` attribute pointing to the original callable function. This allows wrapped functions to be introspected. It also copies `__annotations__` if defined. And now it also gracefully skips over missing attributes such as `__doc__` which might not be defined for the wrapped callable.

In the above example, the cache can be removed by recovering the original function:

```python
>>> get_phone_number = get_phone_number.__wrapped__
```

(By Nick Coghlan and Terrence Cole; issue 9567, issue 3445, and issue 8814.)

- To help write classes with rich comparison methods, a new decorator `functools.total_ordering()` will use a existing equality and inequality methods to fill in the remaining methods.

For example, supplying `__eq__` and `__lt__` will enable `total_ordering()` to fill-in `__le__`, `__gt__` and `__ge__`:

```python
@total_ordering
class Student:
    def __eq__(self, other):
        return ((self.lastname.lower(), self.firstname)
                 (other.lastname.lower(), other.firstname))
    def __lt__(self, other):
        return ((self.lastname.lower(), self.firstname)
                 (other.lastname.lower(), other.firstname))
```
With the `total_ordering` decorator, the remaining comparison methods are filled in automatically.

(Contributed by Raymond Hettinger.)

- To aid in porting programs from Python 2, the `functools.cmp_to_key()` function converts an old-style comparison function to modern key function:

```python
>>> # locale-aware sort order
>>> sorted(iterable, key=cmp_to_key(locale.strcoll))
```

For sorting examples and a brief sorting tutorial, see the Sorting HowTo tutorial.

(Contributed by Raymond Hettinger.)

**itertools**

- The `itertools` module has a new `accumulate()` function modeled on APL's `scan` operator and Numpy's `accumulate` function:

```python
>>> from itertools import accumulate
>>> list(accumulate([8, 2, 50]))
[8, 10, 60]
```

```python
>>> prob_dist = [0.1, 0.4, 0.2, 0.3]
>>> list(accumulate(prob_dist))  # cumulative
[0.1, 0.5, 0.7, 1.0]
```
For an example using `accumulate()`, see the examples for the random module.

(Contributed by Raymond Hettinger and incorporating design suggestions from Mark Dickinson.)

collections

- The `collections.Counter` class now has two forms of in-place subtraction, the existing `-=` operator for saturating subtraction and the new `subtract()` method for regular subtraction. The former is suitable for multisets which only have positive counts, and the latter is more suitable for use cases that allow negative counts:

```python
>>> tally = Counter(dogs=5, cat=3)
>>> tally -= Counter(dogs=2, cats=8)  # saturating subtraction
>>> tally
Counter({'dogs': 3})
```

```python
>>> tally = Counter(dogs=5, cats=3)
>>> tally.subtract(dogs=2, cats=8)    # regular subtraction
>>> tally
Counter({'dogs': 3, 'cats': -5})
```

(Contributed by Raymond Hettinger.)

- The `collections.OrderedDict` class has a new method `move_to_end()` which takes an existing key and moves it to either the first or last position in the ordered sequence.

The default is to move an item to the last position. This is
equivalent of renewing an entry with `od[k] = od.pop(k)`.

A fast move-to-end operation is useful for resequencing entries. For example, an ordered dictionary can be used to track order of access by aging entries from the oldest to the most recently accessed.

```python
>>> d = OrderedDict.fromkeys(['a', 'b', 'X', 'd']
>>> list(d)
['a', 'b', 'X', 'd', 'e']
>>> d.move_to_end('X')
>>> list(d)
['a', 'b', 'd', 'e', 'X']
```

(Contributed by Raymond Hettinger.)

- The `collections.deque` class grew two new methods `count()` and `reverse()` that make them more substitutable for `list` objects:

```python
>>> d = deque('simsalabim')
>>> d.count('s')
2
>>> d.reverse()
>>> d
deque(['m', 'i', 'b', 'a', 'l', 'a', 's', 'm', 'i'])
```

(Contributed by Raymond Hettinger.)

**threading**

The `threading` module has a new `Barrier` synchronization class for making multiple threads wait until all of them have reached a
common barrier point. Barriers are useful for making sure that a task with multiple preconditions does not run until all of the predecessor tasks are complete.

Barriers can work with an arbitrary number of threads. This is a generalization of a Rendezvous which is defined for only two threads.

Implemented as a two-phase cyclic barrier, Barrier objects are suitable for use in loops. The separate filling and draining phases assure that all threads get released (drained) before any one of them can loop back and re-enter the barrier. The barrier fully resets after each cycle.

Example of using barriers:

```python
from threading import Barrier, Thread

def get_votes(site):
    ballots = conduct_election(site)
    all_polls_closed.wait()  # do not count until all polls closed
    totals = summarize(ballots)
    publish(site, totals)

all_polls_closed = Barrier(len(sites))
for site in sites:
    Thread(target=get_votes, args=(site,)).start()
```

In this example, the barrier enforces a rule that votes cannot be counted at any polling site until all polls are closed. Notice how a solution with a barrier is similar to one with threading.Thread.join(), but the threads stay alive and continue to do work (summarizing ballots) after the barrier point is crossed.
If any of the predecessor tasks can hang or be delayed, a barrier can be created with an optional *timeout* parameter. Then if the timeout period elapses before all the predecessor tasks reach the barrier point, all waiting threads are released and a *BrokenBarrierError* exception is raised:

```python
def get_votes(site):
    ballots = conductelection(site)
    try:
        all_polls_closed.wait(timeout = midnight - t
    except BrokenBarrierError:
        lockbox = seal_ballots(ballots)
        queue.put(lockbox)
    else:
        totals = summarize(ballots)
        publish(site, totals)
```

In this example, the barrier enforces a more robust rule. If some election sites do not finish before midnight, the barrier times-out and the ballots are sealed and deposited in a queue for later handling.

See *Barrier Synchronization Patterns* for more examples of how barriers can be used in parallel computing. Also, there is a simple but thorough explanation of barriers in *The Little Book of Semaphores*, section 3.6.

(Contributed by Kristján Valur Jónsson with an API review by Jeffrey Yasskin in issue 8777.)

datetime and time

- The `datetime` module has a new type `timezone` that implements the `tzinfo` interface by returning a fixed UTC offset
and timezone name. This makes it easier to create timezone-aware datetime objects:

```python
>>> from datetime import datetime, timezone
datetime.datetime.now(timezone.utc)
datetime.datetime(2010, 12, 8, 21, 4, 2, 923754, tzinfo=datetime.timezone.utc)
```

- Also, `timedelta` objects can now be multiplied by `float` and divided by `float` and `int` objects. And `timedelta` objects can now divide one another.

- The `datetime.date.strftime()` method is no longer restricted to years after 1900. The new supported year range is from 1000 to 9999 inclusive.

- Whenever a two-digit year is used in a time tuple, the interpretation has been governed by `time.accept2dyear`. The default is `True` which means that for a two-digit year, the century is guessed according to the POSIX rules governing the `%y strptime format.

Starting with Py3.2, use of the century guessing heuristic will emit a `DeprecationWarning`. Instead, it is recommended that `time.accept2dyear` be set to `False` so that large date ranges can be used without guesswork:

```python
>>> import time, warnings
>>> warnings.resetwarnings() # remove the de
```
Several functions now have significantly expanded date ranges. When `time.accept2dyear` is false, the `time.asctime()` function will accept any year that fits in a C int, while the `time.mktime()` and `time.strftime()` functions will accept the full range supported by the corresponding operating system functions.

(Contributed by Alexander Belopolsky and Victor Stinner in issue 1289118, issue 5094, issue 6641, issue 2706, issue 1777412, issue 8013, and issue 10827.)

**math**

The `math` module has been updated with six new functions inspired by the C99 standard.

The `isfinite()` function provides a reliable and fast way to detect special values. It returns `True` for regular numbers and `False` for `Nan` or `Infinity`:

```python
>>> [isfinite(x) for x in (123, 4.56, float('Nan'), [True, True, False, False])
```
The `expm1()` function computes $e^{x} - 1$ for small values of $x$ without incurring the loss of precision that usually accompanies the subtraction of nearly equal quantities:

```python
>>> expm1(0.013671875)  # more accurate way to compute e**x-1 for a small x
0.013765762467652909
```

The `erf()` function computes a probability integral or Gaussian error function. The complementary error function, `erfc()`, is $1 - \text{erf}(x)$:

```python
>>> erf(1.0/sqrt(2.0))  # portion of normal distribution within 1 standard deviation
0.682689492137086
>>> erfc(1.0/sqrt(2.0))  # portion of normal distribution outside 1 standard deviation
0.31731050786291404
>>> erf(1.0/sqrt(2.0)) + erfc(1.0/sqrt(2.0))
1.0
```

The `gamma()` function is a continuous extension of the factorial function. See [http://en.wikipedia.org/wiki/Gamma_function](http://en.wikipedia.org/wiki/Gamma_function) for details. Because the function is related to factorials, it grows large even for small values of $x$, so there is also a `lgamma()` function for computing the natural logarithm of the gamma function:

```python
>>> gamma(7.0)  # six factorial
720.0
>>> lgamma(801.0)  # log(800 factorial)
4551.950730698041
```

(Contributed by Mark Dickinson.)
The **abc** module now supports **abstractclassmethod()** and **abstractstaticmethod()**.

These tools make it possible to define an **abstract base class** that requires a particular **classmethod()** or **staticmethod()** to be implemented:

```python
class Temperature(metaclass=abc.ABCMeta):
    @abc.abstractclassmethod
    def from_fahrenheit(cls, t):
        ...
    @abc.abstractclassmethod
    def from_celsius(cls, t):
        ...
```

(Patch submitted by Daniel Urban; **issue 5867.**)

**IO**

The **io.BytesIO** has a new method, **getbuffer()**, which provides functionality similar to **memoryview()**. It creates an editable view of the data without making a copy. The buffer’s random access and support for slice notation are well-suited to in-place editing:

```python
>>> REC_LEN, LOC_START, LOC_LEN = 34, 7, 11
>>> def change_location(buffer, record_number, location):
...     start = record_number * REC_LEN + LOC_START
...     buffer[start:start+LOC_LEN] = location

>>> import io

>>> byte_stream = io.BytesIO(
...     b'G3805  storeroom  Main chassis  '
```
(Contributed by Antoine Pitrou in issue 5506.)

reprlib

When writing a __repr__() method for a custom container, it is easy to forget to handle the case where a member refers back to the container itself. Python's builtin objects such as list and set handle self-reference by displaying "..." in the recursive part of the representation string.

To help write such __repr__() methods, the reprlib module has a new decorator, recursive_repr(), for detecting recursive calls to __repr__() and substituting a placeholder string instead:

```python
>>> class MyList(list):
    @recursive_repr()
    def __repr__(self):
        return '<' + '|'.join(map(repr, self)) + '>

>>> m = MyList('abc')
>>> m.append(m)
>>> m.append('x')
>>> print(m)
```
logging

In addition to dictionary-based configuration described above, the `logging` package has many other improvements.

The logging documentation has been augmented by a `basic tutorial`, an `advanced tutorial`, and a `cookbook` of logging recipes. These documents are the fastest way to learn about logging.

The `logging.basicConfig()` set-up function gained a `style` argument to support three different types of string formatting. It defaults to “%” for traditional %-formatting, can be set to “{” for the new `str.format()` style, or can be set to “$” for the shell-style formatting provided by `string.Template`. The following three configurations are equivalent:

```python
>>> from logging import basicConfig
>>> basicConfig(style='%', format='%(name)s -> %(levelname)s: %(message)s')
>>> basicConfig(style='{', format='{name} -> {levelname} {message}')
>>> basicConfig(style='$', format='$name -> $levelname: $message')
```

If no configuration is set-up before a logging event occurs, there is now a default configuration using a `StreamHandler` directed to `sys.stderr` for events of `WARNING` level or higher. Formerly, an event occurring before a configuration was set-up would either raise an exception or silently drop the event depending on the value of `logging.raiseExceptions`. The new default handler is stored in
logging.lastResort.

The use of filters has been simplified. Instead of creating a Filter object, the predicate can be any Python callable that returns True or False.

There were a number of other improvements that add flexibility and simplify configuration. See the module documentation for a full listing of changes in Python 3.2.

CSV

The csv module now supports a new dialect, unix_dialect, which applies quoting for all fields and a traditional Unix style with `\n` as the line terminator. The registered dialect name is unix.

The csv.DictWriter has a new method, writeheader() for writing-out an initial row to document the field names:

```python
>>> import csv, sys
>>> w = csv.DictWriter(sys.stdout, ['name', 'dept'],
                      "name","dept"
>>> w.writeheader()
>>> w.writerows([                      
    {'name': 'tom', 'dept': 'accounting'},
    {'name': 'susan', 'dept': 'Salesl'}])
>>> w.writerows([                      
    'tom','accounting'
    'susan','sales
```

(New dialect suggested by Jay Talbot in issue 5975, and the new method suggested by Ed Abraham in issue 1537721.)

contextlib
There is a new and slightly mind-blowing tool `ContextDecorator` that is helpful for creating a `context manager` that does double duty as a function decorator.

As a convenience, this new functionality is used by `contextmanager()` so that no extra effort is needed to support both roles.

The basic idea is that both context managers and function decorators can be used for pre-action and post-action wrappers. Context managers wrap a group of statements using a `with` statement, and function decorators wrap a group of statements enclosed in a function. So, occasionally there is a need to write a pre-action or post-action wrapper that can be used in either role.

For example, it is sometimes useful to wrap functions or groups of statements with a logger that can track the time of entry and time of exit. Rather than writing both a function decorator and a context manager for the task, the `contextmanager()` provides both capabilities in a single definition:

```python
from contextlib import contextmanager
import logging

logging.basicConfig(level=logging.INFO)

@contextmanager
def track_entry_and_exit(name):
    logging.info('Entering: {}'.format(name))
    yield
    logging.info('Exiting: {}'.format(name))
```

Formerly, this would have only been usable as a context manager:
with track_entry_and_exit('widget loader'):
    print('Some time consuming activity goes here')
    load_widget()

Now, it can be used as a decorator as well:

@track_entry_and_exit('widget loader')
def activity():
    print('Some time consuming activity goes here')
    load_widget()

Trying to fulfill two roles at once places some limitations on the technique. Context managers normally have the flexibility to return an argument usable by a `with` statement, but there is no parallel for function decorators.

In the above example, there is not a clean way for the `track_entry_and_exit` context manager to return a logging instance for use in the body of enclosed statements.

(Contributed by Michael Foord in issue 9110.)

decimal and fractions

Mark Dickinson crafted an elegant and efficient scheme for assuring that different numeric datatypes will have the same hash value whenever their actual values are equal (issue 8188):

```python
assert hash(Fraction(3, 2)) == hash(1.5) == \
        hash(Decimal("1.5")) == hash(complex(1.5, 0))
```

Some of the hashing details are exposed through a new attribute, `sys.hash_info`, which describes the bit width of the hash value, the
prime modulus, the hash values for *infinity* and *nan*, and the multiplier used for the imaginary part of a number:

```python
>>> sys.hash_info
sys.hash_info(width=64, modulus=2305843009213693951,
```

An early decision to limit the inter-operability of various numeric types has been relaxed. It is still unsupported (and ill-advised) to have implicit mixing in arithmetic expressions such as `Decimal('1.1') + float('1.1')` because the latter loses information in the process of constructing the binary float. However, since existing floating point value can be converted losslessly to either a decimal or rational representation, it makes sense to add them to the constructor and to support mixed-type comparisons.

- The `decimal.Decimal` constructor now accepts `float` objects directly so there is no longer a need to use the `from_float()` method ([issue 8257](https://bugs.python.org/issue8257)).
- Mixed type comparisons are now fully supported so that `Decimal` objects can be directly compared with `float` and `fractions.Fraction` ([issue 2531](https://bugs.python.org/issue2531) and [issue 8188](https://bugs.python.org/issue8188)).

Similar changes were made to `fractions.Fraction` so that the `from_float()` and `from_decimal()` methods are no longer needed ([issue 8294](https://bugs.python.org/issue8294)):

```python
>>> Decimal('1.1')
Decimal('1.000000000000000088817841970012523233890535e-07')
>>> Fraction('1.1')
Fraction(2476979795053773, 2251799813685248)
```

Another useful change for the `decimal` module is that the
Context.clamp attribute is now public. This is useful in creating contexts that correspond to the decimal interchange formats specified in IEEE 754 (see issue 8540).

(Contributed by Mark Dickinson and Raymond Hettinger.)

ftp

The ftplib.FTP class now supports the context manager protocol to unconditionally consume socket.error exceptions and to close the FTP connection when done:

```python
>>> from ftplib import FTP
>>> with FTP("ftp1.at.proftpd.org") as ftp:
    ftp.login()
    ftp.dir()

'230 Anonymous login ok, restrictions apply.'
dr-xr-xr-x 9 ftp ftp 154 May 6 10:43 ...
```

Other file-like objects such as mmap.mmap and fileinput.input() also grew auto-closing context managers:

```python
with fileinput.input(files=("log1.txt", "log2.txt"))
    for line in f:
        process(line)
```

(Contributed by Tarek Ziadé and Giampaolo Rodolà in issue 4972, and by Georg Brandl in issue 8046 and issue 1286.)
The **FTP_TLS** class now accepts a *context* parameter, which is a **ssl.SSLContext** object allowing bundling SSL configuration options, certificates and private keys into a single (potentially long-lived) structure.

(Contributed by Giampaolo Rodolà; issue 8806.)

**popen**

The **os.popen()** and **subprocess.Popen()** functions now support *with* statements for auto-closing of the file descriptors.

(Contributed by Antoine Pitrou and Brian Curtin in issue 7461 and issue 10554.)

**select**

The **select** module now exposes a new, constant attribute, **PIPE_BUF**, which gives the minimum number of bytes which are guaranteed not to block when **select.select()** says a pipe is ready for writing.

```
>>> import select
>>> select.PIPE_BUF
512
```

(Available on Unix systems. Patch by Sébastien Sablé in issue 9862)

**gzip and zipfile**

**gzip.GzipFile** now implements the **io.BufferedIOBase abstract base class** (except for **truncate()**). It also has a **peek()**
method and supports unseekable as well as zero-padded file objects.

The gzip module also gains the `compress()` and `decompress()` functions for easier in-memory compression and decompression. Keep in mind that text needs to be encoded as `bytes` before compressing and decompressing:

```python
>>> s = 'Three shall be the number thou shalt count,
>>> s += 'and the number of the counting shall be the
>>> b = s.encode()                          # convert
89
>>> c = gzip.compress(b)
>>> len(c)
77
>>> gzip.decompress(c).decode()[:42]       # decompress
'Three shall be the number thou shalt count,'

(Contributed by Anand B. Pillai in issue 3488; and by Antoine Pitrou, Nir Aides and Brian Curtin in issue 9962, issue 1675951, issue 7471 and issue 2846.)

Also, the zipfile.ZipExtFile class was reworked internally to represent files stored inside an archive. The new implementation is significantly faster and can be wrapped in a `io.BufferedReader` object for more speedups. It also solves an issue where interleaved calls to `read` and `readline` gave the wrong results.

(Patch submitted by Nir Aides in issue 7610.)

tarfile

The TarFile class can now be used as a context manager. In
addition, its `add()` method has a new option, `filter`, that controls which files are added to the archive and allows the file metadata to be edited.

The new `filter` option replaces the older, less flexible `exclude` parameter which is now deprecated. If specified, the optional `filter` parameter needs to be a `keyword argument`. The user-supplied filter function accepts a `TarInfo` object and returns an updated `TarInfo` object, or if it wants the file to be excluded, the function can return `None`:

```python
>>> import tarfile, glob

>>> def myfilter(tarinfo):
    if tarinfo.isfile():  # only save
        tarinfo.uname = 'monty'  # redact the
    return tarinfo

>>> with tarfile.open(name='myarchive.tar.gz', mode=
for filename in glob.glob('*.txt'):
    tf.add(filename, filter=myfilter)

```

(Proposed by Tarek Ziadé and implemented by Lars Gustäbel in issue 6856.)

**hashlib**

The `hashlib` module has two new constant attributes listing the
hashing algorithms guaranteed to be present in all implementations and those available on the current implementation:

```python
>>> import hashlib
>>> hashlib.algorithms_guaranteed
{'sha1', 'sha224', 'sha384', 'sha256', 'sha512', 'md5'}
>>> hashlib.algorithms_available
```

(Suggested by Carl Chenet in issue 7418.)

**ast**

The **ast** module has a wonderful a general-purpose tool for safely evaluating expression strings using the Python literal syntax. The **ast.literal_eval()** function serves as a secure alternative to the builtin **eval()** function which is easily abused. Python 3.2 adds **bytes** and **set** literals to the list of supported types: strings, bytes, numbers, tuples, lists, dicts, sets, booleans, and None.

```python
>>> from ast import literal_eval

>>> request = "\{"req": 3, 'func': 'pow', 'args': (2,

```
(Implemented by Benjamin Peterson and Georg Brandl.)

OS

Different operating systems use various encodings for filenames and environment variables. The os module provides two new functions, fsencode() and fsdecode(), for encoding and decoding filenames:

```python
>>> filename = 'Sehenswürdigkeiten'
>>> os.fsencode(filename)
b'Sehensw\xc3\xbcrdigkeiten'
```

Some operating systems allow direct access to encoded bytes in the environment. If so, the os.supports_bytes_environ constant will be true.

For direct access to encoded environment variables (if available), use the new os.getenvb() function or use os.environb which is a bytes version of os.environ.

(Contributed by Victor Stinner.)

shutil

The shutil.copytree() function has two new options:

- `ignore_dangling_symlinks`: when symlinks=False so that the function copies a file pointed to by a symlink, not the symlink
itself. This option will silence the error raised if the file doesn't exist.

- *copy_function*: is a callable that will be used to copy files. `shutil.copy2()` is used by default.

(Contributed by Tarek Ziadé.)

In addition, the `shutil` module now supports *archiving operations* for zipfiles, uncompressed tarfiles, gzipped tarfiles, and bzipped tarfiles. And there are functions for registering additional archiving file formats (such as xz compressed tarfiles or custom formats).

The principal functions are `make_archive()` and `unpack_archive()`. By default, both operate on the current directory (which can be set by `os.chdir()`) and on any sub-directories. The archive filename needs to be specified with a full pathname. The archiving step is non-destructive (the original files are left unchanged).

```python
>>> import shutil, pprint

>>> os.chdir('mydata')

>>> f = shutil.make_archive('/var/backup/mydata', 'zip')

>>> f
'/var/backup/mydata.zip'

>>> os.chdir('tmp')

>>> shutil.unpack_archive('/var/backup/mydata.zip')

>>> pprint.pprint(shutil.get_archive_formats())
[('bztar', 'bzip2\'ed tar-file'),
 ('gztar', 'gzip\'ed tar-file'),
 ('tar', 'uncompressed tar file'),
 ('zip', 'ZIP file')]
```
shutil

```python
>>> shutil.register_archive_format(
    name = 'xz',
    function = xz.compress,
    extra_args = [('level', 8)],
    description = 'xz compression'
)
```

(Contributed by Tarek Ziadé.)

sqlite3

The `sqlite3` module was updated to `pysqlite` version 2.6.0. It has two new capabilities.

- The `sqlite3.Connection.in_transit` attribute is true if there is an active transaction for uncommitted changes.
- The `sqlite3.Connection.enable_load_extension()` and `sqlite3.Connection.load_extension()` methods allows you to load SQLite extensions from ".so" files. One well-known extension is the fulltext-search extension distributed with SQLite.

(Contributed by R. David Murray and Shashwat Anand; issue 8845.)

html

A new `html` module was introduced with only a single function, `escape()`, which is used for escaping reserved characters from HTML markup:

```python
>>> import html
>>> html.escape('x > 2 && x < 7')
'x &gt; 2 &amp;&amp; x &lt; 7'
```
socket

The `socket` module has two new improvements.

- Socket objects now have a `detach()` method which puts the socket into closed state without actually closing the underlying file descriptor. The latter can then be reused for other purposes. (Added by Antoine Pitrou; issue 8524.)
- `socket.create_connection()` now supports the context manager protocol to unconditionally consume `socket.error` exceptions and to close the socket when done. (Contributed by Giampaolo Rodolà; issue 9794.)

ssl

The `ssl` module added a number of features to satisfy common requirements for secure (encrypted, authenticated) internet connections:

- A new class, `SSLCertificate`, serves as a container for persistent SSL data, such as protocol settings, certificates, private keys, and various other options. It includes a `wrap_socket()` for creating an SSL socket from an SSL context.
- A new function, `ssl.match_hostname()`, supports server identity verification for higher-level protocols by implementing the rules of HTTPS (from RFC 2818) which are also suitable for other protocols.
- The `ssl.wrap_socket()` constructor function now takes a `ciphers` argument. The `ciphers` string lists the allowed encryption algorithms using the format described in the OpenSSL documentation.
- When linked against recent versions of OpenSSL, the `ssl` module now supports the Server Name Indication extension to the
TLS protocol, allowing multiple “virtual hosts” using different certificates on a single IP port. This extension is only supported in client mode, and is activated by passing the `server_hostname` argument to `ssl.SSLContext.wrap_socket()`.

- Various options have been added to the `ssl` module, such as `OP_NO_SSLv2` which disables the insecure and obsolete SSLv2 protocol.
- The extension now loads all the OpenSSL ciphers and digest algorithms. If some SSL certificates cannot be verified, they are reported as an “unknown algorithm” error.
- The version of OpenSSL being used is now accessible using the module attributes `ssl.OPENSSL_VERSION` (a string), `ssl.OPENSSL_VERSION_INFO` (a 5-tuple), and `ssl.OPENSSL_VERSION_NUMBER` (an integer).

(Contributed by Antoine Pitrou in issue 8850, issue 1589, issue 8322, issue 5639, issue 4870, issue 8484, and issue 8321.)

**nntp**

The `nntplib` module has a revamped implementation with better bytes and text semantics as well as more practical APIs. These improvements break compatibility with the nntplib version in Python 3.1, which was partly dysfunctional in itself.

Support for secure connections through both implicit (using `nntplib.NNTP_SSL`) and explicit (using `nntplib.NNTP.starttls()`) TLS has also been added.

(Contributed by Antoine Pitrou in issue 9360 and Andrew Vant in issue 1926.)
certificates

http.client.HTTPSConnection, urllib.request.HTTPSHandler and urllib.request.urlopen() now take optional arguments to allow for server certificate checking against a set of Certificate Authorities, as recommended in public uses of HTTPS.

(Added by Antoine Pitrou, issue 9003.)

imaplib

Support for explicit TLS on standard IMAP4 connections has been added through the new imaplib.IMAP4.starttls method.

(Contributed by Lorenzo M. Catucci and Antoine Pitrou, issue 4471.)

http.client

There were a number of small API improvements in the http.client module. The old-style HTTP 0.9 simple responses are no longer supported and the strict parameter is deprecated in all classes.

The HTTPConnection and HTTPSConnection classes now have a source_address parameter for a (host, port) tuple indicating where the HTTP connection is made from.

Support for certificate checking and HTTPS virtual hosts were added to HTTPSConnection.

The request() method on connection objects allowed an optional
body argument so that a file object could be used to supply the content of the request. Conveniently, the body argument now also accepts an iterable object so long as it includes an explicit Content-Length header. This extended interface is much more flexible than before.

To establish an HTTPS connection through a proxy server, there is a new set_tunnel() method that sets the host and port for HTTP Connect tunneling.

To match the behavior of http.server, the HTTP client library now also encodes headers with ISO-8859-1 (Latin-1) encoding. It was already doing that for incoming headers, so now the behavior is consistent for both incoming and outgoing traffic. (See work by Armin Ronacher in issue 10980.)

unittest

The unittest module has a number of improvements supporting test discovery for packages, easier experimentation at the interactive prompt, new testcase methods, improved diagnostic messages for test failures, and better method names.

- The command-line call python -m unittest can now accept file paths instead of module names for running specific tests (issue 10620). The new test discovery can find tests within packages, locating any test importable from the top-level directory. The top-level directory can be specified with the -t option, a pattern for matching files with -p, and a directory to start discovery with -s:

  ```bash
  $ python -m unittest discover -s my_proj_dir -p
  ```
Experimentation at the interactive prompt is now easier because the unittest.case.TestCase class can now be instantiated without arguments:

```python
>>> testCase().assertEqual(pow(2, 3), 8)
```

The unittest module has two new methods, `assert Warns()` and `assert WarnsRegex()` to verify that a given warning type is triggered by the code under test:

```python
with self.assertWarns(DeprecationWarning):
    legacy_function('XYZ')
```

Another new method, `assertCountEqual()` is used to compare two iterables to determine if their element counts are equal (whether the same elements are present with the same number of occurrences regardless of order):

```python
def test_anagram(self):
    self.assertCountEqual('algorithm', 'logarithm')
```

A principal feature of the unittest module is an effort to produce meaningful diagnostics when a test fails. When possible, the failure is recorded along with a diff of the output. This is especially helpful for analyzing log files of failed test runs. However, since
diffs can sometime be voluminous, there is a new `maxDiff` attribute that sets maximum length of diffs displayed.

- In addition, the method names in the module have undergone a number of clean-ups.

For example, `assertRegex()` is the new name for `assertRegexpMatches()` which was misnamed because the test uses `re.search()`, not `re.match()`. Other methods using regular expressions are now named using short form “Regex” in preference to “Regexp” – this matches the names used in other unittest implementations, matches Python's old name for the `re` module, and it has unambiguous camel-casing.

(Contributed by Raymond Hettinger and implemented by Ezio Melotti.)

- To improve consistency, some long-standing method aliases are being deprecated in favor of the preferred names:

<table>
<thead>
<tr>
<th>Old Name</th>
<th>Preferred Name</th>
</tr>
</thead>
<tbody>
<tr>
<td><code>assert_()</code></td>
<td><code>assertTrue()</code></td>
</tr>
<tr>
<td><code>assertEquals()</code></td>
<td><code>assertEqual()</code></td>
</tr>
<tr>
<td><code>assertNotEquals()</code></td>
<td><code>assertNotEqual()</code></td>
</tr>
<tr>
<td><code>assertAlmostEquals()</code></td>
<td><code>assertAlmostEqual()</code></td>
</tr>
<tr>
<td><code>assertNotAlmostEquals()</code></td>
<td><code>assertNotAlmostEqual()</code></td>
</tr>
</tbody>
</table>

Likewise, the `TestCase.fail*` methods deprecated in Python 3.1 are expected to be removed in Python 3.3. Also see the `Deprecated aliases` section in the `unittest` documentation.
The `assertDictContainsSubset()` method was deprecated because it was misimplemented with the arguments in the wrong order. This created hard-to-debug optical illusions where tests like `TestCase().assertDictContainsSubset({'a':1, 'b':2}, {'a':1})` would fail.

(Contributed by Raymond Hettinger.)

**random**

The integer methods in the `random` module now do a better job of producing uniform distributions. Previously, they computed selections with `int(n*random())` which had a slight bias whenever \( n \) was not a power of two. Now, multiple selections are made from a range up to the next power of two and a selection is kept only when it falls within the range \( 0 \leq x < n \). The functions and methods affected are `randrange()`, `randint()`, `choice()`, `shuffle()` and `sample()`.

(Contributed by Raymond Hettinger; issue 9025.)

**poplib**

`POP3_SSL` class now accepts a `context` parameter, which is a `ssl.SSLContext` object allowing bundling SSL configuration options, certificates and private keys into a single (potentially long-lived) structure.

(Contributed by Giampaolo Rodolà; issue 8807.)
asyncore

`asyncore.dispatcher` now provides a `handle_accepted()` method returning a `(sock, addr)` pair which is called when a connection has actually been established with a new remote endpoint. This is supposed to be used as a replacement for old `handle_accept()` and avoids the user to call `accept()` directly.

(Contributed by Giampaolo Rodolà; issue 6706.)

tempfile

The `tempfile` module has a new context manager, `TemporaryDirectory` which provides easy deterministic cleanup of temporary directories:

```python
with tempfile.TemporaryDirectory() as tmpdirname:
    print('created temporary dir:', tmpdirname)
```

(Contributed by Neil Schemenauer and Nick Coghlan; issue 5178.)

inspect

- The `inspect` module has a new function `getgeneratorstate()` to easily identify the current state of a generator-iterator:

```python
>>> from inspect import getgeneratorstate
>>> def gen():
    yield 'demo'
>>> g = gen()
>>> getgeneratorstate(g)
```
(Contributed by Rodolpho Eckhardt and Nick Coghlan, issue 10220.)

- To support lookups without the possibility of activating a dynamic attribute, the `inspect` module has a new function, `getattr_static()`. Unlike `hasattr()`, this is a true read-only search, guaranteed not to change state while it is searching:

```
>>> class A:
    @property
def f(self):
    print('Running')
    return 10

>>> a = A()
>>> getattr(a, 'f')
Running
10
>>> inspect.getattr_static(a, 'f')
<property object at 0x1022bd788>
```

(Contributed by Michael Foord.)

pydoc

The `pydoc` module now provides a much-improved Web server
interface, as well as a new command-line option `-b` to automatically open a browser window to display that server:

```
$ pydoc3.2 -b
```

(Contributed by Ron Adam; issue 2001.)

dis

The `dis` module gained two new functions for inspecting code, `code_info()` and `show_code()`. Both provide detailed code object information for the supplied function, method, source code string or code object. The former returns a string and the latter prints it:

```
>>> import dis, random
>>> dis.show_code(random.choice)
Name: choice
Filename: /Library/Frameworks/Python.framework/Versions/3.2/lib/python3.2/random.py
Argument count: 2
Kw-only arguments: 0
Number of locals: 3
Stack size: 11
Flags: OPTIMIZED, NEWLOCALS, NOFREE
Constants:
  0: 'Choose a random element from a non-empty sequence'
  1: 'Cannot choose from an empty sequence'
Names:
  0: _randbelow
  1: len
  2: ValueError
  3: IndexError
Variable names:
  0: self
  1: seq
  2: i
```
In addition, the `dis()` function now accepts string arguments so that the common idiom `dis(compile(s, '', 'eval'))` can be shortened to `dis(s)):

```
>>> dis('3*x+1 if x%2==1 else x//2')

  1   0 LOAD_NAME     0 (x)
  3   0 LOAD_CONST    0 (2)
  6   0 BINARY_MODULO
  7   1 LOAD_CONST    1 (1)
 10   2 COMPARE_OP   2 (==)
 13   28 POP_JUMP_IF_FALSE
 16   2 LOAD_CONST    2 (3)
 19   0 LOAD_NAME    0 (x)
 22   0 BINARY_MULTIPLY
 23   1 LOAD_CONST    1 (1)
 26   0 BINARY_ADD
 27     RETURN_VALUE
```

```
 28   0 LOAD_NAME    0 (x)
 31   0 LOAD_CONST    0 (2)
 34   34 BINARY_FLOOR_DIVIDE
 35     RETURN_VALUE
```

Taken together, these improvements make it easier to explore how CPython is implemented and to see for yourself what the language syntax does under-the-hood.

(Contributed by Nick Coghlan in issue 9147.)

**dbm**

All database modules now support the `get()` and `setdefault()` methods.
(Suggested by Ray Allen in issue 9523.)

c types

A new type, `ctypes.c_ssize_t` represents the C `ssize_t` datatype.

site

The `site` module has three new functions useful for reporting on the details of a given Python installation.

- `getsitepackages()` lists all global site-packages directories.
- `getuserbase()` reports on the user’s base directory where data can be stored.
- `getusersitepackages()` reveals the user-specific site-packages directory path.

```python
>>> import site
>>> site.getsitepackages()
['/Library/Frameworks/Python.framework/Versions/3.2/lib/python3.2/site-packages',
 '/Library/Frameworks/Python.framework/Versions/3.2/lib/site-python',
 '/Library/Python/3.2/site-packages']
>>> site.getuserbase()
'/Users/raymondhettinger/Library/Python/3.2'
>>> site.getusersitepackages()
'/Users/raymondhettinger/Library/Python/3.2/lib/python3.2/site-packages'
```

Conveniently, some of site’s functionality is accessible directly from the command-line:

```
$ python -m site --user-base
/Users/raymondhettinger/.local
```
sysconfig

The new `sysconfig` module makes it straightforward to discover installation paths and configuration variables that vary across platforms and installations.

The module offers access simple access functions for platform and version information:

- `get_platform()` returning values like `linux-i586` or `macosx-10.6-ppc`.
- `get_python_version()` returns a Python version string such as “3.2”.

It also provides access to the paths and variables corresponding to one of seven named schemes used by `distutils`. Those include `posix_prefix`, `posix_home`, `posix_user`, `nt`, `nt_user`, `os2`, `os2_home`:

- `get_paths()` makes a dictionary containing installation paths for the current installation scheme.
- `get_config_vars()` returns a dictionary of platform specific variables.

There is also a convenient command-line interface:

```
C:\Python32>python -m sysconfig
Platform: "win32"
Python version: "3.2"
```
Current installation scheme: "nt"

Paths:

data = "C:\Python32"
include = "C:\Python32\Include"

(Moved out of Distutils by Tarek Ziadé.)
The **pdb** debugger module gained a number of usability improvements:

- **pdb.py** now has a `-c` option that executes commands as given in a `.pdbrc` script file.
- A `.pdbrc` script file can contain `continue` and `next` commands that continue debugging.
- The Pdb class constructor now accepts a `nosigint` argument.
- New commands: `l(list)`, `ll(long list)` and `source` for listing source code.
- New commands: `display` and `undisplay` for showing or hiding the value of an expression if it has changed.
- New command: `interact` for starting an interactive interpreter containing the global and local names found in the current scope.
- Breakpoints can be cleared by breakpoint number.

(Contributed by Georg Brandl, Antonio Cuni and Ilya Sandler.)

**configparser**

The **configparser** module was modified to improve usability and predictability of the default parser and its supported INI syntax. The old ConfigParser class was removed in favor of SafeConfigParser which has in turn been renamed to **ConfigParser**. Support for inline comments is now turned off by default and section or option duplicates are not allowed in a single configuration source.

Config parsers gained a new API based on the mapping protocol:

```python
>>> parser = ConfigParser()
>>> parser.read_string(""
[DEFAULT]
location = upper left
```
The new API is implemented on top of the classical API, so custom parser subclasses should be able to use it without modifications.

The INI file structure accepted by config parsers can now be customized. Users can specify alternative option/value delimiters and comment prefixes, change the name of the DEFAULT section or switch the interpolation syntax.

There is support for pluggable interpolation including an additional interpolation handler ExtendedInterpolation:

```python
class ConfigParser

>>> parser = ConfigParser(interpolation=ExtendedInterpolation)
>>> parser.read_dict({
    'buildout': {
        'directory': '/home/ambv/zope9'
    }})
```
A number of smaller features were also introduced, like support for specifying encoding in read operations, specifying fallback values for get-functions, or reading directly from dictionaries and strings.

(All changes contributed by Łukasz Langa.)

urllib.parse
A number of usability improvements were made for the \texttt{urllib.parse} module.

The \texttt{urlparse()} function now supports IPv6 addresses as described in \textbf{RFC 2732}:

```python
>>> import urllib.parse
ParseResult(scheme='http',
            path='/foo/',
            params='',
            query='',
            fragment='')
```

The \texttt{urldefrag()} function now returns a \textit{named tuple}:

```python
>>> r = urllib.parse.urldefrag('http://python.org/about/#target')
>>> r
DefragResult(url='http://python.org/about/',
             fragment='target')
>>> r[0]
'http://python.org/about/'
>>> r.fragment
'target'
```

And, the \texttt{urlencode()} function is now much more flexible, accepting either a string or bytes type for the \textit{query} argument. If it is a string, then the \textit{safe}, \textit{encoding}, and \textit{error} parameters are sent to \texttt{quote_plus()} for encoding:

```python
>>> urllib.parse.urlencode([
                           ('type', 'telenovela'),
                           ('name', '¿Dónde Está Elisa?')],
                           encoding='latin-1')
```
As detailed in *Parsing ASCII Encoded Bytes*, all the `urllib.parse` functions now accept ASCII-encoded byte strings as input, so long as they are not mixed with regular strings. If ASCII-encoded byte strings are given as parameters, the return types will also be an ASCII-encoded byte strings:

```python
>>> urllib.parse.urlparse(b'http://www.python.org:80/about/
ParseResultBytes(scheme=b'http', netloc=b'www.python.org:80', path=b'/about/', params=b'', query="
```

(Work by Nick Coghlan, Dan Mahn, and Senthil Kumaran in issue 2987, issue 5468, and issue 9873.)

**mailbox**

Thanks to a concerted effort by R. David Murray, the `mailbox` module has been fixed for Python 3.2. The challenge was that mailbox had been originally designed with a text interface, but email messages are best represented with `bytes` because various parts of a message may have different encodings.

The solution harnessed the `email` package’s binary support for parsing arbitrary email messages. In addition, the solution required a number of API changes.

As expected, the `add()` method for `mailbox.Mailbox` objects now accepts binary input.

`StringIO` and text file input are deprecated. Also, string input will fail early if non-ASCII characters are used. Previously it would fail when
the email was processed in a later step.

There is also support for binary output. The `get_file()` method now returns a file in the binary mode (where it used to incorrectly set the file to text-mode). There is also a new `get_bytes()` method that returns a `bytes` representation of a message corresponding to a given `key`.

It is still possible to get non-binary output using the old API's `get_string()` method, but that approach is not very useful. Instead, it is best to extract messages from a `Message` object or to load them from binary input.

(Contributed by R. David Murray, with efforts from Steffen Daode Nurpmeso and an initial patch by Victor Stinner in issue 9124.)

**turtledemo**

The demonstration code for the `turtle` module was moved from the `Demo` directory to main library. It includes over a dozen sample scripts with lively displays. Being on `sys.path`, it can now be run directly from the command-line:

```
$ python -m turtledemo
```

(Moved from the Demo directory by Alexander Belopolsky in issue 10199.)
Multi-threading

- The mechanism for serializing execution of concurrently running Python threads (generally known as the *GIL* or *Global Interpreter Lock*) has been rewritten. Among the objectives were more predictable switching intervals and reduced overhead due to lock contention and the number of ensuing system calls. The notion of a “check interval” to allow thread switches has been abandoned and replaced by an absolute duration expressed in seconds. This parameter is tunable through `sys.setswitchinterval()`. It currently defaults to 5 milliseconds.

  Additional details about the implementation can be read from a python-dev mailing-list message (however, “priority requests” as exposed in this message have not been kept for inclusion).

  (Contributed by Antoine Pitrou.)

- Regular and recursive locks now accept an optional `timeout` argument to their `acquire()` method. (Contributed by Antoine Pitrou; issue 7316.)

- Similarly, `threading.Semaphore.acquire()` also gained a `timeout` argument. (Contributed by Torsten Landschoff; issue 850728.)

- Regular and recursive lock acquisitions can now be interrupted by signals on platforms using Pthreads. This means that Python programs that deadlock while acquiring locks can be successfully killed by repeatedly sending SIGINT to the process (by pressing `Ctrl+C` in most shells). (Contributed by Reid Kleckner; issue 8844.)
Optimizations

A number of small performance enhancements have been added:

- Python's peephole optimizer now recognizes patterns such as \( x \in \{1, 2, 3\} \) as being a test for membership in a set of constants. The optimizer recasts the `set` as a `frozenset` and stores the pre-built constant.

Now that the speed penalty is gone, it is practical to start writing membership tests using set-notation. This style is both semantically clear and operationally fast:

```python
extension = name.rpartition('. ')[2]
if extension in {'xml', 'html', 'xhtml', 'css'}:
    handle(name)
```

(Patch and additional tests contributed by Dave Malcolm; issue 6690).

- Serializing and unserializing data using the `pickle` module is now several times faster.

  (Contributed by Alexandre Vassalotti, Antoine Pitrou and the Unladen Swallow team in issue 9410 and issue 3873.)

- The Timsort algorithm used in `list.sort()` and `sorted()` now runs faster and uses less memory when called with a `key function`. Previously, every element of a list was wrapped with a temporary object that remembered the key value associated with each element. Now, two arrays of keys and values are sorted in parallel. This saves the memory consumed by the sort wrappers,
and it saves time lost to delegating comparisons.

(Patch by Daniel Stutzbach in issue 9915.)

- JSON decoding performance is improved and memory consumption is reduced whenever the same string is repeated for multiple keys. Also, JSON encoding now uses the C speedups when the `sort_keys` argument is true.

  (Contributed by Antoine Pitrou in issue 7451 and by Raymond Hettinger and Antoine Pitrou in issue 10314.)

- Recursive locks (created with the `threading.RLock()` API) now benefit from a C implementation which makes them as fast as regular locks, and between 10x and 15x faster than their previous pure Python implementation.

  (Contributed by Antoine Pitrou; issue 3001.)

- The fast-search algorithm in stringlib is now used by the `split()`, `rsplit()`, `splitlines()` and `replace()` methods on `bytes`, `bytearray` and `str` objects. Likewise, the algorithm is also used by `rfind()`, `rindex()`, `rsplit()` and `rpartition()`.

  (Patch by Florent Xicluna in issue 7622 and issue 7462.)

- Integer to string conversions now work two “digits” at a time, reducing the number of division and modulo operations.

  (issue 6713 by Gawain Bolton, Mark Dickinson, and Victor Stinner.)

There were several other minor optimizations. Set differencing now
runs faster when one operand is much larger than the other (patch by Andress Bennetts in issue 8685). The array.repeat() method has a faster implementation (issue 1569291 by Alexander Belopolsky). The BaseHTTPRequestHandler has more efficient buffering (issue 3709 by Andrew Schaaf). The operator.attrgetter() function has been sped-up (issue 10160 by Christos Georgiou). And ConfigParser loads multi-line arguments a bit faster (issue 7113 by Łukasz Langa).
Python has been updated to Unicode 6.0.0. The update to the standard adds over 2,000 new characters including emoji symbols which are important for mobile phones.

In addition, the updated standard has altered the character properties for two Kannada characters (U+0CF1, U+0CF2) and one New Tai Lue numeric character (U+19DA), making the former eligible for use in identifiers while disqualifying the latter. For more information, see Unicode Character Database Changes.
Codecs

Support was added for \textit{cp720} Arabic DOS encoding (issue 1616979).

MBCS encoding no longer ignores the error handler argument. In the default strict mode, it raises an \texttt{UnicodeDecodeError} when it encounters an undecodable byte sequence and an \texttt{UnicodeEncodeError} for an unencodable character.

The MBCS codec supports \texttt{'strict'} and \texttt{'ignore'} error handlers for decoding, and \texttt{'strict'} and \texttt{'replace'} for encoding.

To emulate Python3.1 MBCS encoding, select the \texttt{'ignore'} handler for decoding and the \texttt{'replace'} handler for encoding.

On Mac OS X, Python decodes command line arguments with \texttt{'utf-8'} rather than the locale encoding.

By default, \texttt{tarfile} uses \texttt{'utf-8'} encoding on Windows (instead of \texttt{'mbcs'}) and the \texttt{'surrogateescape'} error handler on all operating systems.
Documentation

The documentation continues to be improved.

- A table of quick links has been added to the top of lengthy sections such as *Built-in Functions*. In the case of *itertools*, the links are accompanied by tables of cheatsheet-style summaries to provide an overview and memory jog without having to read all of the docs.

- In some cases, the pure Python source code can be a helpful adjunct to the documentation, so now many modules now feature quick links to the latest version of the source code. For example, the *functools* module documentation has a quick link at the top labeled:

  **Source code** `Lib/functools.py`.

  (Contributed by Raymond Hettinger; see [rationale](#).

- The docs now contain more examples and recipes. In particular, *re* module has an extensive section, *Regular Expression Examples*. Likewise, the *itertools* module continues to be updated with new *Itertools Recipes*.

- The *datetime* module now has an auxiliary implementation in pure Python. No functionality was changed. This just provides an easier-to-read alternate implementation.

  (Contributed by Alexander Belopolsky in [issue 9528](#).

- The unmaintained *Demo* directory has been removed. Some demos were integrated into the documentation, some were moved
to the `Tools/demo` directory, and others were removed altogether.

(Contributed by Georg Brandl in issue 7962.)
IDLE

- The format menu now has an option to clean source files by stripping trailing whitespace.

  (Contributed by Raymond Hettinger; issue 5150.)

- IDLE on Mac OS X now works with both Carbon AquaTk and Cocoa AquaTk.

  (Contributed by Kevin Walzer, Ned Deily, and Ronald Oussoren; issue 6075.)
Code Repository

In addition to the existing Subversion code repository at http://svn.python.org there is now a Mercurial repository at http://hg.python.org/.

After the 3.2 release, there are plans to switch to Mercurial as the primary repository. This distributed version control system should make it easier for members of the community to create and share external changesets. See PEP 385 for details.

To learn to use the new version control system, see the tutorial by Joel Spolsky or the Guide to Mercurial Workflows.
Build and C API Changes

Changes to Python’s build process and to the C API include:

- The `idle`, `pydoc` and `2to3` scripts are now installed with a version-specific suffix on make `altinstall` (issue 10679).

- The C functions that access the Unicode Database now accept and return characters from the full Unicode range, even on narrow unicode builds (Py_UNICODE_TOLOWER, Py_UNICODE_ISDECIMAL, and others). A visible difference in Python is that `unicodedata.numeric()` now returns the correct value for large code points, and `repr()` may consider more characters as printable.

  (Reported by Bupjoe Lee and fixed by Amaury Forgeot D’Arc; issue 5127.)

- Computed gotos are now enabled by default on supported compilers (which are detected by the configure script). They can still be disabled selectively by specifying `--without-computed-gotos`.

  (Contributed by Antoine Pitrou; issue 9203.)

- The option `--with-wctype-functions` was removed. The built-in unicode database is now used for all functions.

  (Contributed by Amaury Forgeot D’Arc; issue 9210.)

- Hash values are now values of a new type, Py_hash_t, which is defined to be the same size as a pointer. Previously they were of type long, which on some 64-bit operating systems is still only 32
bits long. As a result of this fix, set and dict can now hold more than $2^{32}$ entries on builds with 64-bit pointers (previously, they could grow to that size but their performance degraded catastrophically).

(Suggested by Raymond Hettinger and implemented by Benjamin Peterson; issue 9778.)

- A new macro Py_VA_COPY copies the state of the variable argument list. It is equivalent to C99 va_copy but available on all Python platforms (issue 2443).

- A new C API function PySys_SetArgvEx() allows an embedded interpreter to set sys.argv without also modifying sys.path (issue 5753).

- PyEval_CallObject is now only available in macro form. The function declaration, which was kept for backwards compatibility reasons, is now removed – the macro was introduced in 1997 (issue 8276).

- There is a new function PyLong_AsLongLongAndOverflow() which is analogous to PyLong_AsLongAndOverflow(). They both serve to convert Python int into a native fixed-width type while providing detection of cases where the conversion won’t fit (issue 7767).

- The PyUnicode_CompareWithASCIIString() function now returns not equal if the Python string is NUL terminated.

- There is a new function PyErr_NewExceptionWithDoc() that is like PyErr_NewException() but allows a docstring to be specified. This lets C exceptions have the same self-documenting
capabilities as their pure Python counterparts (issue 7033).

- When compiled with the `--with-valgrind` option, the pymalloc allocator will be automatically disabled when running under Valgrind. This gives improved memory leak detection when running under Valgrind, while taking advantage of pymalloc at other times (issue 2422).

- Removed the `O?` format from the `PyArg_Parse` functions. The format is no longer used and it had never been documented (issue 8837).

There were a number of other small changes to the C-API. See the Misc/NEWS file for a complete list.

Also, there were a number of updates to the Mac OS X build, see Mac/BuildScript/README.txt for details. For users running a 32/64-bit build, there is a known problem with the default Tcl/Tk on Mac OS X 10.6. Accordingly, we recommend installing an updated alternative such as ActiveState Tcl/Tk 8.5.9. See http://www.python.org/download/mac/tcltk/ for additional details.
Porting to Python 3.2

This section lists previously described changes and other bugfixes that may require changes to your code:

- The `configparser` module has a number of clean-ups. The major change is to replace the old ConfigParser class with long-standing preferred alternative SafeConfigParser. In addition there are a number of smaller incompatibilities:
  - The interpolation syntax is now validated on `get()` and `set()` operations. In the default interpolation scheme, only two tokens with percent signs are valid: `%{(name)s` and `%%`, the latter being an escaped percent sign.
  - The `set()` and `add_section()` methods now verify that values are actual strings. Formerly, unsupported types could be introduced unintentionally.
  - Duplicate sections or options from a single source now raise either `DuplicateSectionError` or `DuplicateOptionError`. Formerly, duplicates would silently overwrite a previous entry.
  - Inline comments are now disabled by default so now the ; character can be safely used in values.
  - Comments now can be indented. Consequently, for ; or # to appear at the start of a line in multiline values, it has to be interpolated. This keeps comment prefix characters in values from being mistaken as comments.
  - "" is now a valid value and is no longer automatically converted to an empty string. For empty strings, use "option =" in a line.
- The `nntplib` module was reworked extensively, meaning that its APIs are often incompatible with the 3.1 APIs.
- `bytearray` objects can no longer be used as filenames; instead, they should be converted to `bytes`.

- The `array.tostring()` and `array.fromstring()` have been renamed to `array.tobytes()` and `array.frombytes()` for clarity. The old names have been deprecated. (See issue 8990.)

- `PyArg_Parse*()` functions:
  - “t#” format has been removed: use “s#” or “s*” instead
  - “w” and “w#” formats has been removed: use “w*” instead

- The PyCObject type, deprecated in 3.1, has been removed. To wrap opaque C pointers in Python objects, the `PyCapsule` API should be used instead; the new type has a well-defined interface for passing typing safety information and a less complicated signature for calling a destructor.

- The `sys.setfilesystemencoding()` function was removed because it had a flawed design.

- The `random.seed()` function and method now salt string seeds with an sha512 hash function. To access the previous version of `seed` in order to reproduce Python 3.1 sequences, set the `version` argument to 1, `random.seed(s, version=1)`.

- The previously deprecated `string.maketrans()` function has been removed in favor of the static methods `bytes.maketrans()` and `bytearray.maketrans()`. This change solves the confusion around which types were supported by the `string` module. Now, `str`, `bytes`, and `bytearray` each have their own `maketrans` and `translate` methods with intermediate translation tables of the appropriate type.
The previously deprecated `contextlib.nested()` function has been removed in favor of a plain `with` statement which can accept multiple context managers. The latter technique is faster (because it is built-in), and it does a better job finalizing multiple context managers when one of them raises an exception:

```python
with open('mylog.txt') as infile, open('a.out', 'w') as outfile:
    for line in infile:
        if '<critical>' in line:
            outfile.write(line)
```

(struct.pack() now only allows bytes for the `s` string pack code. Formerly, it would accept text arguments and implicitly encode them to bytes using UTF-8. This was problematic because it made assumptions about the correct encoding and because a variable-length encoding can fail when writing to fixed length segment of a structure.

Code such as `struct.pack('<6sHHBBB', 'GIF87a', x, y)` should be rewritten with to use bytes instead of text, `struct.pack('<6sHHBBB', b'GIF87a', x, y)`.

(xml.etree.ElementTree class now raises an `xml.etree.ElementTree.ParseError` when a parse fails.)
Previously it raised a `xml.parsers.expat.ExpatError`.

- The new, longer `str()` value on floats may break doctests which rely on the old output format.

- In `subprocess.Popen`, the default value for `close_fds` is now True under Unix; under Windows, it is True if the three standard streams are set to None, False otherwise. Previously, `close_fds` was always False by default, which produced difficult to solve bugs or race conditions when open file descriptors would leak into the child process.

- Support for legacy HTTP 0.9 has been removed from `urllib.request` and `http.client`. Such support is still present on the server side (in `http.server`).

  (Contributed by Antoine Pitrou, issue 10711.)

- SSL sockets in timeout mode now raise `socket.timeout` when a timeout occurs, rather than a generic `SSLError`.

  (Contributed by Antoine Pitrou, issue 10272.)

- The misleading functions `PyEval_AcquireLock()` and `PyEval_ReleaseLock()` have been officially deprecated. The thread-state aware APIs (such as `PyEval_SaveThread()` and `PyEval_RestoreThread()`) should be used instead.

- Due to security risks, `asyncore.handle_accept()` has been deprecated, and a new function, `asyncore.handle_accepted()`, was added to replace it.

  (Contributed by Giampaolo Rodola in issue 6706.)
• Due to the new *GIL* implementation, *PyEval_InitThreads()* cannot be called before *Py_Initialize()* anymore.
What’s New In Python 3.1

Author: Raymond Hettinger

This article explains the new features in Python 3.1, compared to 3.0.
PEP 372: Ordered Dictionaries

Regular Python dictionaries iterate over key/value pairs in arbitrary order. Over the years, a number of authors have written alternative implementations that remember the order that the keys were originally inserted. Based on the experiences from those implementations, a new collections.OrderedDict class has been introduced.

The OrderedDict API is substantially the same as regular dictionaries but will iterate over keys and values in a guaranteed order depending on when a key was first inserted. If a new entry overwrites an existing entry, the original insertion position is left unchanged. Deleting an entry and reinserting it will move it to the end.

The standard library now supports use of ordered dictionaries in several modules. The configparser module uses them by default. This lets configuration files be read, modified, and then written back in their original order. The _asdict() method for collections.namedtuple() now returns an ordered dictionary with the values appearing in the same order as the underlying tuple indicies. The json module is being built-out with an object_pairs_hook to allow OrderedDicts to be built by the decoder. Support was also added for third-party tools like PyYAML.

See also:

**PEP 372 - Ordered Dictionaries**

PEP written by Armin Ronacher and Raymond Hettinger. Implementation written by Raymond Hettinger.
The built-in `format()` function and the `str.format()` method use a mini-language that now includes a simple, non-locale aware way to format a number with a thousands separator. That provides a way to humanize a program's output, improving its professional appearance and readability:

```python
>>> format(1234567, ',d')
'1,234,567'
>>> format(1234567.89, ',.2f')
'1,234,567.89'
>>> format(12345.6 + 8901234.12j, ',f')
'12,345.600000+8,901.234.120000j'
>>> format(Decimal('1234567.89'), ',f')
'1,234,567.89'
```

The supported types are `int`, `float`, `complex` and `decimal.Decimal`.

Discussions are underway about how to specify alternative separators like dots, spaces, apostrophes, or underscores. Locale-aware applications should use the existing `n` format specifier which already has some support for thousands separators.

**See also:**

**PEP 378 - Format Specifier for Thousands Separator**

PEP written by Raymond Hettinger and implemented by Eric Smith and Mark Dickinson.
Other Language Changes

Some smaller changes made to the core Python language are:

- Directories and zip archives containing a `__main__.py` file can now be executed directly by passing their name to the interpreter. The directory/zipfile is automatically inserted as the first entry in `sys.path`. (Suggestion and initial patch by Andy Chu; revised patch by Phillip J. Eby and Nick Coghlan; issue 1739468.)

- The `int()` type gained a `bit_length` method that returns the number of bits necessary to represent its argument in binary:

  ```python
  >>> n = 37
  >>> bin(37)
  '0b100101'
  >>> n.bit_length()
  6
  >>> n = 2**123-1
  >>> n.bit_length()
  123
  >>> (n+1).bit_length()
  124
  
  (Contributed by Fredrik Johansson, Victor Stinner, Raymond Hettinger, and Mark Dickinson; issue 3439.)
  
- The fields in `format()` strings can now be automatically numbered:

  ```python
  >>> 'Sir {} of {}'.format('Gallahad', 'Camelot')
  'Sir Gallahad of Camelot'
  ```
Formerly, the string would have required numbered fields such as: 
'Sir {0} of {1}'.

(Contributed by Eric Smith; issue 5237.)

- The string.maketrans() function is deprecated and is replaced by new static methods, bytes.maketrans() and bytearray.maketrans(). This change solves the confusion around which types were supported by the string module. Now, str, bytes, and bytearray each have their own maketrans and translate methods with intermediate translation tables of the appropriate type.

(Contributed by Georg Brandl; issue 5675.)

- The syntax of the with statement now allows multiple context managers in a single statement:

```python
>>> with open('mylog.txt') as infile, open('a.out', 'w') as outfile:
...     for line in infile:
...         if '<critical>' in line:
...             outfile.write(line)
```

With the new syntax, the contextlib.nested() function is no longer needed and is now deprecated.

(Contributed by Georg Brandl and Mattias Brändström; appspot issue 53094.)

- round(x, n) now returns an integer if x is an integer. Previously it returned a float:

```python
>>> round(1123, -2)
```
Python now uses David Gay’s algorithm for finding the shortest floating point representation that doesn’t change its value. This should help mitigate some of the confusion surrounding binary floating point numbers.

The significance is easily seen with a number like 1.1 which does not have an exact equivalent in binary floating point. Since there is no exact equivalent, an expression like `float('1.1')` evaluates to the nearest representable value which is `0x1.19999999999999ap+0` in hex or `1.10000000000000008881784197001252323389053344726` in decimal. That nearest value was and still is used in subsequent floating point calculations.

What is new is how the number gets displayed. Formerly, Python used a simple approach. The value of `repr(1.1)` was computed as `format(1.1, '.17g')` which evaluated to `1.1000000000000001`. The advantage of using 17 digits was that it relied on IEEE-754 guarantees to assure that `eval(repr(1.1))` would round-trip exactly to its original value. The disadvantage is that many people found the output to be confusing (mistaking intrinsic limitations of binary floating point representation as being a problem with Python itself).

The new algorithm for `repr(1.1)` is smarter and returns `1.1`. Effectively, it searches all equivalent string representations (ones that get stored with the same underlying float value) and returns the shortest representation.
The new algorithm tends to emit cleaner representations when possible, but it does not change the underlying values. So, it is still the case that 1.1 + 2.2 ≠ 3.3 even though the representations may suggest otherwise.

The new algorithm depends on certain features in the underlying floating point implementation. If the required features are not found, the old algorithm will continue to be used. Also, the text pickle protocols assure cross-platform portability by using the old algorithm.

(Contributed by Eric Smith and Mark Dickinson; issue 1580)
New, Improved, and Deprecated Modules

- Added a `collections.Counter` class to support convenient counting of unique items in a sequence or iterable:

  ```python
  >>> Counter(['red', 'blue', 'red', 'green', 'blue'])
  Counter({'blue': 3, 'red': 2, 'green': 1})
  ```

  (Contributed by Raymond Hettinger; issue 1696199.)

- Added a new module, `tkinter.ttk` for access to the Tk themed widget set. The basic idea of ttk is to separate, to the extent possible, the code implementing a widget's behavior from the code implementing its appearance.

  (Contributed by Guilherme Polo; issue 2983.)

- The `gzip.GzipFile` and `bz2.BZ2File` classes now support the context manager protocol:

  ```python
  >>> # Automatically close file after writing
  >>> with gzip.GzipFile(filename, "wb") as f:
  ...    f.write(b"xxx")
  ```

  (Contributed by Antoine Pitrou.)

- The `decimal` module now supports methods for creating a decimal object from a binary `float`. The conversion is exact but can sometimes be surprising:

  ```python
  >>> Decimal.from_float(1.1)
  Decimal('1.100000000000000088817841970012523233890533447265625')
  ```
The long decimal result shows the actual binary fraction being stored for 1.1. The fraction has many digits because 1.1 cannot be exactly represented in binary.

(Contributed by Raymond Hettinger and Mark Dickinson.)

- The `itertools` module grew two new functions. The `itertools.combinations_with_replacement()` function is one of four for generating combinatorics including permutations and Cartesian products. The `itertools.compress()` function mimics its namesake from APL. Also, the existing `itertools.count()` function now has an optional step argument and can accept any type of counting sequence including `fractions.Fraction` and `decimal.Decimal`:

```python
>>> [p+q for p,q in combinations_with_replacement(['LL', 'LO', 'LV', 'LE', 'OO', 'OV', 'OE', 'VV'], 2, 3, 5, 7]
>>> list(compress(data=range(10), selectors=[0, 0, 2, 3, 5, 7])

>>> c = count(start=Fraction(1,2), step=Fraction(3,4))
>>> [next(c), next(c), next(c), next(c)]
[Fraction(1, 2), Fraction(2, 3), Fraction(5, 6),
```

(Contributed by Raymond Hettinger.)

- `collections.namedtuple()` now supports a keyword argument `rename` which lets invalid fieldnames be automatically converted to positional names in the form _0, _1, etc. This is useful when the field names are being created by an external source such as a CSV header, SQL field list, or user input:
>>> query = input()
SELECT region, dept, count(*) FROM main GROUP BY region, dept

>>> cursor.execute(query)

>>> query_fields = [desc[0] for desc in cursor.description]
>>> UserQuery = namedtuple('UserQuery', query_fields)

>>> pprint.pprint([UserQuery(*row) for row in cursor])

[UserQuery(region='South', dept='Shipping', _2=185),
 UserQuery(region='North', dept='Accounting', _2=37),
 UserQuery(region='West', dept='Sales', _2=419)]

(Contributed by Raymond Hettinger; issue 1818.)

- The re.sub(), re.subn() and re.split() functions now accept a flags parameter.

(Contributed by Gregory Smith.)

- The logging module now implements a simple logging.NullHandler class for applications that are not using logging but are calling library code that does. Setting-up a null handler will suppress spurious warnings such as “No handlers could be found for logger foo”:

  >>> h = logging.NullHandler()
  >>> logging.getLogger("foo").addHandler(h)

(Contributed by Vinay Sajip; issue 4384.)

- The runpy module which supports the -m command line switch now supports the execution of packages by looking for and executing a __main__ submodule when a package name is supplied.
(Contributed by Andi Vajda; issue 4195.)

• The **pdb** module can now access and display source code loaded via **zipimport** (or any other conformant **PEP 302** loader).

  (Contributed by Alexander Belopolsky; issue 4201.)

• **functools.partial** objects can now be pickled.

(Suggested by Antoine Pitrou and Jesse Noller. Implemented by Jack Diederich; issue 5228.)

• Add **pydoc** help topics for symbols so that `help('@')` works as expected in the interactive environment.

  (Contributed by David Laban; issue 4739.)

• The **unittest** module now supports skipping individual tests or classes of tests. And it supports marking a test as a expected failure, a test that is known to be broken, but shouldn’t be counted as a failure on a TestResult:

```python
class TestGizmo(unittest.TestCase):
    @unittest.skipUnless(sys.platform.startswith('d', 'o', 's'))
    def test_gizmo_on_windows(self):
        ...

    @unittest.expectedFailure
    def test_gimzo_without_required_library(self):
        ...
```

Also, tests for exceptions have been builtout to work with context managers using the **with** statement:
def test_division_by_zero(self):
    with self.assertRaises(ZeroDivisionError):
        x / 0

In addition, several new assertion methods were added including
assertSetEqual(), assertDictEqual(),
assertDictContainsSubset(), assertListEqual(),
assertTupleEqual(), assertSequenceEqual(),
assertRaisesRegexp(), assertIsNone(), and
assertIsNotNone().

(Contributed by Benjamin Peterson and Antoine Pitrou.)

- The **io** module has three new constants for the **seek()** method
  SEEK_SET, SEEK_CUR, and SEEK_END.

- The **sys.version_info** tuple is now a named tuple:

```python
>>> sys.version_info
sys.version_info(major=3, minor=1, micro=0, releaselevel='alpha', serial=2)
```

(Contributed by Ross Light; issue 4285.)

- The **nntplib** and **imaplib** modules now support IPv6.

  (Contributed by Derek Morr; issue 1655 and issue 1664.)

- The **pickle** module has been adapted for better interoperability
  with Python 2.x when used with protocol 2 or lower. The
  reorganization of the standard library changed the formal
  reference for many objects. For example, **__builtin__.set** in
  Python 2 is called **builtins.set** in Python 3. This change
  confounded efforts to share data between different versions of
Python. But now when protocol 2 or lower is selected, the pickler will automatically use the old Python 2 names for both loading and dumping. This remapping is turned-on by default but can be disabled with the *fix_imports* option:

```python
>>> s = {1, 2, 3}
>>> pickle.dumps(s, protocol=0)
b'c__builtin__\nset\np0\n((lp1\nL1L\naL2L\naL3L

>>> pickle.dumps(s, protocol=0, fix_imports=False)
b'cbuiltins\nset\np0\n((lp1\nL1L\naL2L\naL3L\natp2
Rp3
.'
```

An unfortunate but unavoidable side-effect of this change is that protocol 2 pickles produced by Python 3.1 won’t be readable with Python 3.0. The latest pickle protocol, protocol 3, should be used when migrating data between Python 3.x implementations, as it doesn’t attempt to remain compatible with Python 2.x.

(Contributed by Alexandre Vassalotti and Antoine Pitrou, issue 6137.)

- A new module, *importlib* was added. It provides a complete, portable, pure Python reference implementation of the *import* statement and its counterpart, the *__import__()* function. It represents a substantial step forward in documenting and defining the actions that take place during imports.

(Contributed by Brett Cannon.)
Optimizations

Major performance enhancements have been added:

- The new I/O library (as defined in PEP 3116) was mostly written in Python and quickly proved to be a problematic bottleneck in Python 3.0. In Python 3.1, the I/O library has been entirely rewritten in C and is 2 to 20 times faster depending on the task at hand. The pure Python version is still available for experimentation purposes through the _pyio module.

  (Contributed by Amaury Forgeot d’Arc and Antoine Pitrou.)

- Added a heuristic so that tuples and dicts containing only untrackable objects are not tracked by the garbage collector. This can reduce the size of collections and therefore the garbage collection overhead on long-running programs, depending on their particular use of datatypes.

  (Contributed by Antoine Pitrou, issue 4688.)

- Enabling a configure option named --with-computed-gotos on compilers that support it (notably: gcc, SunPro, icc), the bytecode evaluation loop is compiled with a new dispatch mechanism which gives speedups of up to 20%, depending on the system, the compiler, and the benchmark.

  (Contributed by Antoine Pitrou along with a number of other participants, issue 4753).

- The decoding of UTF-8, UTF-16 and LATIN-1 is now two to four times faster.
The **json** module now has a C extension to substantially improve its performance. In addition, the API was modified so that json works only with `str`, not with `bytes`. That change makes the module closely match the JSON specification which is defined in terms of Unicode.

Unpickling now interns the attribute names of pickled objects. This saves memory and allows pickles to be smaller.
IDLE

- IDLE’s format menu now provides an option to strip trailing whitespace from a source file.

(Contributed by Roger D. Serwy; issue 5150.)
Build and C API Changes

Changes to Python’s build process and to the C API include:

- Integers are now stored internally either in base $2^{15}$ or in base $2^{30}$, the base being determined at build time. Previously, they were always stored in base $2^{15}$. Using base $2^{30}$ gives significant performance improvements on 64-bit machines, but benchmark results on 32-bit machines have been mixed. Therefore, the default is to use base $2^{30}$ on 64-bit machines and base $2^{15}$ on 32-bit machines; on Unix, there's a new configure option `--enable-big-digits` that can be used to override this default.

Apart from the performance improvements this change should be invisible to end users, with one exception: for testing and debugging purposes there's a new `sys.int_info` that provides information about the internal format, giving the number of bits per digit and the size in bytes of the C type used to store each digit:

```python
>>> import sys
>>> sys.int_info
sys.int_info(bits_per_digit=30, sizeof_digit=4)
```

(Contributed by Mark Dickinson; issue 4258.)

- The `PyLong_AsUnsignedLongLong()` function now handles a negative `pylong` by raising `OverflowError` instead of `TypeError`.

(Contributed by Mark Dickinson and Lisandro Dalcin; issue 5175.)
• Deprecated PyNumber_Int(). Use PyNumber_Long() instead.

(Contributed by Mark Dickinson; issue 4910.)

• Added a new PyOS_string_to_double() function to replace the deprecated functions PyOS_ascii_strtod() and PyOS_ascii_atof().

(Contributed by Mark Dickinson; issue 5914.)

• Added PyCapsule as a replacement for the PyCObject API. The principal difference is that the new type has a well defined interface for passing typing safety information and a less complicated signature for calling a destructor. The old type had a problematic API and is now deprecated.

(Contributed by Larry Hastings; issue 5630.)
Porting to Python 3.1

This section lists previously described changes and other bugfixes that may require changes to your code:

- The new floating point string representations can break existing doctests. For example:

```python
def e():
    '''Compute the base of natural logarithms.'''

    >>> e()
    2.7182818284590451
    ...
    return sum(1/math.factorial(x) for x in reversed(doctest.testmod())
```

```
**********************************************************************
Failed example:
e()
Expected:
    2.7182818284590451
Got:
    2.718281828459045
**********************************************************************
```

- The automatic name remapping in the pickle module for protocol 2 or lower can make Python 3.1 pickles unreadable in Python 3.0. One solution is to use protocol 3. Another solution is to set the `fix_imports` option to `False`. See the discussion above for more details.
This article explains the new features in Python 3.0, compared to 2.6. Python 3.0, also known as “Python 3000” or “Py3K”, is the first ever intentionally backwards incompatible Python release. There are more changes than in a typical release, and more that are important for all Python users. Nevertheless, after digesting the changes, you’ll find that Python really hasn’t changed all that much – by and large, we’re mostly fixing well-known annoyances and warts, and removing a lot of old cruft.

This article doesn’t attempt to provide a complete specification of all new features, but instead tries to give a convenient overview. For full details, you should refer to the documentation for Python 3.0, and/or the many PEPs referenced in the text. If you want to understand the complete implementation and design rationale for a particular feature, PEPs usually have more details than the regular documentation; but note that PEPs usually are not kept up-to-date once a feature has been fully implemented.

Due to time constraints this document is not as complete as it should have been. As always for a new release, the Misc/NEWS file in the source distribution contains a wealth of detailed information about every small thing that was changed.
Common Stumbling Blocks
This section lists those few changes that are most likely to trip you up
if you’re used to Python 2.5.

Print Is A Function
The print statement has been replaced with a print() function,
with keyword arguments to replace most of the special syntax of the
old print statement (PEP 3105). Examples:
Old: print "The answer is", 2*2
New: print("The answer is", 2*2)
Old: print x,
New: print(x, end=" ")

# Trailing comma suppresses newline
# Appends a space instead of a newli

Old: print
New: print()

# Prints a newline
# You must call the function!

Old: print >>sys.stderr, "fatal error"
New: print("fatal error", file=sys.stderr)
Old: print (x, y)
New: print((x, y))

# prints repr((x, y))
# Not the same as print(x, y)!

You can also customize the separator between items, e.g.:
print("There are <", 2**32, "> possibilities!", sep=

which produces:


There are \(<4294967296>\) possibilities!

Note:

- The \texttt{print()} function doesn't support the “softspace” feature of the old \texttt{print} statement. For example, in Python 2.x, \texttt{print "A\n", "B"} would write "A
B
"; but in Python 3.0, \texttt{print("A\n", "B")} writes "A
 B
".
- Initially, you’ll be finding yourself typing the old \texttt{print x} a lot in interactive mode. Time to retrain your fingers to type \texttt{print(x)} instead!
- When using the \texttt{2to3} source-to-source conversion tool, all \texttt{print} statements are automatically converted to \texttt{print()} function calls, so this is mostly a non-issue for larger projects.

**Views And Iterators Instead Of Lists**

Some well-known APIs no longer return lists:

- \texttt{dict} methods \texttt{dict.keys()}, \texttt{dict.items()} and \texttt{dict.values()} return “views” instead of lists. For example, this no longer works: \texttt{k = d.keys(); k.sort()}. Use \texttt{k = sorted(d)} instead (this works in Python 2.5 too and is just as efficient).

- Also, the \texttt{dict.iterkeys()}, \texttt{dict.iteritems()} and \texttt{dict.itervalues()} methods are no longer supported.

- \texttt{map()} and \texttt{filter()} return iterators. If you really need a list and the input sequences are all of equal length, a quick fix is to wrap \texttt{map()} in \texttt{list()}, e.g. \texttt{list(map(...))}, but a better fix is often to use a list comprehension (especially when the original...
code uses `lambda`, or rewriting the code so it doesn’t need a list at all. Particularly tricky is `map()` invoked for the side effects of the function; the correct transformation is to use a regular `for` loop (since creating a list would just be wasteful).

If the input sequences are not of equal length, `map()` will stop at the termination of the shortest of the sequences. For full compatibility with `map` from Python 2.x, also wrap the sequences in `itertools.zip_longest()`, e.g. `map(func, *sequences)` becomes `list(map(func, itertools.zip_longest(*sequences)))`.

- `range()` now behaves like `xrange()` used to behave, except it works with values of arbitrary size. The latter no longer exists.

- `zip()` now returns an iterator.

### Ordering Comparisons

Python 3.0 has simplified the rules for ordering comparisons:

- The ordering comparison operators (`<`, `<=`, `>=`, `>`) raise a `TypeError` exception when the operands don’t have a meaningful natural ordering. Thus, expressions like `1 < ''`, `0 > None` or `len <= len` are no longer valid, and e.g. `None < None` raises `TypeError` instead of returning `False`. A corollary is that sorting a heterogeneous list no longer makes sense – all the elements must be comparable to each other. Note that this does not apply to the `==` and `!=` operators: objects of different incomparable types always compare unequal to each other.
- `builtins.sorted()` and `list.sort()` no longer accept the `cmp` argument providing a comparison function. Use the `key`
argument instead. N.B. the key and reverse arguments are now “keyword-only”.

- The cmp() function should be treated as gone, and the __cmp__() special method is no longer supported. Use __lt__() for sorting, __eq__() with __hash__(), and other rich comparisons as needed. (If you really need the cmp() functionality, you could use the expression \(a > b) - (a < b)\) as the equivalent for cmp(a, b).

Integers

- **PEP 0237**: Essentially, long renamed to int. That is, there is only one built-in integral type, named int; but it behaves mostly like the old long type.
- **PEP 0238**: An expression like \(1/2\) returns a float. Use \(1//2\) to get the truncating behavior. (The latter syntax has existed for years, at least since Python 2.2.)
- The sys.maxint constant was removed, since there is no longer a limit to the value of integers. However, sys.maxsize can be used as an integer larger than any practical list or string index. It conforms to the implementation’s “natural” integer size and is typically the same as sys.maxint in previous releases on the same platform (assuming the same build options).
- The repr() of a long integer doesn’t include the trailing L anymore, so code that unconditionally strips that character will chop off the last digit instead. (Use str() instead.)
- Octal literals are no longer of the form \(0720\); use \(0o720\) instead.

Text Vs. Data Instead Of Unicode Vs. 8-bit

Everything you thought you knew about binary data and Unicode has changed.
Python 3.0 uses the concepts of text and (binary) data instead of Unicode strings and 8-bit strings. All text is Unicode; however encoded Unicode is represented as binary data. The type used to hold text is `str`, the type used to hold data is `bytes`. The biggest difference with the 2.x situation is that any attempt to mix text and data in Python 3.0 raises `TypeError`, whereas if you were to mix Unicode and 8-bit strings in Python 2.x, it would work if the 8-bit string happened to contain only 7-bit (ASCII) bytes, but you would get `UnicodeDecodeError` if it contained non-ASCII values. This value-specific behavior has caused numerous sad faces over the years.

As a consequence of this change in philosophy, pretty much all code that uses Unicode, encodings or binary data most likely has to change. The change is for the better, as in the 2.x world there were numerous bugs having to do with mixing encoded and unencoded text. To be prepared in Python 2.x, start using `unicode` for all unencoded text, and `str` for binary or encoded data only. Then the `2to3` tool will do most of the work for you.

You can no longer use `u"..."` literals for Unicode text. However, you must use `b"..."` literals for binary data.

As the `str` and `bytes` types cannot be mixed, you must always explicitly convert between them. Use `str.encode()` to go from `str` to `bytes`, and `bytes.decode()` to go from `bytes` to `str`. You can also use `bytes(s, encoding=...)` and `str(b, encoding=...)`, respectively.

Like `str`, the `bytes` type is immutable. There is a separate `mutable` type to hold buffered binary data, `bytearray`. Nearly all APIs that accept `bytes` also accept `bytearray`. The mutable API is based on `collections.MutableSequence`.

All backslashes in raw string literals are interpreted literally. This means that '\U' and '\u' escapes in raw strings are not treated specially. For example, `r'\u20ac'` is a string of 6 characters in Python 3.0, whereas in 2.6, `ur'\u20ac'` was the
single “euro” character. (Of course, this change only affects raw string literals; the euro character is \u20ac in Python 3.0.)

- The built-in basestring abstract type was removed. Use str instead. The str and bytes types don’t have functionality enough in common to warrant a shared base class. The 2to3 tool (see below) replaces every occurrence of basestring with str.

- Files opened as text files (still the default mode for open()) always use an encoding to map between strings (in memory) and bytes (on disk). Binary files (opened with a b in the mode argument) always use bytes in memory. This means that if a file is opened using an incorrect mode or encoding, I/O will likely fail loudly, instead of silently producing incorrect data. It also means that even Unix users will have to specify the correct mode (text or binary) when opening a file. There is a platform-dependent default encoding, which on Unixy platforms can be set with the LANG environment variable (and sometimes also with some other platform-specific locale-related environment variables). In many cases, but not all, the system default is UTF-8; you should never count on this default. Any application reading or writing more than pure ASCII text should probably have a way to override the encoding. There is no longer any need for using the encoding-aware streams in the codecs module.

- The initial values of sys.stdin, sys.stdout and sys.stderr are now unicode-only text files (i.e., they are instances of io.TextIOWrapper). To read and write bytes data with these streams, you need to use their io.TextIOWrapper.buffer attribute.

- Filenames are passed to and returned from APIs as (Unicode) strings. This can present platform-specific problems because on some platforms filenames are arbitrary byte strings. (On the other hand, on Windows filenames are natively stored as Unicode.) As a work-around, most APIs (e.g. open()) and many functions in
the os module) that take filenames accept bytes objects as well as strings, and a few APIs have a way to ask for a bytes return value. Thus, os.listdir() returns a list of bytes instances if the argument is a bytes instance, and os.getcwdb() returns the current working directory as a bytes instance. Note that when os.listdir() returns a list of strings, filenames that cannot be decoded properly are omitted rather than raising UnicodeError.

- Some system APIs like os.environ and sys.argv can also present problems when the bytes made available by the system is not interpretable using the default encoding. Setting the LANG variable and rerunning the program is probably the best approach.
- PEP 3138: The repr() of a string no longer escapes non-ASCII characters. It still escapes control characters and code points with non-printable status in the Unicode standard, however.
- PEP 3120: The default source encoding is now UTF-8.
- PEP 3131: Non-ASCII letters are now allowed in identifiers. (However, the standard library remains ASCII-only with the exception of contributor names in comments.)
- The StringIO and cStringIO modules are gone. Instead, import the io module and use io.StringIO or io.BytesIO for text and data respectively.
- See also the Unicode HOWTO, which was updated for Python 3.0.
Overview Of Syntax Changes

This section gives a brief overview of every syntactic change in Python 3.0.

New Syntax

- **PEP 3107**: Function argument and return value annotations. This provides a standardized way of annotating a function’s parameters and return value. There are no semantics attached to such annotations except that they can be introspected at runtime using the `__annotations__` attribute. The intent is to encourage experimentation through metaclasses, decorators or frameworks.

- **PEP 3102**: Keyword-only arguments. Named parameters occurring after `*args` in the parameter list must be specified using keyword syntax in the call. You can also use a bare `*` in the parameter list to indicate that you don’t accept a variable-length argument list, but you do have keyword-only arguments.

- Keyword arguments are allowed after the list of base classes in a class definition. This is used by the new convention for specifying a metaclass (see next section), but can be used for other purposes as well, as long as the metaclass supports it.

- **PEP 3104**: `nonlocal` statement. Using `nonlocal` you can now assign directly to a variable in an outer (but non-global) scope. `nonlocal` is a new reserved word.

- **PEP 3132**: Extended Iterable Unpacking. You can now write
things like a, b, *rest = some_sequence. And even
*rest, a = stuff. The rest object is always a (possibly
empty) list; the right-hand side may be any iterable. Example:

(a, *rest, b) = range(5)

This sets a to 0, b to 4, and rest to [1, 2, 3].

- Dictionary comprehensions: {k: v for k, v in stuff}
  means the same thing as dict(stuff) but is more flexible.
  (This is PEP 0274 vindicated. :-)

- Set literals, e.g. {1, 2}. Note that {} is an empty dictionary; use
  set() for an empty set. Set comprehensions are also supported;
  e.g., {x for x in stuff} means the same thing as
  set(stuff) but is more flexible.

- New octal literals, e.g. 0o720 (already in 2.6). The old octal
  literals (0720) are gone.

- New binary literals, e.g. 0b1010 (already in 2.6), and there is a
  new corresponding built-in function, bin().

- Bytes literals are introduced with a leading b or B, and there is a
  new corresponding built-in function, bytes().

Changed Syntax

- PEP 3109 and PEP 3134: new raise statement syntax: raise
  [expr [from expr]]. See below.

- as and with are now reserved words. (Since 2.6, actually.)
• True, False, and None are reserved words. (2.6 partially enforced the restrictions on None already.)

• Change from except exc, var to except exc as var. See PEP 3110.

• PEP 3115: New Metaclass Syntax. Instead of:

```python
class C:
    __metaclass__ = M
...
```

you must now use:

```python
class C(metaclass=M):
    ...
```

The module-global __metaclass__ variable is no longer supported. (It was a crutch to make it easier to default to new-style classes without deriving every class from object.)

• List comprehensions no longer support the syntactic form ` [...] for var in item1, item2, ...]`. Use `[ ... for var in (item1, item2, ...) ]` instead. Also note that list comprehensions have different semantics: they are closer to syntactic sugar for a generator expression inside a `list()` constructor, and in particular the loop control variables are no longer leaked into the surrounding scope.

• The ellipsis `( ... )` can be used as an atomic expression anywhere. (Previously it was only allowed in slices.) Also, it must now be spelled as `...`. (Previously it could also be spelled as `...`, by a mere accident of the grammar.)
Removed Syntax

- **PEP 3113**: Tuple parameter unpacking removed. You can no longer write `def foo(a, (b, c)): ....` Use `def foo(a, b_c): b, c = b_c` instead.
- Removed backticks (use `repr()` instead).
- Removed `<>` (use `!=` instead).
- Removed keyword: `exec()` is no longer a keyword; it remains as a function. (Fortunately the function syntax was also accepted in 2.x.) Also note that `exec()` no longer takes a stream argument; instead of `exec(f)` you can use `exec(f.read())`.
- Integer literals no longer support a trailing `l` or `L`.
- String literals no longer support a leading `u` or `U`.
- The `from module import *` syntax is only allowed at the module level, no longer inside functions.
- The only acceptable syntax for relative imports is `from . [module] import name`. All `import` forms not starting with `.` are interpreted as absolute imports. ([PEP 0328](https://www.python.org/dev/peps/pep-0328/))
- Classic classes are gone.
Changes Already Present In Python 2.6

Since many users presumably make the jump straight from Python 2.5 to Python 3.0, this section reminds the reader of new features that were originally designed for Python 3.0 but that were back-ported to Python 2.6. The corresponding sections in *What’s New in Python 2.6* should be consulted for longer descriptions.

- **PEP 343: The ‘with’ statement.** The `with` statement is now a standard feature and no longer needs to be imported from the `__future__`. Also check out *Writing Context Managers* and *The contextlib module*.
- **PEP 366: Explicit Relative Imports From a Main Module.** This enhances the usefulness of the `-m` option when the referenced module lives in a package.
- **PEP 370: Per-user site-packages Directory.**
- **PEP 371: The multiprocessing Package.**
- **PEP 3101: Advanced String Formatting.** Note: the 2.6 description mentions the `format()` method for both 8-bit and Unicode strings. In 3.0, only the `str` type (text strings with Unicode support) supports this method; the `bytes` type does not. The plan is to eventually make this the only API for string formatting, and to start deprecating the `%` operator in Python 3.1.
- **PEP 3105: print As a Function.** This is now a standard feature and no longer needs to be imported from `__future__`. More details were given above.
- **PEP 3110: Exception-Handling Changes.** The `except exc as var` syntax is now standard and `except exc, var` is no longer supported. (Of course, the `as var` part is still optional.)
- **PEP 3112: Byte Literals.** The `b"..."` string literal notation (and its variants like `b'...'`, `b"""...""""""", and `br"..."`) now produces a literal of type `bytes`. 
• **PEP 3116: New I/O Library.** The `io` module is now the standard way of doing file I/O. The built-in `open()` function is now an alias for `io.open()` and has additional keyword arguments `encoding`, `errors`, `newline` and `closefd`. Also note that an invalid `mode` argument now raises `ValueError`, not `IOError`. The binary file object underlying a text file object can be accessed as `f.buffer` (but beware that the text object maintains a buffer of itself in order to speed up the encoding and decoding operations).

• **PEP 3118: Revised Buffer Protocol.** The old built-in `buffer()` is now really gone; the new built-in `memoryview()` provides (mostly) similar functionality.

• **PEP 3119: Abstract Base Classes.** The `abc` module and the ABCs defined in the `collections` module plays a somewhat more prominent role in the language now, and built-in collection types like `dict` and `list` conform to the `collections.MutableMapping` and `collections.MutableSequence` ABCs, respectively.

• **PEP 3127: Integer Literal Support and Syntax.** As mentioned above, the new octal literal notation is the only one supported, and binary literals have been added.

• **PEP 3129: Class Decorators.**

• **PEP 3141: A Type Hierarchy for Numbers.** The `numbers` module is another new use of ABCs, defining Python’s “numeric tower”. Also note the new `fractions` module which implements `numbers.Rational`.
Library Changes

Due to time constraints, this document does not exhaustively cover the very extensive changes to the standard library. PEP 3108 is the reference for the major changes to the library. Here's a capsule review:

- Many old modules were removed. Some, like gopherlib (no longer used) and md5 (replaced by hashlib), were already deprecated by PEP 0004. Others were removed as a result of the removal of support for various platforms such as Irix, BeOS and Mac OS 9 (see PEP 0011). Some modules were also selected for removal in Python 3.0 due to lack of use or because a better replacement exists. See PEP 3108 for an exhaustive list.

- The bsddb3 package was removed because its presence in the core standard library has proved over time to be a particular burden for the core developers due to testing instability and Berkeley DB’s release schedule. However, the package is alive and well, externally maintained at http://www.jcea.es/programacion/pybsddb.htm.

- Some modules were renamed because their old name disobeyed PEP 0008, or for various other reasons. Here’s the list:

<table>
<thead>
<tr>
<th>Old Name</th>
<th>New Name</th>
</tr>
</thead>
<tbody>
<tr>
<td>_winreg</td>
<td>winreg</td>
</tr>
<tr>
<td>ConfigParser</td>
<td>configparser</td>
</tr>
<tr>
<td>copy_reg</td>
<td>copyreg</td>
</tr>
<tr>
<td>Queue</td>
<td>queue</td>
</tr>
</tbody>
</table>
A common pattern in Python 2.x is to have one version of a module implemented in pure Python, with an optional accelerated version implemented as a C extension; for example, pickle and cPickle. This places the burden of importing the accelerated version and falling back on the pure Python version on each user of these modules. In Python 3.0, the accelerated versions are considered implementation details of the pure Python versions. Users should always import the standard version, which attempts to import the accelerated version and falls back to the pure Python version. The pickle / cPickle pair received this treatment. The profile module is on the list for 3.1. The StringIO module has been turned into a class in the io module.

Some related modules have been grouped into packages, and usually the submodule names have been simplified. The resulting new packages are:

- dbm (anydbm, dbhash, dbm, dumbdbm, gdbm, whichdb).
- html (HTMLParser, htmlentitydefs).
- http (httplib, BaseHTTPServer, CGIHTTPServer, SimpleHTTPServer, Cookie, cookielib).
- tkinter (all Tkinter-related modules except turtle).

The target audience of turtle doesn’t really care about tkinter. Also note that as of Python 2.6, the functionality of turtle has been greatly enhanced.
- **urllib** *(urllib, urllib2, urlparse, robotparser)*.
- **xmlrpc** *(xmlrpclib, DocXMLRPCServer, SimpleXMLRPCServer)*.

Some other changes to standard library modules, not covered by **PEP 3108**:

- **Killed sets.** Use the built-in `set()` class.
- **Cleanup of the `sys` module:** removed `sys.exitfunc()`, `sys.exc_clear()`, `sys.exc_type`, `sys.exc_value`, `sys.exc_traceback`. (Note that `sys.last_type` etc. remain.)
- **Cleanup of the `array.array` type:** the `read()` and `write()` methods are gone; use `fromfile()` and `tofile()` instead. Also, the `'c'` typecode for `array` is gone – use either `'b'` for bytes or `'u'` for Unicode characters.
- **Cleanup of the `operator` module:** removed `sequenceIncludes()` and `isCallable()`.
- **Cleanup of the `thread` module:** `acquire_lock()` and `release_lock()` are gone; use `acquire()` and `release()` instead.
- **Cleanup of the `random` module:** removed the `jumpahead()` API.
- **The new module is gone.**
- **The functions** `os.tmpnam()`, `os.tempnam()` and `os.tmpfile()` have been removed in favor of the `tempfile` module.
- **The `tokenize` module** has been changed to work with bytes. The main entry point is now `tokenize.tokenize()`, instead of `generate_tokens`.
- **`string.letters` and its friends** (`string.lowercase` and `string.uppercase`) are gone. Use `string.ascii_letters` etc. instead. (The reason for the removal is that `string.letters` and friends had locale-specific behavior, which is a bad idea for such attractively-named global
• Renamed module __builtin__ to builtins (removing the underscores, adding an ‘s’). The __builtins__ variable found in most global namespaces is unchanged. To modify a builtin, you should use builtins, not __builtins__!
**PEP 3101**: A New Approach To String Formatting

- A new system for built-in string formatting operations replaces the % string formatting operator. (However, the % operator is still supported; it will be deprecated in Python 3.1 and removed from the language at some later time.) Read **PEP 3101** for the full scoop.
Changes To Exceptions

The APIs for raising and catching exception have been cleaned up and new powerful features added:

- **PEP 0352**: All exceptions must be derived (directly or indirectly) from `BaseException`. This is the root of the exception hierarchy. This is not new as a recommendation, but the `requirement` to inherit from `BaseException` is new. (Python 2.6 still allowed classic classes to be raised, and placed no restriction on what you can catch.) As a consequence, string exceptions are finally truly and utterly dead.

- Almost all exceptions should actually derive from `Exception`; `BaseException` should only be used as a base class for exceptions that should only be handled at the top level, such as `SystemExit` or `KeyboardInterrupt`. The recommended idiom for handling all exceptions except for this latter category is to use `except Exception`.

- `StandardError` was removed.

- Exceptions no longer behave as sequences. Use the `args` attribute instead.

- **PEP 3109**: Raising exceptions. You must now use `raise Exception(args)` instead of `raise Exception, args`. Additionally, you can no longer explicitly specify a traceback; instead, if you `have` to do this, you can assign directly to the `__traceback__` attribute (see below).

- **PEP 3110**: Catching exceptions. You must now use `except
SomeException as variable instead of except SomeException, variable. Moreover, the variable is explicitly deleted when the except block is left.

- **PEP 3134**: Exception chaining. There are two cases: implicit chaining and explicit chaining. Implicit chaining happens when an exception is raised in an except or finally handler block. This usually happens due to a bug in the handler block; we call this a secondary exception. In this case, the original exception (that was being handled) is saved as the _context_ attribute of the secondary exception. Explicit chaining is invoked with this syntax:

```python
raise SecondaryException() from primary_exception
```

(where primary_exception is any expression that produces an exception object, probably an exception that was previously caught). In this case, the primary exception is stored on the _cause_ attribute of the secondary exception. The traceback printed when an unhandled exception occurs walks the chain of _cause_ and _context_ attributes and prints a separate traceback for each component of the chain, with the primary exception at the top. (Java users may recognize this behavior.)

- **PEP 3134**: Exception objects now store their traceback as the _traceback_ attribute. This means that an exception object now contains all the information pertaining to an exception, and there are fewer reasons to use `sys.exc_info()` (though the latter is not removed).

- A few exception messages are improved when Windows fails to load an extension module. For example, error code 193 is
now %1 is not a valid Win32 application. Strings now deal with non-English locales.
Miscellaneous Other Changes

Operators And Special Methods

- `!=` now returns the opposite of `==`, unless `==` returns `NotImplemented`.
- The concept of “unbound methods” has been removed from the language. When referencing a method as a class attribute, you now get a plain function object.
- `__getslice__()`, `__setslice__()`, and `__delslice__()` were killed. The syntax `a[i:j]` now translates to `a.__getitem__(slice(i, j))` (or `__setitem__()` or `__delitem__()`), when used as an assignment or deletion target, respectively.
- **PEP 3114**: the standard `next()` method has been renamed to `__next__()`. 
- The `__oct__()` and `__hex__()` special methods are removed – `oct()` and `hex()` use `__index__()` now to convert the argument to an integer.
- Removed support for `__members__` and `__methods__`.
- The function attributes named `func_X` have been renamed to use the `__X__` form, freeing up these names in the function attribute namespace for user-defined attributes. To wit, `func_closure`, `func_code`, `func_defaults`, `func_dict`, `func_doc`, `func_globals`, `func_name` were renamed to `__closure__`, `__code__`, `__defaults__`, `__dict__`, `__doc__`, `__globals__`, `__name__`, respectively.
- `__nonzero__()` is now `__bool__()`.

Builtins
PEP 3135: New super(). You can now invoke super() without arguments and (assuming this is in a regular instance method defined inside a class statement) the right class and instance will automatically be chosen. With arguments, the behavior of super() is unchanged.

PEP 3111: raw_input() was renamed to input(). That is, the new input() function reads a line from sys.stdin and returns it with the trailing newline stripped. It raises EOFError if the input is terminated prematurely. To get the old behavior of input(), use eval(input()).

A new built-in function next() was added to call the __next__() method on an object.

The round() function rounding strategy and return type have changed. Exact halfway cases are now rounded to the nearest even result instead of away from zero. (For example, round(2.5) now returns 2 rather than 3.) round(x[, n]) now delegates to x.__round__(n) instead of always returning a float. It generally returns an integer when called with a single argument and a value of the same type as x when called with two arguments.

Moved intern() to sys.intern().

Removed: apply(). Instead of apply(f, args) use f(*args).

Removed callable(). Instead of callable(f) you can use isinstance(f, collections.Callable). The operator.isCallable() function is also gone.

Removed coerce(). This function no longer serves a purpose now that classic classes are gone.

Removed execfile(). Instead of execfile(fn) use exec(open(fn).read()).

Removed the file type. Use open(). There are now several different kinds of streams that open can return in the io module.
removed reduce(). use `functools.reduce()` if you really need it; however, 99 percent of the time an explicit for loop is more readable.

removed reload(). use `imp.reload()`.

removed `dict.has_key()` – use the in operator instead.
Build and C API Changes

Due to time constraints, here is a very incomplete list of changes to the C API.

- Support for several platforms was dropped, including but not limited to Mac OS 9, BeOS, RISCOS, Irix, and Tru64.
- **PEP 3118**: New Buffer API.
- **PEP 3121**: Extension Module Initialization & Finalization.
- **PEP 3123**: Making `PyObject_HEAD` conform to standard C.
- No more C API support for restricted execution.
- PyNumber_Coerce(), PyNumber_CoerceEx(), PyMember_Get(), and PyMember_Set() C APIs are removed.
- New C API `PyImport_ImportModuleNoBlock()`, works like `PyImport_ImportModule()` but won't block on the import lock (returning an error instead).
- Renamed the boolean conversion C-level slot and method: `nb_nonzero` is now `nb_bool`.
- Removed METH_OLDARGS and WITH_CYCLE_GC from the C API.
Performance

The net result of the 3.0 generalizations is that Python 3.0 runs the pystone benchmark around 10% slower than Python 2.5. Most likely the biggest cause is the removal of special-casing for small integers. There's room for improvement, but it will happen after 3.0 is released!
Porting To Python 3.0

For porting existing Python 2.5 or 2.6 source code to Python 3.0, the best strategy is the following:

0. (Prerequisite:) Start with excellent test coverage.
1. Port to Python 2.6. This should be no more work than the average port from Python 2.x to Python 2.(x+1). Make sure all your tests pass.
2. (Still using 2.6:) Turn on the -3 command line switch. This enables warnings about features that will be removed (or change) in 3.0. Run your test suite again, and fix code that you get warnings about until there are no warnings left, and all your tests still pass.
3. Run the 2to3 source-to-source translator over your source code tree. (See 2to3 - Automated Python 2 to 3 code translation for more on this tool.) Run the result of the translation under Python 3.0. Manually fix up any remaining issues, fixing problems until all tests pass again.

It is not recommended to try to write source code that runs unchanged under both Python 2.6 and 3.0; you'd have to use a very contorted coding style, e.g. avoiding print statements, metaclasses, and much more. If you are maintaining a library that needs to support both Python 2.6 and Python 3.0, the best approach is to modify step 3 above by editing the 2.6 version of the source code and running the 2to3 translator again, rather than editing the 3.0 version of the source code.

For porting C extensions to Python 3.0, please see Porting Extension Modules to Python 3.
What’s New in Python 2.7

Author: A.M. Kuchling (amk at amk.ca)

This article explains the new features in Python 2.7. The final release of 2.7 is currently scheduled for July 2010; the detailed schedule is described in PEP 373.

Numeric handling has been improved in many ways, for both floating-point numbers and for the Decimal class. There are some useful additions to the standard library, such as a greatly enhanced unittest module, the argparse module for parsing command-line options, convenient ordered-dictionary and Counter classes in the collections module, and many other improvements.

Python 2.7 is planned to be the last of the 2.x releases, so we worked on making it a good release for the long term. To help with porting to Python 3, several new features from the Python 3.x series have been included in 2.7.

This article doesn’t attempt to provide a complete specification of the new features, but instead provides a convenient overview. For full details, you should refer to the documentation for Python 2.7 at http://docs.python.org. If you want to understand the rationale for the design and implementation, refer to the PEP for a particular new feature or the issue on http://bugs.python.org in which a change was discussed. Whenever possible, “What’s New in Python” links to the bug/patch item for each change.
The Future for Python 2.x

Python 2.7 is intended to be the last major release in the 2.x series. The Python maintainers are planning to focus their future efforts on the Python 3.x series.

This means that 2.7 will remain in place for a long time, running production systems that have not been ported to Python 3.x. Two consequences of the long-term significance of 2.7 are:

- It's very likely the 2.7 release will have a longer period of maintenance compared to earlier 2.x versions. Python 2.7 will continue to be maintained while the transition to 3.x continues, and the developers are planning to support Python 2.7 with bug-fix releases beyond the typical two years.

- A policy decision was made to silence warnings only of interest to developers. DeprecationWarning and its descendants are now ignored unless otherwise requested, preventing users from seeing warnings triggered by an application. This change was also made in the branch that will become Python 3.2. (Discussed on stdlib-sig and carried out in issue 7319.)

In previous releases, DeprecationWarning messages were enabled by default, providing Python developers with a clear indication of where their code may break in a future major version of Python.

However, there are increasingly many users of Python-based applications who are not directly involved in the development of those applications. DeprecationWarning messages are irrelevant to such users, making them worry about an application
that's actually working correctly and burdening application developers with responding to these concerns.

You can re-enable display of DeprecationWarning messages by running Python with the -Wdefault (short form: -Wd) switch, or by setting the PYTHONWARNINGS environment variable to "default" (or "d") before running Python. Python code can also re-enable them by calling warnings.simplefilter('default').
Python 3.1 Features

Much as Python 2.6 incorporated features from Python 3.0, version 2.7 incorporates some of the new features in Python 3.1. The 2.x series continues to provide tools for migrating to the 3.x series.

A partial list of 3.1 features that were backported to 2.7:

- The syntax for set literals ({1, 2, 3} is a mutable set).
- Dictionary and set comprehensions ({ i: i*2 for i in range(3)}).
- Multiple context managers in a single `with` statement.
- A new version of the `io` library, rewritten in C for performance.
- The ordered-dictionary type described in PEP 372: Adding an Ordered Dictionary to collections.
- The new `,` format specifier described in PEP 378: Format Specifier for Thousands Separator.
- The `memoryview` object.
- A small subset of the `importlib` module, described below.
- The `repr()` of a float $x$ is shorter in many cases: it's now based on the shortest decimal string that's guaranteed to round back to $x$. As in previous versions of Python, it's guaranteed that `float(repr(x))` recovers $x$.
- Float-to-string and string-to-float conversions are correctly rounded. The `round()` function is also now correctly rounded.
- The `PyCapsule` type, used to provide a C API for extension modules.
- The `PyLong_AsLongAndOverflow()` C API function.

Other new Python3-mode warnings include:

- `operator.isCallable()`
operator.sequenceIncludes(), which are not supported in 3.x, now trigger warnings.

- The -3 switch now automatically enables the -Qwarn switch that causes warnings about using classic division with integers and long integers.
PEP 372: Adding an Ordered Dictionary to collections

Regular Python dictionaries iterate over key/value pairs in arbitrary order. Over the years, a number of authors have written alternative implementations that remember the order that the keys were originally inserted. Based on the experiences from those implementations, 2.7 introduces a new `OrderedDict` class in the `collections` module.

The `OrderedDict` API provides the same interface as regular dictionaries but iterates over keys and values in a guaranteed order depending on when a key was first inserted:

```python
>>> from collections import OrderedDict
>>> d = OrderedDict([('first', 1), ...
...                   ('second', 2), ...
...                   ('third', 3)])
>>> d.items()
[('first', 1), ('second', 2), ('third', 3)]
```

If a new entry overwrites an existing entry, the original insertion position is left unchanged:

```python
>>> d['second'] = 4
>>> d.items()
[('first', 1), ('second', 4), ('third', 3)]
```

Deleting an entry and reinserting it will move it to the end:

```python
>>> del d['second']
>>> d['second'] = 5
>>> d.items()
[('first', 1), ('third', 3), ('second', 5)]
```
The `popitem()` method has an optional `last` argument that defaults to True. If `last` is True, the most recently added key is returned and removed; if it's False, the oldest key is selected:

```python
>>> od = OrderedDict([(x, 0) for x in range(20)])
>>> od.popitem()
(19, 0)
>>> od.popitem()
(18, 0)
>>> od.popitem(last=False)
(0, 0)
>>> od.popitem(last=False)
(1, 0)
```

Comparing two ordered dictionaries checks both the keys and values, and requires that the insertion order was the same:

```python
>>> od1 = OrderedDict([('first', 1),
                      ('second', 2),
                      ('third', 3)])
>>> od2 = OrderedDict([('third', 3),
                      ('first', 1),
                      ('second', 2)])
>>> od1 == od2
False
>>> # Move 'third' key to the end
>>> del od2['third']; od2['third'] = 3
>>> od1 == od2
True
```

Comparing an `OrderedDict` with a regular dictionary ignores the insertion order and just compares the keys and values.

How does the `OrderedDict` work? It maintains a doubly-linked list of keys, appending new keys to the list as they're inserted. A secondary
dictionary maps keys to their corresponding list node, so deletion doesn't have to traverse the entire linked list and therefore remains $O(1)$.

The standard library now supports use of ordered dictionaries in several modules.

- The ConfigParser module uses them by default, meaning that configuration files can now be read, modified, and then written back in their original order.
- The `_asdict()` method for `collections.namedtuple()` now returns an ordered dictionary with the values appearing in the same order as the underlying tuple indices.
- The `json` module's `JSONDecoder` class constructor was extended with an `object_pairs_hook` parameter to allow `OrderedDict` instances to be built by the decoder. Support was also added for third-party tools like PyYAML.

See also:

**PEP 372 - Adding an ordered dictionary to collections**

PEP written by Armin Ronacher and Raymond Hettinger; implemented by Raymond Hettinger.
PEP 378: Format Specifier for Thousands Separator

To make program output more readable, it can be useful to add separators to large numbers, rendering them as 18,446,744,073,709,551,616 instead of 18446744073709551616.

The fully general solution for doing this is the `locale` module, which can use different separators ("," in North America, "." in Europe) and different grouping sizes, but `locale` is complicated to use and unsuitable for multi-threaded applications where different threads are producing output for different locales.

Therefore, a simple comma-grouping mechanism has been added to the mini-language used by the `str.format()` method. When formatting a floating-point number, simply include a comma between the width and the precision:

```python
>>> '{:20,.2f}'.format(18446744073709551616.0)
'18,446,744,073,709,551,616.00'
```

When formatting an integer, include the comma after the width:

```python
>>> '{:20,d}'.format(18446744073709551616)
'18,446,744,073,709,551,616'
```

This mechanism is not adaptable at all; commas are always used as the separator and the grouping is always into three-digit groups. The comma-formatting mechanism isn't as general as the `locale` module, but it's easier to use.

See also:
PEP 378 - FormatSpecifier for Thousands Separator

PEP written by Raymond Hettinger; implemented by Eric Smith.
PEP 389: The argparse Module for Parsing Command Lines

The `argparse` module for parsing command-line arguments was added as a more powerful replacement for the `optparse` module.

This means Python now supports three different modules for parsing command-line arguments: `getopt`, `optparse`, and `argparse`. The `getopt` module closely resembles the C library's `getopt()` function, so it remains useful if you're writing a Python prototype that will eventually be rewritten in C. `optparse` becomes redundant, but there are no plans to remove it because there are many scripts still using it, and there's no automated way to update these scripts. (Making the `argparse` API consistent with `optparse`'s interface was discussed but rejected as too messy and difficult.)

In short, if you're writing a new script and don't need to worry about compatibility with earlier versions of Python, use `argparse` instead of `optparse`.

Here's an example:

```python
import argparse

parser = argparse.ArgumentParser(description='Command-line example.

# Add optional switches
parser.add_argument('-v', action='store_true', dest='verbose', help='produce verbose output')
parser.add_argument('-o', action='store', dest='output', metavar='FILE', help='direct output to FILE instead of
stdout')
```
parser.add_argument('-C', action='store', type=int, 
    metavar='NUM', default=0, 
    help='display NUM lines of added context

# Allow any number of additional arguments.
parsing.add_argument(nargs='*', action='store', dest='is_verbose', 
    help='input filenames (default is stdin)

args = parser.parse_args()
print args.__dict__

Unless you override it, -h and --help switches are automatically added, 
and produce neatly formatted output:

-> ./python.exe argparse-example.py --help
usage: argparse-example.py [-h] [-v] [-o FILE] [-C NUM

Command-line example.

positional arguments:
    inputs input filenames (default is stdin)

optional arguments:
    -h, --help     show this help message and exit
    -v             produce verbose output
    -o FILE        direct output to FILE instead of stdout
    -C NUM         display NUM lines of added context

As with optparse, the command-line switches and arguments are 
returned as an object with attributes named by the dest parameters:

-> ./python.exe argparse-example.py -v
{'output': None,
 'is_verbose': True,
 'context': 0,
argparse has much fancier validation than optparse; you can specify an exact number of arguments as an integer, 0 or more arguments by passing `*`, 1 or more by passing `+`, or an optional argument with `?`. A top-level parser can contain sub-parsers to define subcommands that have different sets of switches, as in `svn commit`, `svn checkout`, etc. You can specify an argument's type as `FileType`, which will automatically open files for you and understands that `-` means standard input or output.

**See also:** [argparse module documentation](https://docs.python.org/3/library/argparse.html)

**Upgrading optparse code to use argparse**

Part of the Python documentation, describing how to convert code that uses `optparse`.

**PEP 389 - argparse - New Command Line Parsing Module**

PEP written and implemented by Steven Bethard.
PEP 391: Dictionary-Based Configuration For Logging

The `logging` module is very flexible; applications can define a tree of logging subsystems, and each logger in this tree can filter out certain messages, format them differently, and direct messages to a varying number of handlers.

All this flexibility can require a lot of configuration. You can write Python statements to create objects and set their properties, but a complex set-up requires verbose but boring code. `logging` also supports a `fileConfig()` function that parses a file, but the file format doesn't support configuring filters, and it's messier to generate programmatically.

Python 2.7 adds a `dictConfig()` function that uses a dictionary to configure logging. There are many ways to produce a dictionary from different sources: construct one with code; parse a file containing JSON; or use a YAML parsing library if one is installed.

The following example configures two loggers, the root logger and a logger named “network”. Messages sent to the root logger will be sent to the system log using the syslog protocol, and messages to the “network” logger will be written to a `network.log` file that will be rotated once the log reaches 1Mb.

```python
import logging
import logging.config

cfgdict = {
    'version': 1,  # Configuration schema in use; must
    'formatters': {
```
'standard': {
  'format': ('%(asctime)s % (name)-15s '
  '(%levelname)-8s % (message)s'))

'handlers': {'netlog': {'backupCount': 10,
  'class': 'logging.handlers.RotatingFileHandler',
  'filename': '/logs/network.log',
  'formatter': 'standard',
  'level': 'INFO',
  'maxBytes': 1024*1024},
'syslog': {'class': 'logging.handlers.SysLogHandler',
  'formatter': 'standard',
  'level': 'ERROR'}}

# Specify all the subordinate loggers
'loggers': {
  'network': {
    'handlers': ['netlog']
  }
}

# Specify properties of the root logger
'root': {
  'handlers': ['syslog']
}

# Set up configuration
logging.config.dictConfig(configdict)

# As an example, log two error messages
logger = logging.getLogger('/')
logger.error('Database not found')

netlogger = logging.getLogger('network')
netlogger.error('Connection failed')
Three smaller enhancements to the `logging` module, all implemented by Vinay Sajip, are:

- The `SysLogHandler` class now supports syslogging over TCP. The constructor has a `socktype` parameter giving the type of socket to use, either `socket.SOCK_DGRAM` for UDP or `socket.SOCK_STREAM` for TCP. The default protocol remains UDP.

- Logger instances gained a `getChild()` method that retrieves a descendant logger using a relative path. For example, once you retrieve a logger by doing `log = getLogger('app')`, calling `log.getChild('network.listen')` is equivalent to `getLogger('app.network.listen')`.

- The `LoggerAdapter` class gained a `isEnabledFor()` method that takes a `level` and returns whether the underlying logger would process a message of that level of importance.

**PEP 391 - Dictionary-Based Configuration For Logging**

PEP written and implemented by Vinay Sajip.
PEP 3106: Dictionary Views

The dictionary methods keys(), values(), and items() are different in Python 3.x. They return an object called a view instead of a fully materialized list.

It’s not possible to change the return values of keys(), values(), and items() in Python 2.7 because too much code would break. Instead the 3.x versions were added under the new names viewkeys(), viewvalues(), and viewitems().

```
>>> d = dict((i*10, chr(65+i)) for i in range(26))
>>> d
>>> d.viewkeys()
dict_keys([0, 130, 10, 140, 20, 150, 30, ..., 250])
```

Views can be iterated over, but the key and item views also behave like sets. The & operator performs intersection, and | performs a union:

```
>>> d1 = dict((i*10, chr(65+i)) for i in range(26))
>>> d2 = dict((i**.5, i) for i in range(1000))
>>> d1.viewkeys() & d2.viewkeys()
set([0.0, 10.0, 20.0, 30.0])
>>> d1.viewkeys() | range(0, 30)
set([0, 1, 130, 3, 4, 5, 6, ..., 120, 250])
```

The view keeps track of the dictionary and its contents change as the dictionary is modified:

```
>>> vk = d.viewkeys()
```
However, note that you can't add or remove keys while you're iterating over the view:

```python
>>> for k in vk:
...     d[k*2] = k
...
Traceback (most recent call last):
  File "<stdin>", line 1, in <module>
RuntimeError: dictionary changed size during iteration
```

You can use the view methods in Python 2.x code, and the 2to3 converter will change them to the standard keys(), values(), and items() methods.

**See also:**

**PEP 3106 - Revamping dict.keys(), .values() and .items()**

PEP written by Guido van Rossum. Backported to 2.7 by Alexandre Vassalotti; issue 1967.
PEP 3137: The memoryview Object

The `memoryview` object provides a view of another object's memory content that matches the `bytes` type's interface.

```python
>>> import string
>>> m = memoryview(string.ascii_letters)
>>> m
<memory at 0x37f850>
>>> len(m)  # Returns length of underlying object
52
>>> m[0], m[25], m[26]  # Indexing returns one byte
('a', 'z', 'A')
>>> m2 = m[0:26]  # Slicing returns another memoryview
>>> m2
<memory at 0x37f080>
```

The content of the view can be converted to a string of bytes or a list of integers:

```python
>>> m2.tobytes()
'abcdefghijklmnopqrstuvwxyz'
>>> m2.tolist()
[97, 98, 99, 100, 101, 102, 103, ... 121, 122]
```

`memoryview` objects allow modifying the underlying object if it's a mutable object.

```python
>>> m2[0] = 75
Traceback (most recent call last):
  File "<stdin>", line 1, in <module>
TypeError: cannot modify read-only memory
```
>>> b = bytearray(string.letters)  # Creating a mutable object
>>> b
bytearray(b'abcdefghijklmnopqrstuvwxyzABCDEFGHIJKLMNOPQRSTUVWXYZ')
>>> mb = memoryview(b)
>>> mb[0] = '*'  # Assign to view, changing the bytearray.
>>> mb[0:5]  # The bytearray has been changed.
bytearray(b'*bcde')

**PEP 3137 - Immutable Bytes and Mutable Buffer**

PEP written by Guido van Rossum. Implemented by Travis Oliphant, Antoine Pitrou and others. Backported to 2.7 by Antoine Pitrou; issue 2396.
Other Language Changes

Some smaller changes made to the core Python language are:

- The syntax for set literals has been backported from Python 3.x. Curly brackets are used to surround the contents of the resulting mutable set; set literals are distinguished from dictionaries by not containing colons and values. `{}` continues to represent an empty dictionary; use `set()` for an empty set.

```python
>>> {1, 2, 3, 4, 5}
set([1, 2, 3, 4, 5])
>>> set() # empty set
set([])
>>> {} # empty dict
{}
```

Backported by Alexandre Vassalotti; issue 2335.

- Dictionary and set comprehensions are another feature backported from 3.x, generalizing list/generator comprehensions to use the literal syntax for sets and dictionaries.

```python
>>> {x: x*x for x in range(6)}
{0: 0, 1: 1, 2: 4, 3: 9, 4: 16, 5: 25}
>>> {('a'*x) for x in range(6)}
set(['', 'a', 'aa', 'aaa', 'aaaa', 'aaaaa'])
```

Backported by Alexandre Vassalotti; issue 2333.

- The `with` statement can now use multiple context managers in one statement. Context managers are processed from left to right and each one is treated as beginning a new `with` statement. This
means that:

```python
with A() as a, B() as b:
    ... suite of statements ...
```

is equivalent to:

```python
with A() as a:
    with B() as b:
        ... suite of statements ...
```

The `contextlib.nested()` function provides a very similar function, so it's no longer necessary and has been deprecated.

(Proposed in http://codereview.appspot.com/53094; implemented by Georg Brandl.)

- Conversions between floating-point numbers and strings are now correctly rounded on most platforms. These conversions occur in many different places: `str()` on floats and complex numbers; the `float` and `complex` constructors; numeric formatting; serializing and deserializing floats and complex numbers using the `marshal`, `pickle` and `json` modules; parsing of float and imaginary literals in Python code; and `Decimal`-to-float conversion.

Related to this, the `repr()` of a floating-point number `x` now returns a result based on the shortest decimal string that's guaranteed to round back to `x` under correct rounding (with round-half-to-even rounding mode). Previously it gave a string based on rounding `x` to 17 decimal digits.

The rounding library responsible for this improvement works on
Windows and on Unix platforms using the gcc, icc, or suncc compilers. There may be a small number of platforms where correct operation of this code cannot be guaranteed, so the code is not used on such systems. You can find out which code is being used by checking `sys.float_repr_style`, which will be `short` if the new code is in use and `legacy` if it isn’t.

Implemented by Eric Smith and Mark Dickinson, using David Gay’s `dtoa.c` library; [issue 7117](https://bugs.python.org/issue7117).

- Conversions from long integers and regular integers to floating point now round differently, returning the floating-point number closest to the number. This doesn’t matter for small integers that can be converted exactly, but for large numbers that will unavoidably lose precision, Python 2.7 now approximates more closely. For example, Python 2.6 computed the following:

```python
>>> n = 295147905179352891391
>>> float(n)
2.9514790517935283e+20
>>> n - long(float(n))
65535L
```

Python 2.7’s floating-point result is larger, but much closer to the true value:

```python
>>> n = 295147905179352891391
>>> float(n)
2.9514790517935289e+20
>>> n - long(float(n))
-1L
```

(Implemented by Mark Dickinson; [issue 3166](https://bugs.python.org/issue3166).)
Integer division is also more accurate in its rounding behaviours. (Also implemented by Mark Dickinson; issue 1811.)

- Implicit coercion for complex numbers has been removed; the interpreter will no longer ever attempt to call a `__coerce__()` method on complex objects. (Removed by Meador Inge and Mark Dickinson; issue 5211.)

- The `str.format()` method now supports automatic numbering of the replacement fields. This makes using `str.format()` more closely resemble using `%s` formatting:

```python
>>> '{}:{}:{}'.format(2009, 04, 'Sunday')
'2009:4:Sunday'
>>> '{}:{}:{day}'.format(2009, 4, day='Sunday')
'2009:4:Sunday'
```

The auto-numbering takes the fields from left to right, so the first `{...}` specifier will use the first argument to `str.format()`, the next specifier will use the next argument, and so on. You can’t mix auto-numbering and explicit numbering – either number all of your specifier fields or none of them – but you can mix auto-numbering and named fields, as in the second example above. (Contributed by Eric Smith; issue 5237.)

Complex numbers now correctly support usage with `format()`, and default to being right-aligned. Specifying a precision or comma-separation applies to both the real and imaginary parts of the number, but a specified field width and alignment is applied to the whole of the resulting `1.5+3j` output. (Contributed by Eric Smith; issue 1588 and issue 7988.)

The ‘F’ format code now always formats its output using
uppercase characters, so it will now produce ‘INF’ and ‘NAN’.
(Contributed by Eric Smith; issue 3382.)

A low-level change: the `object.__format__()` method now triggers a `PendingDeprecationWarning` if it’s passed a format string, because the `__format__()` method for `object` converts the object to a string representation and formats that. Previously the method silently applied the format string to the string representation, but that could hide mistakes in Python code. If you’re supplying formatting information such as an alignment or precision, presumably you’re expecting the formatting to be applied in some object-specific way. (Fixed by Eric Smith; issue 7994.)

- The `int()` and `long()` types gained a `bit_length` method that returns the number of bits necessary to represent its argument in binary:

```python
>>> n = 37
>>> bin(n)
'0b100101'
>>> n.bit_length()
6
>>> n = 2**123-1
>>> n.bit_length()
123
>>> (n+1).bit_length()
124
```

(Contributed by Fredrik Johansson and Victor Stinner; issue 3439.)

- The `import` statement will no longer try an absolute import if a relative import (e.g. `from .os import sep`) fails. This fixes a
bug, but could possibly break certain `import` statements that were only working by accident. (Fixed by Meador Inge; [issue 7902](#).)

- It's now possible for a subclass of the built-in `unicode` type to override the `__unicode__() method. (Implemented by Victor Stinner; [issue 1583863](#).)

- The `bytearray` type's `translate()` method now accepts `None` as its first argument. (Fixed by Georg Brandl; [issue 4759](#).)

- When using `@classmethod` and `@staticmethod` to wrap methods as class or static methods, the wrapper object now exposes the wrapped function as their `__func__` attribute. (Contributed by Amaury Forgeot d'Arc, after a suggestion by George Sakkis; [issue 5982](#).)

- When a restricted set of attributes were set using `__slots__`, deleting an unset attribute would not raise `AttributeError` as you would expect. Fixed by Benjamin Peterson; [issue 7604](#).

- Two new encodings are now supported: “cp720”, used primarily for Arabic text; and “cp858”, a variant of CP 850 that adds the euro symbol. (CP720 contributed by Alexander Belchenko and Amaury Forgeot d'Arc in [issue 1616979](#); CP858 contributed by Tim Hatch in [issue 8016](#).)

- The file object will now set the filename attribute on the `IOError` exception when trying to open a directory on POSIX platforms (noted by Jan Kaliszewski; [issue 4764](#), and now explicitly checks for and forbids writing to read-only file objects instead of trusting the C library to catch and report the error (fixed by Stefan Krah; [issue 5677](#)).
- The Python tokenizer now translates line endings itself, so the `compile()` built-in function now accepts code using any line-ending convention. Additionally, it no longer requires that the code end in a newline.

- Extra parentheses in function definitions are illegal in Python 3.x, meaning that you get a syntax error from `def f((x)): pass`. In Python3-warning mode, Python 2.7 will now warn about this odd usage. (Noted by James Lingard; issue 7362.)

- It's now possible to create weak references to old-style class objects. New-style classes were always weak-referenceable. (Fixed by Antoine Pitrou; issue 8268.)

- When a module object is garbage-collected, the module's dictionary is now only cleared if no one else is holding a reference to the dictionary (issue 7140).

**Interpreter Changes**

A new environment variable, `PYTHONWARNINGS`, allows controlling warnings. It should be set to a string containing warning settings, equivalent to those used with the `-W` switch, separated by commas. (Contributed by Brian Curtin; issue 7301.)

For example, the following setting will print warnings every time they occur, but turn warnings from the Cookie module into an error. (The exact syntax for setting an environment variable varies across operating systems and shells.)

```bash
export PYTHONWARNINGS=all,error:::Cookie:0
```
Optimizations

Several performance enhancements have been added:

- A new opcode was added to perform the initial setup for `with` statements, looking up the `__enter__()` and `__exit__()` methods. (Contributed by Benjamin Peterson.)

- The garbage collector now performs better for one common usage pattern: when many objects are being allocated without deallocating any of them. This would previously take quadratic time for garbage collection, but now the number of full garbage collections is reduced as the number of objects on the heap grows. The new logic only performs a full garbage collection pass when the middle generation has been collected 10 times and when the number of survivor objects from the middle generation exceeds 10% of the number of objects in the oldest generation. (Suggested by Martin von Löwis and implemented by Antoine Pitrou; issue 4074.)

- The garbage collector tries to avoid tracking simple containers which can’t be part of a cycle. In Python 2.7, this is now true for tuples and dicts containing atomic types (such as ints, strings, etc.). Transitively, a dict containing tuples of atomic types won’t be tracked either. This helps reduce the cost of each garbage collection by decreasing the number of objects to be considered and traversed by the collector. (Contributed by Antoine Pitrou; issue 4688.)

- Long integers are now stored internally either in base 2**15 or in base 2**30, the base being determined at build time. Previously, they were always stored in base 2**15. Using base 2**30 gives
significant performance improvements on 64-bit machines, but
benchmark results on 32-bit machines have been mixed.
Therefore, the default is to use base $2^{30}$ on 64-bit machines
and base $2^{15}$ on 32-bit machines; on Unix, there's a new
configure option --enable-big-digits that can be used to override
this default.

Apart from the performance improvements this change should be
invisible to end users, with one exception: for testing and
debugging purposes there's a new structseq sys.long_info
that provides information about the internal format, giving the
number of bits per digit and the size in bytes of the C type used to
store each digit:

```python
>>> import sys
>>> sys.long_info
sys.long_info(bits_per_digit=30, sizeof_digit=4)
```

(Contributed by Mark Dickinson; issue 4258.)

Another set of changes made long objects a few bytes smaller: 2
bytes smaller on 32-bit systems and 6 bytes on 64-bit.
(Contributed by Mark Dickinson; issue 5260.)

- The division algorithm for long integers has been made faster by
tightening the inner loop, doing shifts instead of multiplications,
and fixing an unnecessary extra iteration. Various benchmarks
show speedups of between 50% and 150% for long integer
divisions and modulo operations. (Contributed by Mark Dickinson;
issue 5512.) Bitwise operations are also significantly faster (initial
patch by Gregory Smith; issue 1087418).

- The implementation of % checks for the left-side operand being a
Python string and special-cases it; this results in a 1-3% performance increase for applications that frequently use % with strings, such as templating libraries. (Implemented by Collin Winter; issue 5176.)

- List comprehensions with an if condition are compiled into faster bytecode. (Patch by Antoine Pitrou, back-ported to 2.7 by Jeffrey Yasskin; issue 4715.)

- Converting an integer or long integer to a decimal string was made faster by special-casing base 10 instead of using a generalized conversion function that supports arbitrary bases. (Patch by Gawain Bolton; issue 6713.)

- The split(), replace(), rindex(), rpartition(), and rsplit() methods of string-like types (strings, Unicode strings, and bytearray objects) now use a fast reverse-search algorithm instead of a character-by-character scan. This is sometimes faster by a factor of 10. (Added by Florent Xicluna; issue 7462 and issue 7622.)

- The pickle and cPickle modules now automatically intern the strings used for attribute names, reducing memory usage of the objects resulting from unpickling. (Contributed by Jake McGuire; issue 5084.)

- The cPickle module now special-cases dictionaries, nearly halving the time required to pickle them. (Contributed by Collin Winter; issue 5670.)
New and Improved Modules

As in every release, Python’s standard library received a number of enhancements and bug fixes. Here's a partial list of the most notable changes, sorted alphabetically by module name. Consult the Misc/NEWS file in the source tree for a more complete list of changes, or look through the Subversion logs for all the details.

- The bdb module's base debugging class Bdb gained a feature for skipping modules. The constructor now takes an iterable containing glob-style patterns such as django.*; the debugger will not step into stack frames from a module that matches one of these patterns. (Contributed by Maru Newby after a suggestion by Senthil Kumaran; issue 5142.)

- The binascii module now supports the buffer API, so it can be used with memoryview instances and other similar buffer objects. (Backported from 3.x by Florent Xicluna; issue 7703.)

- Updated module: the bsddb module has been updated from 4.7.2devel9 to version 4.8.4 of the pybsddb package. The new version features better Python 3.x compatibility, various bug fixes, and adds several new BerkeleyDB flags and methods. (Updated by Jesús Cea Avión; issue 8156. The pybsddb changelog can be read at http://hg.jcea.es/pybsddb/file/tip/ChangeLog.)

- The bz2 module’s BZ2File now supports the context management protocol, so you can write with bz2.BZ2File(...) as f:. (Contributed by Hagen Fürstenau; issue 3860.)

- New class: the Counter class in the collections module is
useful for tallying data. Counter instances behave mostly like dictionaries but return zero for missing keys instead of raising a KeyError:

```python
>>> from collections import Counter
>>> c = Counter()
>>> for letter in 'here is a sample of english text'
...     c[letter] += 1
... >>> c
Counter({'	': 6, 'e': 5, 's': 3, 'a': 2, 'i': 2, 'l': 2, 't': 2, 'g': 1, 'f': 1, 'm': 1, 'o': 1, 'n': 1, 'p': 1, 'r': 1, 'x': 1})
>>> c['e']
5
>>> c['z']
0
```

There are three additional Counter methods. most_common() returns the N most common elements and their counts. elements() returns an iterator over the contained elements, repeating each element as many times as its count. subtract() takes an iterable and subtracts one for each element instead of adding; if the argument is a dictionary or another Counter, the counts are subtracted.

```python
>>> c.most_common(5)
[(' ', 6), ('e', 5), ('s', 3), ('a', 2), ('i', 2), ('l', 2), ('t', 2), ('g', 1), ('f', 1), ('m', 1), ('o', 1), ('n', 1), ('p', 1), ('r', 1), ('x', 1)]
>>> c.elements() ->
'a', 'a', ' ', ' ', ' ', ' ', ' ', ' ', ' ', ' ', ' ', ' ', ' ', 'e', 'e', 'e', 'e', 'e', 'g', 'f', 'i', 'i', 'h', 'h', 'm', 'l', 'l', 'o', 'n', 'p', 's', 's', 's', 'r', 't', 't', 't', 'x'
>>> c['e']
5
```
Contributed by Raymond Hettinger; issue 1696199.

New class: `OrderedDict` is described in the earlier section *PEP 372: Adding an Ordered Dictionary to collections*.

New method: The `deque` data type now has a `count()` method that returns the number of contained elements equal to the supplied argument `x`, and a `reverse()` method that reverses the elements of the deque in-place. `deque` also exposes its maximum length as the read-only `maxlen` attribute. (Both features added by Raymond Hettinger.)

The `namedtuple` class now has an optional `rename` parameter. If `rename` is true, field names that are invalid because they've been repeated or aren't legal Python identifiers will be renamed to legal names that are derived from the field's position within the list of fields:

```python
>>> from collections import namedtuple
>>> T = namedtuple('T', ['field1', '$illegal', 'for'])
>>> T._fields
('field1', '_1', '_2', 'field2')
```

(Added by Raymond Hettinger; issue 1818.)

Finally, the `Mapping` abstract base class now returns `NotImplemented` if a mapping is compared to another type that
isn’t a Mapping. (Fixed by Daniel Stutzbach; issue 8729.)

- Constructors for the parsing classes in the ConfigParser module now take a allow_no_value parameter, defaulting to false; if true, options without values will be allowed. For example:

```python
>>> import ConfigParser, StringIO
>>> sample_config = ""
... [mysqld]
... user = mysql
... pid-file = /var/run/mysqld/mysqld.pid
... skip-bdb
... ""
>>> config = ConfigParser.RawConfigParser(allow_no_value)
>>> config.readfp(StringIO.StringIO(sample_config))
>>> config.get('mysqld', 'user')
'mysql'
>>> print config.get('mysqld', 'skip-bdb')
None
>>> print config.get('mysqld', 'unknown')
Traceback (most recent call last):
...
NoOptionError: No option 'unknown' in section: '"
```

(Contributed by Mats Kindahl; issue 7005.)

- Deprecated function: contextlib.nested(), which allows handling more than one context manager with a single with statement, has been deprecated, because the with statement now supports multiple context managers.

- The cookielib module now ignores cookies that have an invalid version field, one that doesn’t contain an integer value. (Fixed by John J. Lee; issue 3924.)
The `copy` module's `deepcopy()` function will now correctly copy bound instance methods. (Implemented by Robert Collins; issue 1515.)

The `ctypes` module now always converts None to a C NULL pointer for arguments declared as pointers. (Changed by Thomas Heller; issue 4606.) The underlying `libffi` library has been updated to version 3.0.9, containing various fixes for different platforms. (Updated by Matthias Klose; issue 8142.)

New method: the `datetime` module's `timedelta` class gained a `total_seconds()` method that returns the number of seconds in the duration. (Contributed by Brian Quinlan; issue 5788.)

New method: the `Decimal` class gained a `from_float()` class method that performs an exact conversion of a floating-point number to a `Decimal`. This exact conversion strives for the closest decimal approximation to the floating-point representation's value; the resulting decimal value will therefore still include the inaccuracy, if any. For example, `Decimal.from_float(0.1)` returns `Decimal('0.10000000000000000555111512312578270211')` (Implemented by Raymond Hettinger; issue 4796.)

Comparing instances of `Decimal` with floating-point numbers now produces sensible results based on the numeric values of the operands. Previously such comparisons would fall back to Python's default rules for comparing objects, which produced arbitrary results based on their type. Note that you still cannot combine `Decimal` and floating-point in other operations such as addition, since you should be explicitly choosing how to convert...
between float and Decimal. (Fixed by Mark Dickinson; issue 2531.)

The constructor for Decimal now accepts floating-point numbers (added by Raymond Hettinger; issue 8257) and non-European Unicode characters such as Arabic-Indic digits (contributed by Mark Dickinson; issue 6595).

Most of the methods of the Context class now accept integers as well as Decimal instances; the only exceptions are the canonical() and is_canonical() methods. (Patch by Juan José Conti; issue 7633.)

When using Decimal instances with a string’s format() method, the default alignment was previously left-alignment. This has been changed to right-alignment, which is more sensible for numeric types. (Changed by Mark Dickinson; issue 6857.)

Comparisons involving a signaling NaN value (or sNAN) now signal InvalidOperation instead of silently returning a true or false value depending on the comparison operator. Quiet NaN values (or NaN) are now hashable. (Fixed by Mark Dickinson; issue 7279.)

- The difflib module now produces output that is more compatible with modern diff/patch tools through one small change, using a tab character instead of spaces as a separator in the header giving the filename. (Fixed by Anatoly Techtonik; issue 7585.)

- The Distutils sdist command now always regenerates the MANIFEST file, since even if the MANIFEST.in or setup.py files haven’t been modified, the user might have created some
new files that should be included. (Fixed by Tarek Ziadé; issue 8688.)

- The `doctest` module’s `IGNORE_EXCEPTION_DETAIL` flag will now ignore the name of the module containing the exception being tested. (Patch by Lennart Regebro; issue 7490.)

- The `email` module’s `Message` class will now accept a Unicode-valued payload, automatically converting the payload to the encoding specified by `output_charset`. (Added by R. David Murray; issue 1368247.)

- The `Fraction` class now accepts a single float or `Decimal` instance, or two rational numbers, as arguments to its constructor. (Implemented by Mark Dickinson; rationals added in issue 5812, and float/decimal in issue 8294.)

  Ordering comparisons (`<`, `<=`, `>`, `>=`) between fractions and complex numbers now raise a `TypeError`. This fixes an oversight, making the `Fraction` match the other numeric types.

- New class: `FTP_TLS` in the `ftplib` module provides secure FTP connections using TLS encapsulation of authentication as well as subsequent control and data transfers. (Contributed by Giampaolo Rodola; issue 2054.)

  The `storbinary()` method for binary uploads can now restart uploads thanks to an added `rest` parameter (patch by Pablo Mouzo; issue 6845.)

- New class decorator: `total_ordering()` in the `functools` module takes a class that defines an `__eq__()` method and one of `__lt__()`, `__le__()`, `__gt__()`, or `__ge__()`, and
generates the missing comparison methods. Since the

__cmp__() method is being deprecated in Python 3.x, this
decorator makes it easier to define ordered classes. (Added by
Raymond Hettinger; issue 5479.)

New function: cmp_to_key() will take an old-style comparison
function that expects two arguments and return a new callable
that can be used as the key parameter to functions such as

sorted(), min() and max(), etc. The primary intended use is
to help with making code compatible with Python 3.x. (Added by
Raymond Hettinger.)

- New function: the gc module's is_tracked() returns true if a
given instance is tracked by the garbage collector, false
otherwise. (Contributed by Antoine Pitrou; issue 4688.)

- The gzip module's GzipFile now supports the context
management protocol, so you can write with

gzip.GzipFile(...) as f: (contributed by Hagen
Fürstenau; issue 3860), and it now implements the
io.BufferedIOBase ABC, so you can wrap it with
io.BufferedReader for faster processing (contributed by Nir
Aides; issue 7471). It's also now possible to override the
modification time recorded in a gzipped file by providing an
optional timestamp to the constructor. (Contributed by Jacques
Frechet; issue 4272.)

Files in gzip format can be padded with trailing zero bytes; the
gzip module will now consume these trailing bytes. (Fixed by
Tadek Pietraszek and Brian Curtin; issue 2846.)

- New attribute: the hashlib module now has an algorithms
attribute containing a tuple naming the supported algorithms. In Python 2.7, `hashlib.algorithms` contains (`'md5', 'sha1', 'sha224', 'sha256', 'sha384', 'sha512'`). (Contributed by Carl Chenet; issue 7418.)

- The default `HTTPResponse` class used by the `httpplib` module now supports buffering, resulting in much faster reading of HTTP responses. (Contributed by Kristján Valur Jónsson; issue 4879.)

  The `HTTPConnection` and `HTTPSConnection` classes now support a `source_address` parameter, a `(host, port)` 2-tuple giving the source address that will be used for the connection. (Contributed by Eldon Ziegler; issue 3972.)

- The `ihooks` module now supports relative imports. Note that `ihooks` is an older module for customizing imports, superseded by the `imputil` module added in Python 2.0. (Relative import support added by Neil Schemenauer.)

- The `imaplib` module now supports IPv6 addresses. (Contributed by Derek Morr; issue 1655.)

- New function: the `inspect` module's `getcallargs()` takes a callable and its positional and keyword arguments, and figures out which of the callable's parameters will receive each argument, returning a dictionary mapping argument names to their values. For example:

```python
>>> from inspect import getcallargs
>>> def f(a, b=1, *pos, **named):
...    pass
>>> getcallargs(f, 1, 2, 3)
{'a': 1, 'b': 2, 'pos': (3,), 'named': {}}
```
Contributed by George Sakkis; issue 3135.

- Updated module: The io library has been upgraded to the version shipped with Python 3.1. For 3.1, the I/O library was entirely rewritten in C and is 2 to 20 times faster depending on the task being performed. The original Python version was renamed to the _pyio module.

One minor resulting change: the io.TextIOBase class now has an errors attribute giving the error setting used for encoding and decoding errors (one of 'strict', 'replace', 'ignore').

The io.FileIO class now raises an OSError when passed an invalid file descriptor. (Implemented by Benjamin Peterson; issue 4991.) The truncate() method now preserves the file position; previously it would change the file position to the end of the new file. (Fixed by Pascal Chambon; issue 6939.)

- New function: itertools.compress(data, selectors) takes two iterators. Elements of data are returned if the corresponding value in selectors is true:

```
>>> itertools.compress(['ABCDEF', [1,0,1,0,1,1]])
A, C, E, F
```
itertools.combinations_with_replacement(iter, r) returns all the possible r-length combinations of elements from the iterable iter. Unlike combinations(), individual elements can be repeated in the generated combinations:

\[
\text{itertools.combinations_with_replacement('abc', 2)} = \\
(('a', 'a'), ('a', 'b'), ('a', 'c'), \\
 ('b', 'b'), ('b', 'c'), ('c', 'c'))
\]

Note that elements are treated as unique depending on their position in the input, not their actual values.

The itertools.count() function now has a step argument that allows incrementing by values other than 1. count() also now allows keyword arguments, and using non-integer values such as floats or Decimal instances. (Implemented by Raymond Hettinger; issue 5032.)

itertools.combinations() and itertools.product() previously raised ValueError for values of r larger than the input iterable. This was deemed a specification error, so they now return an empty iterator. (Fixed by Raymond Hettinger; issue 4816.)

- Updated module: The json module was upgraded to version 2.0.9 of the simplejson package, which includes a C extension that makes encoding and decoding faster. (Contributed by Bob Ippolito; issue 4136.)

To support the new collections.OrderedDict type, json.load() now has an optional object_pairs_hook parameter that will be called with any object literal that decodes to a list of
pairs. (Contributed by Raymond Hettinger; issue 5381.)

- The `mailbox` module's `Maildir` class now records the timestamp on the directories it reads, and only re-reads them if the modification time has subsequently changed. This improves performance by avoiding unneeded directory scans. (Fixed by A.M. Kuchling and Antoine Pitrou; issue 1607951, issue 6896.)

- New functions: the `math` module gained `erf()` and `erfc()` for the error function and the complementary error function, `expm1()` which computes \(e^{**x} - 1\) with more precision than using `exp()` and subtracting 1, `gamma()` for the Gamma function, and `lgamma()` for the natural log of the Gamma function. (Contributed by Mark Dickinson and nirinAraseliarison; issue 3366.)

- The `multiprocessing` module's `Manager*` classes can now be passed a callable that will be called whenever a subprocess is started, along with a set of arguments that will be passed to the callable. (Contributed bylekma; issue 5585.)

The Pool class, which controls a pool of worker processes, now has an optional `maxtasksperchild` parameter. Worker processes will perform the specified number of tasks and then exit, causing the Pool to start a new worker. This is useful if tasks may leak memory or other resources, or if some tasks will cause the worker to become very large. (Contributed by Charles Cazabon; issue 6963.)

- The `nntplib` module now supports IPv6 addresses. (Contributed by Derek Morr; issue 1664.)

- New functions: the `os` module wraps the following POSIX system
calls: `getresgid()` and `getresuid()`, which return the real, effective, and saved GIDs and UIDs; `setresgid()` and `setresuid()`, which set real, effective, and saved GIDs and UIDs to new values; `initgroups()`, which initialize the group access list for the current process. (GID/UID functions contributed by Travis H.; issue 6508. Support for initgroups added by Jean-Paul Calderone; issue 7333.)

The `os.fork()` function now re-initializes the import lock in the child process; this fixes problems on Solaris when `fork()` is called from a thread. (Fixed by Zsolt Cserna; issue 7242.)

- In the `os.path` module, the `normpath()` and `abspath()` functions now preserve Unicode; if their input path is a Unicode string, the return value is also a Unicode string. (`normpath()` fixed by Matt Giuca in issue 5827; `abspath()` fixed by Ezio Melotti in issue 3426.)

- The `pydoc` module now has help for the various symbols that Python uses. You can now do `help('<<')` or `help('@')`, for example. (Contributed by David Laban; issue 4739.)

- The `re` module’s `split()`, `sub()`, and `subn()` now accept an optional `flags` argument, for consistency with the other functions in the module. (Added by Gregory P. Smith.)

- New function: `run_path()` in the `runpy` module will execute the code at a provided `path` argument. `path` can be the path of a Python source file (`example.py`), a compiled bytecode file (`example.pyc`), a directory (`./package/`), or a zip archive (`example.zip`). If a directory or zip path is provided, it will be added to the front of `sys.path` and the module `__main__` will
be imported. It’s expected that the directory or zip contains a
__main__.py; if it doesn’t, some other __main__.py might be
imported from a location later in sys.path. This makes more of
the machinery of runpy available to scripts that want to mimic the
way Python’s command line processes an explicit path name.
(Added by Nick Coghlan; issue 6816.)

• New function: in the shutil module, make_archive() takes a
filename, archive type (zip or tar-format), and a directory path,
and creates an archive containing the directory’s contents. (Added
by Tarek Ziadé.)

shutil’s copyfile() and copytree() functions now raise a
SpecialFileError exception when asked to copy a named
pipe. Previously the code would treat named pipes like a regular
file by opening them for reading, and this would block indefinitely.
(Fixed by Antoine Pitrou; issue 3002.)

• The signal module no longer re-installs the signal handler
unless this is truly necessary, which fixes a bug that could make it
impossible to catch the EINTR signal robustly. (Fixed by Charles-
François Natali; issue 8354.)

• New functions: in the site module, three new functions return
various site- and user-specific paths. getsitepackages() returns a list containing all global site-packages directories,
getusersitepackages() returns the path of the user’s site-
packages directory, and getuserbase() returns the value of the
USER_BASE environment variable, giving the path to a directory
that can be used to store data. (Contributed by Tarek Ziadé; issue
6693.)
The **site** module now reports exceptions occurring when the sitecustomize module is imported, and will no longer catch and swallow the **KeyboardInterrupt** exception. (Fixed by Victor Stinner; issue 3137.)

- The **create_connection()** function gained a **source_address** parameter, a *(host, port)* 2-tuple giving the source address that will be used for the connection. (Contributed by Eldon Ziegler; issue 3972.)

The **recv_into()** and **recvfrom_into()** methods will now write into objects that support the buffer API, most usefully the **bytearray** and **memoryview** objects. (Implemented by Antoine Pitrou; issue 8104.)

- The **SocketServer** module's **TCPServer** class now supports socket timeouts and disabling the Nagle algorithm. The **disable_nagle_algorithm** class attribute defaults to False; if overridden to be True, new request connections will have the **TCP_NODELAY** option set to prevent buffering many small sends into a single TCP packet. The **timeout** class attribute can hold a timeout in seconds that will be applied to the request socket; if no request is received within that time, **handle_timeout()** will be called and **handle_request()** will return. (Contributed by Kristján Valur Jónsson; issue 6192 and issue 6267.)

- Updated module: the **sqlite3** module has been updated to version 2.6.0 of the **pysqlite package**. Version 2.6.0 includes a number of bugfixes, and adds the ability to load SQLite extensions from shared libraries. Call the **enable_load_extension(True)** method to enable extensions, and then call **load_extension()** to load a
particular shared library. (Updated by Gerhard Häring.)

- The *ssl* module's *ssl.SSLSocket* objects now support the buffer API, which fixed a test suite failure (fix by Antoine Pitrou; issue 7133) and automatically set OpenSSL's SSL_MODE_AUTO_RETRY, which will prevent an error code being returned from *recv()* operations that trigger an SSL renegotiation (fix by Antoine Pitrou; issue 8222).

  The *ssl.wrap_socket()* constructor function now takes a *ciphers* argument that’s a string listing the encryption algorithms to be allowed; the format of the string is described in the OpenSSL documentation. (Added by Antoine Pitrou; issue 8322.)

  Another change makes the extension load all of OpenSSL’s ciphers and digest algorithms so that they’re all available. Some SSL certificates couldn’t be verified, reporting an “unknown algorithm” error. (Reported by Beda Kosata, and fixed by Antoine Pitrou; issue 8484.)

  The version of OpenSSL being used is now available as the module attributes *ssl.OPENSSL_VERSION* (a string), *ssl.OPENSSL_VERSION_INFO* (a 5-tuple), and *ssl.OPENSSL_VERSION_NUMBER* (an integer). (Added by Antoine Pitrou; issue 8321.)

- The *struct* module will no longer silently ignore overflow errors when a value is too large for a particular integer format code (one of bBhHiIlLqQ); it now always raises a *struct.error* exception. (Changed by Mark Dickinson; issue 1523.) The *pack()* function will also attempt to use *__index__()* to convert and pack non-integers before trying the *__int__()*
method or reporting an error. (Changed by Mark Dickinson; issue 8300.)

- New function: the `subprocess` module's `check_output()` runs a command with a specified set of arguments and returns the command's output as a string when the command runs without error, or raises a `CalledProcessError` exception otherwise.

```python
>>> subprocess.check_output(['df', '-h', '.'])
'Filesystem Size Used Avail Capacity Mounted on
/dev/disk0s2  52G   49G   3.0G    94%   /
'
>>> subprocess.check_output(['df', '-h', '/bogus'])
subprocess.CalledProcessError: Command ['df', '-h', '/bogus'] Returned non-zero exit status 1

(Contributed by Gregory P. Smith.)

The `subprocess` module will now retry its internal system calls on receiving an EINTR signal. (Reported by several people; final patch by Gregory P. Smith in issue 1068268.)

- New function: `is_declared_global()` in the `symtable` module returns true for variables that are explicitly declared to be global, false for ones that are implicitly global. (Contributed by Jeremy Hylton.)

- The `syslog` module will now use the value of `sys.argv[0]` as the identifier instead of the previous default value of 'python'. (Changed by Sean Reifschneider; issue 8451.)

- The `sys.version_info` value is now a named tuple, with attributes named major, minor, micro, releaselevel, and
sys.getwindowsversion() also returns a named tuple, with attributes named major, minor, build, platform, service_pack, service_pack_major, service_pack_minor, suite_mask, and product_type. (Contributed by Brian Curtin; issue 7766.)

- The tarfile module's default error handling has changed, to no longer suppress fatal errors. The default error level was previously 0, which meant that errors would only result in a message being written to the debug log, but because the debug log is not activated by default, these errors go unnoticed. The default error level is now 1, which raises an exception if there's an error. (Changed by Lars Gustäbel; issue 7357.)

tarfile now supports filtering the TarInfo objects being added to a tar file. When you call add(), you may supply an optional filter argument that's a callable. The filter callable will be passed the TarInfo for every file being added, and can modify and return it. If the callable returns None, the file will be excluded from the resulting archive. This is more powerful than the existing exclude argument, which has therefore been deprecated. (Added by Lars Gustäbel; issue 6856.) The TarFile class also now supports the context manager protocol. (Added by Lars Gustäbel; issue 7232.)

- The wait() method of the threading.Event class now returns the internal flag on exit. This means the method will usually return true because wait() is supposed to block until the internal flag becomes true. The return value will only be false if a timeout was provided and the operation timed out. (Contributed by
The Unicode database provided by the unicedata module is now used internally to determine which characters are numeric, whitespace, or represent line breaks. The database also includes information from the Unihan.txt data file (patch by Anders Chrigström and Amaury Forgeot d'Arc; issue 1571184) and has been updated to version 5.2.0 (updated by Florent Xicluna; issue 8024).

The urlparse module's urlsplit() now handles unknown URL schemes in a fashion compliant with RFC 3986: if the URL is of the form "<something>://...", the text before the :// is treated as the scheme, even if it's a made-up scheme that the module doesn't know about. This change may break code that worked around the old behaviour. For example, Python 2.6.4 or 2.5 will return the following:

```python
>>> import urlparse
>>> urlparse.urlsplit('invented://host/filename?query')
('invented', '', '//host/filename?query', '', ')
```

Python 2.7 (and Python 2.6.5) will return:

```python
>>> import urlparse
>>> urlparse.urlsplit('invented://host/filename?query')
('invented', 'host', '/filename?query', '', '')
```

(Python 2.7 actually produces slightly different output, since it returns a named tuple instead of a standard tuple.)

The urlparse module also supports IPv6 literal addresses as
defined by RFC 2732 (contributed by Senthil Kumaran; issue 2987).

```
>>> urlparse.urlparse('http://[1080::8:800:200C:417A]/foo'
ParseResult(scheme='http', netloc='[1080::8:800:200C:417A]',
path='/foo', params='', query='', fragment=''))
```

- New class: the WeakSet class in the weakref module is a set that only holds weak references to its elements; elements will be removed once there are no references pointing to them. (Originally implemented in Python 3.x by Raymond Hettinger, and backported to 2.7 by Michael Foord.)

- The ElementTree library, xml.etree, no longer escapes ampersands and angle brackets when outputting an XML processing instruction (which looks like `<?xml-stylesheet href="#style1"?>`) or comment (which looks like `<!-- comment -->`). (Patch by Neil Muller; issue 2746.)

- The XML-RPC client and server, provided by the xmlrpclib and SimpleXMLRPCServer modules, have improved performance by supporting HTTP/1.1 keep-alive and by optionally using gzip encoding to compress the XML being exchanged. The gzip compression is controlled by the encode_threshold attribute of SimpleXMLRPCRequestHandler, which contains a size in bytes; responses larger than this will be compressed. (Contributed by Kristján Valur Jónsson; issue 6267.)

- The zipfile module's ZipFile now supports the context management protocol, so you can write with `zipfile.ZipFile(...) as f:`. (Contributed by Brian Curtin; issue 5511.)
**zipfile** now also supports archiving empty directories and extracts them correctly. (Fixed by Kuba Wieczorek; [issue 4710](https://github.com/python/cpython/issues/4710).) Reading files out of an archive is faster, and interleaving `read()` and `readline()` now works correctly. (Contributed by Nir Aides; [issue 7610](https://github.com/python/cpython/issues/7610).)

The `is_zipfile()` function now accepts a file object, in addition to the path names accepted in earlier versions. (Contributed by Gabriel Genellina; [issue 4756](https://github.com/python/cpython/issues/4756).)

The `writestr()` method now has an optional `compress_type` parameter that lets you override the default compression method specified in the `ZipFile` constructor. (Contributed by Ronald Oussoren; [issue 6003](https://github.com/python/cpython/issues/6003).)

### New module: importlib

Python 3.1 includes the `importlib` package, a re-implementation of the logic underlying Python's `import` statement. `importlib` is useful for implementors of Python interpreters and to users who wish to write new importers that can participate in the import process. Python 2.7 doesn't contain the complete `importlib` package, but instead has a tiny subset that contains a single function, `import_module()`.

```python
import_module(name, package=None) imports a module. `name` is a string containing the module or package's name. It's possible to do relative imports by providing a string that begins with a `.` character, such as `..utils.errors`. For relative imports, the `package` argument must be provided and is the name of the package that will be used as the anchor for the relative import. `import_module()`
both inserts the imported module into `sys.modules` and returns the module object.

Here are some examples:

```python
>>> from importlib import import_module
>>> anydbm = import_module('anydbm')  # Standard absolute import
>>> anydbm
<module 'anydbm' from '/p/python/Lib/anydbm.py'>
>>> # Relative import
>>> file_util = import_module('..file_util', 'distutils.command')
>>> file_util
<module 'distutils.file_util' from '/python/Lib/distutils/file_util.pyc'>
```

`importlib` was implemented by Brett Cannon and introduced in Python 3.1.

**New module: sysconfig**

The `sysconfig` module has been pulled out of the Distutils package, becoming a new top-level module in its own right. `sysconfig` provides functions for getting information about Python's build process: compiler switches, installation paths, the platform name, and whether Python is running from its source directory.

Some of the functions in the module are:

- `get_config_var()` returns variables from Python's Makefile and the `pyconfig.h` file.
- `get_config_vars()` returns a dictionary containing all of the configuration variables.
- `getpath()` returns the configured path for a particular type of module: the standard library, site-specific modules, platform-
specific modules, etc.

- `is_python_build()` returns true if you're running a binary from a Python source tree, and false otherwise.

Consult the `sysconfig` documentation for more details and for a complete list of functions.

The Distutils package and `sysconfig` are now maintained by Tarek Ziadé, who has also started a Distutils2 package (source repository at http://hg.python.org/distutils2/) for developing a next-generation version of Distutils.

**ttk: Themed Widgets for Tk**

Tcl/Tk 8.5 includes a set of themed widgets that re-implement basic Tk widgets but have a more customizable appearance and can therefore more closely resemble the native platform’s widgets. This widget set was originally called Tile, but was renamed to Ttk (for “themed Tk”) on being added to Tcl/Tk release 8.5.

To learn more, read the `ttk` module documentation. You may also wish to read the Tcl/Tk manual page describing the Ttk theme engine, available at http://www.tcl.tk/man/tcl8.5/TkCmd/ttk_intro.htm. Some screenshots of the Python/Ttk code in use are at http://code.google.com/p/python-ttk/wiki/Screenshots.

The `ttk` module was written by Guilherme Polo and added in issue 2983. An alternate version called Tile.py, written by Martin Franklin and maintained by Kevin Walzer, was proposed for inclusion in issue 2618, but the authors argued that Guilherme Polo's work was more comprehensive.
Updated module: unittest

The unittest module was greatly enhanced; many new features were added. Most of these features were implemented by Michael Foord, unless otherwise noted. The enhanced version of the module is downloadable separately for use with Python versions 2.4 to 2.6, packaged as the unittest2 package, from http://pypi.python.org/pypi/unittest2.

When used from the command line, the module can automatically discover tests. It's not as fancy as py.test or nose, but provides a simple way to run tests kept within a set of package directories. For example, the following command will search the test/ subdirectory for any importable test files named test*.py:

```
python -m unittest discover -s test
```

Consult the unittest module documentation for more details. (Developed in issue 6001.)

The main() function supports some other new options:

- **-b** or **--buffer** will buffer the standard output and standard error streams during each test. If the test passes, any resulting output will be discarded; on failure, the buffered output will be displayed.

- **-c** or **--catch** will cause the control-C interrupt to be handled more gracefully. Instead of interrupting the test process immediately, the currently running test will be completed and then the partial results up to the interruption will be reported. If you’re impatient, a second press of control-C will cause an immediate interruption.
This control-C handler tries to avoid causing problems when the code being tested or the tests being run have defined a signal handler of their own, by noticing that a signal handler was already set and calling it. If this doesn’t work for you, there’s a removeHandler() decorator that can be used to mark tests that should have the control-C handling disabled.

- `-f` or `--failfast` makes test execution stop immediately when a test fails instead of continuing to execute further tests. (Suggested by Cliff Dyer and implemented by Michael Foord; issue 8074.)

The progress messages now show ‘x’ for expected failures and ‘u’ for unexpected successes when run in verbose mode. (Contributed by Benjamin Peterson.)

Test cases can raise the SkipTest exception to skip a test (issue 1034053).

The error messages for `assertEqual()`, `assertTrue()`, and `assertFalse()` failures now provide more information. If you set the `longMessage` attribute of your `TestCase` classes to True, both the standard error message and any additional message you provide will be printed for failures. (Added by Michael Foord; issue 5663.)

The `assertRaises()` method now returns a context handler when called without providing a callable object to run. For example, you can write this:

```python
with self.assertRaises(KeyError):
    {}['foo']
```

(Implemented by Antoine Pitrou; issue 4444.)
Module- and class-level setup and teardown fixtures are now supported. Modules can contain `setUpModule()` and `tearDownModule()` functions. Classes can have `setUpClass()` and `tearDownClass()` methods that must be defined as class methods (using `@classmethod` or equivalent). These functions and methods are invoked when the test runner switches to a test case in a different module or class.

The methods `addCleanup()` and `doCleanups()` were added. `addCleanup()` lets you add cleanup functions that will be called unconditionally (after `setUp()` if `setUp()` fails, otherwise after `tearDown()`). This allows for much simpler resource allocation and deallocation during tests (issue 5679).

A number of new methods were added that provide more specialized tests. Many of these methods were written by Google engineers for use in their test suites; Gregory P. Smith, Michael Foord, and GvR worked on merging them into Python's version of `unittest`.

- `assertIsNone()` and `assertIsNotNone()` take one expression and verify that the result is or is not None.
- `assertIs()` and `assertIsNot()` take two values and check whether the two values evaluate to the same object or not. (Added by Michael Foord; issue 2578.)
- `assertIsInstance()` and `assertNotIsInstance()` check whether the resulting object is an instance of a particular class, or of one of a tuple of classes. (Added by Georg Brandl; issue 7031.)
- `assertGreater()`, `assertGreaterEqual()`, `assertLess()`, and `assertLessEqual()` compare two quantities.
- `assertMultiLineEqual()` compares two strings, and if they’re not equal, displays a helpful comparison that highlights the
differences in the two strings. This comparison is now used by default when Unicode strings are compared with `assertEqual()`.

- `assertRegexpMatches()` and `assertNotRegexpMatches()` checks whether the first argument is a string matching or not matching the regular expression provided as the second argument (issue 8038).
- `assertRaisesRegexp()` checks whether a particular exception is raised, and then also checks that the string representation of the exception matches the provided regular expression.
- `assertIn()` and `assertNotIn()` tests whether `first` is or is not in `second`.
- `assertItemsEqual()` tests whether two provided sequences contain the same elements.
- `assertSetEqual()` compares whether two sets are equal, and only reports the differences between the sets in case of error.
- Similarly, `assertListEqual()` and `assertTupleEqual()` compare the specified types and explain any differences without necessarily printing their full values; these methods are now used by default when comparing lists and tuples using `assertEqual()`. More generally, `assertSequenceEqual()` compares two sequences and can optionally check whether both sequences are of a particular type.
- `assertDictEqual()` compares two dictionaries and reports the differences; it’s now used by default when you compare two dictionaries using `assertEqual()`. `assertDictContainsSubset()` checks whether all of the key/value pairs in `first` are found in `second`.
- `assertAlmostEqual()` and `assertNotAlmostEqual()` test whether `first` and `second` are approximately equal. This method can either round their difference to an optionally-specified number of places (the default is 7) and compare it to zero, or require the difference to be smaller than a supplied `delta` value.
• **loadTestsFromName()** properly honors the **suiteClass** attribute of the **TestLoader**. (Fixed by Mark Roddy; issue 6866.)

• A new hook lets you extend the **assertEqual()** method to handle new data types. The **addTypeEqualityFunc()** method takes a type object and a function. The function will be used when both of the objects being compared are of the specified type. This function should compare the two objects and raise an exception if they don't match; it’s a good idea for the function to provide additional information about why the two objects aren’t matching, much as the new sequence comparison methods do.

    `unittest.main()` now takes an optional **exit** argument. If False, **main()** doesn’t call **sys.exit()**, allowing **main()** to be used from the interactive interpreter. (Contributed by J. Pablo Fernández; issue 3379.)

    **TestResult** has new **startTestRun()** and **stopTestRun()** methods that are called immediately before and after a test run. (Contributed by Robert Collins; issue 5728.)

    With all these changes, the **unittest.py** was becoming awkwardly large, so the module was turned into a package and the code split into several files (by Benjamin Peterson). This doesn’t affect how the module is imported or used.

    **See also:**

    Describes the new features, how to use them, and the rationale for various design decisions. (By Michael Foord.)

    Updated module: ElementTree 1.3
The version of the ElementTree library included with Python was updated to version 1.3. Some of the new features are:

- The various parsing functions now take a *parser* keyword argument giving an *XMLParser* instance that will be used. This makes it possible to override the file’s internal encoding:

```python
p = ET.XMLParser(encoding='utf-8')
t = ET.XML("""<root/>"""", parser=p)
```

Errors in parsing XML now raise a *ParseError* exception, whose instances have a *position* attribute containing a *(line, column)* tuple giving the location of the problem.

- ElementTree’s code for converting trees to a string has been significantly reworked, making it roughly twice as fast in many cases. The *ElementTree.write()* and *Element.write()* methods now have a *method* parameter that can be “xml” (the default), “html”, or “text”. HTML mode will output empty elements as `<empty></empty>` instead of `<empty/>`, and text mode will skip over elements and only output the text chunks. If you set the *tag* attribute of an element to None but leave its children in place, the element will be omitted when the tree is written out, so you don’t need to do more extensive rearrangement to remove a single element.

Namespace handling has also been improved. All *xmlns:* `<whatever>` declarations are now output on the root element, not scattered throughout the resulting XML. You can set the default namespace for a tree by setting the *default_namespace* attribute and can register new prefixes with *register_namespace()*.

In XML mode, you can use the
true/false xml_declaration parameter to suppress the XML declaration.

- New Element method: extend() appends the items from a sequence to the element's children. Elements themselves behave like sequences, so it's easy to move children from one element to another:

```python
from xml.etree import ElementTree as ET

t = ET.XML("""<list>
  <item>1</item> <item>2</item> <item>3</item>
</list>""")
new = ET.XML('<root/>')
new.extend(t)

# Outputs <root><item>1</item>...</root>
print ET.tostring(new)
```

- New Element method: iter() yields the children of the element as a generator. It's also possible to write for child in elem: to loop over an element's children. The existing method getiterator() is now deprecated, as is getchildren() which constructs and returns a list of children.

- New Element method: itertext() yields all chunks of text that are descendants of the element. For example:

```python
t = ET.XML("""<list>
  <item>1</item> <item>2</item> <item>3</item>
</list>""")

# Outputs ['
  , '1', ' ', '2', ' ', '3', '\n
print list(t.itertext())
• Deprecated: using an element as a Boolean (i.e., if elem:) would return true if the element had any children, or false if there were no children. This behaviour is confusing – None is false, but so is a childless element? – so it will now trigger a FutureWarning. In your code, you should be explicit: write len(elem) != 0 if you’re interested in the number of children, or elem is not None.

Fredrik Lundh develops ElementTree and produced the 1.3 version; you can read his article describing 1.3 at http://effbot.org/zone/elementtree-13-intro.htm. Florent Xicluna updated the version included with Python, after discussions on python-dev and in issue 6472.)
Build and C API Changes

Changes to Python’s build process and to the C API include:

- The latest release of the GNU Debugger, GDB 7, can be scripted using Python. When you begin debugging an executable program P, GDB will look for a file named P-gdb.py and automatically read it. Dave Malcolm contributed a python-gdb.py that adds a number of commands useful when debugging Python itself. For example, py-up and py-down go up or down one Python stack frame, which usually corresponds to several C stack frames. py-print prints the value of a Python variable, and py-bt prints the Python stack trace. (Added as a result of issue 8032.)

- If you use the .gdbinit file provided with Python, the “pyo” macro in the 2.7 version now works correctly when the thread being debugged doesn’t hold the GIL; the macro now acquires it before printing. (Contributed by Victor Stinner; issue 3632.)

- Py_AddPendingCall() is now thread-safe, letting any worker thread submit notifications to the main Python thread. This is particularly useful for asynchronous IO operations. (Contributed by Kristján Valur Jónsson; issue 4293.)

- New function: PyCode_NewEmpty() creates an empty code object; only the filename, function name, and first line number are required. This is useful for extension modules that are attempting to construct a more useful traceback stack. Previously such extensions needed to call PyCode_New(), which had many more arguments. (Added by Jeffrey Yasskin.)

- New function: PyErr_NewExceptionWithDoc() creates a new
exception class, just as the existing `PyErr_NewException()`
does, but takes an extra `char *` argument containing the
docstring for the new exception class. (Added by 'lekma' on the
Python bug tracker; issue 7033.)

- New function: `PyFrame_GetLineNumber()` takes a frame
  object and returns the line number that the frame is currently
  executing. Previously code would need to get the index of the
  bytecode instruction currently executing, and then look up the line
  number corresponding to that address. (Added by Jeffrey
  Yasskin.)

- New functions: `PyLong_AsLongAndOverflow()` and
  `PyLong_AsLongLongAndOverflow()` approximates a Python
  long integer as a C `long` or `long long`. If the number is too
  large to fit into the output type, an `overflow` flag is set and returned
  to the caller. (Contributed by Case Van Horsen; issue 7528 and
  issue 7767.)

- New function: stemming from the rewrite of string-to-float
  conversion, a new `PyOS_string_to_double()` function was
  added. The old `PyOS_ascii_strtod()` and
  `PyOS_ascii_atof()` functions are now deprecated.

- New function: `PySys_SetArgvEx()` sets the value of
  `sys.argv` and can optionally update `sys.path` to include the
directory containing the script named by `sys.argv[0]`
depending on the value of an `updatepath` parameter.

This function was added to close a security hole for applications
that embed Python. The old function, `PySys_SetArgv()`, would
always update `sys.path`, and sometimes it would add the
current directory. This meant that, if you ran an application embedding Python in a directory controlled by someone else, attackers could put a Trojan-horse module in the directory (say, a file named os.py) that your application would then import and run.

If you maintain a C/C++ application that embeds Python, check whether you're calling **PySys_SetArgv()** and carefully consider whether the application should be using **PySys_SetArgvEx()** with *updatepath* set to false.

Security issue reported as **CVE-2008-5983**; discussed in issue **5753**, and fixed by Antoine Pitrou.

- New macros: the Python header files now define the following macros: **Py_ISALNUM**, **Py_ISALPHA**, **Py_ISDIGIT**, **Py_ISLOWER**, **Py_ISSPACE**, **Py_ISUPPER**, **Py_ISXDIGIT**, and **Py_TOLOWER**, **Py_TOUPPER**. All of these functions are analogous to the C standard macros for classifying characters, but ignore the current locale setting, because in several places Python needs to analyze characters in a locale-independent way. (Added by Eric Smith; issue **5793**.)

- Removed function: **PyEval_CallObject** is now only available as a macro. A function version was being kept around to preserve ABI linking compatibility, but that was in 1997; it can certainly be deleted by now. (Removed by Antoine Pitrou; issue **8276**.)

- New format codes: the **PyFormat_FromString()**, **PyFormat_FromStringV()**, and **PyErr_Format()** functions now accept **%lld** and **%llu** format codes for displaying C's long long types. (Contributed by Mark Dickinson; issue **7228**.)
The complicated interaction between threads and process forking has been changed. Previously, the child process created by `os.fork()` might fail because the child is created with only a single thread running, the thread performing the `os.fork()`. If other threads were holding a lock, such as Python's import lock, when the fork was performed, the lock would still be marked as “held” in the new process. But in the child process nothing would ever release the lock, since the other threads weren’t replicated, and the child process would no longer be able to perform imports.

Python 2.7 acquires the import lock before performing an `os.fork()`, and will also clean up any locks created using the `threading` module. C extension modules that have internal locks, or that call `fork()` themselves, will not benefit from this clean-up.

(Fixed by Thomas Wouters; issue 1590864.)

The `Py_Finalize()` function now calls the internal `threading._shutdown()` function; this prevents some exceptions from being raised when an interpreter shuts down. (Patch by Adam Olsen; issue 1722344.)

When using the `PyMemberDef` structure to define attributes of a type, Python will no longer let you try to delete or set a `T_STRING_INPLACE` attribute.

Global symbols defined by the `ctypes` module are now prefixed with `Py`, or with `_ctypes`. (Implemented by Thomas Heller; issue 3102.)

New configure option: the `--with-system-expat` switch allows building the `pyexpat` module to use the system Expat library.
New configure option: the \texttt{--with-valgrind} option will now disable the \texttt{pymalloc} allocator, which is difficult for the Valgrind memory-error detector to analyze correctly. Valgrind will therefore be better at detecting memory leaks and overruns. (Contributed by James Henstridge; issue 2422.)

New configure option: you can now supply an empty string to \texttt{--with-dbmliborder=} in order to disable all of the various DBM modules. (Added by Arfrever Frehtes Taifersar Arahesis; issue 6491.)

The \texttt{configure} script now checks for floating-point rounding bugs on certain 32-bit Intel chips and defines a \texttt{X87\_DOUBLE\_ROUNDING} preprocessor definition. No code currently uses this definition, but it's available if anyone wishes to use it. (Added by Mark Dickinson; issue 2937.)

\texttt{configure} also now sets a \texttt{LDCXXSHARED} Makefile variable for supporting C++ linking. (Contributed by Arfrever Frehtes Taifersar Arahesis; issue 1222585.)

The build process now creates the necessary files for pkg-config support. (Contributed by Clinton Roy; issue 3585.)

The build process now supports Subversion 1.7. (Contributed by Arfrever Frehtes Taifersar Arahesis; issue 6094.)

Capsules

Python 3.1 adds a new C datatype, \texttt{PyCapsule}, for providing a C API to an extension module. A capsule is essentially the holder of a C
void * pointer, and is made available as a module attribute; for example, the socket module's API is exposed as socket.CAPI, and uniconedata exposes ucnhash_CAPI. Other extensions can import the module, access its dictionary to get the capsule object, and then get the void * pointer, which will usually point to an array of pointers to the module's various API functions.

There is an existing data type already used for this, PyCObject, but it doesn't provide type safety. Evil code written in pure Python could cause a segmentation fault by taking a PyCObject from module A and somehow substituting it for the PyCObject in module B. Capsules know their own name, and getting the pointer requires providing the name:

```c
void *vtable;

if (!PyCapsule_IsValid(capsule, "mymodule.CAPI") {
    PyErr_SetString(PyExc_ValueError, "argument type invalid");
    return NULL;
}

vtable = PyCapsule_GetPointer(capsule, "mymodule.CAPI");
```

You are assured that vtable points to whatever you’re expecting. If a different capsule was passed in, PyCapsule_IsValid() would detect the mismatched name and return false. Refer to Providing a C API for an Extension Module for more information on using these objects.

Python 2.7 now uses capsules internally to provide various extension-module APIs, but the PyCObject_AsVoidPtr() was modified to handle capsules, preserving compile-time compatibility with the
CObject interface. Use of PyCObject_AsVoidPtr() will signal a PendingDeprecationWarning, which is silent by default.

Implemented in Python 3.1 and backported to 2.7 by Larry Hastings; discussed in issue 5630.

Port-Specific Changes: Windows

- The msvcrtn module now contains some constants from the crtassem.h header file: CRT_ASSEMBLY_VERSION, VC_ASSEMBLY_PUBLICKEYTOKEN, and LIBRARIES_ASSEMBLY_NAME_PREFIX. (Contributed by David Cournapeau; issue 4365.)

- The _winreg module for accessing the registry now implements the CreateKeyEx() and DeleteKeyEx() functions, extended versions of previously-supported functions that take several extra arguments. The DisableReflectionKey(), EnableReflectionKey(), and QueryReflectionKey() were also tested and documented. (Implemented by Brian Curtin: issue 7347.)

- The new _beginthreadex() API is used to start threads, and the native thread-local storage functions are now used. (Contributed by Kristján Valur Jónsson; issue 3582.)

- The os.kill() function now works on Windows. The signal value can be the constants CTRL_C_EVENT, CTRL_BREAK_EVENT, or any integer. The first two constants will send Control-C and Control-Break keystroke events to subprocesses; any other value will use the TerminateProcess() API. (Contributed by Miki Tebeka; issue 1220212.)

- The os.listdir() function now correctly fails for an empty path. (Fixed by Hirokazu Yamamoto; issue 5913.)
The `mimelib` module will now read the MIME database from the Windows registry when initializing. (Patch by Gabriel Genellina; issue 4969.)

**Port-Specific Changes: Mac OS X**

- The path `/Library/Python/2.7/site-packages` is now appended to `sys.path`, in order to share added packages between the system installation and a user-installed copy of the same version. (Changed by Ronald Oussoren; issue 4865.)

**Port-Specific Changes: FreeBSD**

- FreeBSD 7.1's `SO_SETFIB` constant, used with `getsockopt()`/`setsockopt()` to select an alternate routing table, is now available in the `socket` module. (Added by Kyle VanderBeek; issue 8235.)
Other Changes and Fixes

- Two benchmark scripts, `iobench` and `ccbench`, were added to the Tools directory. `iobench` measures the speed of the built-in file I/O objects returned by `open()` while performing various operations, and `ccbench` is a concurrency benchmark that tries to measure computing throughput, thread switching latency, and IO processing bandwidth when performing several tasks using a varying number of threads.
- The `Tools/i18n/msgfmt.py` script now understands plural forms in `.po` files. (Fixed by Martin von Löwis; issue 5464.)
- When importing a module from a `.pyc` or `.pyo` file with an existing `.py` counterpart, the `co_filename` attributes of the resulting code objects are overwritten when the original filename is obsolete. This can happen if the file has been renamed, moved, or is accessed through different paths. (Patch by Žiga Seilnacht and Jean-Paul Calderone; issue 1180193.)
- The `regrtest.py` script now takes a `--randseed=` switch that takes an integer that will be used as the random seed for the -r option that executes tests in random order. The -r option also reports the seed that was used (Added by Collin Winter.)
- Another `regrtest.py` switch is -j, which takes an integer specifying how many tests run in parallel. This allows reducing the total runtime on multi-core machines. This option is compatible with several other options, including the -R switch which is known to produce long runtimes. (Added by Antoine Pitrou, issue 6152.) This can also be used with a new -F switch that runs selected tests in a loop until they fail. (Added by Antoine Pitrou; issue 7312.)
- When executed as a script, the `py_compile.py` module now accepts `-` as an argument, which will read standard input for the list of filenames to be compiled. (Contributed by Piotr
Ożarowski; issue 8233.)
Porting to Python 2.7

This section lists previously described changes and other bugfixes that may require changes to your code:

- The `range()` function processes its arguments more consistently; it will now call `__int__() on non-float, non-integer arguments that are supplied to it. (Fixed by Alexander Belopolsky; issue 1533.)

- The string `format()` method changed the default precision used for floating-point and complex numbers from 6 decimal places to 12, which matches the precision used by `str()`. (Changed by Eric Smith; issue 5920.)

- Because of an optimization for the `with` statement, the special methods `__enter__() and __exit__() must belong to the object's type, and cannot be directly attached to the object's instance. This affects new-style classes (derived from `object`) and C extension types. (issue 6101.)

- Due to a bug in Python 2.6, the `exc_value` parameter to `__exit__() methods was often the string representation of the exception, not an instance. This was fixed in 2.7, so `exc_value` will be an instance as expected. (Fixed by Florent Xicluna; issue 7853.)

- When a restricted set of attributes were set using `__slots__`, deleting an unset attribute would not raise `AttributeError as you would expect. Fixed by Benjamin Peterson; issue 7604.)

In the standard library:

- Operations with `datetime` instances that resulted in a year falling outside the supported range didn't always raise `OverflowError`. Such errors are now checked more carefully
and will now raise the exception. (Reported by Mark Leander, patch by Anand B. Pillai and Alexander Belopolsky; issue 7150.)

- When using Decimal instances with a string’s `format()` method, the default alignment was previously left-alignment. This has been changed to right-alignment, which might change the output of your programs. (Changed by Mark Dickinson; issue 6857.)

  Comparisons involving a signaling NaN value (or `sNAN`) now signal `InvalidOperation` instead of silently returning a true or false value depending on the comparison operator. Quiet NaN values (or `NaN`) are now hashable. (Fixed by Mark Dickinson; issue 7279.)

- The ElementTree library, `xml.etree`, no longer escapes ampersands and angle brackets when outputting an XML processing instruction (which looks like `<?xml-stylesheet href="#style1"?>`) or comment (which looks like `<!– comment –>`). (Patch by Neil Muller; issue 2746.)

- The `readline()` method of `StringIO` objects now does nothing when a negative length is requested, as other file-like objects do. (issue 7348).

- The `syslog` module will now use the value of `sys.argv[0]` as the identifier instead of the previous default value of `'python'`. (Changed by Sean Reifschneider; issue 8451.)

- The `tarfile` module’s default error handling has changed, to no longer suppress fatal errors. The default error level was previously 0, which meant that errors would only result in a message being written to the debug log, but because the debug log is not
activated by default, these errors go unnoticed. The default error level is now 1, which raises an exception if there's an error. (Changed by Lars Gustäbel; issue 7357.)

- The urlparse module's urlsplit() now handles unknown URL schemes in a fashion compliant with RFC 3986: if the URL is of the form "<something>://...", the text before the :// is treated as the scheme, even if it's a made-up scheme that the module doesn't know about. This change may break code that worked around the old behaviour. For example, Python 2.6.4 or 2.5 will return the following:

```python
>>> import urlparse
>>> urlparse.urlsplit('invented://host/filename?query')
('invented', '', '//host/filename?query', '', '')
```

Python 2.7 (and Python 2.6.5) will return:

```python
>>> import urlparse
>>> urlparse.urlsplit('invented://host/filename?query')
('invented', 'host', '/filename?query', '', '')
```

(Python 2.7 actually produces slightly different output, since it returns a named tuple instead of a standard tuple.)

For C extensions:

- C extensions that use integer format codes with the PyArg_Parse* family of functions will now raise a TypeError exception instead of triggering a DeprecationWarning (issue 5080).
- Use the new PyOS_string_to_double() function instead of the old PyOS_ascii_strtod() and PyOS_ascii_atof()
functions, which are now deprecated.

For applications that embed Python:

- The \texttt{PySys\_SetArgvEx()} function was added, letting applications close a security hole when the existing \texttt{PySys\_SetArgv()} function was used. Check whether you're calling \texttt{PySys\_SetArgv()} and carefully consider whether the application should be using \texttt{PySys\_SetArgvEx()} with \textit{updatepath} set to false.

What’s New in Python 2.6

Author: A.M. Kuchling (amk at amk.ca)

This article explains the new features in Python 2.6, released on October 1 2008. The release schedule is described in PEP 361.

The major theme of Python 2.6 is preparing the migration path to Python 3.0, a major redesign of the language. Whenever possible, Python 2.6 incorporates new features and syntax from 3.0 while remaining compatible with existing code by not removing older features or syntax. When it's not possible to do that, Python 2.6 tries to do what it can, adding compatibility functions in a future_builtins module and a -3 switch to warn about usages that will become unsupported in 3.0.

Some significant new packages have been added to the standard library, such as the multiprocessing and json modules, but there aren’t many new features that aren’t related to Python 3.0 in some way.

Python 2.6 also sees a number of improvements and bugfixes throughout the source. A search through the change logs finds there were 259 patches applied and 612 bugs fixed between Python 2.5 and 2.6. Both figures are likely to be underestimates.

This article doesn’t attempt to provide a complete specification of the new features, but instead provides a convenient overview. For full details, you should refer to the documentation for Python 2.6. If you want to understand the rationale for the design and implementation, refer to the PEP for a particular new feature. Whenever possible, “What’s New in Python” links to the bug/patch item for each change.
Python 3.0

The development cycle for Python versions 2.6 and 3.0 was synchronized, with the alpha and beta releases for both versions being made on the same days. The development of 3.0 has influenced many features in 2.6.

Python 3.0 is a far-ranging redesign of Python that breaks compatibility with the 2.x series. This means that existing Python code will need some conversion in order to run on Python 3.0. However, not all the changes in 3.0 necessarily break compatibility. In cases where new features won’t cause existing code to break, they’ve been backported to 2.6 and are described in this document in the appropriate place. Some of the 3.0-derived features are:

- A \_\_complex\_\_() method for converting objects to a complex number.
- Alternate syntax for catching exceptions: except \_\_str\_\_() as exc.
- The addition of \_\_functools\_.\_\_reduce\_\_() as a synonym for the built-in \_\_\_reduce\_\_() function.

Python 3.0 adds several new built-in functions and changes the semantics of some existing builtins. Functions that are new in 3.0 such as \_\_bin\_\_() have simply been added to Python 2.6, but existing builtins haven’t been changed; instead, the \_\_future\_\_builtins module has versions with the new 3.0 semantics. Code written to be compatible with 3.0 can do from \_\_future\_\_builtins import hex, map as necessary.

A new command-line switch, -3, enables warnings about features that will be removed in Python 3.0. You can run code with this switch to see
how much work will be necessary to port code to 3.0. The value of this switch is available to Python code as the boolean variable `sys.py3kwarning`, and to C extension code as `Py_Py3kWarningFlag`.

**See also:** The 3xxx series of PEPs, which contains proposals for Python 3.0. **PEP 3000** describes the development process for Python 3.0. Start with **PEP 3100** that describes the general goals for Python 3.0, and then explore the higher-numbered PEPS that propose specific features.
Changes to the Development Process

While 2.6 was being developed, the Python development process underwent two significant changes: we switched from SourceForge’s issue tracker to a customized Roundup installation, and the documentation was converted from LaTeX to reStructuredText.

New Issue Tracker: Roundup

For a long time, the Python developers had been growing increasingly annoyed by SourceForge’s bug tracker. SourceForge’s hosted solution doesn’t permit much customization; for example, it wasn’t possible to customize the life cycle of issues.

The infrastructure committee of the Python Software Foundation therefore posted a call for issue trackers, asking volunteers to set up different products and import some of the bugs and patches from SourceForge. Four different trackers were examined: Jira, Launchpad, Roundup, and Trac. The committee eventually settled on Jira and Roundup as the two candidates. Jira is a commercial product that offers no-cost hosted instances to free-software projects; Roundup is an open-source project that requires volunteers to administer it and a server to host it.

After posting a call for volunteers, a new Roundup installation was set up at http://bugs.python.org. One installation of Roundup can host multiple trackers, and this server now also hosts issue trackers for Jython and for the Python web site. It will surely find other uses in the future. Where possible, this edition of “What’s New in Python” links to the bug/patch item for each change.
Hosting of the Python bug tracker is kindly provided by Upfront Systems of Stellenbosch, South Africa. Martin von Löwis put a lot of effort into importing existing bugs and patches from SourceForge; his scripts for this import operation are at http://svn.python.org/view/tracker/importer/ and may be useful to other projects wishing to move from SourceForge to Roundup.

New Documentation Format: reStructuredText
Using Sphinx

The Python documentation was written using LaTeX since the project started around 1989. In the 1980s and early 1990s, most documentation was printed out for later study, not viewed online. LaTeX was widely used because it provided attractive printed output while remaining straightforward to write once the basic rules of the markup were learned.

Today LaTeX is still used for writing publications destined for printing, but the landscape for programming tools has shifted. We no longer print out reams of documentation; instead, we browse through it online
and HTML has become the most important format to support. Unfortunately, converting LaTeX to HTML is fairly complicated and Fred L. Drake Jr., the long-time Python documentation editor, spent a lot of time maintaining the conversion process. Occasionally people would suggest converting the documentation into SGML and later XML, but performing a good conversion is a major task and no one ever committed the time required to finish the job.

During the 2.6 development cycle, Georg Brandl put a lot of effort into building a new toolchain for processing the documentation. The resulting package is called Sphinx, and is available from http://sphinx.pocoo.org/.

Sphinx concentrates on HTML output, producing attractively styled and modern HTML; printed output is still supported through conversion to LaTeX. The input format is reStructuredText, a markup syntax supporting custom extensions and directives that is commonly used in the Python community.

Sphinx is a standalone package that can be used for writing, and almost two dozen other projects (listed on the Sphinx web site) have adopted Sphinx as their documentation tool.

PEP 343: The ‘with’ statement

The previous version, Python 2.5, added the ‘with’ statement as an optional feature, to be enabled by a `from __future__ import with_statement` directive. In 2.6 the statement no longer needs to be specially enabled; this means that `with` is now always a keyword. The rest of this section is a copy of the corresponding section from the “What’s New in Python 2.5” document; if you’re familiar with the ‘with’ statement from Python 2.5, you can skip this section.

The ‘with’ statement clarifies code that previously would use `try...finally` blocks to ensure that clean-up code is executed. In this section, I’ll discuss the statement as it will commonly be used. In the next section, I’ll examine the implementation details and show how to write objects for use with this statement.

The `with` statement is a control-flow structure whose basic structure is:

```
with expression [as variable]:
    with-block
```

The expression is evaluated, and it should result in an object that supports the context management protocol (that is, has `__enter__()` and `__exit__()` methods).

The object’s `__enter__()` is called before `with-block` is executed and therefore can run set-up code. It also may return a value that is bound to the name `variable`, if given. (Note carefully that `variable` is not assigned the result of `expression`.)

After execution of the `with-block` is finished, the object’s `__exit__()`
method is called, even if the block raised an exception, and can therefore run clean-up code.

Some standard Python objects now support the context management protocol and can be used with the `with` statement. File objects are one example:

```python
with open('/etc/passwd', 'r') as f:
    for line in f:
        print line
        ... more processing code ...
```

After this statement has executed, the file object in `f` will have been automatically closed, even if the `for` loop raised an exception part-way through the block.

**Note:** In this case, `f` is the same object created by `open()`, because file.__enter__() returns `self`.

The `threading` module's locks and condition variables also support the `with` statement:

```python
lock = threading.Lock()
with lock:
    # Critical section of code
    ...
```

The lock is acquired before the block is executed and always released once the block is complete.

The `localcontext()` function in the `decimal` module makes it easy to save and restore the current decimal context, which encapsulates the desired precision and rounding characteristics for
computations:

```python
from decimal import Decimal, Context, localcontext

# Displays with default precision of 28 digits
v = Decimal('578')
print v.sqrt()

with localcontext(Context(prec=16)):
    # All code in this block uses a precision of 16
    # The original context is restored on exiting the block.
    print v.sqrt()
```

Writing Context Managers

Under the hood, the `with` statement is fairly complicated. Most people will only use `with` in company with existing objects and don’t need to know these details, so you can skip the rest of this section if you like. Authors of new objects will need to understand the details of the underlying implementation and should keep reading.

A high-level explanation of the context management protocol is:

- The expression is evaluated and should result in an object called a “context manager”. The context manager must have `__enter__()` and `__exit__()` methods.
- The context manager’s `__enter__()` method is called. The value returned is assigned to `VAR`. If no `as VAR` clause is present, the value is simply discarded.
- The code in `BLOCK` is executed.
- If `BLOCK` raises an exception, the context manager’s `__exit__()` method is called with three arguments, the exception details (`type`, `value`, `traceback`), the same values
returned by `sys.exc_info()`, which can also be None if no exception occurred). The method's return value controls whether an exception is re-raised: any false value re-raises the exception, and True will result in suppressing it. You'll only rarely want to suppress the exception, because if you do the author of the code containing the `with` statement will never realize anything went wrong.

- If `BLOCK` didn't raise an exception, the `__exit__()` method is still called, but `type`, `value`, and `traceback` are all None.

Let's think through an example. I won’t present detailed code but will only sketch the methods necessary for a database that supports transactions.

(For people unfamiliar with database terminology: a set of changes to the database are grouped into a transaction. Transactions can be either committed, meaning that all the changes are written into the database, or rolled back, meaning that the changes are all discarded and the database is unchanged. See any database textbook for more information.)

Let's assume there's an object representing a database connection. Our goal will be to let the user write code like this:

```python
db_connection = DatabaseConnection()
with db_connection as cursor:
    cursor.execute('insert into ...')
    cursor.execute('delete from ...')
    # ... more operations ...
```

The transaction should be committed if the code in the block runs flawlessly or rolled back if there's an exception. Here's the basic interface for `DatabaseConnection` that I'll assume:
class DatabaseConnection:
    # Database interface
    def cursor(self):
        "Returns a cursor object and starts a new transaction"
    def commit(self):
        "Commits current transaction"
    def rollback(self):
        "Rolls back current transaction"

The __enter__() method is pretty easy, having only to start a new transaction. For this application the resulting cursor object would be a useful result, so the method will return it. The user can then add as cursor to their 'with' statement to bind the cursor to a variable name.

class DatabaseConnection:
    ...
    def __enter__(self):
        # Code to start a new transaction
        cursor = self.cursor()
        return cursor

The __exit__() method is the most complicated because it's where most of the work has to be done. The method has to check if an exception occurred. If there was no exception, the transaction is committed. The transaction is rolled back if there was an exception.

In the code below, execution will just fall off the end of the function, returning the default value of None. None is false, so the exception will be re-raised automatically. If you wished, you could be more explicit and add a return statement at the marked location.
The contextlib module

The `contextlib` module provides some functions and a decorator that are useful when writing objects for use with the `with` statement.

The decorator is called `contextmanager()`, and lets you write a single generator function instead of defining a new class. The generator should yield exactly one value. The code up to the `yield` will be executed as the `__enter__()` method, and the value yielded will be the method's return value that will get bound to the variable in the `with` statement's `as` clause, if any. The code after the `yield` will be executed in the `__exit__()` method. Any exception raised in the block will be raised by the `yield` statement.

Using this decorator, our database example from the previous section could be written as:

```python
from contextlib import contextmanager

@contextmanager
def db_transaction(connection):
    cursor = connection.cursor()
    try:
        yield cursor
```
except:
    connection.rollback()
    raise
else:
    connection.commit()

db = DatabaseConnection()
with db_transaction(db) as cursor:
    ...

The `contextlib` module also has a `nested(mgr1, mgr2, ...)` function that combines a number of context managers so you don't need to write nested `with` statements. In this example, the single `with` statement both starts a database transaction and acquires a thread lock:

```
lock = threading.Lock()
with nested (db_transaction(db), lock) as (cursor, l):
    ...
```

Finally, the `closing()` function returns its argument so that it can be bound to a variable, and calls the argument's `.close()` method at the end of the block.

```
import urllib, sys
from contextlib import closing

with closing(urllib.urlopen('http://www.yahoo.com'))
    for line in f:
        sys.stdout.write(line)
```

PEP 343 - The “with” statement

PEP written by Guido van Rossum and Nick Coghlan; implemented by Mike Bland, Guido van Rossum, and Neal Norwitz. The PEP shows the code generated for a 'with' statement, which can be helpful in learning how the statement works.

The documentation for the `contextlib` module.
PEP 366: Explicit Relative Imports From a Main Module

Python's `-m` switch allows running a module as a script. When you ran a module that was located inside a package, relative imports didn't work correctly.

The fix for Python 2.6 adds a `__package__` attribute to modules. When this attribute is present, relative imports will be relative to the value of this attribute instead of the `__name__` attribute.

PEP 302-style importers can then set `__package__` as necessary. The `runpy` module that implements the `-m` switch now does this, so relative imports will now work correctly in scripts running from inside a package.
PEP 370: Per-user site-packages Directory

When you run Python, the module search path `sys.path` usually includes a directory whose path ends in "site-packages". This directory is intended to hold locally-installed packages available to all users using a machine or a particular site installation.

Python 2.6 introduces a convention for user-specific site directories. The directory varies depending on the platform:

- Unix and Mac OS X: `~/.local/`
- Windows: `%APPDATA%/Python`

Within this directory, there will be version-specific subdirectories, such as `lib/python2.6/site-packages` on Unix/Mac OS and `Python26/site-packages` on Windows.

If you don’t like the default directory, it can be overridden by an environment variable. `PYTHONUSERBASE` sets the root directory used for all Python versions supporting this feature. On Windows, the directory for application-specific data can be changed by setting the `APPDATA` environment variable. You can also modify the `site.py` file for your Python installation.

The feature can be disabled entirely by running Python with the `-s` option or setting the `PYTHONNOUSERSITE` environment variable.

**PEP 370 - Per-user site-packages Directory**

PEP written and implemented by Christian Heimes.
PEP 371: The multiprocessing Package

The new `multiprocessing` package lets Python programs create new processes that will perform a computation and return a result to the parent. The parent and child processes can communicate using queues and pipes, synchronize their operations using locks and semaphores, and can share simple arrays of data.

The `multiprocessing` module started out as an exact emulation of the `threading` module using processes instead of threads. That goal was discarded along the path to Python 2.6, but the general approach of the module is still similar. The fundamental class is the `Process`, which is passed a callable object and a collection of arguments. The `start()` method sets the callable running in a subprocess, after which you can call the `is_alive()` method to check whether the subprocess is still running and the `join()` method to wait for the process to exit.

Here's a simple example where the subprocess will calculate a factorial. The function doing the calculation is written strangely so that it takes significantly longer when the input argument is a multiple of 4.

```python
import time
from multiprocessing import Process, Queue

def factorial(queue, N):
    """Compute a factorial."
    # If N is a multiple of 4, this function will take much longer.
    if (N % 4) == 0:
        time.sleep(.05 * N/4)
```
A Queue is used to communicate the result of the factorial. The Queue object is stored in a global variable. The child process will use the value of the variable when the child was created; because it's a Queue, parent and child can use the object to communicate. (If the parent were to change the value of the global variable, the child's value would be unaffected, and vice versa.)

Two other classes, Pool and Manager, provide higher-level interfaces. Pool will create a fixed number of worker processes, and requests can then be distributed to the workers by calling apply() or apply_async() to add a single request, and map() or map_async() to add a number of requests. The following code uses a Pool to spread requests across 5 worker processes and retrieve a
list of results:

```python
from multiprocessing import Pool

def factorial(N, dictionary):
    "Compute a factorial."
    ...
    p = Pool(5)
    result = p.map(factorial, range(1, 1000, 10))
    for v in result:
        print v
```

This produces the following output:

```
1
39916800
51090942171709440000
8222838654177922817725562880000000
334525266131638071081700620534407516651520000000000
...
```

The other high-level interface, the Manager class, creates a separate server process that can hold master copies of Python data structures. Other processes can then access and modify these data structures using proxy objects. The following example creates a shared dictionary by calling the `dict()` method; the worker processes then insert values into the dictionary. (Locking is not done for you automatically, which doesn’t matter in this example. Manager's methods also include `Lock()`, `RLock()`, and `Semaphore()` to create shared locks.)

```python
import time
from multiprocessing import Pool, Manager
```
def factorial(N, dictionary):
    "Compute a factorial."
    # Calculate the result
    fact = 1L
    for i in range(1, N+1):
        fact = fact * i

    # Store result in dictionary
    dictionary[N] = fact

if __name__ == '__main__':
    p = Pool(5)
    mgr = Manager()
    d = mgr.dict() # Create shared dictionary

    # Run tasks using the pool
    for N in range(1, 1000, 10):
        p.apply_async(factorial, (N, d))

    # Mark pool as closed -- no more tasks can be added
    p.close()

    # Wait for tasks to exit
    p.join()

    # Output results
    for k, v in sorted(d.items()):
        print k, v

This will produce the output:

1 1
11 39916800
21 51090942171709440000
31 8222838654177922817725562880000000
41 334525266613163807108170062053440751665152000000000
See also: The documentation for the `multiprocessing` module.

**PEP 371 - Addition of the multiprocessing package**

PEP written by Jesse Noller and Richard Oudkerk; implemented by Richard Oudkerk and Jesse Noller.
PEP 3101: Advanced String Formatting

In Python 3.0, the % operator is supplemented by a more powerful string formatting method, \texttt{format()}. Support for the \texttt{str.format()} method has been backported to Python 2.6.

In 2.6, both 8-bit and Unicode strings have a \texttt{.format()} method that treats the string as a template and takes the arguments to be formatted. The formatting template uses curly brackets (\{, \}) as special characters:

\begin{verbatim}
>>> # Substitute positional argument 0 into the string
>>> "User ID: \{0\}".format("root")
'User ID: root'
>>> # Use the named keyword arguments
>>> "User ID: \{uid\} Last seen: \{last_login\}".format(uid="root",
...       last_login = "5 Mar 2008 07:20")
'User ID: root Last seen: 5 Mar 2008 07:20'
\end{verbatim}

Curly brackets can be escaped by doubling them:

\begin{verbatim}
>>> "Empty dict: {{}}".format()
"Empty dict: {}"
\end{verbatim}

Field names can be integers indicating positional arguments, such as \{0\}, \{1\}, etc. or names of keyword arguments. You can also supply compound field names that read attributes or access dictionary keys:

\begin{verbatim}
>>> import sys
>>> print 'Platform: \{0.platform\}\nPython version: \{1\}
Platform: darwin
Python version: 2.6a1+ (trunk:61261M, Mar 5 2008, 2
\end{verbatim}
Note that when using dictionary-style notation such as [.mp4], you don’t need to put any quotation marks around the string; it will look up the value using .mp4 as the key. Strings beginning with a number will be converted to an integer. You can’t write more complicated expressions inside a format string.

So far we’ve shown how to specify which field to substitute into the resulting string. The precise formatting used is also controllable by adding a colon followed by a format specifier. For example:

```
>>> # Field 0: left justify, pad to 15 characters
>>> # Field 1: right justify, pad to 6 characters
>>> fmt = '{0:15} ${1:>6}'
>>> fmt.format('Registration', 35)
'Registration $ 35'
>>> fmt.format('Tutorial', 50)
'Tutorial $ 50'
>>> fmt.format('Banquet', 125)
'Banquet $ 125'
```

Format specifiers can reference other fields through nesting:

```
>>> fmt = '{0:{1}}'
>>> width = 15
>>> fmt.format('Invoice #1234', width)
'Invoice #1234'
>>> width = 35
>>> fmt.format('Invoice #1234', width)
'I
Invoice #1234
'
The alignment of a field within the desired width can be specified:

<table>
<thead>
<tr>
<th>Character</th>
<th>Effect</th>
</tr>
</thead>
<tbody>
<tr>
<td>&lt; (default)</td>
<td>Left-align</td>
</tr>
<tr>
<td>&gt;</td>
<td>Right-align</td>
</tr>
<tr>
<td>^</td>
<td>Center</td>
</tr>
<tr>
<td>=</td>
<td>(For numeric types only) Pad after the sign.</td>
</tr>
</tbody>
</table>

Format specifiers can also include a presentation type, which controls how the value is formatted. For example, floating-point numbers can be formatted as a general number or in exponential notation:

```python
>>> '{0:g}'.format(3.75)
'3.75'
>>> '{0:e}'.format(3.75)
'3.750000e+00'
```

A variety of presentation types are available. Consult the 2.6 documentation for a complete list; here's a sample:

<table>
<thead>
<tr>
<th>Character</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>b</td>
<td>Binary. Outputs the number in base 2.</td>
</tr>
<tr>
<td>c</td>
<td>Character. Converts the integer to the corresponding Unicode character before printing.</td>
</tr>
<tr>
<td>d</td>
<td>Decimal Integer. Outputs the number in base 10.</td>
</tr>
<tr>
<td>o</td>
<td>Octal format. Outputs the number in base 8.</td>
</tr>
<tr>
<td>x</td>
<td>Hex format. Outputs the number in base 16, using lower-case letters for the digits above 9.</td>
</tr>
<tr>
<td>e</td>
<td>Exponent notation. Prints the number in scientific notation using the letter 'e' to indicate the exponent.</td>
</tr>
<tr>
<td>g</td>
<td>General format. This prints the number as a fixed-point number, unless the number is too large, in which case it switches to ‘e’ exponent notation.</td>
</tr>
<tr>
<td>----</td>
<td>-----------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------</td>
</tr>
<tr>
<td>n</td>
<td>Number. This is the same as ‘g’ (for floats) or ‘d’ (for integers), except that it uses the current locale setting to insert the appropriate number separator characters.</td>
</tr>
<tr>
<td>%</td>
<td>Percentage. Multiplies the number by 100 and displays in fixed (‘f’) format, followed by a percent sign.</td>
</tr>
</tbody>
</table>

Classes and types can define a `__format__()` method to control how they’re formatted. It receives a single argument, the format specifier:

```python
def __format__(self, format_spec):
    if isinstance(format_spec, unicode):
        return unicode(str(self))
    else:
        return str(self)
```

There’s also a `format()` built-in that will format a single value. It calls the type’s `__format__()` method with the provided specifier:

```python
>>> format(75.6564, '.2f')
'75.66'
```

- The reference documentation for format fields.

**PEP 3101 - Advanced String Formatting**

- PEP written by Talin. Implemented by Eric Smith.
PEP 3105: print As a Function

The `print` statement becomes the `print()` function in Python 3.0. Making `print()` a function makes it possible to replace the function by doing `def print(...)` or importing a new function from somewhere else.

Python 2.6 has a `__future__` import that removes `print` as language syntax, letting you use the functional form instead. For example:

```python
>>> from __future__ import print_function
>>> print('# of entries', len(dictionary), file=sys.
```

The signature of the new function is:

```python
def print(*args, sep=' ', end='
', file=None)
```

The parameters are:

- `args`: positional arguments whose values will be printed out.
- `sep`: the separator, which will be printed between arguments.
- `end`: the ending text, which will be printed after all of the arguments have been output.
- `file`: the file object to which the output will be sent.

PEP 3105 - Make print a function
   PEP written by Georg Brandl.
PEP 3110: Exception-Handling Changes

One error that Python programmers occasionally make is writing the following code:

```
try:
  ...
except TypeError, ValueError:  # Wrong!
  ...
```

The author is probably trying to catch both `TypeError` and `ValueError` exceptions, but this code actually does something different: it will catch `TypeError` and bind the resulting exception object to the local name "ValueError". The `ValueError` exception will not be caught at all. The correct code specifies a tuple of exceptions:

```
try:
  ...
except (TypeError, ValueError):
  ...
```

This error happens because the use of the comma here is ambiguous: does it indicate two different nodes in the parse tree, or a single node that's a tuple?

Python 3.0 makes this unambiguous by replacing the comma with the word “as”. To catch an exception and store the exception object in the variable `exc`, you must write:

```
try:
  ...
except TypeError as exc:
```
Python 3.0 will only support the use of “as”, and therefore interprets the first example as catching two different exceptions. Python 2.6 supports both the comma and “as”, so existing code will continue to work. We therefore suggest using “as” when writing new Python code that will only be executed with 2.6.

See also:

**PEP 3110** - Catching Exceptions in Python 3000
    PEP written and implemented by Collin Winter.
PEP 3112: Byte Literals

Python 3.0 adopts Unicode as the language’s fundamental string type and denotes 8-bit literals differently, either as `b'string'` or using a `bytes` constructor. For future compatibility, Python 2.6 adds `bytes` as a synonym for the `str` type, and it also supports the `b''` notation.

The 2.6 `str` differs from 3.0's `bytes` type in various ways; most notably, the constructor is completely different. In 3.0, `bytes([65, 66, 67])` is 3 elements long, containing the bytes representing `ABC`; in 2.6, `bytes([65, 66, 67])` returns the 12-byte string representing the `str()` of the list.

The primary use of `bytes` in 2.6 will be to write tests of object type such as `isinstance(x, bytes)`. This will help the 2to3 converter, which can’t tell whether 2.x code intends strings to contain either characters or 8-bit bytes; you can now use either `bytes` or `str` to represent your intention exactly, and the resulting code will also be correct in Python 3.0.

There's also a `__future__` import that causes all string literals to become Unicode strings. This means that `\u` escape sequences can be used to include Unicode characters:

```python
from __future__ import unicode_literals
s = ('\u751f\u3080\u304e\u3000\u751f\u3054\u3081\u3000\u751f\u305f\u307e\u3054', '\u3081\u3000\u751f\u305f\u307e\u3054')
print len(s)  # 12 Unicode characters
```

At the C level, Python 3.0 will rename the existing 8-bit string type,
called PyStringObject in Python 2.x, to PyBytesObject. Python 2.6 uses `#define` to support using the names PyBytesObject(), PyBytes_Check(), PyBytes_FromStringAndSize(), and all the other functions and macros used with strings.

Instances of the `bytes` type are immutable just as strings are. A new `bytearray` type stores a mutable sequence of bytes:

```python
>>> bytearray([65, 66, 67])
bytearray(b'ABC')
>>> b = bytearray(u'\u21ef\u3244', 'utf-8')
>>> b
bytearray(b'\xe2\x87\xaf\xe3\x89\x84')
>>> b[0] = '\xe3'
>>> b
bytearray(b'\xe3\x87\xaf\xe3\x89\x84')
>>> unicode(str(b), 'utf-8')
u'\u31ef \u3244'
```

Byte arrays support most of the methods of string types, such as `startswith()`, `endswith()`, `find()`/`rfind()`, and some of the methods of lists, such as `append()`, `pop()`, and `reverse()`.

```python
>>> b = bytearray('ABC')
>>> b.append('d')
>>> b.append(ord('e'))
>>> b
bytearray(b'ABCde')
```

There's also a corresponding C API, with `PyByteArray_FromObject()`, `PyByteArray_FromStringAndSize()`, and various other functions.
See also:

**PEP 3112 - Bytes literals in Python 3000**
PEP written by Jason Orendorff; backported to 2.6 by Christian Heimes.
PEP 3116: New I/O Library

Python's built-in file objects support a number of methods, but file-like objects don't necessarily support all of them. Objects that imitate files usually support read() and write(), but they may not support readline(), for example. Python 3.0 introduces a layered I/O library in the io module that separates buffering and text-handling features from the fundamental read and write operations.

There are three levels of abstract base classes provided by the io module:

- **RawIOBase** defines raw I/O operations: read(), readinto(), write(), seek(), tell(), truncate(), and close(). Most of the methods of this class will often map to a single system call. There are also readable(), writable(), and seekable() methods for determining what operations a given object will allow.

  Python 3.0 has concrete implementations of this class for files and sockets, but Python 2.6 hasn't restructured its file and socket objects in this way.

- **BufferedIOBase** is an abstract base class that buffers data in memory to reduce the number of system calls used, making I/O processing more efficient. It supports all of the methods of RawIOBase, and adds a raw attribute holding the underlying raw object.

  There are five concrete classes implementing this ABC. BufferedWriter and BufferedReader are for objects that support write-only or read-only usage that have a seek() method.
for random access. BufferedRandom objects support read and write access upon the same underlying stream, and BufferedRWPair is for objects such as TTYs that have both read and write operations acting upon unconnected streams of data. The BytesIO class supports reading, writing, and seeking over an in-memory buffer.

- TextIOBase: Provides functions for reading and writing strings (remember, strings will be Unicode in Python 3.0), and supporting universal newlines. TextIOBase defines the readline() method and supports iteration upon objects.

There are two concrete implementations. TextIOWrapper wraps a buffered I/O object, supporting all of the methods for text I/O and adding a buffer attribute for access to the underlying object. StringIO simply buffers everything in memory without ever writing anything to disk.

(In Python 2.6, io.StringIO is implemented in pure Python, so it's pretty slow. You should therefore stick with the existing StringIO module or cStringIO for now. At some point Python 3.0's io module will be rewritten into C for speed, and perhaps the C implementation will be backported to the 2.x releases.)

In Python 2.6, the underlying implementations haven't been restructured to build on top of the io module's classes. The module is being provided to make it easier to write code that's forward-compatible with 3.0, and to save developers the effort of writing their own implementations of buffering and text I/O.

See also:
PEP 3116 - New I/O

PEP 3118: Revised Buffer Protocol

The buffer protocol is a C-level API that lets Python types exchange pointers into their internal representations. A memory-mapped file can be viewed as a buffer of characters, for example, and this lets another module such as re treat memory-mapped files as a string of characters to be searched.

The primary users of the buffer protocol are numeric-processing packages such as NumPy, which expose the internal representation of arrays so that callers can write data directly into an array instead of going through a slower API. This PEP updates the buffer protocol in light of experience from NumPy development, adding a number of new features such as indicating the shape of an array or locking a memory region.

The most important new C API function is PyObject_GetBuffer(PyObject *obj, Py_buffer *view, int flags), which takes an object and a set of flags, and fills in the Py_buffer structure with information about the object's memory representation. Objects can use this operation to lock memory in place while an external caller could be modifying the contents, so there's a corresponding PyBuffer_Release(Py_buffer *view) to indicate that the external caller is done.

The flags argument to PyObject_GetBuffer() specifies constraints upon the memory returned. Some examples are:

- PyBUF_WRITABLE indicates that the memory must be writable.
- PyBUF_LOCK requests a read-only or exclusive lock on the memory.
- PyBUF_C_CONTIGUOUS and PyBUF_F_CONTIGUOUS requests a C-contiguous (last dimension varies the fastest) or Fortran-contiguous (first dimension varies the fastest) array layout.

Two new argument codes for PyArg_ParseTuple(), s* and z*, return locked buffer objects for a parameter.

See also:

**PEP 3118 - Revising the buffer protocol**

PEP written by Travis Oliphant and Carl Banks; implemented by Travis Oliphant.
PEP 3119: Abstract Base Classes

Some object-oriented languages such as Java support interfaces, declaring that a class has a given set of methods or supports a given access protocol. Abstract Base Classes (or ABCs) are an equivalent feature for Python. The ABC support consists of an `abc` module containing a metaclass called ABCMeta, special handling of this metaclass by the `isinstance()` and `issubclass()` builtins, and a collection of basic ABCs that the Python developers think will be widely useful. Future versions of Python will probably add more ABCs.

Let's say you have a particular class and wish to know whether it supports dictionary-style access. The phrase “dictionary-style” is vague, however. It probably means that accessing items with `obj[1]` works. Does it imply that setting items with `obj[2] = value` works? Or that the object will have `keys()`, `values()`, and `items()` methods? What about the iterative variants such as `iterkeys()`? `copy()` and `update()`? Iterating over the object with `iter()`?

The Python 2.6 `collections` module includes a number of different ABCs that represent these distinctions. `Iterable` indicates that a class defines `__iter__()`, and `Container` means the class defines a `__contains__()` method and therefore supports `x in y` expressions. The basic dictionary interface of getting items, setting items, and `keys()`, `values()`, and `items()`, is defined by the `MutableMapping` ABC.

You can derive your own classes from a particular ABC to indicate they support that ABC’s interface:

```python
import collections
```
class Storage(collections.MutableMapping):
...

Alternatively, you could write the class without deriving from the desired ABC and instead register the class by calling the ABC's register() method:

import collections
class Storage:
...
collections.MutableMapping.register(Storage)

For classes that you write, deriving from the ABC is probably clearer. The register() method is useful when you've written a new ABC that can describe an existing type or class, or if you want to declare that some third-party class implements an ABC. For example, if you defined a PrintableType ABC, it's legal to do:

# Register Python's types
PrintableType.register(int)
PrintableType.register(float)
PrintableType.register(str)

Classes should obey the semantics specified by an ABC, but Python can't check this; it's up to the class author to understand the ABC's requirements and to implement the code accordingly.

To check whether an object supports a particular interface, you can now write:

def func(d):
if not isinstance(d, collections.MutableMapping):
    raise ValueError("Mapping object expected, not %r")

Don't feel that you must now begin writing lots of checks as in the above example. Python has a strong tradition of duck-typing, where explicit type-checking is never done and code simply calls methods on an object, trusting that those methods will be there and raising an exception if they aren't. Be judicious in checking for ABCs and only do it where it's absolutely necessary.

You can write your own ABCs by using `abc.ABCMeta` as the metaclass in a class definition:

```python
from abc import ABCMeta, abstractmethod

class Drawable():
    __metaclass__ = ABCMeta

    @abstractmethod
def draw(self, x, y, scale=1.0):
        pass

    def draw_doubled(self, x, y):
        self.draw(x, y, scale=2.0)

class Square(Drawable):
    def draw(self, x, y, scale):
        ...
```

In the `Drawable` ABC above, the `draw_doubled()` method renders the object at twice its size and can be implemented in terms of other methods described in `Drawable`. Classes implementing this ABC therefore don't need to provide their own implementation of
draw_doubled(), though they can do so. An implementation of draw() is necessary, though; the ABC can’t provide a useful generic implementation.

You can apply the @abstractmethod decorator to methods such as draw() that must be implemented; Python will then raise an exception for classes that don’t define the method. Note that the exception is only raised when you actually try to create an instance of a subclass lacking the method:

```python
>>> class Circle(Drawable):
...     pass
...
>>> c = Circle()
Traceback (most recent call last):
  File "<stdin>", line 1, in <module>
TypeError: Can't instantiate abstract class Circle with abstract methods draw
```

Abstract data attributes can be declared using the @abstractproperty decorator:

```python
from abc import abstractproperty
...

@abstractproperty
def readonly(self):
    return self._x
```

Subclasses must then define a readonly() property.

See also:

**PEP 3119 - Introducing Abstract Base Classes**
PEP written by Guido van Rossum and Talin. Implemented by Guido van Rossum. Backported to 2.6 by Benjamin Aranguren, with Alex Martelli.
PEP 3127: Integer Literal Support and Syntax

Python 3.0 changes the syntax for octal (base-8) integer literals, prefixing them with “0o” or “0O” instead of a leading zero, and adds support for binary (base-2) integer literals, signalled by a “0b” or “0B” prefix.

Python 2.6 doesn’t drop support for a leading 0 signalling an octal number, but it does add support for “0o” and “0b”:

```python
>>> 0o21, 2*8 + 1
(17, 17)
>>> 0b101111
47
```

The `oct()` builtin still returns numbers prefixed with a leading zero, and a new `bin()` builtin returns the binary representation for a number:

```python
>>> oct(42)
'052'
>>> future_builtins.oct(42)
'0o52'
>>> bin(173)
'0b10101101'
```

The `int()` and `long()` builtins will now accept the “0o” and “0b” prefixes when base-8 or base-2 are requested, or when the `base` argument is zero (signalling that the base used should be determined from the string):

**PEP 3127 - Integer Literal Support and Syntax**

PEP written by Patrick Maupin; backported to 2.6 by Eric Smith.
PEP 3129: Class Decorators

Decorators have been extended from functions to classes. It’s now legal to write:

```python
@foo
@bar
class A:
    pass
```

This is equivalent to:

```python
class A:
    pass
A = foo(bar(A))
```

See also:

PEP 3129 - Class Decorators
PEP written by Collin Winter.
PEP 3141: A Type Hierarchy for Numbers

Python 3.0 adds several abstract base classes for numeric types inspired by Scheme's numeric tower. These classes were backported to 2.6 as the numbers module.

The most general ABC is Number. It defines no operations at all, and only exists to allow checking if an object is a number by doing `isinstance(obj, Number)`.

Complex is a subclass of Number. Complex numbers can undergo the basic operations of addition, subtraction, multiplication, division, and exponentiation, and you can retrieve the real and imaginary parts and obtain a number's conjugate. Python's built-in complex type is an implementation of Complex.

Real further derives from Complex, and adds operations that only work on real numbers: `floor()`, `trunc()`, rounding, taking the remainder mod N, floor division, and comparisons.

Rational numbers derive from Real, have numerator and denominator properties, and can be converted to floats. Python 2.6 adds a simple rational-number class, Fraction, in the fractions module. (It's called Fraction instead of Rational to avoid a name clash with numbers.Rational.)

Integral numbers derive from Rational, and can be shifted left and right with `<<` and `>>`, combined using bitwise operations such as `&` and `|`, and can be used as array indexes and slice boundaries.

In Python 3.0, the PEP slightly redefines the existing builtins
round(), math.floor(), math.ceil(), and adds a new one, math.trunc(), that’s been backported to Python 2.6. math.trunc() rounds toward zero, returning the closest Integral that’s between the function’s argument and zero.

**PEP 3141 - A Type Hierarchy for Numbers**
PEP written by Jeffrey Yasskin.

**Scheme’s numerical tower**, from the Guile manual.

**Scheme’s number datatypes** from the R5RS Scheme specification.

The **fractions** Module

To fill out the hierarchy of numeric types, the fractions module provides a rational-number class. Rational numbers store their values as a numerator and denominator forming a fraction, and can exactly represent numbers such as $\frac{2}{3}$ that floating-point numbers can only approximate.

The Fraction constructor takes two Integral values that will be the numerator and denominator of the resulting fraction.

```python
>>> from fractions import Fraction
>>> a = Fraction(2, 3)
>>> b = Fraction(2, 5)
>>> float(a), float(b)
(0.6666666666666666, 0.40000000000000002)
>>> a+b
Fraction(16, 15)
>>> a/b
```
For converting floating-point numbers to rationals, the `float` type now has an `as_integer_ratio()` method that returns the numerator and denominator for a fraction that evaluates to the same floating-point value:

```python
>>> (2.5).as_integer_ratio()
(5, 2)
>>> (3.1415).as_integer_ratio()
(7074029114692207L, 2251799813685248L)
>>> (1./3).as_integer_ratio()
(6004799503160661L, 18014398509481984L)
```

Note that values that can only be approximated by floating-point numbers, such as `1./3`, are not simplified to the number being approximated; the fraction attempts to match the floating-point value **exactly**.

The `fractions` module is based upon an implementation by Sjoerd Mullender that was in Python’s `Demo/classes/` directory for a long time. This implementation was significantly updated by Jeffrey Yasskin.
Other Language Changes

Some smaller changes made to the core Python language are:

- Directories and zip archives containing a `__main__.py` file can now be executed directly by passing their name to the interpreter. The directory or zip archive is automatically inserted as the first entry in `sys.path`. (Suggestion and initial patch by Andy Chu, subsequently revised by Phillip J. Eby and Nick Coghlan; issue 1739468.)

- The `hasattr()` function was catching and ignoring all errors, under the assumption that they meant a `__getattr__()` method was failing somehow and the return value of `hasattr()` would therefore be False. This logic shouldn't be applied to `KeyboardInterrupt` and `SystemExit`, however; Python 2.6 will no longer discard such exceptions when `hasattr()` encounters them. (Fixed by Benjamin Peterson; issue 2196.)

- When calling a function using the `**` syntax to provide keyword arguments, you are no longer required to use a Python dictionary; any mapping will now work:

```python
>>> def f(**kw):
...     print sorted(kw)
... >>>
>>> ud=UserDict.UserDict()
>>> ud['a'] = 1
>>> ud['b'] = 'string'
>>> f(**ud)
['a', 'b']
```
It's also become legal to provide keyword arguments after a *args argument to a function call.

```python
>>> def f(*args, **kw):
>>>     print args, kw
... >>> f(1, 2, 3, *(4, 5, 6), keyword=13)
(1, 2, 3, 4, 5, 6) {'keyword': 13}
```

Previously this would have been a syntax error. (Contributed by Amaury Forgeot d'Arc; issue 3473.)

- A new builtin, `next(iterator, [default])` returns the next item from the specified iterator. If the `default` argument is supplied, it will be returned if `iterator` has been exhausted; otherwise, the `StopIteration` exception will be raised. (Backported in issue 2719.)

- Tuples now have `index()` and `count()` methods matching the list type's `index()` and `count()` methods:

```python
>>> t = (0, 1, 2, 3, 4, 0, 1, 2)
>>> t.index(3)
3
>>> t.count(0)
2
```

(Contributed by Raymond Hettinger)

- The built-in types now have improved support for extended slicing syntax, accepting various combinations of `(start, stop, step)`. Previously, the support was partial and certain corner
cases wouldn’t work. (Implemented by Thomas Wouters.)

- Properties now have three attributes, getter, setter and deleter, that are decorators providing useful shortcuts for adding a getter, setter or deleter function to an existing property. You would use them like this:

```python
class C(object):
    @property
def x(self):
        return self._x

    @x.setter
def x(self, value):
        self._x = value

    @x.deleter
def x(self):
        del self._x

class D(C):
    @C.x.setter
def x(self, value):
        self._x = value / 2

>>> s=set('1234567890')
```
Many floating-point features were added. The `float()` function will now turn the string `nan` into an IEEE 754 Not A Number value, and `+inf` and `-inf` into positive or negative infinity. This works on any platform with IEEE 754 semantics. (Contributed by Christian Heimes; issue 1635.)

Other functions in the `math` module, `isinf()` and `isnan()`, return true if their floating-point argument is infinite or Not A Number. (issue 1640)

Conversion functions were added to convert floating-point numbers into hexadecimal strings (issue 3008). These functions convert floats to and from a string representation without introducing rounding errors from the conversion between decimal and binary. Floats have a `hex()` method that returns a string representation, and the `float.fromhex()` method converts a string back into a number:

```
>>> a = 3.75
>>> a.hex()
'0x1.e000000000000p+1'
>>> float.fromhex('0x1.e000000000000p+1')
3.75
>>> b=1./3
>>> b.hex()
'0x1.5555555555555p-2'
```
A numerical nicety: when creating a complex number from two floats on systems that support signed zeros (-0 and +0), the `complex()` constructor will now preserve the sign of the zero. (Fixed by Mark T. Dickinson; issue 1507.)

Classes that inherit a `__hash__()` method from a parent class can set `__hash__ = None` to indicate that the class isn’t hashable. This will make `hash(obj)` raise a `TypeError` and the class will not be indicated as implementing the Hashable ABC.

You should do this when you’ve defined a `__cmp__()` or `__eq__()` method that compares objects by their value rather than by identity. All objects have a default hash method that uses `id(obj)` as the hash value. There’s no tidy way to remove the `__hash__()` method inherited from a parent class, so assigning `None` was implemented as an override. At the C level, extensions can set `tp_hash` to `PyObject_HashNotImplemented()`. (Fixed by Nick Coghlan and Amaury Forgeot d’Arc; issue 2235.)

- The `GeneratorExit` exception now subclasses `BaseException` instead of `Exception`. This means that an exception handler that does `except Exception:` will not inadvertently catch `GeneratorExit`. (Contributed by Chad Austin; issue 1537.)

- Generator objects now have a `gi_code` attribute that refers to the original code object backing the generator. (Contributed by Collin Winter; issue 1473257.)

- The `compile()` built-in function now accepts keyword arguments as well as positional parameters. (Contributed by
The complex() constructor now accepts strings containing parenthesized complex numbers, meaning that complex(repr(cplx)) will now round-trip values. For example, complex('(3+4j)') now returns the value (3+4j). (issue 1491866)

The string translate() method now accepts None as the translation table parameter, which is treated as the identity transformation. This makes it easier to carry out operations that only delete characters. (Contributed by Bengt Richter and implemented by Raymond Hettinger; issue 1193128.)

The built-in dir() function now checks for a __dir__() method on the objects it receives. This method must return a list of strings containing the names of valid attributes for the object, and lets the object control the value that dir() produces. Objects that have __getattr__() or __getattribute__() methods can use this to advertise pseudo-attributes they will honor. (issue 1591665)

Instance method objects have new attributes for the object and function comprising the method; the new synonym for im_self is __self__, and im_func is also available as __func__. The old names are still supported in Python 2.6, but are gone in 3.0.

An obscure change: when you use the locals() function inside a class statement, the resulting dictionary no longer returns free variables. (Free variables, in this case, are variables referenced in the class statement that aren’t attributes of the class.)
Optimizations

- The `warnings` module has been rewritten in C. This makes it possible to invoke warnings from the parser, and may also make the interpreter’s startup faster. (Contributed by Neal Norwitz and Brett Cannon; issue 1631171.)

- Type objects now have a cache of methods that can reduce the work required to find the correct method implementation for a particular class; once cached, the interpreter doesn’t need to traverse base classes to figure out the right method to call. The cache is cleared if a base class or the class itself is modified, so the cache should remain correct even in the face of Python’s dynamic nature. (Original optimization implemented by Armin Rigo, updated for Python 2.6 by Kevin Jacobs; issue 1700288.)

  By default, this change is only applied to types that are included with the Python core. Extension modules may not necessarily be compatible with this cache, so they must explicitly add `Py_TPFLAGS_HAVE_VERSION_TAG` to the module’s `tp_flags` field to enable the method cache. (To be compatible with the method cache, the extension module’s code must not directly access and modify the `tp_dict` member of any of the types it implements. Most modules don’t do this, but it’s impossible for the Python interpreter to determine that. See issue 1878 for some discussion.)

- Function calls that use keyword arguments are significantly faster by doing a quick pointer comparison, usually saving the time of a full string comparison. (Contributed by Raymond Hettinger, after an initial implementation by Antoine Pitrou; issue 1819.)
• All of the functions in the `struct` module have been rewritten in C, thanks to work at the Need For Speed sprint. (Contributed by Raymond Hettinger.)

• Some of the standard built-in types now set a bit in their type objects. This speeds up checking whether an object is a subclass of one of these types. (Contributed by Neal Norwitz.)

• Unicode strings now use faster code for detecting whitespace and line breaks; this speeds up the `split()` method by about 25% and `splitlines()` by 35%. (Contributed by Antoine Pitrou.) Memory usage is reduced by using pymalloc for the Unicode string's data.

• The `with` statement now stores the `__exit__()` method on the stack, producing a small speedup. (Implemented by Jeffrey Yasskin.)

• To reduce memory usage, the garbage collector will now clear internal free lists when garbage-collecting the highest generation of objects. This may return memory to the operating system sooner.

Interpreter Changes

Two command-line options have been reserved for use by other Python implementations. The `-J` switch has been reserved for use by Jython for Jython-specific options, such as switches that are passed to the underlying JVM. `-X` has been reserved for options specific to a particular implementation of Python such as CPython, Jython, or IronPython. If either option is used with Python 2.6, the interpreter will report that the option isn’t currently used.
Python can now be prevented from writing .pyc or .pyo files by supplying the -B switch to the Python interpreter, or by setting the PYTHONDONTWRITEBYTECODE environment variable before running the interpreter. This setting is available to Python programs as the sys.dont_write_bytecode variable, and Python code can change the value to modify the interpreter’s behaviour. (Contributed by Neal Norwitz and Georg Brandl.)

The encoding used for standard input, output, and standard error can be specified by setting the PYTHONIOENCODING environment variable before running the interpreter. The value should be a string in the form <encoding> or <encoding>:<errorhandler>. The encoding part specifies the encoding’s name, e.g. utf-8 or latin-1; the optional errorhandler part specifies what to do with characters that can’t be handled by the encoding, and should be one of “error”, “ignore”, or “replace”. (Contributed by Martin von Löwis.)
New and Improved Modules

As in every release, Python's standard library received a number of enhancements and bug fixes. Here's a partial list of the most notable changes, sorted alphabetically by module name. Consult the Misc/NEWS file in the source tree for a more complete list of changes, or look through the Subversion logs for all the details.

- The asyncore and asynchat modules are being actively maintained again, and a number of patches and bugfixes were applied. (Maintained by Josiah Carlson; see issue 1736190 for one patch.)

- The bsddb module also has a new maintainer, Jesús Cea Avión, and the package is now available as a standalone package. The web page for the package is www.jcea.es/programacion/pybsddb.htm. The plan is to remove the package from the standard library in Python 3.0, because its pace of releases is much more frequent than Python's.

  The bsddb.dbshelve module now uses the highest pickling protocol available, instead of restricting itself to protocol 1. (Contributed by W. Barnes.)

- The cgi module will now read variables from the query string of an HTTP POST request. This makes it possible to use form actions with URLs that include query strings such as “/cgi-bin/add.py?category=1”. (Contributed by Alexandre Fiori and Nubis; issue 1817.)

  The parse_qs() and parse_qsl() functions have been relocated from the cgi module to the urlparse module. The
versions still available in the `cgi` module will trigger `PendingDeprecationWarning` messages in 2.6 (issue 600362).

- The `cmath` module underwent extensive revision, contributed by Mark Dickinson and Christian Heimes. Five new functions were added:
  - `polar()` converts a complex number to polar form, returning the modulus and argument of the complex number.
  - `rect()` does the opposite, turning a modulus, argument pair back into the corresponding complex number.
  - `phase()` returns the argument (also called the angle) of a complex number.
  - `isnan()` returns True if either the real or imaginary part of its argument is a NaN.
  - `isinf()` returns True if either the real or imaginary part of its argument is infinite.

The revisions also improved the numerical soundness of the `cmath` module. For all functions, the real and imaginary parts of the results are accurate to within a few units of least precision (ulps) whenever possible. See issue 1381 for the details. The branch cuts for `asinh()`, `atanh()` and `atan()` have also been corrected.

The tests for the module have been greatly expanded; nearly 2000 new test cases exercise the algebraic functions.

On IEEE 754 platforms, the `cmath` module now handles IEEE 754 special values and floating-point exceptions in a manner consistent with Annex ‘G’ of the C99 standard.
A new data type in the `collections` module: `namedtuple(typename, fieldnames)` is a factory function that creates subclasses of the standard tuple whose fields are accessible by name as well as index. For example:

```python
>>> var_type = collections.namedtuple('variable', ...
...   'id name type size')
>>> # Names are separated by spaces or commas.
>>> # 'id, name, type, size' would also work.
>>> var_type._fields
('id', 'name', 'type', 'size')

>>> var = var_type(1, 'frequency', 'int', 4)
>>> print var[0], var.id  # Equivalent
1 1
>>> print var[2], var.type  # Equivalent
int int
>>> var._asdict()
{'size': 4, 'type': 'int', 'id': 1, 'name': 'frequency'}

>>> v2 = var._replace(name='amplitude')
>>> v2
variable(id=1, name='amplitude', type='int', size=4)
```

Several places in the standard library that returned tuples have been modified to return `namedtuple` instances. For example, the `Decimal.as_tuple()` method now returns a named tuple with `sign`, `digits`, and `exponent` fields.

(Contributed by Raymond Hettinger.)

Another change to the `collections` module is that the `deque` type now supports an optional `maxlen` parameter; if supplied, the deque’s size will be restricted to no more than `maxlen` items. Adding more items to a full deque causes old items to be
discarded.

```python
>>> from collections import deque
>>> dq=deque(maxlen=3)
>>> dq
deque([], maxlen=3)
>>> dq.append(1) ; dq.append(2) ; dq.append(3)
>>> dq
deque([1, 2, 3], maxlen=3)
>>> dq.append(4)
>>> dq
deque([2, 3, 4], maxlen=3)
```
(Contributed by Raymond Hettinger.)

- The Cookie module's Morsel objects now support an `httponly` attribute. In some browsers, cookies with this attribute set cannot be accessed or manipulated by JavaScript code. (Contributed by Arvin Schnell; issue 1638033.)

- A new window method in the `curses` module, `chgat()`, changes the display attributes for a certain number of characters on a single line. (Contributed by Fabian Kreutz.)

```python
# Boldface text starting at y=0, x=21
# and affecting the rest of the line.
stdscr.chgat(0, 21, curses.A_BOLD)
```

The Textbox class in the `curses.textpad` module now supports editing in insert mode as well as overwrite mode. Insert mode is enabled by supplying a true value for the `insert_mode` parameter when creating the Textbox instance.

- The `datetime` module's `strftime()` methods now support a
format code that expands to the number of microseconds in the object, zero-padded on the left to six places. (Contributed by Skip Montanaro; issue 1158.)

• The **decimal** module was updated to version 1.66 of the **General Decimal Specification**. New features include some methods for some basic mathematical functions such as `exp()` and `log10()`:

  ```python
  >>> Decimal(1).exp()
  Decimal("2.718281828459045235360287471")
  >>> Decimal("2.7182818").ln()
  Decimal("0.999999895305022877376682436")
  >>> Decimal(1000).log10()
  Decimal("3")
  ```

  The `as_tuple()` method of Decimal objects now returns a named tuple with sign, digits, and exponent fields.

  (Implemented by Facundo Batista and Mark Dickinson. Named tuple support added by Raymond Hettinger.)

• The **difflib** module’s SequenceMatcher class now returns named tuples representing matches, with a, b, and size attributes. (Contributed by Raymond Hettinger.)

• An optional `timeout` parameter, specifying a timeout measured in seconds, was added to the **ftplib.FTP** class constructor as well as the `connect()` method. (Added by Facundo Batista.) Also, the FTP class's `storbinary()` and `storlines()` now take an optional `callback` parameter that will be called with each block of data after the data has been sent. (Contributed by Phil Schwartz; issue 1221598.)
- The `reduce()` built-in function is also available in the `functools` module. In Python 3.0, the builtin has been dropped and `reduce()` is only available from `functools`; currently there are no plans to drop the builtin in the 2.x series. (Patched by Christian Heimes; issue 1739906.)

- When possible, the `getpass` module will now use `/dev/tty` to print a prompt message and read the password, falling back to standard error and standard input. If the password may be echoed to the terminal, a warning is printed before the prompt is displayed. (Contributed by Gregory P. Smith.)

- The `glob.glob()` function can now return Unicode filenames if a Unicode path was used and Unicode filenames are matched within the directory. (issue 1001604)

- A new function in the `heapq` module, `merge(iter1, iter2, ...)`, takes any number of iterables returning data in sorted order, and returns a new generator that returns the contents of all the iterators, also in sorted order. For example:

  ```python
  >>> list(heapq.merge([1, 3, 5, 9], [2, 8, 16]))
  [1, 2, 3, 5, 8, 9, 16]
  ```

  Another new function, `heappushpop(heap, item)`, pushes `item` onto `heap`, then pops off and returns the smallest item. This is more efficient than making a call to `heappush()` and then `heappop()`.

  `heapq` is now implemented to only use less-than comparison, instead of the less-than-or-equal comparison it previously used. This makes `heapq`'s usage of a type match the `list.sort()`
method. (Contributed by Raymond Hettinger.)

- An optional timeout parameter, specifying a timeout measured in seconds, was added to the `httplib.HTTPConnection` and `HTTPSConnection` class constructors. (Added by Facundo Batista.)

- Most of the `inspect` module's functions, such as `getmoduleinfo()` and `getargs()`, now return named tuples. In addition to behaving like tuples, the elements of the return value can also be accessed as attributes. (Contributed by Raymond Hettinger.)

Some new functions in the module include `isgenerator()`, `isgeneratorfunction()`, and `isabstract()`.

- The `itertools` module gained several new functions.

  ```python
  izip_longest(iter1, iter2, ..., [fillvalue])
  ```

  makes tuples from each of the elements; if some of the iterables are shorter than others, the missing values are set to `fillvalue`. For example:

  ```python
  >>> tuple(itertools.izip_longest([1, 2, 3], [1, 2, 3], fillvalue=None))
  [(1, 1), (2, 2), (3, 3), (None, 4), (None, 5)]
  ```

  ```python
  product(iter1, iter2, ..., [repeat=N])
  ```

  returns the Cartesian product of the supplied iterables, a set of tuples containing every possible combination of the elements returned from each iterable.

  ```python
  >>> list(itertools.product([1, 2, 3], [4, 5, 6]))
  [(1, 4), (1, 5), (1, 6),
  ```
The optional *repeat* keyword argument is used for taking the product of an iterable or a set of iterables with themselves, repeated $N$ times. With a single iterable argument, $N$-tuples are returned:

```python
>>> list(itertools.product([1, 2], repeat=3))
[(1, 1, 1), (1, 1, 2), (1, 2, 1), (1, 2, 2),
 (2, 1, 1), (2, 1, 2), (2, 2, 1), (2, 2, 2)]
```

With two iterables, $2N$-tuples are returned.

```python
>>> list(itertools.product([1, 2], [3, 4], repeat=2))
[(1, 3, 1, 3), (1, 3, 1, 4), (1, 3, 2, 3), (1, 3, 2, 4),
 (1, 4, 1, 3), (1, 4, 1, 4), (1, 4, 2, 3), (1, 4, 2, 4),
 (2, 3, 1, 3), (2, 3, 1, 4), (2, 3, 2, 3), (2, 3, 2, 4),
 (2, 4, 1, 3), (2, 4, 1, 4), (2, 4, 2, 3), (2, 4, 2, 4)]
```

`combinations(iterable, r)` returns sub-sequences of length $r$ from the elements of *iterable*.

```python
>>> list(itertools.combinations('123', 2))
[('1', '2'), ('1', '3'), ('2', '3')]
>>> list(itertools.combinations('123', 3))
[('1', '2', '3')]
>>> list(itertools.combinations('1234', 3))
[('1', '2', '3'), ('1', '2', '4'), ('1', '3', '4'), ('2', '3', '4')]
```

`permutations(iter[, r])` returns all the permutations of length $r$ of the iterable's elements. If $r$ is not specified, it will default to the number of elements produced by the iterable.
\begin{verbatim}
>>> list(itertools.permutations([1,2,3,4], 2))
[(1, 2), (1, 3), (1, 4),
 (2, 1), (2, 3), (2, 4),
 (3, 1), (3, 2), (3, 4),
 (4, 1), (4, 2), (4, 3)]
\end{verbatim}

\texttt{itertools.chain(*iterables)} is an existing function in \texttt{itertools} that gained a new constructor in Python 2.6. \texttt{itertools.chain.from_iterable(iterable)} takes a single iterable that should return other iterables. \texttt{chain()} will then return all the elements of the first iterable, then all the elements of the second, and so on.

\begin{verbatim}
>>> list(itertools.chain.from_iterable([[1,2,3],[1,2,3,4,5,6]]))
[(1, 2, 3), (1, 2, 3, 4, 5, 6)]
\end{verbatim}

(All contributed by Raymond Hettinger.)

- The \texttt{logging} module's \texttt{FileHandler} class and its subclasses \texttt{WatchedFileHandler}, \texttt{RotatingFileHandler}, and \texttt{TimedRotatingFileHandler} now have an optional \texttt{delay} parameter to their constructors. If \texttt{delay} is true, opening of the log file is deferred until the first \texttt{emit()} call is made. (Contributed by Vinay Sajip.)

\texttt{TimedRotatingFileHandler} also has a \texttt{utc} constructor parameter. If the argument is true, UTC time will be used in determining when midnight occurs and in generating filenames; otherwise local time will be used.

- Several new functions were added to the \texttt{math} module:
  - \texttt{isinf()} and \texttt{.isnan()} determine whether a given float is a
(positive or negative) infinity or a NaN (Not a Number), respectively.

- `copysign()` copies the sign bit of an IEEE 754 number, returning the absolute value of $x$ combined with the sign bit of $y$. For example, `math.copysign(1, -0.0)` returns -1.0. (Contributed by Christian Heimes.)
- `factorial()` computes the factorial of a number. (Contributed by Raymond Hettinger; issue 2138.)
- `fsum()` adds up the stream of numbers from an iterable, and is careful to avoid loss of precision through using partial sums. (Contributed by Jean Brouwers, Raymond Hettinger, and Mark Dickinson; issue 2819.)
- `acosh()`, `asinh()` and `atanh()` compute the inverse hyperbolic functions.
- `log1p()` returns the natural logarithm of $1 + x$ (base $e$).
- `trunc()` rounds a number toward zero, returning the closest Integral that's between the function’s argument and zero. Added as part of the backport of PEP 3141's type hierarchy for numbers.

- The `math` module has been improved to give more consistent behaviour across platforms, especially with respect to handling of floating-point exceptions and IEEE 754 special values.

Whenever possible, the module follows the recommendations of the C99 standard about 754's special values. For example, `sqrt(-1.)` should now give a `ValueError` across almost all platforms, while `sqrt(float('NaN'))` should return a NaN on all IEEE 754 platforms. Where Annex ‘F’ of the C99 standard recommends signaling ‘divide-by-zero’ or ‘invalid’, Python will raise `ValueError`. Where Annex ‘F’ of the C99 standard recommends signaling ‘overflow’, Python will raise `OverflowError`. (See issue 711019 and issue 1640.)
mmap objects now have a `rfind()` method that searches for a substring beginning at the end of the string and searching backwards. The `find()` method also gained an `end` parameter giving an index at which to stop searching. (Contributed by John Lenton.)

The `operator` module gained a `methodcaller()` function that takes a name and an optional set of arguments, returning a callable that will call the named function on any arguments passed to it. For example:

```python
>>> # Equivalent to lambda s: s.replace('old', 'new')
>>> replacer = operator.methodcaller('replace', 'old')
>>> replacer('old wine in old bottles')
'new wine in new bottles'
```

(Contributed by Georg Brandl, after a suggestion by Gregory Petrosyan.)

The `attrgetter()` function now accepts dotted names and performs the corresponding attribute lookups:

```python
>>> inst_name = operator.attrgetter(...     '__class__.__name__')
>>> inst_name('')
'str'
>>> inst_name(help)
'_Helper'
```

(Contributed by Georg Brandl, after a suggestion by Barry Warsaw.)
The `os` module now wraps several new system calls. `fchmod(fd, mode)` and `fchown(fd, uid, gid)` change the mode and ownership of an opened file, and `lchmod(path, mode)` changes the mode of a symlink. (Contributed by Georg Brandl and Christian Heimes.)

`chflags()` and `lchflags()` are wrappers for the corresponding system calls (where they're available), changing the flags set on a file. Constants for the flag values are defined in the `stat` module; some possible values include `UF_IMMUTABLE` to signal the file may not be changed and `UF_APPEND` to indicate that data can only be appended to the file. (Contributed by M. Levinson.)

`os.closerange(low, high)` efficiently closes all file descriptors from `low` to `high`, ignoring any errors and not including `high` itself. This function is now used by the `subprocess` module to make starting processes faster. (Contributed by Georg Brandl; issue 1663329.)

The `os.environ` object's `clear()` method will now unset the environment variables using `os.unsetenv()` in addition to clearing the object's keys. (Contributed by Martin Horcicka; issue 1181.)

The `os.walk()` function now has a `followlinks` parameter. If set to True, it will follow symlinks pointing to directories and visit the directory's contents. For backward compatibility, the parameter's default value is false. Note that the function can fall into an infinite recursion if there's a symlink that points to a parent directory. (issue 1273829)
In the `os.path` module, the `splitext()` function has been changed to not split on leading period characters. This produces better results when operating on Unix's dot-files. For example, `os.path.splitext('.ipython')` now returns `('.ipython', '')` instead of `('', '.ipython')`. (issue 1115886)

A new function, `os.path.relpath(path, start='.')`, returns a relative path from the `start` path, if it's supplied, or from the current working directory to the destination `path`. (Contributed by Richard Barran; issue 1339796.)

On Windows, `os.path.expandvars()` will now expand environment variables given in the form “%var%”, and “~user” will be expanded into the user's home directory path. (Contributed by Josiah Carlson; issue 957650.)

The Python debugger provided by the `pdb` module gained a new command: “run” restarts the Python program being debugged and can optionally take new command-line arguments for the program. (Contributed by Rocky Bernstein; issue 1393667.)

The `pdb.post_mortem()` function, used to begin debugging a traceback, will now use the traceback returned by `sys.exc_info()` if no traceback is supplied. (Contributed by Facundo Batista; issue 1106316.)

The `pickletools` module now has an optimize() function that takes a string containing a pickle and removes some unused opcodes, returning a shorter pickle that contains the same data structure. (Contributed by Raymond Hettinger.)

A `get_data()` function was added to the `pkgutil` module that
returns the contents of resource files included with an installed Python package. For example:

```python
>>> import pkgutil
>>> print(pkgutil.get_data('test', 'exception_hierarchy.txt'))
BaseException
   +-- SystemExit
   +-- KeyboardInterrupt
   +-- GeneratorExit
   +-- Exception
      +-- StopIteration
      +-- StandardError
...
```

(Contributed by Paul Moore; issue 2439.)

- The `pyexpat` module's Parser objects now allow setting their `buffer_size` attribute to change the size of the buffer used to hold character data. (Contributed by Achim Gaedke; issue 1137.)

- The `Queue` module now provides queue variants that retrieve entries in different orders. The `PriorityQueue` class stores queued items in a heap and retrieves them in priority order, and `LifoQueue` retrieves the most recently added entries first, meaning that it behaves like a stack. (Contributed by Raymond Hettinger.)

- The `random` module's Random objects can now be pickled on a 32-bit system and unpickled on a 64-bit system, and vice versa. Unfortunately, this change also means that Python 2.6's Random objects can't be unpickled correctly on earlier versions of Python. (Contributed by Shawn Ligocki; issue 1727780.)
The new `triangular(low, high, mode)` function returns random numbers following a triangular distribution. The returned values are between `low` and `high`, not including `high` itself, and with `mode` as the most frequently occurring value in the distribution. (Contributed by Wladmir van der Laan and Raymond Hettinger; issue 1681432.)

- Long regular expression searches carried out by the `re` module will check for signals being delivered, so time-consuming searches can now be interrupted. (Contributed by Josh Hoyt and Ralf Schmitt; issue 846388.)

The regular expression module is implemented by compiling bytecodes for a tiny regex-specific virtual machine. Untrusted code could create malicious strings of bytecode directly and cause crashes, so Python 2.6 includes a verifier for the regex bytecode. (Contributed by Guido van Rossum from work for Google App Engine; issue 3487.)

- The `rlcompleter` module's Completer.complete() method will now ignore exceptions triggered while evaluating a name. (Fixed by Lorenz Quack; issue 2250.)

- The `sched` module's scheduler instances now have a read-only `queue` attribute that returns the contents of the scheduler's queue, represented as a list of named tuples with the fields `(time, priority, action, argument)`. (Contributed by Raymond Hettinger; issue 1861.)

- The `select` module now has wrapper functions for the Linux ` epoll()` and BSD `kqueue()` system calls. `modify()` method was added to the existing ` poll()` objects; `pollobj.modify(fd,
eventmask) takes a file descriptor or file object and an event mask, modifying the recorded event mask for that file. (Contributed by Christian Heimes; issue 1657.)

- The `shutil.copytree()` function now has an optional `ignore` argument that takes a callable object. This callable will receive each directory path and a list of the directory's contents, and returns a list of names that will be ignored, not copied.

  The `shutil` module also provides an `ignore_patterns()` function for use with this new parameter. `ignore_patterns()` takes an arbitrary number of glob-style patterns and returns a callable that will ignore any files and directories that match any of these patterns. The following example copies a directory tree, but skips both `.svn` directories and Emacs backup files, which have names ending with `~`:

  ```python
  shutil.copytree('Doc/library', '/tmp/library',
                  ignore=shutil.ignore_patterns('*.~'))
  ```

  (Contributed by Tarek Ziadé; issue 2663.)

- Integrating signal handling with GUI handling event loops like those used by Tkinter or GTK+ has long been a problem; most software ends up polling, waking up every fraction of a second to check if any GUI events have occurred. The `signal` module can now make this more efficient. Calling `signal.set_wakeup_fd(fd)` sets a file descriptor to be used; when a signal is received, a byte is written to that file descriptor. There’s also a C-level function, `PySignal_SetWakeupFd()`, for setting the descriptor.
Event loops will use this by opening a pipe to create two descriptors, one for reading and one for writing. The writable descriptor will be passed to `set_wakeup_fd()`, and the readable descriptor will be added to the list of descriptors monitored by the event loop via `select()` or `poll()`. On receiving a signal, a byte will be written and the main event loop will be woken up, avoiding the need to poll.

(Contributed by Adam Olsen; issue 1583.)

The `siginterrupt()` function is now available from Python code, and allows changing whether signals can interrupt system calls or not. (Contributed by Ralf Schmitt.)

The `setitimer()` and `getitimer()` functions have also been added (where they're available). `setitimer()` allows setting interval timers that will cause a signal to be delivered to the process after a specified time, measured in wall-clock time, consumed process time, or combined process+system time. (Contributed by Guilherme Polo; issue 2240.)

- The `smtplib` module now supports SMTP over SSL thanks to the addition of the `SMTP_SSL` class. This class supports an interface identical to the existing `SMTP` class. (Contributed by Monty Taylor.) Both class constructors also have an optional `timeout` parameter that specifies a timeout for the initial connection attempt, measured in seconds. (Contributed by Facundo Batista.)

An implementation of the LMTP protocol ([RFC 2033](https://rfc-editor.org/rfc/rfc2033.html)) was also added to the module. LMTP is used in place of SMTP when transferring e-mail between agents that don’t manage a mail
queue. (LMTP implemented by Leif Hedstrom; issue 957003.)

SMTP.starttls() now complies with RFC 3207 and forgets any knowledge obtained from the server not obtained from the TLS negotiation itself. (Patch contributed by Bill Fenner; issue 829951.)

- The socket module now supports TIPC (http://tipc.sf.net), a high-performance non-IP-based protocol designed for use in clustered environments. TIPC addresses are 4- or 5-tuples. (Contributed by Alberto Bertogli; issue 1646.)

A new function, create_connection(), takes an address and connects to it using an optional timeout value, returning the connected socket object. This function also looks up the address's type and connects to it using IPv4 or IPv6 as appropriate. Changing your code to use create_connection() instead of socket(socket.AF_INET, ...) may be all that's required to make your code work with IPv6.

- The base classes in the SocketServer module now support calling a handle_timeout() method after a span of inactivity specified by the server's timeout attribute. (Contributed by Michael Pomraning.) The serve_forever() method now takes an optional poll interval measured in seconds, controlling how often the server will check for a shutdown request. (Contributed by Pedro Werneck and Jeffrey Yasskin; issue 742598, issue 1193577.)

- The sqlite3 module, maintained by Gerhard Häring, has been updated from version 2.3.2 in Python 2.5 to version 2.4.1.

- The struct module now supports the C99 __Bool type, using
the format character '?'. (Contributed by David Remahl.)

- The Popen objects provided by the `subprocess` module now have `terminate()`, `kill()`, and `send_signal()` methods. On Windows, `send_signal()` only supports the SIGTERM signal, and all these methods are aliases for the Win32 API function `TerminateProcess()`. (Contributed by Christian Heimes.)

- A new variable in the `sys` module, `float_info`, is an object containing information derived from the `float.h` file about the platform's floating-point support. Attributes of this object include `mant_dig` (number of digits in the mantissa), `epsilon` (smallest difference between 1.0 and the next largest value representable), and several others. (Contributed by Christian Heimes; issue 1534.)

Another new variable, `dont_write_bytecode`, controls whether Python writes any `.pyc` or `.pyo` files on importing a module. If this variable is true, the compiled files are not written. The variable is initially set on start-up by supplying the `-B` switch to the Python interpreter, or by setting the `PYTHONDONTWRITEBYTECODE` environment variable before running the interpreter. Python code can subsequently change the value of this variable to control whether bytecode files are written or not. (Contributed by Neal Norwitz and Georg Brandl.)

Information about the command-line arguments supplied to the Python interpreter is available by reading attributes of a named tuple available as `sys.flags`. For example, the `verbose` attribute is true if Python was executed in verbose mode, `debug` is true in debugging mode, etc. These attributes are all read-only.
A new function, `getsizeof()`, takes a Python object and returns the amount of memory used by the object, measured in bytes. Built-in objects return correct results; third-party extensions may not, but can define a `__sizeof__()` method to return the object's size. (Contributed by Robert Schuppenies; issue 2898.)

It's now possible to determine the current profiler and tracer functions by calling `sys.getprofile()` and `sys.gettrace()`. (Contributed by Georg Brandl; issue 1648.)

- The `tarfile` module now supports POSIX.1-2001 (pax) tarfiles in addition to the POSIX.1-1988 (ustar) and GNU tar formats that were already supported. The default format is GNU tar; specify the `format` parameter to open a file using a different format:

```
tar = tarfile.open("output.tar", "w",
                format=tarfile.PAX_FORMAT)
```

The new `encoding` and `errors` parameters specify an encoding and an error handling scheme for character conversions. `'strict'`, `'ignore'`, and `'replace'` are the three standard ways Python can handle errors; `'utf-8'` is a special value that replaces bad characters with their UTF-8 representation. (Character conversions occur because the PAX format supports Unicode filenames, defaulting to UTF-8 encoding.)

The `TarFile.add()` method now accepts an `exclude` argument that's a function that can be used to exclude certain filenames from an archive. The function must take a filename and return true if the file should be excluded or false if it should be
archived. The function is applied to both the name initially passed to `add()` and to the names of files in recursively-added directories.

(All changes contributed by Lars Gustäbel).

- An optional timeout parameter was added to the `telnetlib.Telnet` class constructor, specifying a timeout measured in seconds. (Added by Facundo Batista.)

- The `tempfile.NamedTemporaryFile` class usually deletes the temporary file it created when the file is closed. This behaviour can now be changed by passing `delete=False` to the constructor. (Contributed by Damien Miller; issue 1537850.)

A new class, `tempfile.SpooledTemporaryFile`, behaves like a temporary file but stores its data in memory until a maximum size is exceeded. On reaching that limit, the contents will be written to an on-disk temporary file. (Contributed by Dustin J. Mitchell.)

The `tempfile.NamedTemporaryFile` and `tempfile.SpooledTemporaryFile` classes both work as context managers, so you can write

```python
with tempfile.NamedTemporaryFile() as tmp:
    ....
```

(Contributed by Alexander Belopolsky; issue 2021.)

- The `test.test_support` module gained a number of context managers useful for writing tests. `EnvironmentVarGuard()` is a context manager that temporarily changes environment variables and automatically restores them to their old values.

    Another context manager, `TransientResource`, can surround calls to resources that may or may not be available; it will catch and ignore a specified list of exceptions. For example, a network
test may ignore certain failures when connecting to an external web site:

```python
with test_support.TransientResource(IOError,
    errno=errno.ETIMEDOUT):
    f = urllib.urlopen('https://sf.net')
...
```

Finally, `check_warnings()` resets the warning module's warning filters and returns an object that will record all warning messages triggered (issue 3781):

```python
with test_support.check_warnings() as wrec:
    warnings.simplefilter("always")
    # ... code that triggers a warning ... 
    assert str(wrec.message) == "function is outdated"
    assert len(wrec.warnings) == 1, "Multiple warnings raised"
```

(Contributed by Brett Cannon.)

- The `textwrap` module can now preserve existing whitespace at the beginnings and ends of the newly-created lines by specifying `drop_whitespace=False` as an argument:

```python
>>> S = """This sentence has a bunch of
... extra whitespace."""
>>> print textwrap.fill(S, width=15)
This  sentence
has a bunch
of  extra
whitespace.
>>> print textwrap.fill(S, drop_whitespace=False)
This sentence
has a bunch
The threading module API is being changed to use properties such as daemon instead of setDaemon() and isDaemon() methods, and some methods have been renamed to use underscores instead of camel-case; for example, the activeCount() method is renamed to active_count(). Both the 2.6 and 3.0 versions of the module support the same properties and renamed methods, but don’t remove the old methods. No date has been set for the deprecation of the old APIs in Python 3.x; the old APIs won’t be removed in any 2.x version. (Carried out by several people, most notably Benjamin Peterson.)

The threading module's Thread objects gained an ident property that returns the thread's identifier, a nonzero integer. (Contributed by Gregory P. Smith; issue 2871.)

The timeit module now accepts callables as well as strings for the statement being timed and for the setup code. Two convenience functions were added for creating Timer instances: repeat(stmt, setup, time, repeat, number) and timeit(stmt, setup, time, number) create an instance and call the corresponding method. (Contributed by Erik Demaine; issue 1533909.)

The Tkinter module now accepts lists and tuples for options, separating the elements by spaces before passing the resulting value to Tcl/Tk. (Contributed by Guilherme Polo; issue 2906.)
• The turtle module for turtle graphics was greatly enhanced by Gregor Lingl. New features in the module include:
  
  ◦ Better animation of turtle movement and rotation.
  ◦ Control over turtle movement using the new delay(), tracer(), and speed() methods.
  ◦ The ability to set new shapes for the turtle, and to define a new coordinate system.
  ◦ Turtles now have an undo() method that can roll back actions.
  ◦ Simple support for reacting to input events such as mouse and keyboard activity, making it possible to write simple games.
  ◦ A turtle.cfg file can be used to customize the starting appearance of the turtle's screen.
  ◦ The module's docstrings can be replaced by new docstrings that have been translated into another language.

(issue 1513695)

• An optional timeout parameter was added to the urllib.urlopen() function and the urllib.ftpwrapper class constructor, as well as the urllib2.urlopen() function. The parameter specifies a timeout measured in seconds. For example:

```python
>>> u = urllib2.urlopen("http://slow.example.com", timeout=3)
Traceback (most recent call last):
  ...'
urllib2.URLError: <urlopen error timed out>
>>>
The Unicode database provided by the `unicodedata` module has been updated to version 5.1.0. (Updated by Martin von Löwis; issue 3811.)

The `warnings` module's `formatwarning()` and `showwarning()` gained an optional `line` argument that can be used to supply the line of source code. (Added as part of issue 1631171, which re-implemented part of the `warnings` module in C code.)

A new function, `catch_warnings()`, is a context manager intended for testing purposes that lets you temporarily modify the warning filters and then restore their original values (issue 3781).

The XML-RPC `SimpleXMLRPCServer` and `DocXMLRPCServer` classes can now be prevented from immediately opening and binding to their socket by passing `True` as the `bind_and_activate` constructor parameter. This can be used to modify the instance's `allow_reuse_address` attribute before calling the `server_bind()` and `server_activate()` methods to open the socket and begin listening for connections. (Contributed by Peter Parente; issue 1599845.)

`SimpleXMLRPCServer` also has a `_send_traceback_header` attribute; if true, the exception and formatted traceback are returned as HTTP headers “X-Exception” and “X-Traceback”. This feature is for debugging purposes only and should not be used on production servers because the tracebacks might reveal passwords or other sensitive information. (Contributed by Alan McIntyre as part of his project for Google's...
The **xmlrpclib** module no longer automatically converts `datetime.date` and `datetime.time` to the `xmlrpclib.DateTime` type; the conversion semantics were not necessarily correct for all applications. Code using `xmlrpclib` should convert `date` and `time` instances. (issue 1330538) The code can also handle dates before 1900 (contributed by Ralf Schmitt; issue 2014) and 64-bit integers represented by using `<i8>` in XML-RPC responses (contributed by Riku Lindblad; issue 2985).

The **zipfile** module's `ZipFile` class now has `extract()` and `extractall()` methods that will unpack a single file or all the files in the archive to the current directory, or to a specified directory:

```python
z = zipfile.ZipFile('python-251.zip')

# Unpack a single file, writing it relative
# to the /tmp directory.
z.extract('Python/sysmodule.c', '/tmp')

# Unpack all the files in the archive.
z.extractall()
```

(Contributed by Alan McIntyre; issue 467924.)

The `open()`, `read()` and `extract()` methods can now take either a filename or a `ZipInfo` object. This is useful when an archive accidentally contains a duplicated filename. (Contributed by Graham Horler; issue 1775025.)
Finally, `zipfile` now supports using Unicode filenames for archived files. (Contributed by Alexey Borzenkov; issue 1734346.)

The **ast** module

The **ast** module provides an Abstract Syntax Tree representation of Python code, and Armin Ronacher contributed a set of helper functions that perform a variety of common tasks. These will be useful for HTML templating packages, code analyzers, and similar tools that process Python code.

The `parse()` function takes an expression and returns an AST. The `dump()` function outputs a representation of a tree, suitable for debugging:

```python
import ast
t = ast.parse('"
 d = {}
 for i in 'abcdefghijklm':
   d[i + i] = ord(i) - ord('a') + 1
print d
""
print ast.dump(t)
```

This outputs a deeply nested tree:

```python
Module(body=[
   Assign(targets=[
      Name(id='d', ctx=Store())
   ], value=Dict(keys=[], values=[]))
   For(target=Name(id='i', ctx=Store()),
      iter=Str(s='abcdefghijklm'), body=[
      Assign(targets=[
```
The `literal_eval()` method takes a string or an AST representing a literal expression, parses and evaluates it, and returns the resulting value. A literal expression is a Python expression containing only strings, numbers, dictionaries, etc. but no statements or function calls. If you need to evaluate an expression but cannot accept the security risk of using an `eval()` call, `literal_eval()` will handle it safely:

```python
>>> literal = '("a", "b", {2:4, 3:8, 1:2})'
>>> print ast.literal_eval(literal)
('a', 'b', {1: 2, 2: 4, 3: 8})
>>> print ast.literal_eval("'a' + 'b'")
"a + b"
```
The module also includes NodeVisitor and NodeTransformer classes for traversing and modifying an AST, and functions for common transformations such as changing line numbers.

**The future_builtins module**

Python 3.0 makes many changes to the repertoire of built-in functions, and most of the changes can’t be introduced in the Python 2.x series because they would break compatibility. The `future_builtins` module provides versions of these built-in functions that can be imported when writing 3.0-compatible code.

The functions in this module currently include:

- `ascii(obj)`: equivalent to `repr()`. In Python 3.0, `repr()` will return a Unicode string, while `ascii()` will return a pure ASCII bytestring.
- `filter(predicate, iterable), map(func, iterable1, ...)`: the 3.0 versions return iterators, unlike the 2.x builtins which return lists.
- `hex(value), oct(value)`: instead of calling the `__hex__()` or `__oct__()` methods, these versions will call the `__index__()` method and convert the result to hexadecimal or octal. `oct()` will use the new 0o notation for its result.

**The json module: JavaScript Object Notation**

The new `json` module supports the encoding and decoding of Python
types in JSON (Javascript Object Notation). JSON is a lightweight interchange format often used in web applications. For more information about JSON, see http://www.json.org.

`json` comes with support for decoding and encoding most built-in Python types. The following example encodes and decodes a dictionary:

```python
>>> import json
>>> data = {"spam" : "foo", "parrot" : 42}
>>> in_json = json.dumps(data) # Encode the data
>>> in_json
'{"parrot": 42, "spam": "foo"}"
>>> json.loads(in_json) # Decode into a Python object
{"spam" : "foo", "parrot" : 42}
```

It’s also possible to write your own decoders and encoders to support more types. Pretty-printing of the JSON strings is also supported.

`json` (originally called simplejson) was written by Bob Ippolito.

The `plistlib` module: A Property-List Parser

The `.plist` format is commonly used on Mac OS X to store basic data types (numbers, strings, lists, and dictionaries) by serializing them into an XML-based format. It resembles the XML-RPC serialization of data types.

Despite being primarily used on Mac OS X, the format has nothing Mac-specific about it and the Python implementation works on any platform that Python supports, so the `plistlib` module has been promoted to the standard library.
Using the module is simple:

```python
import sys
import plistlib
import datetime

# Create data structure
data_struct = dict(lastAccessed=datetime.datetime.now(),
version=1, categories=('Personal','Shared','

# Create string containing XML.
plist_str = plistlib.writePlistToString(data_struct)
new_struct = plistlib.readPlistFromString(plist_str)
print data_struct
print new_struct

# Write data structure to a file and read it back.
plistlib.writePlist(data_struct, '/tmp/customizations.plist')
new_struct = plistlib.readPlist('/tmp/customizations.plist')

# read/writePlist accepts file-like objects as well
plistlib.writePlist(data_struct, sys.stdout)
```

**ctypes Enhancements**

Thomas Heller continued to maintain and enhance the **ctypes** module.

**ctypes** now supports a c_bool datatype that represents the C99 bool type. (Contributed by David Remahl; issue 1649190.)

The **ctypes** string, buffer and array types have improved support for extended slicing syntax, where various combinations of (start,
stop, step) are supplied. (Implemented by Thomas Wouters.)

All ctypes data types now support from_buffer() and from_buffer_copy() methods that create a ctypes instance based on a provided buffer object. from_buffer_copy() copies the contents of the object, while from_buffer() will share the same memory area.

A new calling convention tells ctypes to clear the errno or Win32 LastError variables at the outset of each wrapped call. (Implemented by Thomas Heller; issue 1798.)

You can now retrieve the Unix errno variable after a function call. When creating a wrapped function, you can supply use_errno=True as a keyword parameter to the DLL() function and then call the module-level methods set_errno() and get_errno() to set and retrieve the error value.

The Win32 LastError variable is similarly supported by the DLL(), OleDLL(), and WinDLL() functions. You supply use_last_error=True as a keyword parameter and then call the module-level methods set_last_error() and get_last_error().

The byref() function, used to retrieve a pointer to a ctypes instance, now has an optional offset parameter that is a byte count that will be added to the returned pointer.

**Improved SSL Support**

Bill Janssen made extensive improvements to Python 2.6's support for the Secure Sockets Layer by adding a new module, ssl, that's built
atop the OpenSSL library. This new module provides more control over the protocol negotiated, the X.509 certificates used, and has better support for writing SSL servers (as opposed to clients) in Python. The existing SSL support in the socket module hasn’t been removed and continues to work, though it will be removed in Python 3.0.

To use the new module, you must first create a TCP connection in the usual way and then pass it to the ssl.wrap_socket() function. It’s possible to specify whether a certificate is required, and to obtain certificate info by calling the getpeercert() method.

See also: The documentation for the ssl module.
Deprecations and Removals

- String exceptions have been removed. Attempting to use them raises a `TypeError`.

- Changes to the `Exception` interface as dictated by PEP 352 continue to be made. For 2.6, the message attribute is being deprecated in favor of the `args` attribute.

- (3.0-warning mode) Python 3.0 will feature a reorganized standard library that will drop many outdated modules and rename others. Python 2.6 running in 3.0-warning mode will warn about these modules when they are imported.

  The list of deprecated modules is: audiodev, bgenlocations, buildtools, bundlebuilder, Canvas, compiler, dircache, dl, fpformat, gensuitemodule, ihooks, imageop, imgfile, linuxaudiodev, mhlib, mimetools, multifile, new, pure, statvfs, sunaudiodev, test.testall, and toaiff.

- The gopherlib module has been removed.

- The MimeWriter module and mimify module have been deprecated; use the `email` package instead.

- The md5 module has been deprecated; use the `hashlib` module instead.

- The posixfile module has been deprecated; `fcntl.lockf()` provides better locking.
- The popen2 module has been deprecated; use the subprocess module.
- The rgbimg module has been removed.
- The sets module has been deprecated; it’s better to use the built-in set and frozenset types.
- The sha module has been deprecated; use the hashlib module instead.
Build and C API Changes

Changes to Python’s build process and to the C API include:

- Python now must be compiled with C89 compilers (after 19 years!). This means that the Python source tree has dropped its own implementations of memmove() and strerror(), which are in the C89 standard library.

- Python 2.6 can be built with Microsoft Visual Studio 2008 (version 9.0), and this is the new default compiler. See the PCbuild directory for the build files. (Implemented by Christian Heimes.)

- On Mac OS X, Python 2.6 can be compiled as a 4-way universal build. The configure script can take a --with-universal-archs=[32-bit|64-bit|all] switch, controlling whether the binaries are built for 32-bit architectures (x86, PowerPC), 64-bit (x86-64 and PPC-64), or both. (Contributed by Ronald Oussoren.)

- The BerkeleyDB module now has a C API object, available as bsddb.db.api. This object can be used by other C extensions that wish to use the bsddb module for their own purposes. (Contributed by Duncan Grisby.)

- The new buffer interface, previously described in the PEP 3118 section, adds PyObject_GetBuffer() and PyBuffer_Release(), as well as a few other functions.

- Python’s use of the C stdio library is now thread-safe, or at least as thread-safe as the underlying library is. A long-standing potential bug occurred if one thread closed a file object while another thread was reading from or writing to the object. In 2.6 file
objects have a reference count, manipulated by the
PyFile_IncUseCount() and PyFile_DecUseCount() functions. File objects can't be closed unless the reference count
is zero. PyFile_IncUseCount() should be called while the GIL
is still held, before carrying out an I/O operation using the FILE *
pointer, and PyFile_DecUseCount() should be called
immediately after the GIL is re-acquired. (Contributed by Antoine
Pitrou and Gregory P. Smith.)

- Importing modules simultaneously in two different threads no
  longer deadlocks; it will now raise an ImportError. A new API
  function, PyImport_ImportModuleNoBlock(), will look for a
  module in sys.modules first, then try to import it after acquiring
  an import lock. If the import lock is held by another thread, an
  ImportError is raised. (Contributed by Christian Heimes.)

- Several functions return information about the platform's floating-
  point support. PyFloat_GetMax() returns the maximum
  representable floating point value, and PyFloat_GetMin() returns the minimum positive value. PyFloat_GetInfo()
  returns an object containing more information from the float.h
  file, such as "mant_dig" (number of digits in the mantissa),
  "epsilon" (smallest difference between 1.0 and the next largest
  value representable), and several others. (Contributed by
  Christian Heimes; issue 1534.)

- C functions and methods that use PyComplex_AsCComplex() will now accept arguments that have a __complex__() method.
  In particular, the functions in the cmath module will now accept
  objects with this method. This is a backport of a Python 3.0
  change. (Contributed by Mark Dickinson; issue 1675423.)
Python’s C API now includes two functions for case-insensitive string comparisons, `PyOS_stricmp(char*, char*)` and `PyOS_strnicmp(char*, char*, Py_ssize_t)`.

(Contributed by Christian Heimes; issue 1635.)

Many C extensions define their own little macro for adding integers and strings to the module’s dictionary in the `init*` function. Python 2.6 finally defines standard macros for adding values to a module, `PyModule_AddStringMacro` and `PyModule_AddIntMacro()`.

(Contributed by Christian Heimes.)

Some macros were renamed in both 3.0 and 2.6 to make it clearer that they are macros, not functions. `Py_Size()` became `Py_SIZE()`, `Py_Type()` became `Py_TYPE()`, and `Py_Refcnt()` became `Py_REFCNT()`. The mixed-case macros are still available in Python 2.6 for backward compatibility. (issue 1629)

Distutils now places C extensions it builds in a different directory when running on a debug version of Python. (Contributed by Collin Winter; issue 1530959.)

Several basic data types, such as integers and strings, maintain internal free lists of objects that can be re-used. The data structures for these free lists now follow a naming convention: the variable is always named `free_list`, the counter is always named `numfree`, and a macro `Py<typename>_MAXFREELIST` is always defined.

A new Makefile target, “make patchcheck”, prepares the Python source tree for making a patch: it fixes trailing whitespace in all modified `.py` files, checks whether the documentation has been
changed, and reports whether the Misc/ACKS and Misc/NEWS files have been updated. (Contributed by Brett Cannon.)

Another new target, “make profile-opt”, compiles a Python binary using GCC’s profile-guided optimization. It compiles Python with profiling enabled, runs the test suite to obtain a set of profiling results, and then compiles using these results for optimization. (Contributed by Gregory P. Smith.)

Port-Specific Changes: Windows

- The support for Windows 95, 98, ME and NT4 has been dropped. Python 2.6 requires at least Windows 2000 SP4.

- The new default compiler on Windows is Visual Studio 2008 (version 9.0). The build directories for Visual Studio 2003 (version 7.1) and 2005 (version 8.0) were moved into the PC/ directory. The new PCbuild directory supports cross compilation for X64, debug builds and Profile Guided Optimization (PGO). PGO builds are roughly 10% faster than normal builds. (Contributed by Christian Heimes with help from Amaury Forgeot d’Arc and Martin von Löwis.)

- The msvcr90 module now supports both the normal and wide char variants of the console I/O API. The getwch() function reads a keypress and returns a Unicode value, as does the getwche() function. The putwch() function takes a Unicode character and writes it to the console. (Contributed by Christian Heimes.)

- os.path.expandvars() will now expand environment variables in the form “%var%”, and “~user” will be expanded into the user’s home directory path. (Contributed by Josiah Carlson;
The socket module's socket objects now have an ioctl() method that provides a limited interface to the WSAIoctl() system interface.

The _winreg module now has a function, ExpandEnvironmentStrings(), that expands environment variable references such as %NAME% in an input string. The handle objects provided by this module now support the context protocol, so they can be used in with statements. (Contributed by Christian Heimes.)

_winreg also has better support for x64 systems, exposing the DisableReflectionKey(), EnableReflectionKey(), and QueryReflectionKey() functions, which enable and disable registry reflection for 32-bit processes running on 64-bit systems. (issue 1753245)

The msilib module's Record object gained GetInteger() and GetString() methods that return field values as an integer or a string. (Contributed by Floris Bruynooghe; issue 2125.)

Port-Specific Changes: Mac OS X

When compiling a framework build of Python, you can now specify the framework name to be used by providing the --with-framework-name= option to the configure script.

The macfs module has been removed. This in turn required the macostools.touched() function to be removed because it depended on the macfs module. (issue 1490190)

Many other Mac OS modules have been deprecated and will
removed in Python 3.0: _builtinSuites, aepack, aetools, aetypes, applesingle, appletrawmain, appletrunner, argvemulator, Audio_mac, autoGIL, Carbon, cfmfile, CodeWarrior, ColorPicker, EasyDialogs, Explorer, Finder, FrameWork, findertools, ic, icglue, icopen, macerrors, MacOS, macfs, macostools, macresource, MiniAEFrame, Nav, Netscape, OSA Terminology, pimp, PixMapWrapper, StdSuites, SystemEvents, Terminal, and terminalcommand.

**Port-Specific Changes: IRIX**

A number of old IRIX-specific modules were deprecated and will be removed in Python 3.0: a1 and AL, cd, cddb, cdplayer, CL and cl, DEVICE, ERRNO, FILE, FL and fl, flp, fm, GET, GLWS, GL and gl, IN, IOCTL, jpeg, panelparser, readcd, SV and sv, torgb, videoreader, and WAIT.
Porting to Python 2.6

This section lists previously described changes and other bugfixes that may require changes to your code:

- Classes that aren’t supposed to be hashable should set `__hash__ = None` in their definitions to indicate the fact.

- String exceptions have been removed. Attempting to use them raises a `TypeError`.

- The `__init__()` method of `collections.deque` now clears any existing contents of the deque before adding elements from the iterable. This change makes the behavior match `list.__init__()`. 

- `object.__init__()` previously accepted arbitrary arguments and keyword arguments, ignoring them. In Python 2.6, this is no longer allowed and will result in a `TypeError`. This will affect `__init__()` methods that end up calling the corresponding method on `object` (perhaps through using `super()`). See issue 1683368 for discussion.

- The Decimal constructor now accepts leading and trailing whitespace when passed a string. Previously it would raise an `InvalidOperation` exception. On the other hand, the `create_decimal()` method of Context objects now explicitly disallows extra whitespace, raising a `ConversionSyntax` exception.

- Due to an implementation accident, if you passed a file path to the built-in `__import__()` function, it would actually import the
specified file. This was never intended to work, however, and the implementation now explicitly checks for this case and raises an ImportError.

- C API: the PyImport_Import() and PyImport_ImportModule() functions now default to absolute imports, not relative imports. This will affect C extensions that import other modules.

- C API: extension data types that shouldn't be hashable should define their tp_hash slot to PyObject_HashNotImplemented().

- The socket module exception socket.error now inherits from IOError. Previously it wasn't a subclass of StandardError but now it is, through IOError. (Implemented by Gregory P. Smith; issue 1706815.)

- The xmlrpclib module no longer automatically converts datetime.date and datetime.time to the xmlrpclib.DateTime type; the conversion semantics were not necessarily correct for all applications. Code using xmlrpclib should convert date and time instances. (issue 1330538)

- (3.0-warning mode) The Exception class now warns when accessed using slicing or index access; having Exception behave like a tuple is being phased out.

- (3.0-warning mode) Inequality comparisons between two dictionaries or two objects that don't implement comparison methods are reported as warnings. dict1 == dict2 still works, but dict1 < dict2 is being phased out.
Comparisons between cells, which are an implementation detail of Python’s scoping rules, also cause warnings because such comparisons are forbidden entirely in 3.0.

What’s New in Python 2.5

Author: A.M. Kuchling

This article explains the new features in Python 2.5. The final release of Python 2.5 is scheduled for August 2006; PEP 356 describes the planned release schedule.

The changes in Python 2.5 are an interesting mix of language and library improvements. The library enhancements will be more important to Python’s user community, I think, because several widely-useful packages were added. New modules include ElementTree for XML processing (xml.etree), the SQLite database module (sqlite), and the ctypes module for calling C functions.

The language changes are of middling significance. Some pleasant new features were added, but most of them aren’t features that you’ll use every day. Conditional expressions were finally added to the language using a novel syntax; see section PEP 308: Conditional Expressions. The new ‘with’ statement will make writing cleanup code easier (section PEP 343: The ‘with’ statement). Values can now be passed into generators (section PEP 342: New Generator Features). Imports are now visible as either absolute or relative (section PEP 328: Absolute and Relative Imports). Some corner cases of exception handling are handled better (section PEP 341: Unified try/except/finally). All these improvements are worthwhile, but they’re improvements to one specific language feature or another; none of them are broad modifications to Python’s semantics.

As well as the language and library additions, other improvements and bugfixes were made throughout the source tree. A search through the
SVN change logs finds there were 353 patches applied and 458 bugs fixed between Python 2.4 and 2.5. (Both figures are likely to be underestimates.)

This article doesn’t try to be a complete specification of the new features; instead changes are briefly introduced using helpful examples. For full details, you should always refer to the documentation for Python 2.5 at http://docs.python.org. If you want to understand the complete implementation and design rationale, refer to the PEP for a particular new feature.

Comments, suggestions, and error reports for this document are welcome; please e-mail them to the author or open a bug in the Python bug tracker.
PEP 308: Conditional Expressions

For a long time, people have been requesting a way to write conditional expressions, which are expressions that return value A or value B depending on whether a Boolean value is true or false. A conditional expression lets you write a single assignment statement that has the same effect as the following:

```python
if condition:
    x = true_value
else:
    x = false_value
```

There have been endless tedious discussions of syntax on both python-dev and comp.lang.python. A vote was even held that found the majority of voters wanted conditional expressions in some form, but there was no syntax that was preferred by a clear majority. Candidates included C’s `cond ? true_v : false_v`, `if cond then true_v else false_v`, and 16 other variations.

Guido van Rossum eventually chose a surprising syntax:

```python
x = true_value if condition else false_value
```

Evaluation is still lazy as in existing Boolean expressions, so the order of evaluation jumps around a bit. The `condition` expression in the middle is evaluated first, and the `true_value` expression is evaluated only if the condition was true. Similarly, the `false_value` expression is only evaluated when the condition is false.

This syntax may seem strange and backwards; why does the condition go in the middle of the expression, and not in the front as in C’s `c ? x`
The decision was checked by applying the new syntax to the modules in the standard library and seeing how the resulting code read. In many cases where a conditional expression is used, one value seems to be the ‘common case’ and one value is an ‘exceptional case’, used only on rarer occasions when the condition isn’t met. The conditional syntax makes this pattern a bit more obvious:

```
contents = ((doc + '\n') if doc else '')
```

I read the above statement as meaning “here contents is usually assigned a value of doc+'\n'; sometimes doc is empty, in which special case an empty string is returned.” I doubt I will use conditional expressions very often where there isn’t a clear common and uncommon case.

There was some discussion of whether the language should require surrounding conditional expressions with parentheses. The decision was made to not require parentheses in the Python language’s grammar, but as a matter of style I think you should always use them. Consider these two statements:

```
# First version -- no parens
level = 1 if logging else 0

# Second version -- with parens
level = (1 if logging else 0)
```

In the first version, I think a reader’s eye might group the statement into ‘level = 1’, ‘if logging’, ‘else 0’, and think that the condition decides whether the assignment to level is performed. The second version reads better, in my opinion, because it makes it clear that the assignment is always performed and the choice is being made between two values.
Another reason for including the brackets: a few odd combinations of list comprehensions and lambdas could look like incorrect conditional expressions. See PEP 308 for some examples. If you put parentheses around your conditional expressions, you won’t run into this case.

**PEP 308 - Conditional Expressions**
PEP written by Guido van Rossum and Raymond D. Hettinger; implemented by Thomas Wouters.
PEP 309: Partial Function Application

The **functools** module is intended to contain tools for functional-style programming.

One useful tool in this module is the `partial()` function. For programs written in a functional style, you'll sometimes want to construct variants of existing functions that have some of the parameters filled in. Consider a Python function \( f(a, b, c) \); you could create a new function \( g(b, c) \) that was equivalent to \( f(1, b, c) \). This is called “partial function application”.

`partial()` takes the arguments \((function, \text{arg1, arg2, ... kwarg1=value1, kwarg2=value2})\). The resulting object is callable, so you can just call it to invoke \( function \) with the filled-in arguments.

Here’s a small but realistic example:

```python
import functools

def log(message, subsystem):
    "Write the contents of 'message' to the specified subsystem."
    print '%s: %s' % (subsystem, message)
...

server_log = functools.partial(log, subsystem='server')
server_log('Unable to open socket')
```

Here’s another example, from a program that uses PyGTK. Here a context-sensitive pop-up menu is being constructed dynamically. The callback provided for the menu option is a partially applied version of
the open_item() method, where the first argument has been provided.

```python
class Application:
    def open_item(self, path):
        ...
    def init (self):
        open_func = functools.partial(self.open_item)
        popup_menu.append( ("Open", open_func, 1) )
```

Another function in the `functools` module is the `update_wrapper(wrapper, wrapped)` function that helps you write well-behaved decorators. `update_wrapper()` copies the name, module, and docstring attribute to a wrapper function so that tracebacks inside the wrapped function are easier to understand. For example, you might write:

```python
def my_decorator(f):
    def wrapper(*args, **kwd):
        print 'Calling decorated function'
        return f(*args, **kwd)
    functools.update_wrapper(wrapper, f)
    return wrapper
```

`wraps()` is a decorator that can be used inside your own decorators to copy the wrapped function’s information. An alternate version of the previous example would be:

```python
def my_decorator(f):
    @functools.wraps(f)
    def wrapper(*args, **kwd):
        print 'Calling decorated function'
        return f(*args, **kwd)
```
See also:

**PEP 309 - Partial Function Application**

PEP proposed and written by Peter Harris; implemented by Hye-Shik Chang and Nick Coghlan, with adaptations by Raymond Hettinger.
Some simple dependency support was added to Distutils. The `setup()` function now has `requires`, `provides`, and `obsoletes` keyword parameters. When you build a source distribution using the `sdist` command, the dependency information will be recorded in the `PKG-INFO` file.

Another new keyword parameter is `download_url`, which should be set to a URL for the package’s source code. This means it’s now possible to look up an entry in the package index, determine the dependencies for a package, and download the required packages.

```python
VERSION = '1.0'
setup(name='PyPackage',
      version=VERSION,
      requires=['numarray', 'zlib (>=1.1.4)'],
      obsoletes=['OldPackage'],
      download_url=('http://www.example.com/pypackage
                   % VERSION'),
      )
```

Another new enhancement to the Python package index at `http://cheeseshop.python.org` is storing source and binary archives for a package. The new `upload` Distutils command will upload a package to the repository.

Before a package can be uploaded, you must be able to build a distribution using the `sdist` Distutils command. Once that works, you can run `python setup.py upload` to add your package to the
PyPI archive. Optionally you can GPG-sign the package by supplying the --sign and --identity options.

Package uploading was implemented by Martin von Löwis and Richard Jones.

**PEP 314 - Metadata for Python Software Packages v1.1**

PEP proposed and written by A.M. Kuchling, Richard Jones, and Fred Drake; implemented by Richard Jones and Fred Drake.
PEP 328: Absolute and Relative Imports

The simpler part of PEP 328 was implemented in Python 2.4: parentheses could now be used to enclose the names imported from a module using the `from ... import ...` statement, making it easier to import many different names.

The more complicated part has been implemented in Python 2.5: importing a module can be specified to use absolute or package-relative imports. The plan is to move toward making absolute imports the default in future versions of Python.

Let's say you have a package directory like this:

```
pkg/
pkg/__init__.py
pkg/main.py
pkg/string.py
```

This defines a package named `pkg` containing the `pkg.main` and `pkg.string` submodules.

Consider the code in the `main.py` module. What happens if it executes the statement `import string`? In Python 2.4 and earlier, it will first look in the package's directory to perform a relative import, finds `pkg/string.py`, imports the contents of that file as the `pkg.string` module, and that module is bound to the name `string` in the `pkg.main` module's namespace.

That's fine if `pkg.string` was what you wanted. But what if you wanted Python's standard `string` module? There's no clean way to ignore `pkg.string` and look for the standard module; generally you
had to look at the contents of `sys.modules`, which is slightly unclean. Holger Krekel's `py.std` package provides a tidier way to perform imports from the standard library, `import py; py.std.string.join()`, but that package isn't available on all Python installations.

Reading code which relies on relative imports is also less clear, because a reader may be confused about which module, `string` or `pkg.string`, is intended to be used. Python users soon learned not to duplicate the names of standard library modules in the names of their packages' submodules, but you can't protect against having your submodule's name being used for a new module added in a future version of Python.

In Python 2.5, you can switch `import`'s behaviour to absolute imports using a `from __future__ import absolute_import` directive. This absolute- import behaviour will become the default in a future version (probably Python 2.7). Once absolute imports are the default, `import string` will always find the standard library's version. It's suggested that users should begin using absolute imports as much as possible, so it's preferable to begin writing `from pkg import string` in your code.

Relative imports are still possible by adding a leading period to the module name when using the `from ... import` form:

```python
# Import names from pkg.string
from .string import name1, name2
# Import pkg.string
from . import string
```

This imports the `string` module relative to the current package, so in
pkg.main this will import name1 and name2 from pkg.string. Additional leading periods perform the relative import starting from the parent of the current package. For example, code in the A.B.C module can do:

```python
from . import D  # Imports A.B.D
from .. import E  # Imports A.E
from ..F import G  # Imports A.F.G
```

Leading periods cannot be used with the `import modname` form of the import statement, only the `from ... import` form.

**PEP 328 - Imports: Multi-Line and Absolute/Relative**

PEP written by Aahz; implemented by Thomas Wouters.

[http://codespeak.net/py/current/doc/index.html](http://codespeak.net/py/current/doc/index.html)

The py library by Holger Krekel, which contains the py.std package.
PEP 338: Executing Modules as Scripts

The `-m` switch added in Python 2.4 to execute a module as a script gained a few more abilities. Instead of being implemented in C code inside the Python interpreter, the switch now uses an implementation in a new module, `runpy`.

The `runpy` module implements a more sophisticated import mechanism so that it's now possible to run modules in a package such as `pychecker.checker`. The module also supports alternative import mechanisms such as the `zipimport` module. This means you can add a .zip archive's path to `sys.path` and then use the `-m` switch to execute code from the archive.

See also:

**PEP 338 - Executing modules as scripts**

PEP written and implemented by Nick Coghlan.
PEP 341: Unified try/except/finally

Until Python 2.5, the `try` statement came in two flavours. You could use a `finally` block to ensure that code is always executed, or one or more `except` blocks to catch specific exceptions. You couldn’t combine both `except` blocks and a `finally` block, because generating the right bytecode for the combined version was complicated and it wasn’t clear what the semantics of the combined statement should be.

Guido van Rossum spent some time working with Java, which does support the equivalent of combining `except` blocks and a `finally` block, and this clarified what the statement should mean. In Python 2.5, you can now write:

```python
try:
    block-1 ...
except Exception1:
    handler-1 ...
except Exception2:
    handler-2 ...
else:
    else-block
finally:
    final-block
```

The code in `block-1` is executed. If the code raises an exception, the various `except` blocks are tested: if the exception is of class `Exception1`, `handler-1` is executed; otherwise if it’s of class `Exception2`, `handler-2` is executed, and so forth. If no exception is raised, the `else-block` is executed.
No matter what happened previously, the final-block is executed once the code block is complete and any raised exceptions handled. Even if there's an error in an exception handler or the else-block and a new exception is raised, the code in the final-block is still run.

**PEP 341 - Unifying try-except and try-finally**

PEP written by Georg Brandl; implementation by Thomas Lee.
PEP 342: New Generator Features

Python 2.5 adds a simple way to pass values into a generator. As introduced in Python 2.3, generators only produce output; once a generator's code was invoked to create an iterator, there was no way to pass any new information into the function when its execution is resumed. Sometimes the ability to pass in some information would be useful. Hackish solutions to this include making the generator's code look at a global variable and then changing the global variable's value, or passing in some mutable object that callers then modify.

To refresh your memory of basic generators, here’s a simple example:

```python
def counter (maximum):
    i = 0
    while i < maximum:
        yield i
        i += 1
```

When you call `counter(10)`, the result is an iterator that returns the values from 0 up to 9. On encountering the `yield` statement, the iterator returns the provided value and suspends the function's execution, preserving the local variables. Execution resumes on the following call to the iterator's `next()` method, picking up after the `yield` statement.

In Python 2.3, `yield` was a statement; it didn’t return any value. In 2.5, `yield` is now an expression, returning a value that can be assigned to a variable or otherwise operated on:

```python
val = (yield i)
```
I recommend that you always put parentheses around a `yield` expression when you’re doing something with the returned value, as in the above example. The parentheses aren’t always necessary, but it’s easier to always add them instead of having to remember when they’re needed.

(PEP 342 explains the exact rules, which are that a `yield`-expression must always be parenthesized except when it occurs at the top-level expression on the right-hand side of an assignment. This means you can write `val = yield i` but have to use parentheses when there’s an operation, as in `val = (yield i) + 12`.)

Values are sent into a generator by calling its `send(value)` method. The generator’s code is then resumed and the `yield` expression returns the specified `value`. If the regular `next()` method is called, the `yield` returns `None`.

Here’s the previous example, modified to allow changing the value of the internal counter.

```python
def counter (maximum):
    i = 0
    while i < maximum:
        val = (yield i)
        # If value provided, change counter
        if val is not None:
            i = val
        else:
            i += 1
```

And here’s an example of changing the counter:

```python
>>> it = counter(10)
>>> print it.next()
```
yield will usually return None, so you should always check for this case. Don't just use its value in expressions unless you’re sure that the send() method will be the only method used to resume your generator function.

In addition to send(), there are two other new methods on generators:

- **throw(type, value=None, traceback=None)** is used to raise an exception inside the generator; the exception is raised by the yield expression where the generator’s execution is paused.

- **close()** raises a new GeneratorExit exception inside the generator to terminate the iteration. On receiving this exception, the generator’s code must either raise GeneratorExit or StopIteration. Catching the GeneratorExit exception and returning a value is illegal and will trigger a RuntimeWarning; if the function raises some other exception, that exception is propagated to the caller. close() will also be called by Python’s garbage collector when the generator is garbage-collected.
If you need to run cleanup code when a `GeneratorExit` occurs, I suggest using a `try: ... finally:` suite instead of catching `GeneratorExit`.

The cumulative effect of these changes is to turn generators from one-way producers of information into both producers and consumers.

Generators also become *coroutines*, a more generalized form of subroutines. Subroutines are entered at one point and exited at another point (the top of the function, and a `return` statement), but coroutines can be entered, exited, and resumed at many different points (the `yield` statements). We'll have to figure out patterns for using coroutines effectively in Python.

The addition of the `close()` method has one side effect that isn't obvious. `close()` is called when a generator is garbage-collected, so this means the generator's code gets one last chance to run before the generator is destroyed. This last chance means that `try...finally` statements in generators can now be guaranteed to work; the `finally` clause will now always get a chance to run. The syntactic restriction that you couldn't mix `yield` statements with a `try...finally` suite has therefore been removed. This seems like a minor bit of language trivia, but using generators and `try...finally` is actually necessary in order to implement the `with` statement described by PEP 343. I'll look at this new statement in the following section.

Another even more esoteric effect of this change: previously, the `gi_frame` attribute of a generator was always a frame object. It's now possible for `gi_frame` to be `None` once the generator has been exhausted.

**PEP 342 - Coroutines via Enhanced Generators**
PEP written by Guido van Rossum and Phillip J. Eby; implemented by Phillip J. Eby. Includes examples of some fancier uses of generators as coroutines.
Earlier versions of these features were proposed in **PEP 288** by Raymond Hettinger and **PEP 325** by Samuele Pedroni.

The Wikipedia entry for coroutines.

[http://www.sidhe.org/~dan/blog/archives/000178.html](http://www.sidhe.org/~dan/blog/archives/000178.html)
An explanation of coroutines from a Perl point of view, written by Dan Sugalski.
PEP 343: The ‘with’ statement

The ‘with’ statement clarifies code that previously would use try...finally blocks to ensure that clean-up code is executed. In this section, I'll discuss the statement as it will commonly be used. In the next section, I'll examine the implementation details and show how to write objects for use with this statement.

The ‘with’ statement is a new control-flow structure whose basic structure is:

```python
with expression [as variable]:
   with-block
```

The expression is evaluated, and it should result in an object that supports the context management protocol (that is, has `__enter__()` and `__exit__()` methods.

The object's `__enter__()` is called before `with-block` is executed and therefore can run set-up code. It also may return a value that is bound to the name `variable`, if given. (Note carefully that `variable` is not assigned the result of `expression`.)

After execution of the `with-block` is finished, the object's `__exit__()` method is called, even if the block raised an exception, and can therefore run clean-up code.

To enable the statement in Python 2.5, you need to add the following directive to your module:

```python
from __future__ import with_statement
```
The statement will always be enabled in Python 2.6.

Some standard Python objects now support the context management protocol and can be used with the `with` statement. File objects are one example:

```python
with open('/etc/passwd', 'r') as f:
    for line in f:
        print line
    ... more processing code ...
```

After this statement has executed, the file object in `f` will have been automatically closed, even if the `for` loop raised an exception part-way through the block.

**Note:** In this case, `f` is the same object created by `open()`, because `file.__enter__()` returns `self`.

The `threading` module’s locks and condition variables also support the `with` statement:

```python
lock = threading.Lock()
with lock:
    # Critical section of code
    ...
```

The lock is acquired before the block is executed and always released once the block is complete.

The new `localcontext()` function in the `decimal` module makes it easy to save and restore the current decimal context, which encapsulates the desired precision and rounding characteristics for computations:
from decimal import Decimal, Context, localcontext

# Displays with default precision of 28 digits
v = Decimal('578')
print v.sqrt()

with localcontext(Context(prec=16)):
    # All code in this block uses a precision of 16
    # The original context is restored on exiting the block.
    print v.sqrt()

Writing Context Managers

Under the hood, the 'with' statement is fairly complicated. Most people will only use 'with' in company with existing objects and don't need to know these details, so you can skip the rest of this section if you like. Authors of new objects will need to understand the details of the underlying implementation and should keep reading.

A high-level explanation of the context management protocol is:

- The expression is evaluated and should result in an object called a “context manager”. The context manager must have __enter__() and __exit__() methods.
- The context manager’s __enter__() method is called. The value returned is assigned to VAR. If no 'as VAR' clause is present, the value is simply discarded.
- The code in BLOCK is executed.
- If BLOCK raises an exception, the __exit__(type, value, traceback) is called with the exception details, the same values returned by sys.exc_info(). The method’s return value controls whether the exception is re-raised: any false value re-raises the exception, and True will result in suppressing it. You'll
only rarely want to suppress the exception, because if you do the author of the code containing the 'with' statement will never realize anything went wrong.

- If BLOCK didn't raise an exception, the __exit__() method is still called, but type, value, and traceback are all None.

Let's think through an example. I won't present detailed code but will only sketch the methods necessary for a database that supports transactions.

(For people unfamiliar with database terminology: a set of changes to the database are grouped into a transaction. Transactions can be either committed, meaning that all the changes are written into the database, or rolled back, meaning that the changes are all discarded and the database is unchanged. See any database textbook for more information.)

Let's assume there's an object representing a database connection. Our goal will be to let the user write code like this:

```python
db_connection = DatabaseConnection()
with db_connection as cursor:
    cursor.execute('insert into ...')
    cursor.execute('delete from ...')
    # ... more operations ...
```

The transaction should be committed if the code in the block runs flawlessly or rolled back if there's an exception. Here's the basic interface for DatabaseConnection that I'll assume:

```python
class DatabaseConnection:
    # Database interface
    def cursor (self):
        """Returns a cursor object and starts a new tr""
```
The `__enter__()` method is pretty easy, having only to start a new transaction. For this application the resulting cursor object would be a useful result, so the method will return it. The user can then add as `cursor` to their `with` statement to bind the cursor to a variable name.

```python
class DatabaseConnection:
    ...
    def __enter__(self):
        # Code to start a new transaction
        cursor = self.cursor()
        return cursor
```

The `__exit__()` method is the most complicated because it’s where most of the work has to be done. The method has to check if an exception occurred. If there was no exception, the transaction is committed. The transaction is rolled back if there was an exception.

In the code below, execution will just fall off the end of the function, returning the default value of `None`. `None` is false, so the exception will be re-raised automatically. If you wished, you could be more explicit and add a `return` statement at the marked location.

```python
class DatabaseConnection:
    ...
    def __exit__(self, type, value, tb):
        if tb is None:
            # No exception, so commit
            self.commit()
```
else:
    # Exception occurred, so rollback.
    self.rollback()
    # return False

The contextlib module

The new contextlib module provides some functions and a decorator that are useful for writing objects for use with the ‘with’ statement.

The decorator is called contextmanager(), and lets you write a single generator function instead of defining a new class. The generator should yield exactly one value. The code up to the yield will be executed as the __enter__() method, and the value yielded will be the method’s return value that will get bound to the variable in the ‘with’ statement’s as clause, if any. The code after the yield will be executed in the __exit__() method. Any exception raised in the block will be raised by the yield statement.

Our database example from the previous section could be written using this decorator as:

```python
from contextlib import contextmanager

def db_transaction(connection):
    cursor = connection.cursor()
    try:
        yield cursor
    except:
        connection.rollback()
    raise
```
else:
    connection.commit()

db = DatabaseConnection()
with db_transaction(db) as cursor:
    ...

The `contextlib` module also has a `nested(mgr1, mgr2, ...)` function that combines a number of context managers so you don't need to write nested `with` statements. In this example, the single `with` statement both starts a database transaction and acquires a thread lock:

```python
lock = threading.Lock()
with nested (db_transaction(db), lock) as (cursor, l
    ...
```

Finally, the `closing(object)` function returns `object` so that it can be bound to a variable, and calls `object.close` at the end of the block.

```python
import urllib, sys
from contextlib import closing

with closing(urllib.urlopen('http://www.yahoo.com'))
    for line in f:
        sys.stdout.write(line)
```

**PEP 343 - The “with” statement**

PEP written by Guido van Rossum and Nick Coghlan; implemented by Mike Bland, Guido van Rossum, and Neal
Norwitz. The PEP shows the code generated for a 'with' statement, which can be helpful in learning how the statement works.

The documentation for the `contextlib` module.
PEP 352: Exceptions as New-Style Classes

Exception classes can now be new-style classes, not just classic classes, and the built-in Exception class and all the standard built-in exceptions (NameError, ValueError, etc.) are now new-style classes.

The inheritance hierarchy for exceptions has been rearranged a bit. In 2.5, the inheritance relationships are:

```
BaseException       # New in Python 2.5
<table>
<thead>
<tr>
<th></th>
</tr>
</thead>
<tbody>
<tr>
<td></td>
</tr>
<tr>
<td>- KeyboardInterrupt</td>
</tr>
<tr>
<td>- SystemExit</td>
</tr>
<tr>
<td>- Exception</td>
</tr>
<tr>
<td></td>
</tr>
<tr>
<td></td>
</tr>
<tr>
<td>- (all other current built-in exceptions)</td>
</tr>
</tbody>
</table>
```

This rearrangement was done because people often want to catch all exceptions that indicate program errors. KeyboardInterrupt and SystemExit aren’t errors, though, and usually represent an explicit action such as the user hitting Control-C or code calling sys.exit(). A bare except: will catch all exceptions, so you commonly need to list KeyboardInterrupt and SystemExit in order to re-raise them. The usual pattern is:

```
try:
    ...
except (KeyboardInterrupt, SystemExit):
    raise
except:
    # Log error...
    # Continue running program...
```
In Python 2.5, you can now write `except Exception` to achieve the same result, catching all the exceptions that usually indicate errors but leaving `KeyboardInterrupt` and `SystemExit` alone. As in previous versions, a bare `except:` still catches all exceptions.

The goal for Python 3.0 is to require any class raised as an exception to derive from `BaseException` or some descendant of `BaseException`, and future releases in the Python 2.x series may begin to enforce this constraint. Therefore, I suggest you begin making all your exception classes derive from `Exception` now. It's been suggested that the bare `except:` form should be removed in Python 3.0, but Guido van Rossum hasn't decided whether to do this or not.

Raising of strings as exceptions, as in the statement `raise "Error occurred"`, is deprecated in Python 2.5 and will trigger a warning. The aim is to be able to remove the string-exception feature in a few releases.

**See also:**

**PEP 352 - Required Superclass for Exceptions**

PEP written by Brett Cannon and Guido van Rossum; implemented by Brett Cannon.
PEP 353: Using ssize_t as the index type

A wide-ranging change to Python’s C API, using a new Py_ssize_t type definition instead of int, will permit the interpreter to handle more data on 64-bit platforms. This change doesn’t affect Python’s capacity on 32-bit platforms.

Various pieces of the Python interpreter used C’s int type to store sizes or counts; for example, the number of items in a list or tuple were stored in an int. The C compilers for most 64-bit platforms still define int as a 32-bit type, so that meant that lists could only hold up to $2^{31} - 1 = 2147483647$ items. (There are actually a few different programming models that 64-bit C compilers can use – see http://www.unix.org/version2/whatsnew/lp64_wp.html for a discussion – but the most commonly available model leaves int as 32 bits.)

A limit of 2147483647 items doesn’t really matter on a 32-bit platform because you’ll run out of memory before hitting the length limit. Each list item requires space for a pointer, which is 4 bytes, plus space for a PyObject representing the item. 2147483647*4 is already more bytes than a 32-bit address space can contain.

It’s possible to address that much memory on a 64-bit platform, however. The pointers for a list that size would only require 16 GiB of space, so it’s not unreasonable that Python programmers might construct lists that large. Therefore, the Python interpreter had to be changed to use some type other than int, and this will be a 64-bit type on 64-bit platforms. The change will cause incompatibilities on 64-bit machines, so it was deemed worth making the transition now, while the number of 64-bit users is still relatively small. (In 5 or 10 years, we may all be on 64-bit machines, and the transition would be
more painful then.)

This change most strongly affects authors of C extension modules. Python strings and container types such as lists and tuples now use `Py_ssize_t` to store their size. Functions such as `PyList_Size()` now return `Py_ssize_t`. Code in extension modules may therefore need to have some variables changed to `Py_ssize_t`.

The `PyArg_ParseTuple()` and `Py_BuildValue()` functions have a new conversion code, `n`, for `Py_ssize_t`. `PyArg_ParseTuple()`’s `s#` and `t#` still output `int` by default, but you can define the macro `PY_SSIZE_T_CLEAN` before including `Python.h` to make them return `Py_ssize_t`.

**PEP 353** has a section on conversion guidelines that extension authors should read to learn about supporting 64-bit platforms.

**See also:**

**PEP 353 - Using ssize_t as the index type**

PEP written and implemented by Martin von Löwis.
PEP 357: The ‘__index__’ method

The NumPy developers had a problem that could only be solved by adding a new special method, __index__(). When using slice notation, as in [start:stop:step], the values of the start, stop, and step indexes must all be either integers or long integers. NumPy defines a variety of specialized integer types corresponding to unsigned and signed integers of 8, 16, 32, and 64 bits, but there was no way to signal that these types could be used as slice indexes.

Slicing can’t just use the existing __int__() method because that method is also used to implement coercion to integers. If slicing used __int__(), floating-point numbers would also become legal slice indexes and that’s clearly an undesirable behaviour.

Instead, a new special method called __index__() was added. It takes no arguments and returns an integer giving the slice index to use. For example:

```python
class C:
    def __index__ (self):
        return self.value
```

The return value must be either a Python integer or long integer. The interpreter will check that the type returned is correct, and raises a TypeError if this requirement isn’t met.

A corresponding nb_index slot was added to the C-level PyNumberMethods structure to let C extensions implement this protocol. PyNumber_Index(obj) can be used in extension code to call the __index__( ) function and retrieve its result.

**PEP 357 - Allowing Any Object to be Used for Slicing**

PEP written and implemented by Travis Oliphant.
Other Language Changes

Here are all of the changes that Python 2.5 makes to the core Python language.

- The `dict` type has a new hook for letting subclasses provide a default value when a key isn’t contained in the dictionary. When a key isn’t found, the dictionary’s `__missing__(key)` method will be called. This hook is used to implement the new `defaultdict` class in the `collections` module. The following example defines a dictionary that returns zero for any missing key:

```python
class zerodict (dict):
    def __missing__ (self, key):
        return 0

d = zerodict({1:1, 2:2})
print d[1], d[2]  # Prints 1, 2
print d[3], d[4]  # Prints 0, 0
```

- Both 8-bit and Unicode strings have new `partition(sep)` and `rpartition(sep)` methods that simplify a common use case.

  The `find(S)` method is often used to get an index which is then used to slice the string and obtain the pieces that are before and after the separator. `partition(sep)` condenses this pattern into a single method call that returns a 3-tuple containing the substring before the separator, the separator itself, and the substring after the separator. If the separator isn’t found, the first element of the tuple is the entire string and the other two elements are empty. `rpartition(sep)` also returns a 3-tuple but starts searching from the end of the string; the `r` stands for ‘reverse’.
Some examples:

```python
>>> ('http://www.python.org').partition('://')
('http', '://', 'www.python.org')
>>> ('file:/usr/share/doc/index.html').partition('file:/usr/share/doc/index.html', '', '')
>>> (u'Subject: a quick question').partition(':')
(u'Subject', u':', u'a quick question')
>>> 'www.python.org'.rpartition('.')
('www.python', '.', 'org')
>>> 'www.python.org'.rpartition(':')
('', '', 'www.python.org')
```

(Implemented by Fredrik Lundh following a suggestion by Raymond Hettinger.)

- The `startswith()` and `endswith()` methods of string types now accept tuples of strings to check for.

```python
def is_image_file (filename):
    return filename.endswith(('.gif', '.jpg', '.tiff'))
```

(Implemented by Georg Brandl following a suggestion by Tom Lynn.)

- The `min()` and `max()` built-in functions gained a `key` keyword parameter analogous to the `key` argument for `sort()`. This parameter supplies a function that takes a single argument and is called for every value in the list; `min()/max()` will return the element with the smallest/largest return value from this function. For example, to find the longest string in a list, you can do:

```python
L = ['medium', 'longest', 'short']
```
# Prints 'longest'
print max(L, key=len)

# Prints 'short', because lexicographically 'short'
print max(L)

(Contributed by Steven Bethard and Raymond Hettinger.)

- Two new built-in functions, \texttt{any()} and \texttt{all()}, evaluate whether an iterator contains any true or false values. \texttt{any()} returns \texttt{True} if any value returned by the iterator is true; otherwise it will return \texttt{False}. \texttt{all()} returns \texttt{True} only if all of the values returned by the iterator evaluate as true. (Suggested by Guido van Rossum, and implemented by Raymond Hettinger.)

- The result of a class's \texttt{__hash__()} method can now be either a long integer or a regular integer. If a long integer is returned, the hash of that value is taken. In earlier versions the hash value was required to be a regular integer, but in 2.5 the \texttt{id()} built-in was changed to always return non-negative numbers, and users often seem to use \texttt{id(self)} in \texttt{__hash__()} methods (though this is discouraged).

- ASCII is now the default encoding for modules. It's now a syntax error if a module contains string literals with 8-bit characters but doesn't have an encoding declaration. In Python 2.4 this triggered a warning, not a syntax error. See \texttt{PEP 263} for how to declare a module's encoding; for example, you might add a line like this near the top of the source file:

  
  
  ```
  # -*- coding: latin1 -*-
  ``

- A new warning, \texttt{UnicodeWarning}, is triggered when you attempt
to compare a Unicode string and an 8-bit string that can’t be converted to Unicode using the default ASCII encoding. The result of the comparison is false:

```python
>>> chr(128) == unichr(128)  # Can't convert chr(128)
__main__:1: UnicodeWarning: Unicode equal comparison failed to convert both arguments to Unicode - interpreting them as being unequal
False
>>> chr(127) == unichr(127)  # chr(127) can be converted
True
```

Previously this would raise a `UnicodeDecodeError` exception, but in 2.5 this could result in puzzling problems when accessing a dictionary. If you looked up `unichr(128)` and `chr(128)` was being used as a key, you’d get a `UnicodeDecodeError` exception. Other changes in 2.5 resulted in this exception being raised instead of suppressed by the code in `dictobject.c` that implements dictionaries.

Raising an exception for such a comparison is strictly correct, but the change might have broken code, so instead `UnicodeWarning` was introduced.

(Implemented by Marc-André Lemburg.)

- One error that Python programmers sometimes make is forgetting to include an `__init__.py` module in a package directory. Debugging this mistake can be confusing, and usually requires running Python with the `-v` switch to log all the paths searched. In Python 2.5, a new `ImportWarning` warning is triggered when an import would have picked up a directory as a package but no `__init__.py` was found. This warning is silently ignored by
default; provide the -Wd option when running the Python executable to display the warning message. (Implemented by Thomas Wouters.)

- The list of base classes in a class definition can now be empty. As an example, this is now legal:

```python
class C():
    pass
```

(Implemented by Brett Cannon.)

### Interactive Interpreter Changes

In the interactive interpreter, `quit` and `exit` have long been strings so that new users get a somewhat helpful message when they try to quit:

```python
>>> quit
'Use Ctrl-D (i.e. EOF) to exit.'
```

In Python 2.5, `quit` and `exit` are now objects that still produce string representations of themselves, but are also callable. Newbies who try `quit()` or `exit()` will now exit the interpreter as they expect. (Implemented by Georg Brandl.)

The Python executable now accepts the standard long options `--help` and `--version`; on Windows, it also accepts the `/?` option for displaying a help message. (Implemented by Georg Brandl.)

### Optimizations
Several of the optimizations were developed at the NeedForSpeed sprint, an event held in Reykjavik, Iceland, from May 21–28 2006. The sprint focused on speed enhancements to the CPython implementation and was funded by EWT LLC with local support from CCP Games. Those optimizations added at this sprint are specially marked in the following list.

- When they were introduced in Python 2.4, the built-in `set` and `frozenset` types were built on top of Python’s dictionary type. In 2.5 the internal data structure has been customized for implementing sets, and as a result sets will use a third less memory and are somewhat faster. (Implemented by Raymond Hettinger.)
- The speed of some Unicode operations, such as finding substrings, string splitting, and character map encoding and decoding, has been improved. (Substring search and splitting improvements were added by Fredrik Lundh and Andrew Dalke at the NeedForSpeed sprint. Character maps were improved by Walter Dörwald and Martin von Löwis.)
- The `long(str, base)` function is now faster on long digit strings because fewer intermediate results are calculated. The peak is for strings of around 800–1000 digits where the function is 6 times faster. (Contributed by Alan McIntyre and committed at the NeedForSpeed sprint.)
- It’s now illegal to mix iterating over a file with `for line in file` and calling the file object’s `read()`/*`readline()`*/readlines()` methods. Iteration uses an internal buffer and the read*() methods don’t use that buffer. Instead they would return the data following the buffer, causing the data to appear out of order. Mixing iteration and these methods will now trigger a `ValueError` from the read*() method. (Implemented by Thomas Wouters.)
- The `struct` module now compiles structure format strings into
an internal representation and caches this representation, yielding a 20% speedup. (Contributed by Bob Ippolito at the NeedForSpeed sprint.)

- The re module got a 1 or 2% speedup by switching to Python's allocator functions instead of the system's malloc() and free(). (Contributed by Jack Diederich at the NeedForSpeed sprint.)

- The code generator’s peephole optimizer now performs simple constant folding in expressions. If you write something like \( a = 2 + 3 \), the code generator will do the arithmetic and produce code corresponding to \( a = 5 \). (Proposed and implemented by Raymond Hettinger.)

- Function calls are now faster because code objects now keep the most recently finished frame (a “zombie frame”) in an internal field of the code object, reusing it the next time the code object is invoked. (Original patch by Michael Hudson, modified by Armin Rigo and Richard Jones; committed at the NeedForSpeed sprint.) Frame objects are also slightly smaller, which may improve cache locality and reduce memory usage a bit. (Contributed by Neal Norwitz.)

- Python’s built-in exceptions are now new-style classes, a change that speeds up instantiation considerably. Exception handling in Python 2.5 is therefore about 30% faster than in 2.4. (Contributed by Richard Jones, Georg Brandl and Sean Reifschneider at the NeedForSpeed sprint.)

- Importing now caches the paths tried, recording whether they exist or not so that the interpreter makes fewer open() and stat() calls on startup. (Contributed by Martin von Löwis and Georg Brandl.)
New, Improved, and Removed Modules

The standard library received many enhancements and bug fixes in Python 2.5. Here's a partial list of the most notable changes, sorted alphabetically by module name. Consult the Misc/NEWS file in the source tree for a more complete list of changes, or look through the SVN logs for all the details.

- The **audioop** module now supports the a-LAW encoding, and the code for u-LAW encoding has been improved. (Contributed by Lars Immisch.)

- The **codecs** module gained support for incremental codecs. The codec.lookup() function now returns a CodecInfo instance instead of a tuple. CodecInfo instances behave like a 4-tuple to preserve backward compatibility but also have the attributes `encode`, `decode`, `incrementalencoder`, `incrementaldecoder`, `streamwriter`, and `streamreader`. Incremental codecs can receive input and produce output in multiple chunks; the output is the same as if the entire input was fed to the non-incremental codec. See the **codecs** module documentation for details. (Designed and implemented by Walter Dörwald.)

- The **collections** module gained a new type, `defaultdict`, that subclasses the standard `dict` type. The new type mostly behaves like a dictionary but constructs a default value when a key isn't present, automatically adding it to the dictionary for the requested key value.

  The first argument to `defaultdict`'s constructor is a factory
function that gets called whenever a key is requested but not found. This factory function receives no arguments, so you can use built-in type constructors such as `list()` or `int()`. For example, you can make an index of words based on their initial letter like this:

```python
words = """Nel mezzo del cammin di nostra vita
mi ritrovai per una selva oscura
che la diritta via era smarrita""".lower().split()

index = defaultdict(list)

for w in words:
    init_letter = w[0]
    index[init_letter].append(w)
```

Printing `index` results in the following output:

```python
defaultdict(<type 'list'>, {'c': ['cammin', 'che', 'd': ['del', 'di', 'diritta'], 'm': ['mezzo'], 'l': ['la'], 'o': ['oscura'], 'n': ['nel'], 'p': ['per'], 's': ['selva', 'smarrita'], 'r': ['ritrovai'], 'u': ['una'], 'v': ['vita']})
```

(Contributed by Guido van Rossum.)

- The deque double-ended queue type supplied by the `collections` module now has a `remove(value)` method that removes the first occurrence of `value` in the queue, raising `ValueError` if the value isn’t found. (Contributed by Raymond Hettinger.)

- New module: The `contextlib` module contains helper functions
for use with the new `with` statement. See section *The contextlib module* for more about this module.

- New module: The `cProfile` module is a C implementation of the existing `profile` module that has much lower overhead. The module's interface is the same as `profile`: you run `cProfile.run('main()')` to profile a function, can save profile data to a file, etc. It's not yet known if the Hotshot profiler, which is also written in C but doesn't match the `profile` module’s interface, will continue to be maintained in future versions of Python. (Contributed by Armin Rigo.)

Also, the `pstats` module for analyzing the data measured by the profiler now supports directing the output to any file object by supplying a `stream` argument to the `Stats` constructor. (Contributed by Skip Montanaro.)

- The `csv` module, which parses files in comma-separated value format, received several enhancements and a number of bugfixes. You can now set the maximum size in bytes of a field by calling the `csv.field_size_limit(new_limit)` function; omitting the `new_limit` argument will return the currently-set limit. The reader class now has a `line_num` attribute that counts the number of physical lines read from the source; records can span multiple physical lines, so `line_num` is not the same as the number of records read.

The CSV parser is now stricter about multi-line quoted fields. Previously, if a line ended within a quoted field without a terminating newline character, a newline would be inserted into the returned field. This behavior caused problems when reading files that contained carriage return characters within fields, so the
code was changed to return the field without inserting newlines. As a consequence, if newlines embedded within fields are important, the input should be split into lines in a manner that preserves the newline characters.

(Contributed by Skip Montanaro and Andrew McNamara.)

- The `datetime` class in the `datetime` module now has a `strptime(string, format)` method for parsing date strings, contributed by Josh Spoerri. It uses the same format characters as `time.strptime()` and `time.strftime()`:

```python
from datetime import datetime

ts = datetime.strptime('10:13:15 2006-03-07', '%H:%M:%S %Y-%m-%d')
```

- The `SequenceMatcher.get_matching_blocks()` method in the `difflib` module now guarantees to return a minimal list of blocks describing matching subsequences. Previously, the algorithm would occasionally break a block of matching elements into two list entries. (Enhancement by Tim Peters.)

- The `doctest` module gained a `SKIP` option that keeps an example from being executed at all. This is intended for code snippets that are usage examples intended for the reader and aren't actually test cases.

  An `encoding` parameter was added to the `testfile()` function and the `DocFileSuite` class to specify the file's encoding. This makes it easier to use non-ASCII characters in tests contained within a docstring. (Contributed by Bjorn Tillenius.)
- The `email` package has been updated to version 4.0. (Contributed by Barry Warsaw.)

- The `fileinput` module was made more flexible. Unicode filenames are now supported, and a `mode` parameter that defaults to "r" was added to the `input()` function to allow opening files in binary or `universal newlines` mode. Another new parameter, `openhook`, lets you use a function other than `open()` to open the input files. Once you're iterating over the set of files, the `FileInput` object's new `fileno()` returns the file descriptor for the currently opened file. (Contributed by Georg Brandl.)

- In the `gc` module, the new `get_count()` function returns a 3-tuple containing the current collection counts for the three GC generations. This is accounting information for the garbage collector; when these counts reach a specified threshold, a garbage collection sweep will be made. The existing `gc.collect()` function now takes an optional `generation` argument of 0, 1, or 2 to specify which generation to collect. (Contributed by Barry Warsaw.)

- The `nsmallest()` and `nlargest()` functions in the `heapq` module now support a `key` keyword parameter similar to the one provided by the `min()`/`max()` functions and the `sort()` methods. For example:

```python
e >>> import heapq
e >>> L = ['short', 'medium', 'longest', 'longer still']
e >>> heapq.nsmallest(2, L)  # Return two lowest elements
['longer still', 'longest']
e >>> heapq.nsmallest(2, L, key=len)  # Return two shortest elements
['short', 'medium']
```
(Contributed by Raymond Hettinger.)

- The `itertools.islice()` function now accepts None for the start and step arguments. This makes it more compatible with the attributes of slice objects, so that you can now write the following:

```python
s = slice(5)  # Create slice object
itertools.islice(iterable, s.start, s.stop, s.step)
```

(Contributed by Raymond Hettinger.)

- The `format()` function in the `locale` module has been modified and two new functions were added, `format_string()` and `currency()`.

  The `format()` function's `val` parameter could previously be a string as long as no more than one `%char` specifier appeared; now the parameter must be exactly one `%char` specifier with no surrounding text. An optional `monetary` parameter was also added which, if True, will use the locale's rules for formatting currency in placing a separator between groups of three digits.

  To format strings with multiple `%char` specifiers, use the new `format_string()` function that works like `format()` but also supports mixing `%char` specifiers with arbitrary text.

  A new `currency()` function was also added that formats a number according to the current locale's settings.

  (Contributed by Georg Brandl.)

- The `mailbox` module underwent a massive rewrite to add the capability to modify mailboxes in addition to reading them. A new
set of classes that include mbox, MH, and Maildir are used to read mailboxes, and have an `add(message)` method to add messages, `remove(key)` to remove messages, and `lock() / unlock()` to lock/unlock the mailbox. The following example converts a maildir-format mailbox into an mbox-format one:

```python
import mailbox

# 'factory=None' uses email.Message.Message as the class representing individual messages.
src = mailbox.Maildir('maildir', factory=None)
dest = mailbox.mbox('/tmp/mbox')

for msg in src:
    dest.add(msg)
```

(Contributed by Gregory K. Johnson. Funding was provided by Google's 2005 Summer of Code.)

- New module: the `msilib` module allows creating Microsoft Installer `.msi` files and CAB files. Some support for reading the `.msi` database is also included. (Contributed by Martin von Löwis.)

- The `nis` module now supports accessing domains other than the system default domain by supplying a `domain` argument to the `nis.match()` and `nis.maps()` functions. (Contributed by Ben Bell.)

- The `operator` module's `itemgetter()` and `attrgetter()` functions now support multiple fields. A call such as `operator.attrgetter('a', 'b')` will return a function that
retrieves the a and b attributes. Combining this new feature with the sort() method's key parameter lets you easily sort lists using multiple fields. (Contributed by Raymond Hettinger.)

- The optparse module was updated to version 1.5.1 of the Optik library. The OptionParser class gained an epilog attribute, a string that will be printed after the help message, and a destroy() method to break reference cycles created by the object. (Contributed by Greg Ward.)

- The os module underwent several changes. The stat_float_times variable now defaults to true, meaning that os.stat() will now return time values as floats. (This doesn't necessarily mean that os.stat() will return times that are precise to fractions of a second; not all systems support such precision.)

  Constants named os.SEEK_SET, os.SEEK_CUR, and os.SEEK_END have been added; these are the parameters to the os.lseek() function. Two new constants for locking are os.O_SHLOCK and os.O_EXLOCK.

  Two new functions, wait3() and wait4(), were added. They're similar the waitpid() function which waits for a child process to exit and returns a tuple of the process ID and its exit status, but wait3() and wait4() return additional information. wait3() doesn't take a process ID as input, so it waits for any child process to exit and returns a 3-tuple of process-id, exit-status, resource-usage as returned from the resource.getrusage() function. wait4(pid) does take a process ID. (Contributed by Chad J. Schroeder.)
On FreeBSD, the `os.stat()` function now returns times with nanosecond resolution, and the returned object now has `st_gen` and `st_birthtime`. The `st_flags` attribute is also available, if the platform supports it. (Contributed by Antti Louko and Diego Pettenò.)

- The Python debugger provided by the `pdb` module can now store lists of commands to execute when a breakpoint is reached and execution stops. Once breakpoint #1 has been created, enter `commands 1` and enter a series of commands to be executed, finishing the list with `end`. The command list can include commands that resume execution, such as `continue` or `next`. (Contributed by Grégoire Dooms.)

- The `pickle` and `cPickle` modules no longer accept a return value of `None` from the `__reduce__()` method; the method must return a tuple of arguments instead. The ability to return `None` was deprecated in Python 2.4, so this completes the removal of the feature.

- The `pkgutil` module, containing various utility functions for finding packages, was enhanced to support PEP 302’s import hooks and now also works for packages stored in ZIP-format archives. (Contributed by Phillip J. Eby.)

- The `pybench` benchmark suite by Marc-André Lemburg is now included in the `Tools/pybench` directory. The `pybench` suite is an improvement on the commonly used `pystone.py` program because `pybench` provides a more detailed measurement of the interpreter’s speed. It times particular operations such as function calls, tuple slicing, method lookups, and numeric operations, instead of performing many different operations and reducing the
result to a single number as `pystone.py` does.

- The `pyexpat` module now uses version 2.0 of the Expat parser. (Contributed by Trent Mick.)

- The `Queue` class provided by the `Queue` module gained two new methods. `join()` blocks until all items in the queue have been retrieved and all processing work on the items have been completed. Worker threads call the other new method, `task_done()`, to signal that processing for an item has been completed. (Contributed by Raymond Hettinger.)

- The old regex and `regsub` modules, which have been deprecated ever since Python 2.0, have finally been deleted. Other deleted modules: `statcache`, `tzparse`, `wrandom`.

- Also deleted: the `lib-old` directory, which includes ancient modules such as `dircmp` and `ni`, was removed. `lib-old` wasn't on the default `sys.path`, so unless your programs explicitly added the directory to `sys.path`, this removal shouldn't affect your code.

- The `rlcompleter` module is no longer dependent on importing the `readline` module and therefore now works on non-Unix platforms. (Patch from Robert Kiendl.)

- The `SimpleXMLRPCServer` and `DocXMLRPCServer` classes now have a `rpc_paths` attribute that constrains XML-RPC operations to a limited set of URL paths; the default is to allow only `'/ '` and `'/RPC2'`. Setting `rpc_paths` to `None` or an empty tuple disables this path checking.
- The **socket** module now supports AF_NETLINK sockets on Linux, thanks to a patch from Philippe Biondi. Netlink sockets are a Linux-specific mechanism for communications between a user-space process and kernel code; an introductory article about them is at [http://www.linuxjournal.com/article/7356](http://www.linuxjournal.com/article/7356). In Python code, netlink addresses are represented as a tuple of 2 integers, (pid, group_mask).

  Two new methods on socket objects, `recv_into(buffer)` and `recvfrom_into(buffer)`, store the received data in an object that supports the buffer protocol instead of returning the data as a string. This means you can put the data directly into an array or a memory-mapped file.

  Socket objects also gained `getfamily()`, `gettype()`, and `getproto()` accessor methods to retrieve the family, type, and protocol values for the socket.

- New module: the **spwd** module provides functions for accessing the shadow password database on systems that support shadow passwords.

- The **struct** is now faster because it compiles format strings into Struct objects with `pack()` and `unpack()` methods. This is similar to how the **re** module lets you create compiled regular expression objects. You can still use the module-level `pack()` and `unpack()` functions; they'll create Struct objects and cache them. Or you can use Struct instances directly:

```python
s = struct.Struct('ih3s')
data = s.pack(1972, 187, 'abc')
```
year, number, name = s.unpack(data)

You can also pack and unpack data to and from buffer objects directly using the `pack_into(buffer, offset, v1, v2, ...)` and `unpack_from(buffer, offset)` methods. This lets you store data directly into an array or a memory-mapped file.

(Struct objects were implemented by Bob Ippolito at the NeedForSpeed sprint. Support for buffer objects was added by Martin Blais, also at the NeedForSpeed sprint.)

- The Python developers switched from CVS to Subversion during the 2.5 development process. Information about the exact build version is available as the `sys.subversion` variable, a 3-tuple of `(interpreter-name, branch-name, revision-range)`. For example, at the time of writing my copy of 2.5 was reporting ('CPython', 'trunk', '45313:45315').

  This information is also available to C extensions via the `Py_GetBuildInfo()` function that returns a string of build information like this: "trunk:45355:45356M, Apr 13 2006, 07:42:19". (Contributed by Barry Warsaw.)

- Another new function, `sys._current_frames()`, returns the current stack frames for all running threads as a dictionary mapping thread identifiers to the topmost stack frame currently active in that thread at the time the function is called. (Contributed by Tim Peters.)

- The `TarFile` class in the `tarfile` module now has an `extractall()` method that extracts all members from the
archive into the current working directory. It’s also possible to set a different directory as the extraction target, and to unpack only a subset of the archive’s members.

The compression used for a tarfile opened in stream mode can now be autodetected using the mode `r|*'. (Contributed by Lars Gustäbel.)

- The **threading** module now lets you set the stack size used when new threads are created. The `stack_size([size])` function returns the currently configured stack size, and supplying the optional `size` parameter sets a new value. Not all platforms support changing the stack size, but Windows, POSIX threading, and OS/2 all do. (Contributed by Andrew MacIntyre.)

- The **unicodedata** module has been updated to use version 4.1.0 of the Unicode character database. Version 3.2.0 is required by some specifications, so it’s still available as `unicodedata.ucd_3_2_0`.

- New module: the **uuid** module generates universally unique identifiers (UUIDs) according to RFC 4122. The RFC defines several different UUID versions that are generated from a starting string, from system properties, or purely randomly. This module contains a UUID class and functions named `uuid1()`, `uuid3()`, `uuid4()`, and `uuid5()` to generate different versions of UUID. (Version 2 UUIDs are not specified in RFC 4122 and are not supported by this module.)

```python
>>> import uuid
>>> # make a UUID based on the host ID and current time
>>> uuid.uuid1()
UUID('a8098c1a-f86e-11da-bd1a-00112444be1e')
```
The `weakref` module's `WeakKeyDictionary` and `WeakValueDictionary` types gained new methods for iterating over the weak references contained in the dictionary. `iterkeyrefs()` and `keyrefs()` methods were added to `WeakKeyDictionary`, and `itervaluerefs()` and `valuerefs()` were added to `WeakValueDictionary.

(Contributed by Fred L. Drake, Jr.)

The `webbrowser` module received a number of enhancements. It's now usable as a script with `python -m webbrowser`, taking a URL as the argument; there are a number of switches to control the behaviour (`-n` for a new browser window, `-t` for a new tab). New module-level functions, `open_new()` and `open_new_tab()`, were added to support this. The module's `open()` function supports an additional feature, an `autoraise` parameter that signals whether to raise the open window when possible. A number of additional browsers were added to the supported list such as Firefox, Opera, Konqueror, and elinks.
(Contributed by Oleg Broytmann and Georg Brandl.)

- The xmlrpc library module now supports returning datetime objects for the XML-RPC date type. Supply use_datetime=True to the loads() function or the Unmarshaller class to enable this feature. (Contributed by Skip Montanaro.)

- The zipfile module now supports the ZIP64 version of the format, meaning that a .zip archive can now be larger than 4 GiB and can contain individual files larger than 4 GiB. (Contributed by Ronald Oussoren.)

- The zlib module's Compress and Decompress objects now support a copy() method that makes a copy of the object's internal state and returns a new Compress or Decompress object. (Contributed by Chris AtLee.)

The ctypes package

The ctypes package, written by Thomas Heller, has been added to the standard library. ctypes lets you call arbitrary functions in shared libraries or DLLs. Long-time users may remember the dl module, which provides functions for loading shared libraries and calling functions in them. The ctypes package is much fancier.

To load a shared library or DLL, you must create an instance of the CDLL class and provide the name or path of the shared library or DLL. Once that's done, you can call arbitrary functions by accessing them as attributes of the CDLL object.

```
import ctypes
```
```python
libc = ctypes.CDLL('libc.so.6')
result = libc.printf("Line of output\n")
```

Type constructors for the various C types are provided: `c_int()`, `c_float()`, `c_double()`, `c_char_p()` (equivalent to `char *`), and so forth. Unlike Python’s types, the C versions are all mutable; you can assign to their `value` attribute to change the wrapped value. Python integers and strings will be automatically converted to the corresponding C types, but for other types you must call the correct type constructor. (And I mean *must*; getting it wrong will often result in the interpreter crashing with a segmentation fault.)

You shouldn’t use `c_char_p()` with a Python string when the C function will be modifying the memory area, because Python strings are supposed to be immutable; breaking this rule will cause puzzling bugs. When you need a modifiable memory area, use `create_string_buffer()`:

```python
s = "this is a string"
buf = ctypes.create_string_buffer(s)
libc.strfry(buf)
```

C functions are assumed to return integers, but you can set the `restype` attribute of the function object to change this:

```python
>>> libc.atof('2.71828')
-1783957616
>>> libc.atof.restype = ctypes.c_double
>>> libc.atof('2.71828')
2.71828
```

`ctypes` also provides a wrapper for Python’s C API as the
**ctypes.pythonapi** object. This object does *not* release the global interpreter lock before calling a function, because the lock must be held when calling into the interpreter's code. There's a **py_object()** type constructor that will create a **PyObject** * pointer. A simple usage:

```python
import ctypes

d = {}
ctypes.pythonapi.PyObject_SetItem(ctypes.py_object(d),
        ctypes.py_object("abc"),  ctypes.py_object(1))
# d is now {'abc': 1}.
```

Don't forget to use **py_object()**; if it's omitted you end up with a segmentation fault.

**ctypes** has been around for a while, but people still write and distribution hand-coded extension modules because you can't rely on **ctypes** being present. Perhaps developers will begin to write Python wrappers atop a library accessed through **ctypes** instead of extension modules, now that **ctypes** is included with core Python.

[http://starship.python.net/crew/theller/ctypes/](http://starship.python.net/crew/theller/ctypes/)

  The ctypes web page, with a tutorial, reference, and FAQ.

The documentation for the **ctypes** module.

**The ElementTree package**

A subset of Fredrik Lundh's ElementTree library for processing XML
has been added to the standard library as `xml.etree`. The available modules are `ElementTree`, `ElementPath`, and `ElementInclude` from `ElementTree 1.2.6`. The `cElementTree` accelerator module is also included.

The rest of this section will provide a brief overview of using `ElementTree`. Full documentation for `ElementTree` is available at [http://effbot.org/zone/element-index.htm](http://effbot.org/zone/element-index.htm).

`ElementTree` represents an XML document as a tree of element nodes. The text content of the document is stored as the `text` and `tail` attributes of (This is one of the major differences between `ElementTree` and the Document Object Model; in the DOM there are many different types of node, including `TextNode`.)

The most commonly used parsing function is `parse()`, that takes either a string (assumed to contain a filename) or a file-like object and returns an `ElementTree` instance:

```python
from xml.etree import ElementTree as ET

tree = ET.parse('ex-1.xml')

feed = urllib.urlopen('http://planet.python.org/rss10.xml')
tree = ET.parse(feed)
```

Once you have an `ElementTree` instance, you can call its `getroot()` method to get the root `Element` node.

There's also an `XML()` function that takes a string literal and returns an `Element` node (not an `ElementTree`). This function provides a tidy way to incorporate XML fragments, approaching the convenience
of an XML literal:

```python
svg = ET.XML(""""<svg width="10px" version="1.0">
  </svg>"""")
svg.set('height', '320px')
svg.append(elem1)
```

Each XML element supports some dictionary-like and some list-like access methods. Dictionary-like operations are used to access attribute values, and list-like operations are used to access child nodes.

<table>
<thead>
<tr>
<th>Operation</th>
<th>Result</th>
</tr>
</thead>
<tbody>
<tr>
<td>elem[n]</td>
<td>Returns n’th child element.</td>
</tr>
<tr>
<td>elem[m:n]</td>
<td>Returns list of m’th through n’th child elements.</td>
</tr>
<tr>
<td>len(elem)</td>
<td>Returns number of child elements.</td>
</tr>
<tr>
<td>list(elem)</td>
<td>Returns list of child elements.</td>
</tr>
<tr>
<td>elem.append(elem2)</td>
<td>Adds elem2 as a child.</td>
</tr>
<tr>
<td>elem.insert(index, elem2)</td>
<td>Inserts elem2 at the specified location.</td>
</tr>
<tr>
<td>del elem[n]</td>
<td>Deletes n’th child element.</td>
</tr>
<tr>
<td>elem.keys()</td>
<td>Returns list of attribute names.</td>
</tr>
<tr>
<td>elem.get(name)</td>
<td>Returns value of attribute name.</td>
</tr>
<tr>
<td>elem.set(name, value)</td>
<td>Sets new value for attribute name.</td>
</tr>
<tr>
<td>elem.attrib</td>
<td>Retrieves the dictionary containing attributes.</td>
</tr>
<tr>
<td>del elem.attrib[name]</td>
<td>Deletes attribute name.</td>
</tr>
</tbody>
</table>
Comments and processing instructions are also represented as Element nodes. To check if a node is a comment or processing instructions:

```python
if elem.tag is ET.Comment:
    ...
elif elem.tag is ET.ProcessingInstruction:
    ...
```

To generate XML output, you should call the ElementTree.write() method. Like parse(), it can take either a string or a file-like object:

```python
# Encoding is US-ASCII
tree.write('output.xml')

# Encoding is UTF-8
f = open('output.xml', 'w')
tree.write(f, encoding='utf-8')
```

(Caution: the default encoding used for output is ASCII. For general XML work, where an element's name may contain arbitrary Unicode characters, ASCII isn't a very useful encoding because it will raise an exception if an element's name contains any characters with values greater than 127. Therefore, it's best to specify a different encoding such as UTF-8 that can handle any Unicode character.)

This section is only a partial description of the ElementTree interfaces. Please read the package's official documentation for more details.

Official documentation for ElementTree.
The hashlib package

A new `hashlib` module, written by Gregory P. Smith, has been added to replace the md5 and sha modules. `hashlib` adds support for additional secure hashes (SHA-224, SHA-256, SHA-384, and SHA-512). When available, the module uses OpenSSL for fast platform optimized implementations of algorithms.

The old md5 and sha modules still exist as wrappers around hashlib to preserve backwards compatibility. The new module's interface is very close to that of the old modules, but not identical. The most significant difference is that the constructor functions for creating new hashing objects are named differently.

```
# Old versions
h = md5.md5()
h = md5.new()

# New version
h = hashlib.md5()

# Old versions
h = sha.sha()
h = sha.new()

# New version
h = hashlib.sha1()

# Hash that weren't previously available
h = hashlib.sha224()
h = hashlib.sha256()
h = hashlib.sha384()
h = hashlib.sha512()
```
Once a hash object has been created, its methods are the same as before: `update(string)` hashes the specified string into the current digest state, `digest()` and `hexdigest()` return the digest value as a binary string or a string of hex digits, and `copy()` returns a new hashing object with the same digest state.

**See also:** The documentation for the `hashlib` module.

**The sqlite3 package**

The `pysqlite` module ([http://www.pysqlite.org](http://www.pysqlite.org)), a wrapper for the SQLite embedded database, has been added to the standard library under the package name `sqlite3`.

SQLite is a C library that provides a lightweight disk-based database that doesn’t require a separate server process and allows accessing the database using a nonstandard variant of the SQL query language. Some applications can use SQLite for internal data storage. It’s also possible to prototype an application using SQLite and then port the code to a larger database such as PostgreSQL or Oracle.

`pysqlite` was written by Gerhard Häring and provides a SQL interface compliant with the DB-API 2.0 specification described by PEP 249.

If you’re compiling the Python source yourself, note that the source tree doesn’t include the SQLite code, only the wrapper module. You’ll need to have the SQLite libraries and headers installed before compiling Python, and the build process will compile the module when the necessary headers are available.
To use the module, you must first create a Connection object that represents the database. Here the data will be stored in the /tmp/example file:

```python
conn = sqlite3.connect('/tmp/example')
```

You can also supply the special name :memory: to create a database in RAM.

Once you have a Connection, you can create a Cursor object and call its execute() method to perform SQL commands:

```python
c = conn.cursor()

# Create table
c.execute('''create table stocks
(date text, trans text, symbol text,
 qty real, price real)''')

# Insert a row of data
c.execute('''insert into stocks
values ('2006-01-05', 'BUY', 'RHAT', 100, 35.14)''')
```

 Usually your SQL operations will need to use values from Python variables. You shouldn’t assemble your query using Python’s string operations because doing so is insecure; it makes your program vulnerable to an SQL injection attack.

 Instead, use the DB-API’s parameter substitution. Put ? as a placeholder wherever you want to use a value, and then provide a tuple of values as the second argument to the cursor’s execute() method. (Other database modules may use a different placeholder, such as %s or :1.) For example:
To retrieve data after executing a SELECT statement, you can either treat the cursor as an iterator, call the cursor’s fetchone() method to retrieve a single matching row, or call fetchall() to get a list of the matching rows.

This example uses the iterator form:

```python
>>> c = conn.cursor()
>>> c.execute('select * from stocks order by price')
>>> for row in c:
...     print row
...
(u'2006-01-05', u'BUY', u'RHAT', 100, 35.140000000000001)
(u'2006-03-28', u'BUY', u'IBM', 1000, 45.0)
(u'2006-04-06', u'SELL', u'IBM', 500, 53.0)
(u'2006-04-05', u'BUY', u'MSOFT', 1000, 72.0)
```

   PEP written by Marc-André Lemburg.

The wsgiref package

The Web Server Gateway Interface (WSGI) v1.0 defines a standard interface between web servers and Python web applications and is described in PEP 333. The wsgiref package is a reference implementation of the WSGI specification.

The package includes a basic HTTP server that will run a WSGI application; this server is useful for debugging but isn't intended for production use. Setting up a server takes only a few lines of code:

```python
from wsgiref import simple_server

wsgi_app = ...

host = ''
port = 8000
httpd = simple_server.make_server(host, port, wsgi_app)
httpd.serve_forever()
```

**PEP 333 - Python Web Server Gateway Interface v1.0**
   PEP written by Phillip J. Eby.
Build and C API Changes

Changes to Python’s build process and to the C API include:

- The Python source tree was converted from CVS to Subversion, in a complex migration procedure that was supervised and flawlessly carried out by Martin von Löwis. The procedure was developed as PEP 347.

- Coverity, a company that markets a source code analysis tool called Prevent, provided the results of their examination of the Python source code. The analysis found about 60 bugs that were quickly fixed. Many of the bugs were refcounting problems, often occurring in error-handling code. See http://scan.coverity.com for the statistics.

- The largest change to the C API came from PEP 353, which modifies the interpreter to use a Py_ssize_t type definition instead of int. See the earlier section PEP 353: Using ssize_t as the index type for a discussion of this change.

- The design of the bytecode compiler has changed a great deal, no longer generating bytecode by traversing the parse tree. Instead the parse tree is converted to an abstract syntax tree (or AST), and it is the abstract syntax tree that’s traversed to produce the bytecode.

It’s possible for Python code to obtain AST objects by using the compile() built-in and specifying _ast.PyCF_ONLY_AST as the value of the flags parameter:

```python
from _ast import PyCF_ONLY_AST
```
```python
ast = compile("""a=0
for i in range(10):
    a += i
""", "<string>", 'exec', PyCF_ONLY_AST)

assignment = ast.body[0]
for_loop = ast.body[1]
```

No official documentation has been written for the AST code yet, but **PEP 339** discusses the design. To start learning about the code, read the definition of the various AST nodes in `Parser/Python.asdl`. A Python script reads this file and generates a set of C structure definitions in `Include/Python-ast.h`. The `PyParser_ASTFromString()` and `PyParser_ASTFromFile()`, defined in `Include/pythonrun.h`, take Python source as input and return the root of an AST representing the contents. This AST can then be turned into a code object by `PyAST_Compile()`. For more information, read the source code, and then ask questions on python-dev.

The AST code was developed under Jeremy Hylton's management, and implemented by (in alphabetical order) Brett Cannon, Nick Coghlan, Grant Edwards, John Ehresman, Kurt Kaiser, Neal Norwitz, Tim Peters, Armin Rigo, and Neil Schemenauer, plus the participants in a number of AST sprints at conferences such as PyCon.

- Evan Jones's patch to obmalloc, first described in a talk at PyCon DC 2005, was applied. Python 2.4 allocated small objects in 256K-sized arenas, but never freed arenas. With this patch, Python will free arenas when they're empty. The net effect is that on some platforms, when you allocate many objects, Python's
memory usage may actually drop when you delete them and the memory may be returned to the operating system. (Implemented by Evan Jones, and reworked by Tim Peters.)

Note that this change means extension modules must be more careful when allocating memory. Python’s API has many different functions for allocating memory that are grouped into families. For example, `PyMem_Malloc()`, `PyMem_Realloc()`, and `PyMem_Free()` are one family that allocates raw memory, while `PyObject_Malloc()`, `PyObject_Realloc()`, and `PyObject_Free()` are another family that's supposed to be used for creating Python objects.

Previously these different families all reduced to the platform's `malloc()` and `free()` functions. This meant it didn't matter if you got things wrong and allocated memory with the `PyMem()` function but freed it with the `PyObject()` function. With 2.5's changes to obmalloc, these families now do different things and mismatches will probably result in a segfault. You should carefully test your C extension modules with Python 2.5.

- The built-in set types now have an official C API. Call `PySet_New()` and `PyFrozenSet_New()` to create a new set, `PySet_Add()` and `PySet_Discard()` to add and remove elements, and `PySet_Contains()` and `PySet_Size()` to examine the set's state. (Contributed by Raymond Hettinger.)

- C code can now obtain information about the exact revision of the Python interpreter by calling the `Py_GetBuildInfo()` function that returns a string of build information like this: "trunk:45355:45356M, Apr 13 2006, 07:42:19". (Contributed by Barry Warsaw.)
Two new macros can be used to indicate C functions that are local to the current file so that a faster calling convention can be used. `Py_LOCAL(type)` declares the function as returning a value of the specified `type` and uses a fast-calling qualifier. `Py_LOCAL_INLINE(type)` does the same thing and also requests the function be inlined. If `PY_LOCAL_AGGRESSIVE()` is defined before `python.h` is included, a set of more aggressive optimizations are enabled for the module; you should benchmark the results to find out if these optimizations actually make the code faster. (Contributed by Fredrik Lundh at the NeedForSpeed sprint.)

`PyErr_NewException(name, base, dict)` can now accept a tuple of base classes as its `base` argument. (Contributed by Georg Brandl.)

The `PyErr_Warn()` function for issuing warnings is now deprecated in favour of `PyErr_WarnEx(category, message, stacklevel)` which lets you specify the number of stack frames separating this function and the caller. A `stacklevel` of 1 is the function calling `PyErr_WarnEx()`, 2 is the function above that, and so forth. (Added by Neal Norwitz.)

The CPython interpreter is still written in C, but the code can now be compiled with a C++ compiler without errors. (Implemented by Anthony Baxter, Martin von Löwis, Skip Montanaro.)

The `PyRange_New()` function was removed. It was never documented, never used in the core code, and had dangerously lax error checking. In the unlikely case that your extensions were using it, you can replace it by something like the following:
Port-Specific Changes

- MacOS X (10.3 and higher): dynamic loading of modules now uses the `dlopen()` function instead of MacOS-specific functions.
- MacOS X: an `--enable-universalsdk` switch was added to the `configure` script that compiles the interpreter as a universal binary able to run on both PowerPC and Intel processors. (Contributed by Ronald Oussoren; issue 2573.)
- Windows: `.dll` is no longer supported as a filename extension for extension modules. `.pyd` is now the only filename extension that will be searched for.
Porting to Python 2.5

This section lists previously described changes that may require changes to your code:

- ASCII is now the default encoding for modules. It's now a syntax error if a module contains string literals with 8-bit characters but doesn't have an encoding declaration. In Python 2.4 this triggered a warning, not a syntax error.
- Previously, the `gi_frame` attribute of a generator was always a frame object. Because of the [PEP 342](https://www.python.org/dev/peps/pep-0342/) changes described in section [PEP 342: New Generator Features](https://www.python.org/dev/peps/pep-0342/), it's now possible for `gi_frame` to be `None`.
- A new warning, `UnicodeWarning`, is triggered when you attempt to compare a Unicode string and an 8-bit string that can't be converted to Unicode using the default ASCII encoding. Previously such comparisons would raise a `UnicodeDecodeError` exception.
- Library: the `csv` module is now stricter about multi-line quoted fields. If your files contain newlines embedded within fields, the input should be split into lines in a manner which preserves the newline characters.
- Library: the `locale` module's `format()` function's would previously accept any string as long as no more than one `%char` specifier appeared. In Python 2.5, the argument must be exactly one `%char` specifier with no surrounding text.
- Library: The `pickle` and `cPickle` modules no longer accept a return value of `None` from the `__reduce__()` method; the method must return a tuple of arguments instead. The modules also no longer accept the deprecated `bin` keyword parameter.
- Library: The `SimpleXMLRPCServer` and `DocXMLRPCServer` classes now have a `rpc_paths` attribute that constrains XML-
RPC operations to a limited set of URL paths; the default is to allow only '/' and '/RPC2'. Setting rpc_paths to None or an empty tuple disables this path checking.

- C API: Many functions now use Py_ssize_t instead of int to allow processing more data on 64-bit machines. Extension code may need to make the same change to avoid warnings and to support 64-bit machines. See the earlier section PEP 353: Using ssize_t as the index type for a discussion of this change.

- C API: The obmalloc changes mean that you must be careful to not mix usage of the PyMem_*() and PyObject_*() families of functions. Memory allocated with one family's *_Malloc() must be freed with the corresponding family's *_Free() function.

What’s New in Python 2.4

Author: A.M. Kuchling

This article explains the new features in Python 2.4.1, released on March 30, 2005.

Python 2.4 is a medium-sized release. It doesn’t introduce as many changes as the radical Python 2.2, but introduces more features than the conservative 2.3 release. The most significant new language features are function decorators and generator expressions; most other changes are to the standard library.

According to the CVS change logs, there were 481 patches applied and 502 bugs fixed between Python 2.3 and 2.4. Both figures are likely to be underestimates.

This article doesn’t attempt to provide a complete specification of every single new feature, but instead provides a brief introduction to each feature. For full details, you should refer to the documentation for Python 2.4, such as the Python Library Reference and the Python Reference Manual. Often you will be referred to the PEP for a particular new feature for explanations of the implementation and design rationale.
PEP 218: Built-In Set Objects

Python 2.3 introduced the sets module. C implementations of set data types have now been added to the Python core as two new built-in types, \texttt{set(iterable)} and \texttt{frozenset(iterable)}. They provide high speed operations for membership testing, for eliminating duplicates from sequences, and for mathematical operations like unions, intersections, differences, and symmetric differences.

```python
>>> a = set('abracadabra')  # form a set
>>> 'z' in a  # fast membership testing
False
>>> a
set(['a', 'r', 'b', 'c', 'd'])
>>> ','.join(a)  # convert back into a string
'arbcd'

>>> b = set('alacazam')  # form a second set
>>> a - b  # letters in a but not in b
set(['r', 'd', 'b'])
>>> a | b  # letters in either a or b
set(['a', 'c', 'r', 'd', 'b', 'm', 'z', 'l'])
>>> a & b  # letters in both a and b
set(['a', 'c'])
>>> a ^ b  # letters in a or b but not both
set(['r', 'd', 'b', 'm', 'z', 'l'])

>>> a.add('z')  # add a new element
>>> a
set(['a', 'c', 'b', 'd', 'r', 'w', 'y', 'x', 'z'])
>>> a.remove('x')  # take one element out
>>> a
set(['a', 'c', 'b', 'd', 'r', 'w', 'y', 'z'])
```

---

This document is a brief overview of Python's built-in set objects, introduced in Python 2.3. It explains how to use sets for various operations such as membership testing, eliminating duplicates, and mathematical set operations like unions, intersections, differences, and symmetric differences. The example code demonstrates how to create sets, perform operations on them, and convert them back into strings.
The `frozenset()` type is an immutable version of `set()`. Since it is immutable and hashable, it may be used as a dictionary key or as a member of another set.

The `sets` module remains in the standard library, and may be useful if you wish to subclass the `Set` or `ImmutableSet` classes. There are currently no plans to deprecate the module.

Originally proposed by Greg Wilson and ultimately implemented by Raymond Hettinger.
PEP 237: Unifying Long Integers and Integers

The lengthy transition process for this PEP, begun in Python 2.2, takes another step forward in Python 2.4. In 2.3, certain integer operations that would behave differently after int/long unification triggered `FutureWarning` warnings and returned values limited to 32 or 64 bits (depending on your platform). In 2.4, these expressions no longer produce a warning and instead produce a different result that’s usually a long integer.

The problematic expressions are primarily left shifts and lengthy hexadecimal and octal constants. For example, `2 << 32` results in a warning in 2.3, evaluating to 0 on 32-bit platforms. In Python 2.4, this expression now returns the correct answer, 8589934592.

**PEP 237 - Unifying Long Integers and Integers**

Original PEP written by Moshe Zadka and GvR. The changes for 2.4 were implemented by Kalle Svensson.
PEP 289: Generator Expressions

The iterator feature introduced in Python 2.2 and the `itertools` module make it easier to write programs that loop through large data sets without having the entire data set in memory at one time. List comprehensions don’t fit into this picture very well because they produce a Python list object containing all of the items. This unavoidably pulls all of the objects into memory, which can be a problem if your data set is very large. When trying to write a functionally-styled program, it would be natural to write something like:

```python
links = [link for link in get_all_links() if not link
for link in links:
    ...
```

instead of

```python
for link in get_all_links():
    if link.followed: continue
    ...
```

The first form is more concise and perhaps more readable, but if you’re dealing with a large number of link objects you’d have to write the second form to avoid having all link objects in memory at the same time.

Generator expressions work similarly to list comprehensions but don’t materialize the entire list; instead they create a generator that will return elements one by one. The above example could be written as:

```python
links = (link for link in get_all_links() if not link
```
Generator expressions always have to be written inside parentheses, as in the above example. The parentheses signalling a function call also count, so if you want to create an iterator that will be immediately passed to a function you could write:

```python
print sum(obj.count for obj in list_all_objects())
```

Generator expressions differ from list comprehensions in various small ways. Most notably, the loop variable (obj in the above example) is not accessible outside of the generator expression. List comprehensions leave the variable assigned to its last value; future versions of Python will change this, making list comprehensions match generator expressions in this respect.

Proposed by Raymond Hettinger and implemented by Jiwon Seo with early efforts steered by Hye-Shik Chang.
PEP 292: Simpler String Substitutions

Some new classes in the standard library provide an alternative mechanism for substituting variables into strings; this style of substitution may be better for applications where untrained users need to edit templates.

The usual way of substituting variables by name is the % operator:

```
>>> '%(page)i: %(title)s' % {'page':2, 'title': 'The Best of Times'}
2: The Best of Times
```

When writing the template string, it can be easy to forget the i or s after the closing parenthesis. This isn’t a big problem if the template is in a Python module, because you run the code, get an “Unsupported format character” `ValueError`, and fix the problem. However, consider an application such as Mailman where template strings or translations are being edited by users who aren’t aware of the Python language. The format string’s syntax is complicated to explain to such users, and if they make a mistake, it’s difficult to provide helpful feedback to them.

PEP 292 adds a Template class to the `string` module that uses $ to indicate a substitution:

```
>>> import string
>>> t = string.Template('$page: $title')
>>> t.substitute({'page':2, 'title': 'The Best of Times'}
2: The Best of Times
```

If a key is missing from the dictionary, the substitute() method will
raise a `KeyError`. There’s also a `safe_substitute()` method that ignores missing keys:

```python
>>> t = string.Template('$page: $title')
>>> t.safe_substitute({'page':3})
'3: $title'
```

**PEP 292 - Simpler String Substitutions**

Written and implemented by Barry Warsaw.
PEP 318: Decorators for Functions and Methods

Python 2.2 extended Python’s object model by adding static methods and class methods, but it didn’t extend Python’s syntax to provide any new way of defining static or class methods. Instead, you had to write a `def` statement in the usual way, and pass the resulting method to a `staticmethod()` or `classmethod()` function that would wrap up the function as a method of the new type. Your code would look like this:

```python
class C:
    def meth (cls):
        ...

    meth = classmethod(meth)  # Rebind name to wrapped-up class method
```

If the method was very long, it would be easy to miss or forget the `classmethod()` invocation after the function body.

The intention was always to add some syntax to make such definitions more readable, but at the time of 2.2’s release a good syntax was not obvious. Today a good syntax still isn’t obvious but users are asking for easier access to the feature; a new syntactic feature has been added to meet this need.

The new feature is called “function decorators”. The name comes from the idea that `classmethod()`, `staticmethod()`, and friends are storing additional information on a function object; they’re *decorating* functions with more details.
The notation borrows from Java and uses the '@' character as an indicator. Using the new syntax, the example above would be written:

```python
class C:
    @classmethod
    def meth(cls):
        ...
```

The `@classmethod` is shorthand for the `meth=classmethod(meth)` assignment. More generally, if you have the following:

```python
@A
@B
@C
def f():
    ...
```

It's equivalent to the following pre-decorator code:

```python
def f(): ...
f = A(B(C(f)))
```

Decorators must come on the line before a function definition, one decorator per line, and can't be on the same line as the `def` statement, meaning that `@A def f(): ...` is illegal. You can only decorate function definitions, either at the module level or inside a class; you can't decorate class definitions.

A decorator is just a function that takes the function to be decorated as an argument and returns either the same function or some new object. The return value of the decorator need not be callable (though it typically is), unless further decorators will be applied to the result. It's
easy to write your own decorators. The following simple example just sets an attribute on the function object:

```python
def deco(func):
    ...    func.attr = 'decorated'
    ...    return func
...
>>> @deco
...    def f(): pass
...
>>> f
<function f at 0x402ef0d4>
>>> f.attr
'decorated'
```

As a slightly more realistic example, the following decorator checks that the supplied argument is an integer:

```python
def require_int(func):
    def wrapper(arg):
        assert isinstance(arg, int)
        return func(arg)

    return wrapper

@require_int
def p1(arg):
    print arg

@require_int
def p2(arg):
    print arg*2
```

An example in PEP 318 contains a fancier version of this idea that lets you both specify the required type and check the returned type.
Decorator functions can take arguments. If arguments are supplied, your decorator function is called with only those arguments and must return a new decorator function; this function must take a single function and return a function, as previously described. In other words, `@A @B @C(args)` becomes:

```
def f(): ...
    _deco = C(args)
    f = A(B(_deco(f)))
```

Getting this right can be slightly brain-bending, but it’s not too difficult.

A small related change makes the `func_name` attribute of functions writable. This attribute is used to display function names in tracebacks, so decorators should change the name of any new function that’s constructed and returned.

**PEP 318 - Decorators for Functions, Methods and Classes**

Written by Kevin D. Smith, Jim Jewett, and Skip Montanaro. Several people wrote patches implementing function decorators, but the one that was actually checked in was patch #979728, written by Mark Russell.

[http://www.python.org/moin/PythonDecoratorLibrary](http://www.python.org/moin/PythonDecoratorLibrary)

This Wiki page contains several examples of decorators.
PEP 322: Reverse Iteration

A new built-in function, `reversed(seq)`, takes a sequence and returns an iterator that loops over the elements of the sequence in reverse order.

```python
>>> for i in reversed(xrange(1,4)):
...     print i
... 3
... 2
... 1
```

Compared to extended slicing, such as `range(1,4)[::-1]`, `reversed()` is easier to read, runs faster, and uses substantially less memory.

Note that `reversed()` only accepts sequences, not arbitrary iterators. If you want to reverse an iterator, first convert it to a list with `list()`.

```python
>>> input = open('/etc/passwd', 'r')
>>> for line in reversed(list(input)):
...     print line
... root:*:0:0:System Administrator:/var/root:/bin/tcsh
```

See also:

**PEP 322 - Reverse Iteration**

Written and implemented by Raymond Hettinger.
PEP 324: New subprocess Module

The standard library provides a number of ways to execute a subprocess, offering different features and different levels of complexity. `os.system(command)` is easy to use, but slow (it runs a shell process which executes the command) and dangerous (you have to be careful about escaping the shell's metacharacters). The `popen2` module offers classes that can capture standard output and standard error from the subprocess, but the naming is confusing. The `subprocess` module cleans this up, providing a unified interface that offers all the features you might need.

Instead of `popen2`'s collection of classes, `subprocess` contains a single class called Popen whose constructor supports a number of different keyword arguments.

```python
class Popen(args, bufsize=0, executable=None, stdin=None, stdout=None, stderr=None, preexec_fn=None, close_fds=False, shell=False, cwd=None, env=None, universal_newlines=False, startupinfo=None, creationflags=0):
```

`args` is commonly a sequence of strings that will be the arguments to the program executed as the subprocess. (If the `shell` argument is true, `args` can be a string which will then be passed on to the shell for interpretation, just as `os.system()` does.)

`stdin`, `stdout`, and `stderr` specify what the subprocess’s input, output, and error streams will be. You can provide a file object or a file descriptor, or you can use the constant `subprocess.PIPE` to create a pipe between the subprocess and the parent.
The constructor has a number of handy options:

- `close_fds` requests that all file descriptors be closed before running the subprocess.
- `cwd` specifies the working directory in which the subprocess will be executed (defaulting to whatever the parent’s working directory is).
- `env` is a dictionary specifying environment variables.
- `preexec_fn` is a function that gets called before the child is started.
- `universal_newlines` opens the child’s input and output using Python’s `universal newlines` feature.

Once you’ve created the Popen instance, you can call its `wait()` method to pause until the subprocess has exited, `poll()` to check if it’s exited without pausing, or `communicate(data)` to send the string `data` to the subprocess’s standard input. `communicate(data)` then reads any data that the subprocess has sent to its standard output or standard error, returning a tuple `(stdout_data, stderr_data)`.

`call()` is a shortcut that passes its arguments along to the Popen constructor, waits for the command to complete, and returns the status code of the subprocess. It can serve as a safer analog to `os.system()`:

```python
sts = subprocess.call(['dpkg', '-i', '/tmp/new-package.deb'])
if sts == 0:
    # Success
    ...
else:
    # dpkg returned an error
    ...
```
The command is invoked without use of the shell. If you really do want to use the shell, you can add `shell=True` as a keyword argument and provide a string instead of a sequence:

```python
sts = subprocess.call('dpkg -i /tmp/new-package.deb')
```

The PEP takes various examples of shell and Python code and shows how they’d be translated into Python code that uses `subprocess`. Reading this section of the PEP is highly recommended.

**PEP 324 - subprocess - New process module**

Written and implemented by Peter Åstrand, with assistance from Fredrik Lundh and others.
PEP 327: Decimal Data Type

Python has always supported floating-point (FP) numbers, based on the underlying C double type, as a data type. However, while most programming languages provide a floating-point type, many people (even programmers) are unaware that floating-point numbers don’t represent certain decimal fractions accurately. The new Decimal type can represent these fractions accurately, up to a user-specified precision limit.

Why is Decimal needed?

The limitations arise from the representation used for floating-point numbers. FP numbers are made up of three components:

- The sign, which is positive or negative.
- The mantissa, which is a single-digit binary number followed by a fractional part. For example, 1.01 in base-2 notation is $1 + 0/2 + 1/4$, or 1.25 in decimal notation.
- The exponent, which tells where the decimal point is located in the number represented.

For example, the number 1.25 has positive sign, a mantissa value of 1.01 (in binary), and an exponent of 0 (the decimal point doesn’t need to be shifted). The number 5 has the same sign and mantissa, but the exponent is 2 because the mantissa is multiplied by 4 (2 to the power of the exponent 2); $1.25 \times 4$ equals 5.

Modern systems usually provide floating-point support that conforms to a standard called IEEE 754. C’s double type is usually implemented as a 64-bit IEEE 754 number, which uses 52 bits of space for the mantissa. This means that numbers can only be
specified to 52 bits of precision. If you’re trying to represent numbers whose expansion repeats endlessly, the expansion is cut off after 52 bits. Unfortunately, most software needs to produce output in base 10, and common fractions in base 10 are often repeating decimals in binary. For example, 1.1 decimal is binary 1.0001100110011\ldots; \ .1 = 1/16 + 1/32 + 1/256 plus an infinite number of additional terms. IEEE 754 has to chop off that infinitely repeated decimal after 52 digits, so the representation is slightly inaccurate.

Sometimes you can see this inaccuracy when the number is printed:

```python
>>> 1.1
1.1000000000000001
```

The inaccuracy isn’t always visible when you print the number because the FP-to- decimal-string conversion is provided by the C library, and most C libraries try to produce sensible output. Even if it’s not displayed, however, the inaccuracy is still there and subsequent operations can magnify the error.

For many applications this doesn’t matter. If I’m plotting points and displaying them on my monitor, the difference between 1.1 and 1.1000000000000001 is too small to be visible. Reports often limit output to a certain number of decimal places, and if you round the number to two or three or even eight decimal places, the error is never apparent. However, for applications where it does matter, it’s a lot of work to implement your own custom arithmetic routines.

Hence, the Decimal type was created.

The Decimal type
A new module, `decimal`, was added to Python’s standard library. It contains two classes, `Decimal` and `Context`. `Decimal` instances represent numbers, and `Context` instances are used to wrap up various settings such as the precision and default rounding mode.

`Decimal` instances are immutable, like regular Python integers and FP numbers; once it’s been created, you can’t change the value an instance represents. `Decimal` instances can be created from integers or strings:

```python
>>> import decimal
>>> decimal.Decimal(1972)
Decimal('1972')
>>> decimal.Decimal('1.1')
Decimal('1.1')
```

You can also provide tuples containing the sign, the mantissa represented as a tuple of decimal digits, and the exponent:

```python
>>> decimal.Decimal((1, (1, 4, 7, 5), -2))
Decimal('-14.75')
```

Cautionary note: the sign bit is a Boolean value, so 0 is positive and 1 is negative.

Converting from floating-point numbers poses a bit of a problem: should the FP number representing 1.1 turn into the decimal number for exactly 1.1, or for 1.1 plus whatever inaccuracies are introduced? The decision was to dodge the issue and leave such a conversion out of the API. Instead, you should convert the floating-point number into a string using the desired precision and pass the string to the `Decimal` constructor:
Once you have `Decimal` instances, you can perform the usual mathematical operations on them. One limitation: exponentiation requires an integer exponent:

```python
>>> a = decimal.Decimal('35.72')
>>> b = decimal.Decimal('1.73')
>>> a+b
Decimal("37.45")
>>> a-b
Decimal("33.99")
>>> a*b
Decimal("61.7956")
>>> a/b
Decimal("20.64739884393063583815028902")
>>> a ** 2
Decimal("1275.9184")
>>> a**b
Traceback (most recent call last):
  ...
  decimal.InvalidOperation: x ** (non-integer)
```

You can combine `Decimal` instances with integers, but not with floating-point numbers:

```python
>>> a + 4
Decimal("39.72")
>>> a + 4.5
Traceback (most recent call last):
  ...
```
Decimal numbers can be used with the `math` and `cmath` modules, but note that they'll be immediately converted to floating-point numbers before the operation is performed, resulting in a possible loss of precision and accuracy. You'll also get back a regular floating-point number and not a Decimal.

```python
>>> import math, cmath
>>> d = decimal.Decimal('123456789012.345')
>>> math.sqrt(d)
351364.18288201344
>>> cmath.sqrt(-d)
351364.18288201344j
```

Decimal instances have a `sqrt()` method that returns a Decimal, but if you need other things such as trigonometric functions you'll have to implement them.

```python
>>> d.sqrt()
Decimal("351364.1828820134592177245001")
```

### The Context type

Instances of the `Context` class encapsulate several settings for decimal operations:

- `prec` is the precision, the number of decimal places.
- `rounding` specifies the rounding mode. The `decimal` module has constants for the various possibilities: `ROUND_DOWN`, `ROUND_CEILING`, `ROUND_HALF_EVEN`, and various others.
traps is a dictionary specifying what happens on encountering certain error conditions: either an exception is raised or a value is returned. Some examples of error conditions are division by zero, loss of precision, and overflow.

There's a thread-local default context available by calling getcontext(); you can change the properties of this context to alter the default precision, rounding, or trap handling. The following example shows the effect of changing the precision of the default context:

```python
>>> decimal.getcontext().prec
28
>>> decimal.Decimal(1) / decimal.Decimal(7)
Decimal('0.1428571428571428571428571429')
>>> decimal.getcontext().prec = 9
>>> decimal.Decimal(1) / decimal.Decimal(7)
Decimal('0.142857143')
```

The default action for error conditions is selectable; the module can either return a special value such as infinity or not-a-number, or exceptions can be raised:

```python
>>> decimal.Decimal(1) / decimal.Decimal(0)
Traceback (most recent call last):
...
decimal.DivisionByZero: x / 0
>>> decimal.getcontext().traps[decimal.DivisionByZero] = True
>>> decimal.Decimal(1) / decimal.Decimal(0)
Decimal('Infinity')
```

The Context instance also has various methods for formatting numbers such as `to_eng_string()` and `to_sci_string()`.
For more information, see the documentation for the `decimal` module, which includes a quick-start tutorial and a reference.

**PEP 327 - Decimal Data Type**

Written by Facundo Batista and implemented by Facundo Batista, Eric Price, Raymond Hettinger, Aahz, and Tim Peters.

[http://www.lahey.com/float.htm](http://www.lahey.com/float.htm)

The article uses Fortran code to illustrate many of the problems that floating-point inaccuracy can cause.

A description of a decimal-based representation. This representation is being proposed as a standard, and underlies the new Python decimal type. Much of this material was written by Mike Cowlishaw, designer of the Rexx language.
PEP 328: Multi-line Imports

One language change is a small syntactic tweak aimed at making it easier to import many names from a module. In a `from module import names` statement, `names` is a sequence of names separated by commas. If the sequence is very long, you can either write multiple imports from the same module, or you can use backslashes to escape the line endings like this:

```python
from SimpleXMLRPCServer import SimpleXMLRPCServer,
    SimpleXMLRPCRequestHandler,
    CGIXMLRPCRequestHandler,
    resolve_dotted_attribute
```

The syntactic change in Python 2.4 simply allows putting the names within parentheses. Python ignores newlines within a parenthesized expression, so the backslashes are no longer needed:

```python
from SimpleXMLRPCServer import (SimpleXMLRPCServer,
    SimpleXMLRPCRequestHandler,
    CGIXMLRPCRequestHandler,
    resolve_dotted_attribute)
```

The PEP also proposes that all `import` statements be absolute imports, with a leading `.` character to indicate a relative import. This part of the PEP was not implemented for Python 2.4, but was completed for Python 2.5.

See also:

**PEP 328 - Imports: Multi-Line and Absolute/Relative**

Written by Aahz. Multi-line imports were implemented by Dima
Dorfman.
PEP 331: Locale-Independent Float/String Conversions

The `locale` modules let Python software select various conversions and display conventions that are localized to a particular country or language. However, the module was careful to not change the numeric locale because various functions in Python's implementation required that the numeric locale remain set to the `'C'` locale. Often this was because the code was using the C library's `atof()` function.

Not setting the numeric locale caused trouble for extensions that used third-party C libraries, however, because they wouldn’t have the correct locale set. The motivating example was GTK+, whose user interface widgets weren’t displaying numbers in the current locale.

The solution described in the PEP is to add three new functions to the Python API that perform ASCII-only conversions, ignoring the locale setting:

- `PyOS_ascii_strtod(str, ptr)` and `PyOS_ascii_atof(str, ptr)` both convert a string to a C double.
- `PyOS_ascii_formatd(buffer, buf_len, format, d)` converts a double to an ASCII string.

The code for these functions came from the GLib library ([http://library.gnome.org/devel/glib/stable/](http://library.gnome.org/devel/glib/stable/)), whose developers kindly relicensed the relevant functions and donated them to the Python Software Foundation. The `locale` module can now change the numeric locale, letting extensions such as GTK+ produce the correct results.

**PEP 331 - Locale-Independent Float/String Conversions**
Written by Christian R. Reis, and implemented by Gustavo Carneiro.
Other Language Changes

Here are all of the changes that Python 2.4 makes to the core Python language.

- Decorators for functions and methods were added (PEP 318).
- Built-in `set()` and `frozenset()` types were added (PEP 218). Other new built-ins include the `reversed(seq)` function (PEP 322).
- Generator expressions were added (PEP 289).
- Certain numeric expressions no longer return values restricted to 32 or 64 bits (PEP 237).
- You can now put parentheses around the list of names in a `from module import names` statement (PEP 328).
- The `dict.update()` method now accepts the same argument forms as the `dict` constructor. This includes any mapping, any iterable of key/value pairs, and keyword arguments. (Contributed by Raymond Hettinger.)
- The string methods `ljust()`, `rjust()`, and `center()` now take an optional argument for specifying a fill character other than a space. (Contributed by Raymond Hettinger.)
- Strings also gained an `rsplit()` method that works like the `split()` method but splits from the end of the string. (Contributed by Sean Reifschneider.)

```python
>>> 'www.python.org'.split('.', 1)
```
Three keyword parameters, `cmp`, `key`, and `reverse`, were added to the `sort()` method of lists. These parameters make some common usages of `sort()` simpler. All of these parameters are optional.

For the `cmp` parameter, the value should be a comparison function that takes two parameters and returns -1, 0, or +1 depending on how the parameters compare. This function will then be used to sort the list. Previously this was the only parameter that could be provided to `sort()`.

`key` should be a single-parameter function that takes a list element and returns a comparison key for the element. The list is then sorted using the comparison keys. The following example sorts a list case-insensitively:

```python
>>> L = ['A', 'b', 'c', 'D']
>>> L.sort()                 # Case-sensitive sort
>>> L
['A', 'D', 'b', 'c']
>>> # Using 'key' parameter to sort list
>>> L.sort(key=lambda x: x.lower())
>>> L
['A', 'b', 'c', 'D']
>>> # Old-fashioned way
>>> L.sort(cmp=lambda x,y: cmp(x.lower(), y.lower))
>>> L
['A', 'b', 'c', 'D']
```

The last example, which uses the `cmp` parameter, is the old way
to perform a case-insensitive sort. It works but is slower than using a key parameter. Using key calls lower() method once for each element in the list while using cmp will call it twice for each comparison, so using key saves on invocations of the lower() method.

For simple key functions and comparison functions, it is often possible to avoid a lambda expression by using an unbound method instead. For example, the above case-insensitive sort is best written as:

```python
>>> L.sort(key=str.lower)
>>> L
['A', 'b', 'c', 'D']
```

Finally, the reverse parameter takes a Boolean value. If the value is true, the list will be sorted into reverse order. Instead of `L.sort() ; L.reverse()`, you can now write `L.sort(reverse=True)`.

The results of sorting are now guaranteed to be stable. This means that two entries with equal keys will be returned in the same order as they were input. For example, you can sort a list of people by name, and then sort the list by age, resulting in a list sorted by age where people with the same age are in name-sorted order.

(All changes to sort() contributed by Raymond Hettinger.)

- There is a new built-in function `sorted(iterable)` that works like the in-place `list.sort()` method but can be used in expressions. The differences are:
• the input may be any iterable;

• a newly formed copy is sorted, leaving the original intact; and

• the expression returns the new sorted copy

```
>>> L = [9,7,8,3,2,4,1,6,5]
>>> [10+i for i in sorted(L)]  # usable in a list comprehension
[11, 12, 13, 14, 15, 16, 17, 18, 19]
>>> L  # original is left intact
[9,7,8,3,2,4,1,6,5]
>>> sorted('Monty Python')  # any iterable may be an input
[ ' ', 'M', 'P', 'h', 'n', 'o', 'o', 't', 'y']
>>> # List the contents of a dict sorted by key values
>>> colormap = dict(red=1, blue=2, green=3, black=4)
>>> for k, v in sorted(colormap.items()):
...      print k, v
...  black 4
  blue 2
  green 3
  red 1
  yellow 5
```

(Contributed by Raymond Hettinger.)

• Integer operations will no longer trigger an OverflowWarning. The OverflowWarning warning will disappear in Python 2.5.

• The interpreter gained a new switch, -m, that takes a name, searches for the corresponding module on sys.path, and runs the module as a script. For example, you can now run the Python profiler with python -m profile. (Contributed by Nick Coghlan.)
The `eval(expr, globals, locals)` and `execfile(filename, globals, locals)` functions and the `exec` statement now accept any mapping type for the `locals` parameter. Previously this had to be a regular Python dictionary. (Contributed by Raymond Hettinger.)

The `zip()` built-in function and `itertools.izip()` now return an empty list if called with no arguments. Previously they raised a `TypeError` exception. This makes them more suitable for use with variable length argument lists:

```python
>>> def transpose(array):
...     return zip(*array)
... >>> transpose([(1, 2, 3), (4, 5, 6)])
[(1, 4), (2, 5), (3, 6)]
>>> transpose([])
[]
```

(Contributed by Raymond Hettinger.)

Encountering a failure while importing a module no longer leaves a partially-initialized module object in `sys.modules`. The incomplete module object left behind would fool further imports of the same module into succeeding, leading to confusing errors. (Fixed by Tim Peters.)

None is now a constant; code that binds a new value to the name `None` is now a syntax error. (Contributed by Raymond Hettinger.)

**Optimizations**

The inner loops for list and tuple slicing were optimized and now
run about one-third faster. The inner loops for dictionaries were also optimized, resulting in performance boosts for keys(), values(), items(), iterkeys(), itervalues(), and iteritems. (Contributed by Raymond Hettinger.)

- The machinery for growing and shrinking lists was optimized for speed and for space efficiency. Appending and popping from lists now runs faster due to more efficient code paths and less frequent use of the underlying system realloc(). List comprehensions also benefit. list.extend() was also optimized and no longer converts its argument into a temporary list before extending the base list. (Contributed by Raymond Hettinger.)

- list(), tuple(), map(), filter(), and zip() now run several times faster with non-sequence arguments that supply a __len__() method. (Contributed by Raymond Hettinger.)

- The methods list.__getitem__(), dict.__getitem__(), and dict.__contains__() are now implemented as method_descriptor objects rather than wrapper_descriptor objects. This form of access doubles their performance and makes them more suitable for use as arguments to functionals: map(mydict.__getitem__, keylist). (Contributed by Raymond Hettinger.)

- Added a new opcode, LIST_APPEND, that simplifies the generated bytecode for list comprehensions and speeds them up by about a third. (Contributed by Raymond Hettinger.)

- The peephole bytecode optimizer has been improved to produce shorter, faster bytecode; remarkably, the resulting bytecode is more readable. (Enhanced by Raymond Hettinger.)

- String concatenations in statements of the form s = s + "abc" and s += "abc" are now performed more efficiently in certain circumstances. This optimization won't be present in other Python implementations such as Jython, so you shouldn't rely on it; using the join() method of strings is still recommended when you want to efficiently glue a large number of strings together.
The net result of the 2.4 optimizations is that Python 2.4 runs the pystone benchmark around 5% faster than Python 2.3 and 35% faster than Python 2.2. (pystone is not a particularly good benchmark, but it's the most commonly used measurement of Python's performance. Your own applications may show greater or smaller benefits from Python 2.4.)
New, Improved, and Deprecated Modules

As usual, Python's standard library received a number of enhancements and bug fixes. Here's a partial list of the most notable changes, sorted alphabetically by module name. Consult the Misc/NEWS file in the source tree for a more complete list of changes, or look through the CVS logs for all the details.

- The `asyncore` module's `loop()` function now has a `count` parameter that lets you perform a limited number of passes through the polling loop. The default is still to loop forever.

- The `base64` module now has more complete RFC 3548 support for Base64, Base32, and Base16 encoding and decoding, including optional case folding and optional alternative alphabets. (Contributed by Barry Warsaw.)

- The `bisect` module now has an underlying C implementation for improved performance. (Contributed by Dmitry Vasiliev.)

- The CJKCodecs collections of East Asian codecs, maintained by Hye-Shik Chang, was integrated into 2.4. The new encodings are:
  - Chinese (PRC): gb2312, gbk, gb18030, big5hkscs, hz
  - Chinese (ROC): big5, cp950
Some other new encodings were added: HP Roman8, ISO_8859-11, ISO_8859-16, PCTP-154, and TIS-620.

The UTF-8 and UTF-16 codecs now cope better with receiving partial input. Previously the StreamReader class would try to read more data, making it impossible to resume decoding from the stream. The read() method will now return as much data as it can and future calls will resume decoding where previous ones left off. (Implemented by Walter Dörwald.)

There is a new collections module for various specialized collection datatypes. Currently it contains just one type, deque, a double-ended queue that supports efficiently adding and removing elements from either end:

```python
>>> from collections import deque
>>> d = deque('ghi')  # make a new deque with three items
>>> d.append('j')     # add a new entry to the right side
>>> d.appendleft('f') # add a new entry to the left side
>>> d               # show the representation
deque(['f', 'g', 'h', 'i', 'j'])
>>> d.pop()          # return and remove the rightmost item
'j'
>>> d.popleft()      # return and remove the leftmost item
'f'
>>> list(d)          # list the contents of the deque
['g', 'h', 'i']
>>> 'h' in d         # search the deque
True
```

Several modules, such as the Queue and threading modules, now take advantage of collections.deque for improved performance. (Contributed by Raymond Hettinger.)
The ConfigParser classes have been enhanced slightly. The read() method now returns a list of the files that were successfully parsed, and the set() method raises TypeError if passed a value argument that isn’t a string. (Contributed by John Belmonte and David Goodger.)

The curses module now supports the ncurses extension use_default_colors(). On platforms where the terminal supports transparency, this makes it possible to use a transparent background. (Contributed by Jörg Lehmann.)

The difflib module now includes an HtmlDiff class that creates an HTML table showing a side by side comparison of two versions of a text. (Contributed by Dan Gass.)

The email package was updated to version 3.0, which dropped various deprecated APIs and removes support for Python versions earlier than 2.3. The 3.0 version of the package uses a new incremental parser for MIME messages, available in the email.FeedParser module. The new parser doesn’t require reading the entire message into memory, and doesn’t raise exceptions if a message is malformed; instead it records any problems in the defect attribute of the message. (Developed by Anthony Baxter, Barry Warsaw, Thomas Wouters, and others.)

The heapq module has been converted to C. The resulting tenfold improvement in speed makes the module suitable for handling high volumes of data. In addition, the module has two new functions nlargest() and nsmallest() that use heaps to find the N largest or smallest values in a dataset without the expense of a full sort. (Contributed by Raymond Hettinger.)
The `httplib` module now contains constants for HTTP status codes defined in various HTTP-related RFC documents. Constants have names such as OK, CREATED, CONTINUE, and MOVED_PERMANENTLY; use pydoc to get a full list. (Contributed by Andrew Eland.)

The `imaplib` module now supports IMAP's THREAD command (contributed by Yves Dionne) and new deleteacl() and myrights() methods (contributed by Arnaud Mazin).

The `itertools` module gained a `groupby(iterable[, *func*])` function. `iterable` is something that can be iterated over to return a stream of elements, and the optional `func` parameter is a function that takes an element and returns a key value; if omitted, the key is simply the element itself. `groupby()` then groups the elements into subsequences which have matching values of the key, and returns a series of 2-tuples containing the key value and an iterator over the subsequence.

Here's an example to make this clearer. The `key` function simply returns whether a number is even or odd, so the result of `groupby()` is to return consecutive runs of odd or even numbers.

```python
>>> import itertools
>>> L = [2, 4, 6, 7, 8, 9, 11, 12, 14]
>>> for key_val, it in itertools.groupby(L, lambda x: x % 2):
...     print(key_val, list(it))
... 0 [2, 4, 6]
 1 [7]
 0 [8]
 1 [9, 11]
```
groupby() is typically used with sorted input. The logic for groupby() is similar to the Unix uniq filter which makes it handy for eliminating, counting, or identifying duplicate elements:

```python
>>> word = 'abracadabra'
>>> letters = sorted(word)  # Turn string into a list of letters
['a', 'a', 'a', 'a', 'b', 'b', 'c', 'd', 'r']
>>> for k, g in itertools.groupby(letters):
...     print k, list(g)
...
a ['a', 'a', 'a', 'a', 'a']
b ['b', 'b']
c ['c']
d ['d']
r ['r', 'r']

>>> # List unique letters
>>> [k for k, g in itertools.groupby(letters)]
['a', 'b', 'c', 'd', 'r']
>>> # Count letter occurrences
>>> [(k, len(list(g))) for k, g in itertools.groupby(letters)]
[('a', 5), ('b', 2), ('c', 1), ('d', 1), ('r', 2)]
```

(Contributed by Hye-Shik Chang.)

- `itertools` also gained a function named `tee(iterator, N)` that returns $N$ independent iterators that replicate `iterator`. If $N$ is omitted, the default is 2.

```python
>>> L = [1, 2, 3]
>>> i1, i2 = itertools.tee(L)
```
Note that `tee()` has to keep copies of the values returned by the iterator; in the worst case, it may need to keep all of them. This should therefore be used carefully if the leading iterator can run far ahead of the trailing iterator in a long stream of inputs. If the separation is large, then you might as well use `list()` instead. When the iterators track closely with one another, `tee()` is ideal. Possible applications include bookmarking, windowing, or lookahead iterators. (Contributed by Raymond Hettinger.)

- A number of functions were added to the `locale` module, such as `bind_textdomain_codeset()` to specify a particular encoding and a family of `l*gettext()` functions that return messages in the chosen encoding. (Contributed by Gustavo Niemeyer.)

- Some keyword arguments were added to the `logging` package's `basicConfig()` function to simplify log configuration. The default behavior is to log messages to standard error, but various keyword arguments can be specified to log to a particular file, change the logging format, or set the logging level. For example:

```python
import logging
logging.basicConfig(filename='/var/log/application.log', level=0,  # Log all messages
                        format='%(levelname):%(process):%(thread):%(message)'
```
Other additions to the `logging` package include a `log(level, msg)` convenience method, as well as a `TimedRotatingFileHandler` class that rotates its log files at a timed interval. The module already had `RotatingFileHandler`, which rotated logs once the file exceeded a certain size. Both classes derive from a new `BaseRotatingHandler` class that can be used to implement other rotating handlers.

(Changes implemented by Vinay Sajip.)

- The `marshal` module now shares interned strings on unpacking a data structure. This may shrink the size of certain pickle strings, but the primary effect is to make `.pyc` files significantly smaller. (Contributed by Martin von Löwis.)

- The `nntplib` module's `NNTP` class gained `description()` and `descriptions()` methods to retrieve newsgroup descriptions for a single group or for a range of groups. (Contributed by Jürgen A. Erhard.)

- Two new functions were added to the `operator` module, `attrgetter(attr)` and `itemgetter(index)`. Both functions return callables that take a single argument and return the corresponding attribute or item; these callables make excellent data extractors when used with `map()` or `sorted()`. For example:

```python
>>> L = [('c', 2), ('d', 1), ('a', 4), ('b', 3)]
>>> map(operator.itemgetter(0), L)
['c', 'd', 'a', 'b']
>>> map(operator.itemgetter(1), L)
[2, 1, 4, 3]
```
>>> sorted(L, key=operator.itemgetter(1))  # Sort
[('d', 1), ('c', 2), ('b', 3), ('a', 4)]

(Contributed by Raymond Hettinger.)

- The `optparse` module was updated in various ways. The module now passes its messages through `gettext.gettext()`, making it possible to internationalize Optik's help and error messages. Help messages for options can now include the string `%default`, which will be replaced by the option's default value. (Contributed by Greg Ward.)

- The long-term plan is to deprecate the `rfc822` module in some future Python release in favor of the `email` package. To this end, the `email.Utils.formatdate()` function has been changed to make it usable as a replacement for `rfc822.formatdate()`. You may want to write new e-mail processing code with this in mind. (Change implemented by Anthony Baxter.)

- A new `urandom(n)` function was added to the `os` module, returning a string containing $n$ bytes of random data. This function provides access to platform-specific sources of randomness such as `/dev/urandom` on Linux or the Windows CryptoAPI. (Contributed by Trevor Perrin.)

- Another new function: `os.path.lexists(path)` returns true if the file specified by `path` exists, whether or not it's a symbolic link. This differs from the existing `os.path.exists(path)` function, which returns false if `path` is a symlink that points to a destination that doesn’t exist. (Contributed by Beni Cherniavsky.)

- A new `getsid()` function was added to the `posix` module that
underlies the os module. (Contributed by J. Raynor.)

- The poplib module now supports POP over SSL. (Contributed by Hector Urtubia.)

- The profile module can now profile C extension functions. (Contributed by Nick Bastin.)

- The random module has a new method called getrandbits(N) that returns a long integer N bits in length. The existing randrange() method now uses getrandbits() where appropriate, making generation of arbitrarily large random numbers more efficient. (Contributed by Raymond Hettinger.)

- The regular expression language accepted by the re module was extended with simple conditional expressions, written as (? (group)A|B). group is either a numeric group ID or a group name defined with (?P<group>... ) earlier in the expression. If the specified group matched, the regular expression pattern A will be tested against the string; if the group didn’t match, the pattern B will be used instead. (Contributed by Gustavo Niemeyer.)

- The re module is also no longer recursive, thanks to a massive amount of work by Gustavo Niemeyer. In a recursive regular expression engine, certain patterns result in a large amount of C stack space being consumed, and it was possible to overflow the stack. For example, if you matched a 30000-byte string of a characters against the expression (a|b)+, one stack frame was consumed per character. Python 2.3 tried to check for stack overflow and raise a RuntimeError exception, but certain patterns could sidestep the checking and if you were unlucky Python could segfault. Python 2.4’s regular expression engine can
match this pattern without problems.

- The `signal` module now performs tighter error-checking on the parameters to the `signal.signal()` function. For example, you can’t set a handler on the SIGKILL signal; previous versions of Python would quietly accept this, but 2.4 will raise a `RuntimeError` exception.

- Two new functions were added to the `socket` module. `socketpair()` returns a pair of connected sockets and `getservbyport(port)` looks up the service name for a given port number. (Contributed by Dave Cole and Barry Warsaw.)

- The `sys.exitfunc()` function has been deprecated. Code should be using the existing `atexit` module, which correctly handles calling multiple exit functions. Eventually `sys.exitfunc()` will become a purely internal interface, accessed only by `atexit`.

- The `tarfile` module now generates GNU-format tar files by default. (Contributed by Lars Gustäbel.)

- The `threading` module now has an elegantly simple way to support thread-local data. The module contains a `local` class whose attribute values are local to different threads.

```python
import threading

data = threading.local()
data.number = 42
data.url = ('www.python.org', 80)
```

Other threads can assign and retrieve their own values for the
number and url attributes. You can subclass local to initialize attributes or to add methods. (Contributed by Jim Fulton.)

- The timeit module now automatically disables periodic garbage collection during the timing loop. This change makes consecutive timings more comparable. (Contributed by Raymond Hettinger.)

- The weakref module now supports a wider variety of objects including Python functions, class instances, sets, frozensets, deques, arrays, files, sockets, and regular expression pattern objects. (Contributed by Raymond Hettinger.)

- The xmlrpclib module now supports a multi-call extension for transmitting multiple XML-RPC calls in a single HTTP operation. (Contributed by Brian Quinlan.)

- The mpz, rotor, and xreadlines modules have been removed.

**cookielib**

The cookielib library supports client-side handling for HTTP cookies, mirroring the Cookie module's server-side cookie support. Cookies are stored in cookie jars; the library transparently stores cookies offered by the web server in the cookie jar, and fetches the cookie from the jar when connecting to the server. As in web browsers, policy objects control whether cookies are accepted or not.

In order to store cookies across sessions, two implementations of cookie jars are provided: one that stores cookies in the Netscape format so applications can use the Mozilla or Lynx cookie files, and one that stores cookies in the same format as the Perl libwww library.
urllib2 has been changed to interact with cookielib: HTTPCookieProcessor manages a cookie jar that is used when accessing URLs.

This module was contributed by John J. Lee.

**doctest**

The `doctest` module underwent considerable refactoring thanks to Edward Loper and Tim Peters. Testing can still be as simple as running `doctest.testmod()`, but the refactorings allow customizing the module's operation in various ways.

The new DocTestFinder class extracts the tests from a given object's docstrings:

```python
def f(x, y):
    """""">>> f(2,2)
    4
    >>> f(3,2)
    6
    """
    return x*y

finder = doctest.DocTestFinder()

# Get list of DocTest instances
tests = finder.find(f)
```

The new DocTestRunner class then runs individual tests and can produce a summary of the results:

```python
runner = doctest.DocTestRunner()
for t in tests:
```
tried, failed = runner.run(t)
runner.summarize(verbos=1)

The above example produces the following output:

```
1 items passed all tests:
  2 tests in f
2 tests in 1 items.
2 passed and 0 failed.
Test passed.
```

DocTestRunner uses an instance of the OutputChecker class to compare the expected output with the actual output. This class takes a number of different flags that customize its behaviour; ambitious users can also write a completely new subclass of OutputChecker.

The default output checker provides a number of handy features. For example, with the **doctest.ELLIPSIS** option flag, an ellipsis (…) in the expected output matches any substring, making it easier to accommodate outputs that vary in minor ways:

```
def o(n):
    """>>> o(1)
<__main__.C instance at 0x...>
>>> """
```

Another special string, `<BLANKLINE>`, matches a blank line:

```
def p(n):
    """>>> p(1)
<BLANKLINE>
>>> """
```
Another new capability is producing a diff-style display of the output by specifying the `doctest.REPORT_UDIFF` (unified diffs), `doctest.REPORT_CDIFF` (context diffs), or `doctest.REPORT_NDIFF` (delta-style) option flags. For example:

```
def g(n):
    """>> g(4)
here
is
a
lengthy

>>> ""
L = 'here is a rather lengthy list of words'.split
for word in L[:n]:
    print word
```

Running the above function’s tests with `doctest.REPORT_UDIFF` specified, you get the following output:

```
**********************************************************************
File "t.py", line 15, in g
Failed example:
g(4)
Differences (unified diff with -expected +actual):
@@ -2,3 +2,3 @@
is
+a
-lengthy
+rather
**********************************************************************
```
Build and C API Changes

Some of the changes to Python’s build process and to the C API are:

- Three new convenience macros were added for common return values from extension functions: `Py_RETURN_NONE`, `Py_RETURN_TRUE`, and `Py_RETURN_FALSE`. (Contributed by Brett Cannon.)
- Another new macro, `Py_CLEAR(obj)`, decreases the reference count of `obj` and sets `obj` to the null pointer. (Contributed by Jim Fulton.)
- A new function, `PyTuple_Pack(N, obj1, obj2, ..., objN)`, constructs tuples from a variable length argument list of Python objects. (Contributed by Raymond Hettinger.)
- A new function, `PyDictContains(d, k)`, implements fast dictionary lookups without masking exceptions raised during the look-up process. (Contributed by Raymond Hettinger.)
- The `Py_IS_NAN(X)` macro returns 1 if its float or double argument `X` is a NaN. (Contributed by Tim Peters.)
- C code can avoid unnecessary locking by using the new `PyEval_ThreadsInitialized()` function to tell if any thread operations have been performed. If this function returns false, no lock operations are needed. (Contributed by Nick Coghlan.)
- A new function, `PyArg VaParseTupleAndKeywords()`, is the same as `PyArg_ParseTupleAndKeywords()` but takes a `va_list` instead of a number of arguments. (Contributed by Greg Chapman.)
- A new method flag, `METH_COEXISTS`, allows a function defined in slots to co-exist with a `PyCFunction` having the same name. This can halve the access time for a method such as `set.__contains__()`. (Contributed by Raymond Hettinger.)
- Python can now be built with additional profiling for the interpreter.
itself, intended as an aid to people developing the Python core. Providing \textit{----enable-profiling} to the \texttt{configure} script will let you profile the interpreter with \texttt{gprof}, and providing the \textit{----with-tsc} switch enables profiling using the Pentium’s Time-Stamp-Counter register. Note that the \textit{----with-tsc} switch is slightly misnamed, because the profiling feature also works on the PowerPC platform, though that processor architecture doesn’t call that register “the TSC register”. (Contributed by Jeremy Hylton.)

- The \texttt{tracebackobject} type has been renamed to \texttt{PyTracebackObject}.

### Port-Specific Changes

- The Windows port now builds under MSVC++ 7.1 as well as version 6. (Contributed by Martin von Löwis.)
Porting to Python 2.4

This section lists previously described changes that may require changes to your code:

- Left shifts and hexadecimal/octal constants that are too large no longer trigger a `FutureWarning` and return a value limited to 32 or 64 bits; instead they return a long integer.
- Integer operations will no longer trigger an `OverflowWarning`. The `OverflowWarning` warning will disappear in Python 2.5.
- The `zip()` built-in function and `itertools.izip()` now return an empty list instead of raising a `TypeError` exception if called with no arguments.
- You can no longer compare the date and `datetime` instances provided by the `datetime` module. Two instances of different classes will now always be unequal, and relative comparisons (`<`, `>`) will raise a `TypeError`.
- `dircache.listdir()` now passes exceptions to the caller instead of returning empty lists.
- `LexicalHandler.startDTD()` used to receive the public and system IDs in the wrong order. This has been corrected; applications relying on the wrong order need to be fixed.
- `fcntl.ioctl()` now warns if the `mutate` argument is omitted and relevant.
- The `tarfile` module now generates GNU-format tar files by default.
- Encountering a failure while importing a module no longer leaves a partially- initialized module object in `sys.modules`.
- `None` is now a constant; code that binds a new value to the name None is now a syntax error.
- The `signals.signal()` function now raises a `RuntimeError` exception for certain illegal values; previously these errors would
pass silently. For example, you can no longer set a handler on the SIGKILL signal.

What’s New in Python 2.3

Author: A.M. Kuchling

This article explains the new features in Python 2.3. Python 2.3 was released on July 29, 2003.

The main themes for Python 2.3 are polishing some of the features added in 2.2, adding various small but useful enhancements to the core language, and expanding the standard library. The new object model introduced in the previous version has benefited from 18 months of bugfixes and from optimization efforts that have improved the performance of new-style classes. A few new built-in functions have been added such as sum() and enumerate(). The in operator can now be used for substring searches (e.g. "ab" in "abc" returns True).

Some of the many new library features include Boolean, set, heap, and date/time data types, the ability to import modules from ZIP-format archives, metadata support for the long-awaited Python catalog, an updated version of IDLE, and modules for logging messages, wrapping text, parsing CSV files, processing command-line options, using BerkeleyDB databases... the list of new and enhanced modules is lengthy.

This article doesn’t attempt to provide a complete specification of the new features, but instead provides a convenient overview. For full details, you should refer to the documentation for Python 2.3, such as the Python Library Reference and the Python Reference Manual. If you want to understand the complete implementation and design rationale, refer to the PEP for a particular new feature.
PEP 218: A Standard Set Datatype

The new sets module contains an implementation of a set datatype. The Set class is for mutable sets, sets that can have members added and removed. The ImmutableSet class is for sets that can't be modified, and instances of ImmutableSet can therefore be used as dictionary keys. Sets are built on top of dictionaries, so the elements within a set must be hashable.

Here's a simple example:

```python
>>> import sets
>>> S = sets.Set([1,2,3])
>>> S
Set([1, 2, 3])
>>> 1 in S
True
>>> 0 in S
False
>>> S.add(5)
>>> S.remove(3)
>>> S
Set([1, 2, 5])
```  

The union and intersection of sets can be computed with the union() and intersection() methods; an alternative notation uses the bitwise operators & and |. Mutable sets also have in-place versions of these methods, union_update() and intersection_update().

```python
>>> S1 = sets.Set([1,2,3])
>>> S2 = sets.Set([4,5,6])
>>> S1.union(S2)
```
It's also possible to take the symmetric difference of two sets. This is the set of all elements in the union that aren't in the intersection. Another way of putting it is that the symmetric difference contains all elements that are in exactly one set. Again, there's an alternative notation (^), and an in-place version with the ungainly name symmetric_difference_update().

There are also issubset() and issuperset() methods for checking whether one set is a subset or superset of another:
False
>>> S1.issuperset(S2)
True
>>>
PEP 255: Simple Generators

In Python 2.2, generators were added as an optional feature, to be enabled by a `from __future__ import generators` directive. In 2.3 generators no longer need to be specially enabled, and are now always present; this means that `yield` is now always a keyword. The rest of this section is a copy of the description of generators from the “What’s New in Python 2.2” document; if you read it back when Python 2.2 came out, you can skip the rest of this section.

You’re doubtless familiar with how function calls work in Python or C. When you call a function, it gets a private namespace where its local variables are created. When the function reaches a `return` statement, the local variables are destroyed and the resulting value is returned to the caller. A later call to the same function will get a fresh new set of local variables. But, what if the local variables weren’t thrown away on exiting a function? What if you could later resume the function where it left off? This is what generators provide; they can be thought of as resumable functions.

Here’s the simplest example of a generator function:

```python
def generate_ints(N):
    for i in range(N):
        yield i
```

A new keyword, `yield`, was introduced for generators. Any function containing a `yield` statement is a generator function; this is detected by Python’s bytecode compiler which compiles the function specially as a result.

When you call a generator function, it doesn’t return a single value;
instead it returns a generator object that supports the iterator protocol. On executing the `yield` statement, the generator outputs the value of `i`, similar to a `return` statement. The big difference between `yield` and a `return` statement is that on reaching a `yield` the generator’s state of execution is suspended and local variables are preserved. On the next call to the generator’s `.next()` method, the function will resume executing immediately after the `yield` statement. (For complicated reasons, the `yield` statement isn’t allowed inside the `try` block of a `try...finally` statement; read PEP 255 for a full explanation of the interaction between `yield` and exceptions.)

Here’s a sample usage of the `generate_ints()` generator:

```python
>>> gen = generate_ints(3)
>>> gen
<generator object at 0x8117f90>
>>> gen.next()
0
>>> gen.next()
1
>>> gen.next()
2
>>> gen.next()
Traceback (most recent call last):
  File "stdin", line 1, in ?
  File "stdin", line 2, in generate_ints
StopIteration
```

You could equally write `for i in generate_ints(5)`, or `a,b,c = generate_ints(3)`.

Inside a generator function, the `return` statement can only be used without a value, and signals the end of the procession of values;
afterwards the generator cannot return any further values. return with a value, such as return 5, is a syntax error inside a generator function. The end of the generator’s results can also be indicated by raising StopIteration manually, or by just letting the flow of execution fall off the bottom of the function.

You could achieve the effect of generators manually by writing your own class and storing all the local variables of the generator as instance variables. For example, returning a list of integers could be done by setting self.count to 0, and having the next() method increment self.count and return it. However, for a moderately complicated generator, writing a corresponding class would be much messier. Lib/test/test_generators.py contains a number of more interesting examples. The simplest one implements an in-order traversal of a tree using generators recursively.

```python
# A recursive generator that generates Tree leaves in-order

def inorder(t):
    if t:
        for x in inorder(t.left):
            yield x
        yield t.label
        for x in inorder(t.right):
            yield x
```

Two other examples in Lib/test/test_generators.py produce solutions for the N-Queens problem (placing $N$ queens on an $NxN$ chess board so that no queen threatens another) and the Knight’s Tour (a route that takes a knight to every square of an $NxN$ chessboard without visiting any square twice).

The idea of generators comes from other programming languages,
especially Icon (http://www.cs.arizona.edu/icon/), where the idea of generators is central. In Icon, every expression and function call behaves like a generator. One example from “An Overview of the Icon Programming Language” at http://www.cs.arizona.edu/icon/docs/ipd266.htm gives an idea of what this looks like:

```
sentence := "Store it in the neighboring harbor"
if (i := find("or", sentence)) > 5 then write(i)
```

In Icon the find() function returns the indexes at which the substring “or” is found: 3, 23, 33. In the if statement, i is first assigned a value of 3, but 3 is less than 5, so the comparison fails, and Icon retries it with the second value of 23. 23 is greater than 5, so the comparison now succeeds, and the code prints the value 23 to the screen.

Python doesn’t go nearly as far as Icon in adopting generators as a central concept. Generators are considered part of the core Python language, but learning or using them isn’t compulsory; if they don’t solve any problems that you have, feel free to ignore them. One novel feature of Python’s interface as compared to Icon’s is that a generator’s state is represented as a concrete object (the iterator) that can be passed around to other functions or stored in a data structure.

**PEP 255 - Simple Generators**

Written by Neil Schemenauer, Tim Peters, Magnus Lie Hetland. Implemented mostly by Neil Schemenauer and Tim Peters, with other fixes from the Python Labs crew.
PEP 263: Source Code Encodings

Python source files can now be declared as being in different character set encodings. Encodings are declared by including a specially formatted comment in the first or second line of the source file. For example, a UTF-8 file can be declared with:

```
#!/usr/bin/env python
# -*- coding: UTF-8 -*-
```

Without such an encoding declaration, the default encoding used is 7-bit ASCII. Executing or importing modules that contain string literals with 8-bit characters and have no encoding declaration will result in a `DeprecationWarning` being signalled by Python 2.3; in 2.4 this will be a syntax error.

The encoding declaration only affects Unicode string literals, which will be converted to Unicode using the specified encoding. Note that Python identifiers are still restricted to ASCII characters, so you can’t have variable names that use characters outside of the usual alphanumerics.

See also:

**PEP 263 - Defining Python Source Code Encodings**
Written by Marc-André Lemburg and Martin von Löwis; implemented by Suzuki Hisao and Martin von Löwis.
PEP 273: Importing Modules from ZIP Archives

The new `zipimport` module adds support for importing modules from a ZIP-format archive. You don't need to import the module explicitly; it will be automatically imported if a ZIP archive's filename is added to `sys.path`. For example:

```
aml@nyman:/src/python$ unzip -l /tmp/example.zip
Archive: /tmp/example.zip
    Length Date Time  Name
---------- ---- ---- ----
       8467 11-26-02 22:30 jwzthreading.py
---------- ---- ---- ----
       8467                1 file
aml@nyman:/src/python$ ./python
Python 2.3 (#1, Aug 1 2003, 19:54:32)
>>> import sys
>>> sys.path.insert(0, '/tmp/example.zip') # Add .zip file to front of path
>>> import jwzthreading
>>> jwzthreading.__file__
'/tmp/example.zip/jwzthreading.py'
```

An entry in `sys.path` can now be the filename of a ZIP archive. The ZIP archive can contain any kind of files, but only files named `*.py`, `*.pyc`, or `*.pyo` can be imported. If an archive only contains `*.py` files, Python will not attempt to modify the archive by adding the corresponding `*.pyc` file, meaning that if a ZIP archive doesn't contain `*.pyc` files, importing may be rather slow.

A path within the archive can also be specified to only import from a
subdirectory; for example, the path `/tmp/example.zip/lib/` would only import from the `lib/` subdirectory within the archive.

See also:

**PEP 273 - Import Modules from Zip Archives**

Written by James C. Ahlstrom, who also provided an implementation. Python 2.3 follows the specification in PEP 273, but uses an implementation written by Just van Rossum that uses the import hooks described in PEP 302. See section PEP 302: New Import Hooks for a description of the new import hooks.
PEP 277: Unicode file name support for Windows NT

On Windows NT, 2000, and XP, the system stores file names as Unicode strings. Traditionally, Python has represented file names as byte strings, which is inadequate because it renders some file names inaccessible.

Python now allows using arbitrary Unicode strings (within the limitations of the file system) for all functions that expect file names, most notably the `open()` built-in function. If a Unicode string is passed to `os.listdir()`, Python now returns a list of Unicode strings. A new function, `os.getcwd()`, returns the current directory as a Unicode string.

Byte strings still work as file names, and on Windows Python will transparently convert them to Unicode using the `mbcs` encoding.

Other systems also allow Unicode strings as file names but convert them to byte strings before passing them to the system, which can cause a `UnicodeError` to be raised. Applications can test whether arbitrary Unicode strings are supported as file names by checking `os.path.supports_unicode_filenames`, a Boolean value.

Under MacOS, `os.listdir()` may now return Unicode filenames.

See also:

**PEP 277 - Unicode file name support for Windows NT**

Written by Neil Hodgson; implemented by Neil Hodgson, Martin von Löwis, and Mark Hammond.
PEP 278: Universal Newline Support

The three major operating systems used today are Microsoft Windows, Apple's Macintosh OS, and the various Unix derivatives. A minor irritation of cross-platform work is that these three platforms all use different characters to mark the ends of lines in text files. Unix uses the linefeed (ASCII character 10), MacOS uses the carriage return (ASCII character 13), and Windows uses a two-character sequence of a carriage return plus a newline.

Python's file objects can now support end of line conventions other than the one followed by the platform on which Python is running. Opening a file with the mode '\u' or 'rU' will open a file for reading in universal newlines mode. All three line ending conventions will be translated to a '\n' in the strings returned by the various file methods such as read() and readline().

Universal newline support is also used when importing modules and when executing a file with the execfile() function. This means that Python modules can be shared between all three operating systems without needing to convert the line-endings.

This feature can be disabled when compiling Python by specifying the --without-universal-newlines switch when running Python’s configure script.

See also:

PEP 278 - Universal Newline Support
Written and implemented by Jack Jansen.
A new built-in function, `enumerate()`, will make certain loops a bit clearer. `enumerate(thing)`, where `thing` is either an iterator or a sequence, returns a iterator that will return `(0, thing[0]), (1, thing[1]), (2, thing[2]), and so forth.

A common idiom to change every element of a list looks like this:

```python
for i in range(len(L)):
    item = L[i]
    # ... compute some result based on item ...
    L[i] = result
```

This can be rewritten using `enumerate()` as:

```python
for i, item in enumerate(L):
    # ... compute some result based on item ...
    L[i] = result
```

See also:

**PEP 279 - The enumerate() built-in function**

Written and implemented by Raymond D. Hettinger.
PEP 282: The logging Package

A standard package for writing logs, `logging`, has been added to Python 2.3. It provides a powerful and flexible mechanism for generating logging output which can then be filtered and processed in various ways. A configuration file written in a standard format can be used to control the logging behavior of a program. Python includes handlers that will write log records to standard error or to a file or socket, send them to the system log, or even e-mail them to a particular address; of course, it’s also possible to write your own handler classes.

The Logger class is the primary class. Most application code will deal with one or more Logger objects, each one used by a particular subsystem of the application. Each Logger is identified by a name, and names are organized into a hierarchy using `.` as the component separator. For example, you might have Logger instances named `server`, `server.auth` and `server.network`. The latter two instances are below `server` in the hierarchy. This means that if you turn up the verbosity for `server` or direct `server` messages to a different handler, the changes will also apply to records logged to `server.auth` and `server.network`. There’s also a root Logger that’s the parent of all other loggers.

For simple uses, the `logging` package contains some convenience functions that always use the root log:

```python
import logging
logging.debug('Debugging information')
logging.info('Informational message')
```
logging.warning('Warning: config file %s not found')
logging.error('Error occurred')
logging.critical('Critical error -- shutting down')

This produces the following output:

```
WARNING:root:Warning: config file server.conf not found
ERROR:root:Error occurred
CRITICAL:root: Critical error -- shutting down
```

In the default configuration, informational and debugging messages are suppressed and the output is sent to standard error. You can enable the display of informational and debugging messages by calling the `setLevel()` method on the root logger.

Notice the `warning()` call’s use of string formatting operators; all of the functions for logging messages take the arguments (msg, arg1, arg2, ...) and log the string resulting from `msg % (arg1, arg2, ...)`.

There’s also an `exception()` function that records the most recent traceback. Any of the other functions will also record the traceback if you specify a true value for the keyword argument `exc_info`.

```python
def f():
    try:
        1/0
    except:
        logging.exception('Problem recorded')
f()
```

This produces the following output:

```
ERROR:root:Problem recorded
```
Traceback (most recent call last):
  File "t.py", line 6, in f
  1/0
ZeroDivisionError: integer division or modulo by zero

Slightly more advanced programs will use a logger other than the root logger. The `getLogger(name)` function is used to get a particular log, creating it if it doesn’t exist yet. `getLogger(None)` returns the root logger.

```python
log = logging.getLogger('server')
...
log.info('Listening on port %i', port)
...
log.critical('Disk full')
...```

Log records are usually propagated up the hierarchy, so a message logged to `server.auth` is also seen by `server` and `root`, but a Logger can prevent this by setting its `propagate` attribute to `False`.

There are more classes provided by the `logging` package that can be customized. When a Logger instance is told to log a message, it creates a LogRecord instance that is sent to any number of different Handler instances. Loggers and handlers can also have an attached list of filters, and each filter can cause the LogRecord to be ignored or can modify the record before passing it along. When they’re finally output, LogRecord instances are converted to text by a Formatter class. All of these classes can be replaced by your own specially-written classes.

With all of these features the `logging` package should provide enough flexibility for even the most complicated applications. This is
only an incomplete overview of its features, so please see the package's reference documentation for all of the details. Reading PEP 282 will also be helpful.

See also:

**PEP 282 - A Logging System**

Written by Vinay Sajip and Trent Mick; implemented by Vinay Sajip.
PEP 285: A Boolean Type

A Boolean type was added to Python 2.3. Two new constants were added to the __builtin__ module, True and False. (True and False constants were added to the built-ins in Python 2.2.1, but the 2.2.1 versions are simply set to integer values of 1 and 0 and aren’t a different type.)

The type object for this new type is named bool; the constructor for it takes any Python value and converts it to True or False.

```python
>>> bool(1)
True
>>> bool(0)
False
>>> bool([])
False
>>> bool( (1, ) )
True
```

Most of the standard library modules and built-in functions have been changed to return Booleans.

```python
>>> obj = []
>>> hasattr(obj, 'append')
True
>>> isinstance(obj, list)
True
>>> isinstance(obj, tuple)
False
```

Python’s Booleans were added with the primary goal of making code clearer. For example, if you’re reading a function and encounter the
statement `return 1`, you might wonder whether the 1 represents a Boolean truth value, an index, or a coefficient that multiplies some other quantity. If the statement is `return True`, however, the meaning of the return value is quite clear.

Python’s Booleans were *not* added for the sake of strict type-checking. A very strict language such as Pascal would also prevent you performing arithmetic with Booleans, and would require that the expression in an `if` statement always evaluate to a Boolean result. Python is not this strict and never will be, as [PEP 285](https://www.python.org/dev/peps/pep-0285/) explicitly says. This means you can still use any expression in an `if` statement, even ones that evaluate to a list or tuple or some random object. The Boolean type is a subclass of the `int` class so that arithmetic using a Boolean still works.

```python
>>> True + 1
2
>>> False + 1
1
>>> False * 75
0
>>> True * 75
75
```

To sum up `True` and `False` in a sentence: they're alternative ways to spell the integer values 1 and 0, with the single difference that `str()` and `repr()` return the strings `'True'` and `'False'` instead of `'1'` and `'0'`.

See also:

[PEP 285 - Adding a bool type](https://www.python.org/dev/peps/pep-0285/)  
Written and implemented by GvR.
When encoding a Unicode string into a byte string, unencodable characters may be encountered. So far, Python has allowed specifying the error processing as either “strict” (raising `UnicodeError`), “ignore” (skipping the character), or “replace” (using a question mark in the output string), with “strict” being the default behavior. It may be desirable to specify alternative processing of such errors, such as inserting an XML character reference or HTML entity reference into the converted string.

Python now has a flexible framework to add different processing strategies. New error handlers can be added with `codecs.register_error()`, and codecs then can access the error handler with `codecs.lookup_error()`. An equivalent C API has been added for codecs written in C. The error handler gets the necessary state information such as the string being converted, the position in the string where the error was detected, and the target encoding. The handler can then either raise an exception or return a replacement string.

Two additional error handlers have been implemented using this framework: “backslashreplace” uses Python backslash quoting to represent unencodable characters and “xmlcharrefreplace” emits XML character references.

See also:

**PEP 293 - Codec Error Handling Callbacks**

Written and implemented by Walter Dörwald.
PEP 301: Package Index and Metadata for Distutils

Support for the long-requested Python catalog makes its first appearance in 2.3.

The heart of the catalog is the new Distutils register command. Running `python setup.py register` will collect the metadata describing a package, such as its name, version, maintainer, description, &c., and send it to a central catalog server. The resulting catalog is available from http://www.python.org/pypi.

To make the catalog a bit more useful, a new optional classifiers keyword argument has been added to the Distutils setup() function. A list of Trove-style strings can be supplied to help classify the software.

Here's an example `setup.py` with classifiers, written to be compatible with older versions of the Distutils:

```python
from distutils import core
kw = {
    'name': "Quixote",
    'version': "0.5.1",
    'description': "A highly Pythonic Web application",
    # ...
}

if hasattr(core, 'setup_keywords') and
    'classifiers' in core.setup_keywords:
    kw['classifiers'] = [
        'Topic :: Internet :: WWW/HTTP :: Dynamic Content',
        'Environment :: No Input/Output (Daemon)',
        'Intended Audience :: Developers',
    ]
```
The full list of classifiers can be obtained by running `python setup.py register --list-classifiers`.

See also:

**PEP 301 - Package Index and Metadata for Distutils**
Written and implemented by Richard Jones.
PEP 302: New Import Hooks

While it's been possible to write custom import hooks ever since the ihooks module was introduced in Python 1.3, no one has ever been really happy with it because writing new import hooks is difficult and messy. There have been various proposed alternatives such as the imputil and iu modules, but none of them has ever gained much acceptance, and none of them were easily usable from C code.

PEP 302 borrows ideas from its predecessors, especially from Gordon McMillan's iu module. Three new items are added to the sys module:

- `sys.path_hooks` is a list of callable objects; most often they'll be classes. Each callable takes a string containing a path and either returns an importer object that will handle imports from this path or raises an `ImportError` exception if it can't handle this path.

- `sys.path_importer_cache` caches importer objects for each path, so `sys.path_hooks` will only need to be traversed once for each path.

- `sys.meta_path` is a list of importer objects that will be traversed before `sys.path` is checked. This list is initially empty, but user code can add objects to it. Additional built-in and frozen modules can be imported by an object added to this list.

Importer objects must have a single method, `find_module(fullname, path=None)`. `fullname` will be a module or package name, e.g. `string` or `distutils.core`. `find_module()` must return a loader object that has a single method, `load_module(fullname)`, that creates and returns the corresponding module object.
Pseudo-code for Python’s new import logic, therefore, looks something like this (simplified a bit; see PEP 302 for the full details):

```
for mp in sys.meta_path:
    loader = mp(fullname)
    if loader is not None:
        <module> = loader.load_module(fullname)

for path in sys.path:
    for hook in sys.path_hooks:
        try:
            importer = hook(path)
        except ImportError:
            # ImportError, so try the other path hooks
            pass
        else:
            loader = importer.find_module(fullname)
            <module> = loader.load_module(fullname)

# Not found!
raise ImportError
```

See also:

**PEP 302 - New Import Hooks**

Written by Just van Rossum and Paul Moore. Implemented by Just van Rossum.
PEP 305: Comma-separated Files

Comma-separated files are a format frequently used for exporting data from databases and spreadsheets. Python 2.3 adds a parser for comma-separated files.

Comma-separated format is deceptively simple at first glance:

```
Costs,150,200,3.95
```

Read a line and call `line.split(',')`: what could be simpler? But toss in string data that can contain commas, and things get more complicated:

```
"Costs",150,200,3.95,"Includes taxes, shipping, and"
```

A big ugly regular expression can parse this, but using the new `csv` package is much simpler:

```
import csv

input = open('datafile', 'rb')
reader = csv.reader(input)
for line in reader:
    print line
```

The reader() function takes a number of different options. The field separator isn’t limited to the comma and can be changed to any character, and so can the quoting and line-ending characters.

Different dialects of comma-separated files can be defined and registered; currently there are two dialects, both used by Microsoft
Excel. A separate `csv.writer` class will generate comma-separated files from a succession of tuples or lists, quoting strings that contain the delimiter.

See also:

**PEP 305 - CSV File API**
Written and implemented by Kevin Altis, Dave Cole, Andrew McNamara, Skip Montanaro, Cliff Wells.
PEP 307: Pickle Enhancements

The pickle and cPickle modules received some attention during the 2.3 development cycle. In 2.2, new-style classes could be pickled without difficulty, but they weren't pickled very compactly; PEP 307 quotes a trivial example where a new-style class results in a pickled string three times longer than that for a classic class.

The solution was to invent a new pickle protocol. The pickle.dumps() function has supported a text-or-binary flag for a long time. In 2.3, this flag is redefined from a Boolean to an integer: 0 is the old text-mode pickle format, 1 is the old binary format, and now 2 is a new 2.3-specific format. A new constant, pickle.HIGHEST_PROTOCOL, can be used to select the fanciest protocol available.

Unpickling is no longer considered a safe operation. 2.2's pickle provided hooks for trying to prevent unsafe classes from being unpickled (specifically, a __safe_for_unpickling__ attribute), but none of this code was ever audited and therefore it's all been ripped out in 2.3. You should not unpickle untrusted data in any version of Python.

To reduce the pickling overhead for new-style classes, a new interface for customizing pickling was added using three special methods: __getstate__(), __setstate__(), and __getnewargs__(). Consult PEP 307 for the full semantics of these methods.

As a way to compress pickles yet further, it's now possible to use integer codes instead of long strings to identify pickled classes. The Python Software Foundation will maintain a list of standardized codes; there's also a range of codes for private use. Currently no codes have
been specified.

See also:

**PEP 307 - Extensions to the pickle protocol**
Written and implemented by Guido van Rossum and Tim Peters.
Extended Slices

Ever since Python 1.4, the slicing syntax has supported an optional third “step” or “stride” argument. For example, these are all legal Python syntax: \texttt{L[1:10:2]}, \texttt{L[:-1:1]}, \texttt{L[::-1]}. This was added to Python at the request of the developers of Numerical Python, which uses the third argument extensively. However, Python’s built-in list, tuple, and string sequence types have never supported this feature, raising a \texttt{TypeError} if you tried it. Michael Hudson contributed a patch to fix this shortcoming.

For example, you can now easily extract the elements of a list that have even indexes:

\begin{verbatim}
>>> L = range(10)
>>> L[::2]
[0, 2, 4, 6, 8]
\end{verbatim}

Negative values also work to make a copy of the same list in reverse order:

\begin{verbatim}
>>> L[::-1]
[9, 8, 7, 6, 5, 4, 3, 2, 1, 0]
\end{verbatim}

This also works for tuples, arrays, and strings:

\begin{verbatim}
>>> s='abcd'
>>> s[::2]
'ac'
>>> s[::-1]
'dcba'
\end{verbatim}

If you have a mutable sequence such as a list or an array you can
assign to or delete an extended slice, but there are some differences between assignment to extended and regular slices. Assignment to a regular slice can be used to change the length of the sequence:

```python
>>> a = range(3)
>>> a
[0, 1, 2]
>>> a[1:3] = [4, 5, 6]
>>> a
[0, 4, 5, 6]
```

Extended slices aren't this flexible. When assigning to an extended slice, the list on the right hand side of the statement must contain the same number of items as the slice it is replacing:

```python
>>> a = range(4)
>>> a
[0, 1, 2, 3]
>>> a[:2]
[0, 2]
>>> a[:2] = [0, -1]
>>> a
[0, 1, -1, 3]
>>> a[:2] = [0,1,2]
Traceback (most recent call last):
  File "<stdin>", line 1, in ?
ValueError: attempt to assign sequence of size 3 to extended slice of size 2
```

Deletion is more straightforward:

```python
>>> a = range(4)
>>> a
[0, 1, 2, 3]
>>> a[:2]
[0, 2]
```
One can also now pass slice objects to the \_\_getitem\_\_() methods of the built-in sequences:

```python
>>> range(10).\_\_getitem\_\_(slice(0, 5, 2))
[0, 2, 4]
```

Or use slice objects directly in subscripts:

```python
>>> range(10)[slice(0, 5, 2)]
[0, 2, 4]
```

To simplify implementing sequences that support extended slicing, slice objects now have a method `indices(length)` which, given the length of a sequence, returns a \((\text{start}, \text{stop}, \text{step})\) tuple that can be passed directly to `range().indices()` handles omitted and out-of-bounds indices in a manner consistent with regular slices (and this innocuous phrase hides a welter of confusing details!). The method is intended to be used like this:

```python
class FakeSeq:
    ...
    def calc_item(self, i):
        ...
    def \_\_getitem\_\_(self, item):
        if isinstance(item, slice):
            indices = item.indices(len(self))
            return FakeSeq([self.calc_item(i) for i in indices])
        else:
            return self.calc_item(i)
```
From this example you can also see that the built-in `slice` object is now the type object for the slice type, and is no longer a function. This is consistent with Python 2.2, where `int`, `str`, etc., underwent the same change.
Other Language Changes

Here are all of the changes that Python 2.3 makes to the core Python language.

- The `yield` statement is now always a keyword, as described in section [PEP 255: Simple Generators](https://www.python.org/dev/peps/pep-0255/) of this document.

- A new built-in function `enumerate()` was added, as described in section [PEP 279: `enumerate()`](https://www.python.org/dev/peps/pep-0279/) of this document.

- Two new constants, `True` and `False` were added along with the built-in `bool` type, as described in section [PEP 285: A Boolean Type](https://www.python.org/dev/peps/pep-0285/) of this document.

- The `int()` type constructor will now return a long integer instead of raising an `OverflowError` when a string or floating-point number is too large to fit into an integer. This can lead to the paradoxical result that `isinstance(int(expression), int)` is false, but that seems unlikely to cause problems in practice.

- Built-in types now support the extended slicing syntax, as described in section [Extended Slices](https://www.python.org/dev/peps/pep-0310/) of this document.

- A new built-in function, `sum(iterable, start=0)`, adds up the numeric items in the iterable object and returns their sum. `sum()` only accepts numbers, meaning that you can't use it to concatenate a bunch of strings. (Contributed by Alex Martelli.)

- `list.insert(pos, value)` used to insert `value` at the front of the list when `pos` was negative. The behaviour has now been
changed to be consistent with slice indexing, so when $pos$ is -1 the value will be inserted before the last element, and so forth.

- `list.index(value)`, which searches for `value` within the list and returns its index, now takes optional `start` and `stop` arguments to limit the search to only part of the list.

- Dictionaries have a new method, `pop(key[, *default*])`, that returns the value corresponding to `key` and removes that key/value pair from the dictionary. If the requested key isn't present in the dictionary, `default` is returned if it's specified and `KeyError` raised if it isn't.

```
>>> d = {1:2}
>>> d
{1: 2}
>>> d.pop(4)
Traceback (most recent call last):
  File "stdin", line 1, in ?
KeyError: 4
>>> d.pop(1)
2
>>> d.pop(1)
Traceback (most recent call last):
  File "stdin", line 1, in ?
KeyError: 'pop(): dictionary is empty'
>>> d
{}
>>> `n
```

There's also a new class method, `dict.fromkeys(iterable, value)`, that creates a dictionary with keys taken from the supplied iterator `iterable` and all values set to `value`, defaulting to None.
(Patches contributed by Raymond Hettinger.)

Also, the `dict()` constructor now accepts keyword arguments to simplify creating small dictionaries:

```python
tests>>> dict(red=1, blue=2, green=3, black=4)
{'blue': 2, 'black': 4, 'green': 3, 'red': 1}
```

(Contributed by Just van Rossum.)

- The `assert` statement no longer checks the `__debug__` flag, so you can no longer disable assertions by assigning to `__debug__`. Running Python with the `-O` switch will still generate code that doesn't execute any assertions.

- Most type objects are now callable, so you can use them to create new objects such as functions, classes, and modules. (This means that the new module can be deprecated in a future Python version, because you can now use the type objects available in the `types` module.) For example, you can create a new module object with the following code:

```python
tests>>> import types
>>> m = types.ModuleType('abc', 'docstring')
>>> m
<module 'abc' (built-in)>
>>> m.__doc__
docstring
```

- A new warning, `PendingDeprecationWarning` was added to indicate features which are in the process of being deprecated. The warning will *not* be printed by default. To check for use of features that will be deprecated in the future, supply `-Walways::PendingDeprecationWarning::` on the command line or
use `warnings.filterwarnings()`.

- The process of deprecating string-based exceptions, as in `raise "Error occurred"`, has begun. Raising a string will now trigger `PendingDeprecationWarning`.

- Using None as a variable name will now result in a `SyntaxWarning` warning. In a future version of Python, None may finally become a keyword.

- The `xreadlines()` method of file objects, introduced in Python 2.1, is no longer necessary because files now behave as their own iterator. `xreadlines()` was originally introduced as a faster way to loop over all the lines in a file, but now you can simply write `for line in file_obj`. File objects also have a new read-only encoding attribute that gives the encoding used by the file; Unicode strings written to the file will be automatically converted to bytes using the given encoding.

- The method resolution order used by new-style classes has changed, though you'll only notice the difference if you have a really complicated inheritance hierarchy. Classic classes are unaffected by this change. Python 2.2 originally used a topological sort of a class's ancestors, but 2.3 now uses the C3 algorithm as described in the paper “A Monotonic Superclass Linearization for Dylan”. To understand the motivation for this change, read Michele Simionato's article “Python 2.3 Method Resolution Order”, or read the thread on python-dev starting with the message at http://mail.python.org/pipermail/python-dev/2002-October/029035.html. Samuele Pedroni first pointed out the problem and also implemented the fix by coding the C3 algorithm.
Python runs multithreaded programs by switching between threads after executing N bytecodes. The default value for N has been increased from 10 to 100 bytecodes, speeding up single-threaded applications by reducing the switching overhead. Some multithreaded applications may suffer slower response time, but that's easily fixed by setting the limit back to a lower number using `sys.setcheckinterval(N)`. The limit can be retrieved with the new `sys.getcheckinterval()` function.

One minor but far-reaching change is that the names of extension types defined by the modules included with Python now contain the module and a '.' in front of the type name. For example, in Python 2.2, if you created a socket and printed its `__class__`, you'd get this output:

```python
>>> s = socket.socket()
>>> s.__class__
<type 'socket'>
```

In 2.3, you get this:

```python
>>> s.__class__
<type '__socket.socket'>
```

One of the noted incompatibilities between old- and new-style classes has been removed: you can now assign to the `__name__` and `__bases__` attributes of new-style classes. There are some restrictions on what can be assigned to `__bases__` along the lines of those relating to assigning to an instance's `__class__` attribute.

String Changes
- The `in` operator now works differently for strings. Previously, when evaluating `X in Y` where `X` and `Y` are strings, `X` could only be a single character. That's now changed; `X` can be a string of any length, and `X in Y` will return `True` if `X` is a substring of `Y`. If `X` is the empty string, the result is always `True`.

```python
>>> 'ab' in 'abcd'
True
>>> 'ad' in 'abcd'
False
>>> '' in 'abcd'
True
```

Note that this doesn't tell you where the substring starts; if you need that information, use the `find()` string method.

- The `strip()`, `lstrip()`, and `rstrip()` string methods now have an optional argument for specifying the characters to strip. The default is still to remove all whitespace characters:

```python
>>> ' abc '.strip()
'abc'
>>> '><><abc><><><>'.strip('<>')
'abc'
>>> '><><abc><><><\n'.strip('<>')
'abc'><><\n'
>>> u'\u4000\u4001abc\u4000'.strip(u'\u4000')
u'\u4001abc'
```
accept negative numbers for the \textit{start} and \textit{end} parameters.

- Another new string method is \texttt{zfill()}, originally a function in the \texttt{string} module. \texttt{zfill()} pads a numeric string with zeros on the left until it's the specified width. Note that the \% operator is still more flexible and powerful than \texttt{zfill()}.

\begin{verbatim}
>>> '45'.zfill(4)
'0045'
>>> '12345'.zfill(4)
'12345'
>>> 'goofy'.zfill(6)
'0goofy'
\end{verbatim}

(Contributed by Walter Dörwald.)

- A new type object, \texttt{basestring}, has been added. Both 8-bit strings and Unicode strings inherit from this type, so \texttt{isinstance(obj, basestring)} will return \texttt{True} for either kind of string. It's a completely abstract type, so you can't create \texttt{basestring} instances.

- Interned strings are no longer immortal and will now be garbage-collected in the usual way when the only reference to them is from the internal dictionary of interned strings. (Implemented by Oren Tirosh.)

\section*{Optimizations}

- The creation of new-style class instances has been made much faster; they're now faster than classic classes!
- The \texttt{sort()} method of list objects has been extensively rewritten by Tim Peters, and the implementation is significantly faster.
Multiplication of large long integers is now much faster thanks to an implementation of Karatsuba multiplication, an algorithm that scales better than the \( O(n^2) \) required for the grade-school multiplication algorithm. (Original patch by Christopher A. Craig, and significantly reworked by Tim Peters.)

The `SET_LINENO` opcode is now gone. This may provide a small speed increase, depending on your compiler's idiosyncrasies. See section *Other Changes and Fixes* for a longer explanation. (Removed by Michael Hudson.)

`xrange()` objects now have their own iterator, making `for i in xrange(n)` slightly faster than `for i in range(n)`. (Patch by Raymond Hettinger.)

A number of small rearrangements have been made in various hotspots to improve performance, such as inlining a function or removing some code. (Implemented mostly by GvR, but lots of people have contributed single changes.)

The net result of the 2.3 optimizations is that Python 2.3 runs the pystone benchmark around 25% faster than Python 2.2.
New, Improved, and Deprecated Modules

As usual, Python's standard library received a number of enhancements and bug fixes. Here's a partial list of the most notable changes, sorted alphabetically by module name. Consult the Misc/NEWS file in the source tree for a more complete list of changes, or look through the CVS logs for all the details.

- The `array` module now supports arrays of Unicode characters using the 'u' format character. Arrays also now support using the `+=` assignment operator to add another array's contents, and the `*=` assignment operator to repeat an array. (Contributed by Jason Orendorff.)

- The `bsddb` module has been replaced by version 4.1.6 of the PyBSDDB package, providing a more complete interface to the transactional features of the BerkeleyDB library. The old version of the module has been renamed to `bsdddb185` and is no longer built automatically; you'll have to edit `Modules/Setup` to enable it. Note that the new bsddb package is intended to be compatible with the old module, so be sure to file bugs if you discover any incompatibilities. When upgrading to Python 2.3, if the new interpreter is compiled with a new version of the underlying BerkeleyDB library, you will almost certainly have to convert your database files to the new version. You can do this fairly easily with the new scripts `db2pickle.py` and `pickle2db.py` which you will find in the distribution's `Tools/scripts` directory. If you've already been using the PyBSDDB package and importing it as `bsddb3`, you will have to change your `import` statements to import it as `bsddb`. 
- The new **bz2** module is an interface to the bz2 data compression library. bz2-compressed data is usually smaller than corresponding **zlib**-compressed data. (Contributed by Gustavo Niemeyer.)

- A set of standard date/time types has been added in the new **datetime** module. See the following section for more details.

- The Distutils Extension class now supports an extra constructor argument named **depends** for listing additional source files that an extension depends on. This lets Distutils recompile the module if any of the dependency files are modified. For example, if `sampmodule.c` includes the header file `sample.h`, you would create the Extension object like this:

  ```python
  ext = Extension("samp",
  sources=["sampmodule.c"],
  depends=["sample.h"])
  ```

  Modifying `sample.h` would then cause the module to be recompiled. (Contributed by Jeremy Hylton.)

- Other minor changes to Distutils: it now checks for the CC, CFLAGS, CPP, LDFLAGS, and CPPFLAGS environment variables, using them to override the settings in Python’s configuration (contributed by Robert Weber).

- Previously the **doctest** module would only search the docstrings of public methods and functions for test cases, but it now also examines private ones as well. The DocTestSuite() function creates a `unittest.TestSuite` object from a set of **doctest** tests.
• The new \texttt{gc.get_referents(object)} function returns a list of all the objects referenced by \textit{object}.

• The \texttt{getopt} module gained a new function, \texttt{gnu_getopt()}, that supports the same arguments as the existing \texttt{getopt()} function but uses GNU-style scanning mode. The existing \texttt{getopt()} stops processing options as soon as a non-option argument is encountered, but in GNU-style mode processing continues, meaning that options and arguments can be mixed. For example:

```python
>>> import getopt
>>> print(getopt.getopt(['-f', 'filename', 'output', ''], [('-f', 'filename')], ['output', '-v']))
>>> print(getopt.gnu_getopt(['-f', 'filename', 'output', [('-f', 'filename'), ('-v', '')], ['output']])
```

(Contributed by Peter Åstrand.)

• The \texttt{grp}, \texttt{pwd}, and \texttt{resource} modules now return enhanced tuples:

```python
>>> import grp
>>> g = grp.getgrnam('amk')
>>> g.gr_name, g.gr_gid ('amk', 500)
```

• The \texttt{gzip} module can now handle files exceeding 2 GiB.

• The new \texttt{heapq} module contains an implementation of a heap queue algorithm. A heap is an array-like data structure that keeps items in a partially sorted order such that, for every index \( k \), \( \text{heap}[k] \leq \text{heap}[2 \times k + 1] \) and \( \text{heap}[k] \leq \text{heap}[2 \times k + 2] \). This makes it quick to remove the smallest item, and inserting a
new item while maintaining the heap property is $O(lg n)$. (See http://www.nist.gov/dads/HTML/priorityque.html for more information about the priority queue data structure.)

The `heapq` module provides `heappush()` and `heappop()` functions for adding and removing items while maintaining the heap property on top of some other mutable Python sequence type. Here's an example that uses a Python list:

```python
>>> import heapq
>>> heap = []
>>> for item in [3, 7, 5, 11, 1]:
...     heapq.heappush(heap, item)
...
>>> heap
[1, 3, 5, 11, 7]
>>> heapq.heappop(heap)
1
>>> heapq.heappop(heap)
3
>>> heap
[5, 7, 11]
```

(Contributed by Kevin O'Connor.)

- The IDLE integrated development environment has been updated using the code from the IDLEfork project (http://idlefork.sf.net). The most notable feature is that the code being developed is now executed in a subprocess, meaning that there's no longer any need for manual `reload()` operations. IDLE's core code has been incorporated into the standard library as the `idlelib` package.

- The `imaplib` module now supports IMAP over SSL. (Contributed
by Piers Lauder and Tino Lange.)

- The **itertools** contains a number of useful functions for use with iterators, inspired by various functions provided by the ML and Haskell languages. For example, `itertools.ifilter(predicate, iterator)` returns all elements in the iterator for which the function `predicate()` returns `True`, and `itertools.repeat(obj, N)` returns `obj N` times. There are a number of other functions in the module; see the package's reference documentation for details. (Contributed by Raymond Hettinger.)

- Two new functions in the **math** module, `degrees(rads)` and `radians(degs)`, convert between radians and degrees. Other functions in the **math** module such as `math.sin()` and `math.cos()` have always required input values measured in radians. Also, an optional `base` argument was added to `math.log()` to make it easier to compute logarithms for bases other than `e` and `10`. (Contributed by Raymond Hettinger.)

- Several new POSIX functions (getpgid(), killpg(), lchown(), loadavg(), major(), makedev(), minor(), and mknod()) were added to the **posix** module that underlies the **os** module. (Contributed by Gustavo Niemeyer, Geert Jansen, and Denis S. Otkidach.)

- In the **os** module, the *stat() family of functions can now report fractions of a second in a timestamp. Such time stamps are represented as floats, similar to the value returned by `time.time()`.

  During testing, it was found that some applications will break if
time stamps are floats. For compatibility, when using the tuple interface of the stat_result time stamps will be represented as integers. When using named fields (a feature first introduced in Python 2.2), time stamps are still represented as integers, unless os.stat_float_times() is invoked to enable float return values:

```python
>>> os.stat("/tmp").st_mtime
1034791200
>>> os.stat_float_times(True)
>>> os.stat("/tmp").st_mtime
1034791200.6335014
```

In Python 2.4, the default will change to always returning floats.

Application developers should enable this feature only if all their libraries work properly when confronted with floating point time stamps, or if they use the tuple API. If used, the feature should be activated on an application level instead of trying to enable it on a per-use basis.

- The **optparse** module contains a new parser for command-line arguments that can convert option values to a particular Python type and will automatically generate a usage message. See the following section for more details.

- The old and never-documented **linuxaudiodev** module has been deprecated, and a new version named **ossaudiodev** has been added. The module was renamed because the OSS sound drivers can be used on platforms other than Linux, and the interface has also been tidied and brought up to date in various ways. (Contributed by Greg Ward and Nicholas FitzRoy-Dale.)
• The new `platform` module contains a number of functions that try to determine various properties of the platform you're running on. There are functions for getting the architecture, CPU type, the Windows OS version, and even the Linux distribution version. (Contributed by Marc-André Lemburg.)

• The parser objects provided by the `pyexpat` module can now optionally buffer character data, resulting in fewer calls to your character data handler and therefore faster performance. Setting the parser object's `buffer_text` attribute to `True` will enable buffering.

• The `sample(population, k)` function was added to the `random` module. `population` is a sequence or `xrange` object containing the elements of a population, and `sample()` chooses `k` elements from the population without replacing chosen elements. `k` can be any value up to `len(population)`. For example:

```python
days = ['Mo', 'Tu', 'We', 'Th', 'Fr', 'St', 'Sn']
>>> random.sample(days, 3)  # Choose 3 elements
['St', 'Sn', 'Th']
>>> random.sample(days, 7)  # Choose 7 elements
['Tu', 'Th', 'Mo', 'We', 'St', 'Fr', 'Sn']
>>> random.sample(days, 7)  # Choose 7 again
['We', 'Mo', 'Sn', 'Fr', 'Tu', 'St', 'Th']
>>> random.sample(days, 8)  # Can't choose elements
Traceback (most recent call last):
  File "<stdin>", line 1, in ?
  File "random.py", line 414, in sample
    raise ValueError, "sample larger than population"
ValueError: sample larger than population

>>> random.sample(xrange(1,10000,2), 10)  # Choose 10 odd numbers
[3407, 3805, 1505, 7023, 2401, 2267, 9733, 3151, 8083, 9195]
```
The `random` module now uses a new algorithm, the Mersenne Twister, implemented in C. It's faster and more extensively studied than the previous algorithm.

(All changes contributed by Raymond Hettinger.)

- The `readline` module also gained a number of new functions: `get_history_item()`, `get_current_history_length()`, and `redisplay()`.

- The `reexec` and Bastion modules have been declared dead, and attempts to import them will fail with a `RuntimeError`. New-style classes provide new ways to break out of the restricted execution environment provided by `reexec`, and no one has interest in fixing them or time to do so. If you have applications using `reexec`, rewrite them to use something else.

  (Sticking with Python 2.2 or 2.1 will not make your applications any safer because there are known bugs in the `reexec` module in those versions. To repeat: if you're using `reexec`, stop using it immediately.)

- The `rotor` module has been deprecated because the algorithm it uses for encryption is not believed to be secure. If you need encryption, use one of the several AES Python modules that are available separately.

- The `shutil` module gained a `move(src, dest)` function that recursively moves a file or directory to a new location.

- Support for more advanced POSIX signal handling was added to the `signal` but then removed again as it proved impossible to
make it work reliably across platforms.

- The `socket` module now supports timeouts. You can call the `settimeout(t)` method on a socket object to set a timeout of `t` seconds. Subsequent socket operations that take longer than `t` seconds to complete will abort and raise a `socket.timeout` exception.

  The original timeout implementation was by Tim O’Malley. Michael Gilfix integrated it into the Python `socket` module and shepherded it through a lengthy review. After the code was checked in, Guido van Rossum rewrote parts of it. (This is a good example of a collaborative development process in action.)

- On Windows, the `socket` module now ships with Secure Sockets Layer (SSL) support.

- The value of the C `PYTHON_API_VERSION` macro is now exposed at the Python level as `sys.api_version`. The current exception can be cleared by calling the new `sys.exc_clear()` function.

- The new `tarfile` module allows reading from and writing to tar-format archive files. (Contributed by Lars Gustäbel.)

- The new `textwrap` module contains functions for wrapping strings containing paragraphs of text. The `wrap(text, width)` function takes a string and returns a list containing the text split into lines of no more than the chosen width. The `fill(text, width)` function returns a single string, reformatted to fit into lines no longer than the chosen width. (As you can guess, `fill()` is built on top of `wrap()`. For example:
The module also contains a `TextWrapper` class that actually implements the text wrapping strategy. Both the `TextWrapper` class and the `wrap()` and `fill()` functions support a number of additional keyword arguments for fine-tuning the formatting; consult the module's documentation for details. (Contributed by Greg Ward.)

- The thread and `threading` modules now have companion modules, `dummy_thread` and `dummy_threading`, that provide a do-nothing implementation of the thread module's interface for platforms where threads are not supported. The intention is to simplify thread-aware modules (ones that don't rely on threads to run) by putting the following code at the top:

```python
try:
    import threading as _threading
except ImportError:
    import dummy_threading as _threading
```
In this example, _threading is used as the module name to make it clear that the module being used is not necessarily the actual \texttt{threading} module. Code can call functions and use classes in \_threading whether or not threads are supported, avoiding an \texttt{if} statement and making the code slightly clearer. This module will not magically make multithreaded code run without threads; code that waits for another thread to return or to do something will simply hang forever.

- The \texttt{time} module's \texttt{strptime()} function has long been an annoyance because it uses the platform C library's \texttt{strptime()} implementation, and different platforms sometimes have odd bugs. Brett Cannon contributed a portable implementation that's written in pure Python and should behave identically on all platforms.

- The new \texttt{timeit} module helps measure how long snippets of Python code take to execute. The \texttt{timeit.py} file can be run directly from the command line, or the module's \texttt{Timer} class can be imported and used directly. Here's a short example that figures out whether it's faster to convert an 8-bit string to Unicode by appending an empty Unicode string to it or by using the \texttt{unicode()} function:

```
import timeit

timer1 = timeit.Timer('unicode("abc")')
timer2 = timeit.Timer("abc" + u""")

# Run three trials
print timer1.repeat(repeat=3, number=100000)
print timer2.repeat(repeat=3, number=100000)
```
The Tix module has received various bug fixes and updates for the current version of the Tix package.

The Tkinter module now works with a thread-enabled version of Tcl. Tcl's threading model requires that widgets only be accessed from the thread in which they're created; accesses from another thread can cause Tcl to panic. For certain Tcl interfaces, Tkinter will now automatically avoid this when a widget is accessed from a different thread by marshalling a command, passing it to the correct thread, and waiting for the results. Other interfaces can't be handled automatically but Tkinter will now raise an exception on such an access so that you can at least find out about the problem. See http://mail.python.org/pipermail/python-dev/2002-December/031107.html for a more detailed explanation of this change. (Implemented by Martin von Löwis.)

Calling Tcl methods through _tkinter no longer returns only strings. Instead, if Tcl returns other objects those objects are converted to their Python equivalent, if one exists, or wrapped with a _tkinter.Tcl_Obj object if no Python equivalent exists. This behavior can be controlled through the wantobjects() method of tkapp objects.

When using _tkinter through the Tkinter module (as most Tkinter applications will), this feature is always activated. It should not cause compatibility problems, since Tkinter would always convert string results to Python types where possible.
If any incompatibilities are found, the old behavior can be restored
by setting the wantobjects variable in the Tkinter module to
false before creating the first tkapp object.
import Tkinter
Tkinter.wantobjects = 0
Any breakage caused by this change should be reported as a
bug.
The UserDict module has a new DictMixin class which
defines all dictionary methods for classes that already have a
minimum mapping interface. This greatly simplifies writing classes
that need to be substitutable for dictionaries, such as the classes
in the shelve module.
Adding the mix-in as a superclass provides the full dictionary
interface whenever the class defines __getitem__(),
__setitem__(), __delitem__(), and keys(). For example:

>>> import UserDict
>>> class SeqDict(UserDict.DictMixin):
...
"""Dictionary lookalike implemented with lists.""
...
def __init__(self):
...
self.keylist = []
...
self.valuelist = []
...
def __getitem__(self, key):
...
try:
...
i = self.keylist.index(key)
...
except ValueError:
...
raise KeyError
...
return self.valuelist[i]
...
def __setitem__(self, key, value):
...
try:


The DOM implementation in `xml.dom.minidom` can now generate XML output in a particular encoding by providing an optional encoding argument to the `toxml()` and `toprettyxml()` methods of DOM nodes.

The `xmlrpcclib` module now supports an XML-RPC extension for handling nil data values such as Python's None. Nil values are always supported on unmarshalling an XML-RPC response. To generate requests containing None, you must supply a true value
for the *allow_none* parameter when creating a Marshaller instance.

- The new DocXMLRPCServer module allows writing self-documenting XML-RPC servers. Run it in demo mode (as a program) to see it in action. Pointing the Web browser to the RPC server produces pydoc-style documentation; pointing xmlrpclib to the server allows invoking the actual methods. (Contributed by Brian Quinlan.)

- Support for internationalized domain names (RFCs 3454, 3490, 3491, and 3492) has been added. The “idna” encoding can be used to convert between a Unicode domain name and the ASCII-compatible encoding (ACE) of that name.

    ```python
    u"www.Alliancefrançaise.nu".encode("idna" 'www.xn--alliancefranaise-npb.nu')
    ```

The *socket* module has also been extended to transparently convert Unicode hostnames to the ACE version before passing them to the C library. Modules that deal with hostnames such as *httpplib* and *ftplib*) also support Unicode host names; *httpplib* also sends HTTP Host headers using the ACE version of the domain name. *urllib* supports Unicode URLs with non-ASCII host names as long as the path part of the URL is ASCII only.

To implement this change, the *stringprep* module, the *mkstringprep* tool and the *punycode* encoding have been added.

**Date/Time Type**
Date and time types suitable for expressing timestamps were added as the `datetime` module. The types don’t support different calendars or many fancy features, and just stick to the basics of representing time.

The three primary types are: date, representing a day, month, and year; `time`, consisting of hour, minute, and second; and `datetime`, which contains all the attributes of both date and `time`. There's also a `timedelta` class representing differences between two points in time, and time zone logic is implemented by classes inheriting from the abstract `tzinfo` class.

You can create instances of `date` and `time` by either supplying keyword arguments to the appropriate constructor, e.g. `datetime.date(year=1972, month=10, day=15)`, or by using one of a number of class methods. For example, the `date.today()` class method returns the current local date.

Once created, instances of the date/time classes are all immutable. There are a number of methods for producing formatted strings from objects:

```python
>>> import datetime
>>> now = datetime.datetime.now()
>>> now.isoformat()
'2002-12-30T21:27:03.994956'
>>> now.ctime()  # Only available on date, datetime
'Mon Dec 30 21:27:03 2002'
>>> now.strftime('%Y %d %b')
'2002 30 Dec'
```

The `replace()` method allows modifying one or more fields of a
date or `datetime` instance, returning a new instance:

```python
>>> d = datetime.datetime.now()
>>> d
datetime.datetime(2002, 12, 30, 22, 15, 38, 827738)
>>> d.replace(year=2001, hour = 12)
datetime.datetime(2001, 12, 30, 12, 15, 38, 827738)
```

Instances can be compared, hashed, and converted to strings (the result is the same as that of `isoformat()`). `date` and `datetime` instances can be subtracted from each other, and added to `timedelta` instances. The largest missing feature is that there's no standard library support for parsing strings and getting back a `date` or `datetime`.

For more information, refer to the module's reference documentation. (Contributed by Tim Peters.)

**The optparse Module**

The `getopt` module provides simple parsing of command-line arguments. The new `optparse` module (originally named `Optik`) provides more elaborate command-line parsing that follows the Unix conventions, automatically creates the output for `--help`, and can perform different actions for different options.

You start by creating an instance of `OptionParser` and telling it what your program's options are.

```python
import sys
from optparse import OptionParser
```
op = OptionParser()
op.add_option('-i', '--input',
    action='store', type='string', dest='input',
    help='set input filename')
op.add_option('-l', '--length',
    action='store', type='int', dest='length',
    help='set maximum length of output')

Parsing a command line is then done by calling the parse_args() method.

```python
options, args = op.parse_args(sys.argv[1:])
print options
print args
```

This returns an object containing all of the option values, and a list of strings containing the remaining arguments.

Invoking the script with the various arguments now works as you'd expect it to. Note that the length argument is automatically converted to an integer.

```
$ ./python opt.py -i data arg1
<Values at 0x400cad4c: {'input': 'data', 'length': None} [
'arg1']
$ ./python opt.py --input=data --length=4
<Values at 0x400cad2c: {'input': 'data', 'length': 4} []
$
```

The help message is automatically generated for you:

```
$ ./python opt.py --help
usage: opt.py [options]
```
options:
  -h, --help           show this help message and exit
  -i INPUT, --input=INPUT  set input filename
  -l LENGTH, --length=LENGTH  set maximum length of output

See the module's documentation for more details.

Optik was written by Greg Ward, with suggestions from the readers of the Getopt SIG.
**Pymalloc: A Specialized Object Allocator**

Pymalloc, a specialized object allocator written by Vladimir Marangozov, was a feature added to Python 2.1. Pymalloc is intended to be faster than the system `malloc()` and to have less memory overhead for allocation patterns typical of Python programs. The allocator uses C's `malloc()` function to get large pools of memory and then fulfills smaller memory requests from these pools.

In 2.1 and 2.2, pymalloc was an experimental feature and wasn't enabled by default; you had to explicitly enable it when compiling Python by providing the `--with-pymalloc` option to the `configure` script. In 2.3, pymalloc has had further enhancements and is now enabled by default; you'll have to supply `--without-pymalloc` to disable it.

This change is transparent to code written in Python; however, pymalloc may expose bugs in C extensions. Authors of C extension modules should test their code with pymalloc enabled, because some incorrect code may cause core dumps at runtime.

There's one particularly common error that causes problems. There are a number of memory allocation functions in Python's C API that have previously just been aliases for the C library's `malloc()` and `free()`, meaning that if you accidentally called mismatched functions the error wouldn't be noticeable. When the object allocator is enabled, these functions aren't aliases of `malloc()` and `free()` any more, and calling the wrong function to free memory may get you a core dump. For example, if memory was allocated using `PyObject_Malloc()`, it has to be freed using `PyObject_Free()`, not `free()`. A few modules included with Python fell afoul of this and had to be fixed; doubtless there are more third-party modules that will
have the same problem.

As part of this change, the confusing multiple interfaces for allocating memory have been consolidated down into two API families. Memory allocated with one family must not be manipulated with functions from the other family. There is one family for allocating chunks of memory and another family of functions specifically for allocating Python objects.

- To allocate and free an undistinguished chunk of memory use the “raw memory” family: `PyMem_Malloc()`, `PyMem_Realloc()`, and `PyMem_Free()`.
- The “object memory” family is the interface to the pymalloc facility described above and is biased towards a large number of “small” allocations: `PyObject_Malloc()`, `PyObject_Realloc()`, and `PyObject_Free()`.
- To allocate and free Python objects, use the “object” family `PyObject_New()`, `PyObject_NewVar()`, and `PyObject_Del()`.

Thanks to lots of work by Tim Peters, pymalloc in 2.3 also provides debugging features to catch memory overwrites and doubled frees in both extension modules and in the interpreter itself. To enable this support, compile a debugging version of the Python interpreter by running `configure` with `--with-pydebug`.

To aid extension writers, a header file `Misc/pymemcompat.h` is distributed with the source to Python 2.3 that allows Python extensions to use the 2.3 interfaces to memory allocation while compiling against any version of Python since 1.5.2. You would copy the file from Python’s source distribution and bundle it with the source of your extension.

http://svn.python.org/view/python/trunk/Objects/obmalloc.c

For the full details of the pymalloc implementation, see the comments at the top of the file Objects/obmalloc.c in the Python source code. The above link points to the file within the python.org SVN browser.
Build and C API Changes

Changes to Python’s build process and to the C API include:

- The cycle detection implementation used by the garbage collection has proven to be stable, so it’s now been made mandatory. You can no longer compile Python without it, and the `-with-cycle-gc` switch to `configure` has been removed.
- Python can now optionally be built as a shared library (`libpython2.3.so`) by supplying `--enable-shared` when running Python’s `configure` script. (Contributed by Ondrej Palkovsky.)
- The `DL_EXPORT` and `DL_IMPORT` macros are now deprecated. Initialization functions for Python extension modules should now be declared using the new macro `PyMODINIT_FUNC`, while the Python core will generally use the `PyAPI_FUNC` and `PyAPI_DATA` macros.
- The interpreter can be compiled without any docstrings for the built-in functions and modules by supplying `--without-doc-strings` to the `configure` script. This makes the Python executable about 10% smaller, but will also mean that you can’t get help for Python’s built-ins. (Contributed by Gustavo Niemeyer.)
- The `PyArg_NoArgs()` macro is now deprecated, and code that uses it should be changed. For Python 2.2 and later, the method definition table can specify the `METH_NOARGS` flag, signalling that there are no arguments, and the argument checking can then be removed. If compatibility with pre-2.2 versions of Python is important, the code could use `PyArg_ParseTuple(args, "")` instead, but this will be slower than using `METH_NOARGS`.
- `PyArg_ParseTuple()` accepts new format characters for various sizes of unsigned integers: `B` for unsigned char, `H` for unsigned short int, `I` for unsigned int, and `K` for unsigned long long.
A new function, `PyObject_DelItemString(mapping, char *key)` was added as shorthand for `PyObject_DelItem(mapping, PyString_New(key))`.

File objects now manage their internal string buffer differently, increasing it exponentially when needed. This results in the benchmark tests in `Lib/test/test_bufio.py` speeding up considerably (from 57 seconds to 1.7 seconds, according to one measurement).

It's now possible to define class and static methods for a C extension type by setting either the `METH_CLASS` or `METH_STATIC` flags in a method's `PyMethodDef` structure.

Python now includes a copy of the Expat XML parser's source code, removing any dependence on a system version or local installation of Expat.

If you dynamically allocate type objects in your extension, you should be aware of a change in the rules relating to the `__module__` and `__name__` attributes. In summary, you will want to ensure the type's dictionary contains a `__module__` key; making the module name the part of the type name leading up to the final period will no longer have the desired effect. For more detail, read the API reference documentation or the source.

Port-Specific Changes

Support for a port to IBM's OS/2 using the EMX runtime environment was merged into the main Python source tree. EMX is a POSIX emulation layer over the OS/2 system APIs. The Python port for EMX tries to support all the POSIX-like capability exposed by the EMX runtime, and mostly succeeds; `fork()` and `fcntl()` are restricted by the limitations of the underlying emulation layer. The standard OS/2 port, which uses IBM's Visual Age compiler, also gained support for case-sensitive import semantics as part of the integration of the EMX
port into CVS. (Contributed by Andrew MacIntyre.)

On MacOS, most toolbox modules have been weaklinked to improve backward compatibility. This means that modules will no longer fail to load if a single routine is missing on the current OS version. Instead calling the missing routine will raise an exception. (Contributed by Jack Jansen.)

The RPM spec files, found in the Misc/RPM/ directory in the Python source distribution, were updated for 2.3. (Contributed by Sean Reifschneider.)

Other new platforms now supported by Python include AtheOS (http://www.atheos.cx/), GNU/Hurd, and OpenVMS.
Other Changes and Fixes

As usual, there were a bunch of other improvements and bug fixes scattered throughout the source tree. A search through the CVS change logs finds there were 523 patches applied and 514 bugs fixed between Python 2.2 and 2.3. Both figures are likely to be underestimates.

Some of the more notable changes are:

- If the PYTHONINSPECT environment variable is set, the Python interpreter will enter the interactive prompt after running a Python program, as if Python had been invoked with the `-i` option. The environment variable can be set before running the Python interpreter, or it can be set by the Python program as part of its execution.

- The regrtest.py script now provides a way to allow “all resources except foo.” A resource name passed to the `-u` option can now be prefixed with a hyphen (`'-'`) to mean “remove this resource.” For example, the option `'ua11,-bsddb'` could be used to enable the use of all resources except bsddb.

- The tools used to build the documentation now work under Cygwin as well as Unix.

- The SET_LINENO opcode has been removed. Back in the mists of time, this opcode was needed to produce line numbers in tracebacks and support trace functions (for, e.g., pdb). Since Python 1.5, the line numbers in tracebacks have been computed using a different mechanism that works with “python -O”. For Python 2.3 Michael Hudson implemented a similar scheme to
determine when to call the trace function, removing the need for `SET_LINENO` entirely.

It would be difficult to detect any resulting difference from Python code, apart from a slight speed up when Python is run without `-O`.

C extensions that access the `f_lineno` field of frame objects should instead call `PyCode_Addr2Line(f->f_code, f->f_lineno)`. This will have the added effect of making the code work as desired under “python -O” in earlier versions of Python.

A nifty new feature is that trace functions can now assign to the `f_lineno` attribute of frame objects, changing the line that will be executed next. A `jump` command has been added to the `pdb` debugger taking advantage of this new feature. (Implemented by Richie Hindle.)
Porting to Python 2.3

This section lists previously described changes that may require changes to your code:

- **yield** is now always a keyword; if it’s used as a variable name in your code, a different name must be chosen.

- For strings $X$ and $Y$, $X \text{ in } Y$ now works if $X$ is more than one character long.

- The **int()** type constructor will now return a long integer instead of raising an **OverflowError** when a string or floating-point number is too large to fit into an integer.

- If you have Unicode strings that contain 8-bit characters, you must declare the file’s encoding (UTF-8, Latin-1, or whatever) by adding a comment to the top of the file. See section **PEP 263: Source Code Encodings** for more information.

- Calling Tcl methods through **_tkinter** no longer returns only strings. Instead, if Tcl returns other objects those objects are converted to their Python equivalent, if one exists, or wrapped with a **_tkinter.Tcl_Obj** object if no Python equivalent exists.

- Large octal and hex literals such as 0xffffffff now trigger a **FutureWarning**. Currently they’re stored as 32-bit numbers and result in a negative value, but in Python 2.4 they’ll become positive long integers.

  There are a few ways to fix this warning. If you really need a positive number, just add an **L** to the end of the literal. If you’re
trying to get a 32-bit integer with low bits set and have previously used an expression such as \( ~(1 \ll 31) \), it’s probably clearest to start with all bits set and clear the desired upper bits. For example, to clear just the top bit (bit 31), you could write \( 0xffffffffL \ &~(1L\ll31) \).

- You can no longer disable assertions by assigning to `__debug__`.

- The Distutils `setup()` function has gained various new keyword arguments such as `depends`. Old versions of the Distutils will abort if passed unknown keywords. A solution is to check for the presence of the new `get_distutil_options()` function in your `setup.py` and only uses the new keywords with a version of the Distutils that supports them:

```
from distutils import core

kw = {'sources': 'foo.c', ...}
if hasattr(core, 'get_distutil_options'):
    kw['depends'] = ['foo.h']
ext = Extension(**kw)
```

- Using `None` as a variable name will now result in a `SyntaxWarning` warning.

- Names of extension types defined by the modules included with Python now contain the module and a `'.'` in front of the type name.

What’s New in Python 2.2

Author: A.M. Kuchling
Introduction

This article explains the new features in Python 2.2.2, released on October 14, 2002. Python 2.2.2 is a bugfix release of Python 2.2, originally released on December 21, 2001.

Python 2.2 can be thought of as the “cleanup release”. There are some features such as generators and iterators that are completely new, but most of the changes, significant and far-reaching though they may be, are aimed at cleaning up irregularities and dark corners of the language design.

This article doesn’t attempt to provide a complete specification of the new features, but instead provides a convenient overview. For full details, you should refer to the documentation for Python 2.2, such as the Python Library Reference and the Python Reference Manual. If you want to understand the complete implementation and design rationale for a change, refer to the PEP for a particular new feature.
PEPs 252 and 253: Type and Class Changes

The largest and most far-reaching changes in Python 2.2 are to Python's model of objects and classes. The changes should be backward compatible, so it's likely that your code will continue to run unchanged, but the changes provide some amazing new capabilities. Before beginning this, the longest and most complicated section of this article, I'll provide an overview of the changes and offer some comments.

A long time ago I wrote a Web page listing flaws in Python's design. One of the most significant flaws was that it's impossible to subclass Python types implemented in C. In particular, it's not possible to subclass built-in types, so you can't just subclass, say, lists in order to add a single useful method to them. The UserList module provides a class that supports all of the methods of lists and that can be subclassed further, but there's lots of C code that expects a regular Python list and won't accept a UserList instance.

Python 2.2 fixes this, and in the process adds some exciting new capabilities. A brief summary:

- You can subclass built-in types such as lists and even integers, and your subclasses should work in every place that requires the original type.
- It's now possible to define static and class methods, in addition to the instance methods available in previous versions of Python.
- It's also possible to automatically call methods on accessing or setting an instance attribute by using a new mechanism called properties. Many uses of `__getattr__()` can be rewritten to use properties instead, making the resulting code simpler and
faster. As a small side benefit, attributes can now have docstrings, too.

- The list of legal attributes for an instance can be limited to a particular set using slots, making it possible to safeguard against typos and perhaps make more optimizations possible in future versions of Python.

Some users have voiced concern about all these changes. Sure, they say, the new features are neat and lend themselves to all sorts of tricks that weren’t possible in previous versions of Python, but they also make the language more complicated. Some people have said that they’ve always recommended Python for its simplicity, and feel that its simplicity is being lost.

Personally, I think there’s no need to worry. Many of the new features are quite esoteric, and you can write a lot of Python code without ever needed to be aware of them. Writing a simple class is no more difficult than it ever was, so you don’t need to bother learning or teaching them unless they’re actually needed. Some very complicated tasks that were previously only possible from C will now be possible in pure Python, and to my mind that's all for the better.

I’m not going to attempt to cover every single corner case and small change that were required to make the new features work. Instead this section will paint only the broad strokes. See section Related Links, “Related Links”, for further sources of information about Python 2.2's new object model.

Old and New Classes

First, you should know that Python 2.2 really has two kinds of classes: classic or old-style classes, and new-style classes. The old-style class model is exactly the same as the class model in earlier versions of
Python. All the new features described in this section apply only to new-style classes. This divergence isn’t intended to last forever; eventually old-style classes will be dropped, possibly in Python 3.0.

So how do you define a new-style class? You do it by subclassing an existing new-style class. Most of Python’s built-in types, such as integers, lists, dictionaries, and even files, are new-style classes now. A new-style class named `object`, the base class for all built-in types, has also been added so if no built-in type is suitable, you can just subclass `object`:

```python
class C(object):
    def __init__(self):
        ...
...
```

This means that `class` statements that don’t have any base classes are always classic classes in Python 2.2. (Actually you can also change this by setting a module-level variable named `__metaclass__` — see PEP 253 for the details — but it’s easier to just subclass `object`.)

The type objects for the built-in types are available as built-ins, named using a clever trick. Python has always had built-in functions named `int()`, `float()`, and `str()`. In 2.2, they aren’t functions any more, but type objects that behave as factories when called.

```python
>>> int
<type 'int'>
>>> int('123')
123
```

To make the set of types complete, new type objects such as `dict()`
and `file()` have been added. Here’s a more interesting example, adding a `lock()` method to `file` objects:

```python
class LockableFile(file):
    def lock(self, operation, length=0, start=0, whence=0):
        import fcntl
        return fcntl.lockf(self.fileno(), operation, length, start, whence)
```

The now-obsolete `posixfile` module contained a class that emulated all of a file object’s methods and also added a `lock()` method, but this class couldn’t be passed to internal functions that expected a built-in file, something which is possible with our new `LockableFile`.

**Descriptors**

In previous versions of Python, there was no consistent way to discover what attributes and methods were supported by an object. There were some informal conventions, such as defining `__members__` and `__methods__` attributes that were lists of names, but often the author of an extension type or a class wouldn’t bother to define them. You could fall back on inspecting the `__dict__` of an object, but when class inheritance or an arbitrary `__getattr__()` hook were in use this could still be inaccurate.

The one big idea underlying the new class model is that an API for describing the attributes of an object using *descriptors* has been formalized. Descriptors specify the value of an attribute, stating whether it’s a method or a field. With the descriptor API, static methods and class methods become possible, as well as more exotic
Attribute descriptors are objects that live inside class objects, and have a few attributes of their own:

- `__name__` is the attribute's name.
- `__doc__` is the attribute's docstring.
- `__get__(object)` is a method that retrieves the attribute value from `object`.
- `__set__(object, value)` sets the attribute on `object` to `value`.
- `__delete__(object, value)` deletes the `value` attribute of `object`.

For example, when you write `obj.x`, the steps that Python actually performs are:

```python
descriptor = obj.__class__.x
descriptor.__get__(obj)
```

For methods, `descriptor.__get__()` returns a temporary object that's callable, and wraps up the instance and the method to be called on it. This is also why static methods and class methods are now possible; they have descriptors that wrap up just the method, or the method and the class. As a brief explanation of these new kinds of methods, static methods aren't passed the instance, and therefore resemble regular functions. Class methods are passed the class of the object, but not the object itself. Static and class methods are defined like this:

```python
class C(object):
    def f(arg1, arg2):
        ...
    f = staticmethod(f)
```
The `staticmethod()` function takes the function `f()`, and returns it wrapped up in a descriptor so it can be stored in the class object. You might expect there to be special syntax for creating such methods (`def static f`, `defstatic f()`, or something like that) but no such syntax has been defined yet; that’s been left for future versions of Python.

More new features, such as slots and properties, are also implemented as new kinds of descriptors, and it’s not difficult to write a descriptor class that does something novel. For example, it would be possible to write a descriptor class that made it possible to write Eiffel-style preconditions and postconditions for a method. A class that used this feature might be defined like this:

```python
from eiffel import eiffelmethod

class C(object):
    def f(self, arg1, arg2):
        # The actual function
        ...
    def pre_f(self):
        # Check preconditions
        ...
    def post_f(self):
        # Check postconditions
        ...
    f = eiffelmethod(f, pre_f, post_f)
```

Note that a person using the new `eiffelmethod()` doesn’t have to
understand anything about descriptors. This is why I think the new features don’t increase the basic complexity of the language. There will be a few wizards who need to know about it in order to write `eiffelmethod()` or the ZODB or whatever, but most users will just write code on top of the resulting libraries and ignore the implementation details.

**Multiple Inheritance: The Diamond Rule**

Multiple inheritance has also been made more useful through changing the rules under which names are resolved. Consider this set of classes (diagram taken from PEP 253 by Guido van Rossum):

```python
class A:
    def save(self): ...

class B

class C:
    def save(self): ...

class D
```

The lookup rule for classic classes is simple but not very smart; the base classes are searched depth-first, going from left to right. A reference to `D.save()` will search the classes `D`, `B`, and then `A`, where `save()` would be found and returned. `C.save()` would never be found at all. This is bad, because if `C`’s `save()` method is saving some internal state specific to `C`, not calling it will result in that state
never getting saved.

New-style classes follow a different algorithm that's a bit more complicated to explain, but does the right thing in this situation. (Note that Python 2.3 changes this algorithm to one that produces the same results in most cases, but produces more useful results for really complicated inheritance graphs.)

1. List all the base classes, following the classic lookup rule and include a class multiple times if it's visited repeatedly. In the above example, the list of visited classes is [D, B, A, C, A].

2. Scan the list for duplicated classes. If any are found, remove all but one occurrence, leaving the last one in the list. In the above example, the list becomes [D, B, C, A] after dropping duplicates.

Following this rule, referring to D.save() will return C.save(), which is the behaviour we're after. This lookup rule is the same as the one followed by Common Lisp. A new built-in function, super(), provides a way to get at a class's superclasses without having to reimplement Python's algorithm. The most commonly used form will be super(class, obj), which returns a bound superclass object (not the actual class object). This form will be used in methods to call a method in the superclass; for example, D's save() method would look like this:

```python
class D (B,C):
    def save (self):
        # Call superclass .save()
        super(D, self).save()
        # Save D's private information here
        ...
```

super() can also return unbound superclass objects when called as
super(class) or super(class1, class2), but this probably won't often be useful.

Attribute Access

A fair number of sophisticated Python classes define hooks for attribute access using \_\_getattr\_\_(); most commonly this is done for convenience, to make code more readable by automatically mapping an attribute access such as obj.parent into a method call such as obj.get_parent. Python 2.2 adds some new ways of controlling attribute access.

First, \_\_getattr\_\_(attr\_name) is still supported by new-style classes, and nothing about it has changed. As before, it will be called when an attempt is made to access obj.foo and no attribute named foo is found in the instance's dictionary.

New-style classes also support a new method, \_\_getattribute\_\_(attr\_name). The difference between the two methods is that \_\_getattribute\_\_(\) is always called whenever any attribute is accessed, while the old \_\_getattr\_\_(\) is only called if foo isn't found in the instance's dictionary.

However, Python 2.2's support for properties will often be a simpler way to trap attribute references. Writing a \_\_getattr\_\_(\) method is complicated because to avoid recursion you can't use regular attribute accesses inside them, and instead have to mess around with the contents of \_\_dict\_. \_\_getattribute\_\_(\) methods also end up being called by Python when it checks for other methods such as \_\_repr\_\_(\) or \_\_coerce\_\_(\), and so have to be written with this in mind. Finally, calling a function on every attribute access results in a
sizable performance loss.

`property` is a new built-in type that packages up three functions that get, set, or delete an attribute, and a docstring. For example, if you want to define a size attribute that's computed, but also settable, you could write:

```python
class C(object):
    def get_size (self):
        result = ... computation ...
        return result
    def set_size (self, size):
        ... compute something based on the size
        and set internal state appropriately ...

    # Define a property. The 'delete this attribute
    # method is defined as None, so the attribute
    # can't be deleted.
    size = property(get_size, set_size,
                    None,
                    "Storage size of this instance")
```

That is certainly clearer and easier to write than a pair of `__getattr__()`/`__setattr__()` methods that check for the size attribute and handle it specially while retrieving all other attributes from the instance's `__dict__`. Accesses to size are also the only ones which have to perform the work of calling a function, so references to other attributes run at their usual speed.

Finally, it's possible to constrain the list of attributes that can be referenced on an object using the new `__slots__` class attribute. Python objects are usually very dynamic; at any time it's possible to define a new attribute on an instance by just doing `obj.new_attr=1`. 
A new-style class can define a class attribute named __slots__ to limit the legal attributes to a particular set of names. An example will make this clear:

```python
>>> class C(object):
...     __slots__ = ('template', 'name')
...
>>> obj = C()
>>> print obj.template
None
>>> obj.template = 'Test'
>>> print obj.template
Test
>>> obj.newattr = None
AttributeError: 'C' object has no attribute 'newattr'
```

Note how you get an AttributeError on the attempt to assign to an attribute not listed in __slots__.

Related Links

This section has just been a quick overview of the new features, giving enough of an explanation to start you programming, but many details have been simplified or ignored. Where should you go to get a more complete picture?

http://www.python.org/2.2/descrintro.html is a lengthy tutorial introduction to the descriptor features, written by Guido van Rossum. If my description has whetted your appetite, go read this tutorial next, because it goes into much more detail about the new features while still remaining quite easy to read.
Next, there are two relevant PEPs, **PEP 252** and **PEP 253**. **PEP 252** is titled “Making Types Look More Like Classes”, and covers the descriptor API. **PEP 253** is titled “Subtyping Built-in Types”, and describes the changes to type objects that make it possible to subtype built-in objects. **PEP 253** is the more complicated PEP of the two, and at a few points the necessary explanations of types and meta-types may cause your head to explode. Both PEPs were written and implemented by Guido van Rossum, with substantial assistance from the rest of the Zope Corp. team.

Finally, there’s the ultimate authority: the source code. Most of the machinery for the type handling is in `Objects/typeobject.c`, but you should only resort to it after all other avenues have been exhausted, including posting a question to python-list or python-dev.
PEP 234: Iterators

Another significant addition to 2.2 is an iteration interface at both the C and Python levels. Objects can define how they can be looped over by callers.

In Python versions up to 2.1, the usual way to make for item in obj work is to define a `__getitem__()` method that looks something like this:

```python
def __getitem__(self, index):
    return <next item>
```

`__getitem__()` is more properly used to define an indexing operation on an object so that you can write `obj[5]` to retrieve the sixth element. It’s a bit misleading when you’re using this only to support `for` loops. Consider some file-like object that wants to be looped over; the `index` parameter is essentially meaningless, as the class probably assumes that a series of `__getitem__()` calls will be made with `index` incrementing by one each time. In other words, the presence of the `__getitem__()` method doesn’t mean that using `file[5]` to randomly access the sixth element will work, though it really should.

In Python 2.2, iteration can be implemented separately, and `__getitem__()` methods can be limited to classes that really do support random access. The basic idea of iterators is simple. A new built-in function, `iter(obj)` or `iter(C, sentinel)`, is used to get an iterator. `iter(obj)` returns an iterator for the object `obj`, while `iter(C, sentinel)` returns an iterator that will invoke the callable object `C` until it returns `sentinel` to signal that the iterator is done.
Python classes can define an `__iter__()` method, which should create and return a new iterator for the object; if the object is its own iterator, this method can just return `self`. In particular, iterators will usually be their own iterators. Extension types implemented in C can implement a `tp_iter` function in order to return an iterator, and extension types that want to behave as iterators can define a `tp_iternext` function.

So, after all this, what do iterators actually do? They have one required method, `next()`, which takes no arguments and returns the next value. When there are no more values to be returned, calling `next()` should raise the `StopIteration` exception.

```python
>>> L = [1,2,3]
>>> i = iter(L)
>>> print i
<iterator object at 0x8116870>
>>> i.next()
1
>>> i.next()
2
>>> i.next()
3
>>> i.next()
Traceback (most recent call last):
  File "<stdin>" , line 1, in ?
StopIteration
```

In 2.2, Python’s `for` statement no longer expects a sequence; it expects something for which `iter()` will return an iterator. For backward compatibility and convenience, an iterator is automatically constructed for sequences that don’t implement `__iter__()` or a
tp_iter slot, so for i in [1,2,3] will still work. Wherever the Python interpreter loops over a sequence, it's been changed to use the iterator protocol. This means you can do things like this:

```python
>>> L = [1,2,3]
>>> i = iter(L)
>>> a,b,c = i
>>> a, b, c
(1, 2, 3)
```

Iterator support has been added to some of Python’s basic types. Calling `iter()` on a dictionary will return an iterator which loops over its keys:

```python
>>> m = {'Jan': 1, 'Feb': 2, 'Mar': 3, 'Apr': 4, 'May': 5, 'Jun': 6, 'Jul': 7, 'Aug': 8, 'Sep': 9, 'Oct': 10, 'Nov': 11, 'Dec': 12}
>>> for key in m: print key, m[key]
... Mar 3
Feb 2
Aug 8
Sep 9
May 5
Jun 6
Jul 7
Jan 1
Apr 4
Nov 11
Dec 12
Oct 10
```

That's just the default behaviour. If you want to iterate over keys, values, or key/value pairs, you can explicitly call the `iterkeys()`, `itervalues()`, or `iteritems()` methods to get an appropriate
iterator. In a minor related change, the in operator now works on dictionaries, so key in dict is now equivalent to dict.has_key(key).

Files also provide an iterator, which calls the readline() method until there are no more lines in the file. This means you can now read each line of a file using code like this:

```
for line in file:
    # do something for each line
...
```

Note that you can only go forward in an iterator; there's no way to get the previous element, reset the iterator, or make a copy of it. An iterator object could provide such additional capabilities, but the iterator protocol only requires a next() method.

**PEP 234 - Iterators**
Written by Ka-Ping Yee and GvR; implemented by the Python Labs crew, mostly by GvR and Tim Peters.
Generators are another new feature, one that interacts with the introduction of iterators.

You’re doubtless familiar with how function calls work in Python or C. When you call a function, it gets a private namespace where its local variables are created. When the function reaches a `return` statement, the local variables are destroyed and the resulting value is returned to the caller. A later call to the same function will get a fresh new set of local variables. But, what if the local variables weren’t thrown away on exiting a function? What if you could later resume the function where it left off? This is what generators provide; they can be thought of as resumable functions.

Here’s the simplest example of a generator function:

```python
def generate_ints(N):
    for i in range(N):
        yield i
```

A new keyword, `yield`, was introduced for generators. Any function containing a `yield` statement is a generator function; this is detected by Python’s bytecode compiler which compiles the function specially as a result. Because a new keyword was introduced, generators must be explicitly enabled in a module by including a `from __future__ import generators` statement near the top of the module’s source code. In Python 2.3 this statement will become unnecessary.

When you call a generator function, it doesn’t return a single value; instead it returns a generator object that supports the iterator protocol. On executing the `yield` statement, the generator outputs the value of
i, similar to a return statement. The big difference between yield and a return statement is that on reaching a yield the generator's state of execution is suspended and local variables are preserved. On the next call to the generator's next() method, the function will resume executing immediately after the yield statement. (For complicated reasons, the yield statement isn't allowed inside the try block of a try...finally statement; read PEP 255 for a full explanation of the interaction between yield and exceptions.)

Here's a sample usage of the generate_ints() generator:

```
>>> gen = generate_ints(3)
>>> gen
<generator object at 0x8117f90>
>>> gen.next()
0
>>> gen.next()
1
>>> gen.next()
2
>>> gen.next()
Traceback (most recent call last):
  File "<stdin>" , line 1, in ?
    File "<stdin>" , line 2, in generate_ints
StopIteration
```

You could equally write for i in generate_ints(5), or a,b,c = generate_ints(3).

Inside a generator function, the return statement can only be used without a value, and signals the end of the procession of values; afterwards the generator cannot return any further values. return with a value, such as return 5, is a syntax error inside a generator
function. The end of the generator’s results can also be indicated by raising **StopIteration** manually, or by just letting the flow of execution fall off the bottom of the function.

You could achieve the effect of generators manually by writing your own class and storing all the local variables of the generator as instance variables. For example, returning a list of integers could be done by setting `self.count` to 0, and having the `next()` method increment `self.count` and return it. However, for a moderately complicated generator, writing a corresponding class would be much messier. `Lib/test/test_generators.py` contains a number of more interesting examples. The simplest one implements an in-order traversal of a tree using generators recursively.

```python
# A recursive generator that generates Tree leaves in in-order.

def inorder(t):
    if t:
        for x in inorder(t.left):
            yield x
        yield t.label
        for x in inorder(t.right):
            yield x
```

Two other examples in `Lib/test/test_generators.py` produce solutions for the N-Queens problem (placing $N$ queens on an $NxN$ chess board so that no queen threatens another) and the Knight’s Tour (a route that takes a knight to every square of an $NxN$ chessboard without visiting any square twice).

The idea of generators comes from other programming languages, especially Icon (http://www.cs.arizona.edu/icon/), where the idea of generators is central. In Icon, every expression and function call behaves like a generator. One example from “An Overview of the Icon
Programming Language at http://www.cs.arizona.edu/icon/docs/ipd266.htm gives an idea of what this looks like:

```lisp
sentence := "Store it in the neighboring harbor"
if (i := find("or", sentence)) > 5 then write(i)
```

In Icon the `find()` function returns the indexes at which the substring “or” is found: 3, 23, 33. In the `if` statement, `i` is first assigned a value of 3, but 3 is less than 5, so the comparison fails, and Icon retries it with the second value of 23. 23 is greater than 5, so the comparison now succeeds, and the code prints the value 23 to the screen.

Python doesn’t go nearly as far as Icon in adopting generators as a central concept. Generators are considered a new part of the core Python language, but learning or using them isn’t compulsory; if they don’t solve any problems that you have, feel free to ignore them. One novel feature of Python’s interface as compared to Icon’s is that a generator’s state is represented as a concrete object (the iterator) that can be passed around to other functions or stored in a data structure.

**PEP 255 - Simple Generators**

Written by Neil Schemenauer, Tim Peters, Magnus Lie Hetland. Implemented mostly by Neil Schemenauer and Tim Peters, with other fixes from the Python Labs crew.
In recent versions, the distinction between regular integers, which are 32-bit values on most machines, and long integers, which can be of arbitrary size, was becoming an annoyance. For example, on platforms that support files larger than $2^{32}$ bytes, the `tell()` method of file objects has to return a long integer. However, there were various bits of Python that expected plain integers and would raise an error if a long integer was provided instead. For example, in Python 1.5, only regular integers could be used as a slice index, and `'abc'[1L:]` would raise a `TypeError` exception with the message ‘slice index must be int’.

Python 2.2 will shift values from short to long integers as required. The ‘L’ suffix is no longer needed to indicate a long integer literal, as now the compiler will choose the appropriate type. (Using the ‘L’ suffix will be discouraged in future 2.x versions of Python, triggering a warning in Python 2.4, and probably dropped in Python 3.0.) Many operations that used to raise an `OverflowError` will now return a long integer as their result. For example:

```
>>> 1234567890123
1234567890123L
>>> 2 ** 64
18446744073709551616L
```

In most cases, integers and long integers will now be treated identically. You can still distinguish them with the `type()` built-in function, but that’s rarely needed.

**PEP 237 - Unifying Long Integers and Integers**
Written by Moshe Zadka and Guido van Rossum. Implemented mostly by Guido van Rossum.
PEP 238: Changing the Division Operator

The most controversial change in Python 2.2 heralds the start of an effort to fix an old design flaw that’s been in Python from the beginning. Currently Python’s division operator, `/`, behaves like C’s division operator when presented with two integer arguments: it returns an integer result that’s truncated down when there would be a fractional part. For example, `3/2` is 1, not 1.5, and `(-1)/2` is -1, not -0.5. This means that the results of division can vary unexpectedly depending on the type of the two operands and because Python is dynamically typed, it can be difficult to determine the possible types of the operands.

(The controversy is over whether this is really a design flaw, and whether it’s worth breaking existing code to fix this. It’s caused endless discussions on python-dev, and in July 2001 erupted into an storm of acidly sarcastic postings on comp.lang.python. I won’t argue for either side here and will stick to describing what’s implemented in 2.2. Read PEP 238 for a summary of arguments and counter-arguments.)

Because this change might break code, it’s being introduced very gradually. Python 2.2 begins the transition, but the switch won’t be complete until Python 3.0.

First, I’ll borrow some terminology from PEP 238. “True division” is the division that most non-programmers are familiar with: `3/2` is 1.5, `1/4` is 0.25, and so forth. “Floor division” is what Python’s `/` operator currently does when given integer operands; the result is the floor of the value returned by true division. “Classic division” is the current mixed behaviour of `/`; it returns the result of floor division when the operands are integers, and returns the result of true division when one
of the operands is a floating-point number.

Here are the changes 2.2 introduces:

- A new operator, `//`, is the floor division operator. (Yes, we know it looks like C++'s comment symbol.) `//` always performs floor division no matter what the types of its operands are, so `1 // 2` is 0 and `1.0 // 2.0` is also 0.0.

  `//` is always available in Python 2.2; you don’t need to enable it using a `__future__` statement.

- By including a `from __future__ import division` in a module, the `/` operator will be changed to return the result of true division, so `1/2` is 0.5. Without the `__future__` statement, `/` still means classic division. The default meaning of `/` will not change until Python 3.0.

- Classes can define methods called `__truediv__()` and `__floordiv__()` to overload the two division operators. At the C level, there are also slots in the `PyNumberMethods` structure so extension types can define the two operators.

- Python 2.2 supports some command-line arguments for testing whether code will works with the changed division semantics. Running `python` with `-Q warn` will cause a warning to be issued whenever division is applied to two integers. You can use this to find code that’s affected by the change and fix it. By default, Python 2.2 will simply perform classic division without a warning; the warning will be turned on by default in Python 2.3.

PEP 238 - Changing the Division Operator
Written by Moshe Zadka and Guido van Rossum. Implemented by Guido van Rossum.
Unicode Changes

Python’s Unicode support has been enhanced a bit in 2.2. Unicode strings are usually stored as UCS-2, as 16-bit unsigned integers. Python 2.2 can also be compiled to use UCS-4, 32-bit unsigned integers, as its internal encoding by supplying --enable-unicode=ucs4 to the configure script. (It’s also possible to specify --disable-unicode to completely disable Unicode support.)

When built to use UCS-4 (a “wide Python”), the interpreter can natively handle Unicode characters from U+000000 to U+110000, so the range of legal values for the unichr() function is expanded accordingly. Using an interpreter compiled to use UCS-2 (a “narrow Python”), values greater than 65535 will still cause unichr() to raise a ValueError exception. This is all described in PEP 261, “Support for ‘wide’ Unicode characters”; consult it for further details.

Another change is simpler to explain. Since their introduction, Unicode strings have supported an encode() method to convert the string to a selected encoding such as UTF-8 or Latin-1. A symmetric decode([*encoding*]) method has been added to 8-bit strings (though not to Unicode strings) in 2.2. decode() assumes that the string is in the specified encoding and decodes it, returning whatever is returned by the codec.

Using this new feature, codecs have been added for tasks not directly related to Unicode. For example, codecs have been added for uu-encoding, MIME’s base64 encoding, and compression with the zlib module:

```python
>>> s = """Here is a lengthy piece of redundant, overly verbose, and repetitive text.
```
... ""
>>> data = s.encode('zlib')
>>> data
'x\x9c\r\xc9\xc1\r\x80 \x10\x04\xc0?Ul...
>>> data.decode('zlib')
'Here is a lengthy piece of redundant, overly verbose, and repetitive text.'
>>> print s.encode('uu')
begin 666 <data>
M2&5R92!I<R!A(&QE;F=T:'D@<&EEV4@;V8@<F5D=6YD86YT+!'=F5R8F]S92P*86YD(')E<&5T:71I=F4@=&5X="X*
end
>>> "sheesh".encode('rot-13')
'furrefu'

To convert a class instance to Unicode, a \underline{\texttt{\_\_unicode\_}}() method can be defined by a class, analogous to \underline{\texttt{\_\_str\_}}().

\underline{\texttt{\_\_unicode\_}}(), \underline{\texttt{\_\_str\_}}(), and \underline{\texttt{\_\_unicode\_}}() were implemented by Marc-André Lemburg. The changes to support using UCS-4 internally were implemented by Fredrik Lundh and Martin von Löwis.

\textbf{See also:}

\underline{\texttt{PEP 261}} - Support for ‘wide’ Unicode characters

Written by Paul Prescod.
PEP 227: Nested Scopes

In Python 2.1, statically nested scopes were added as an optional feature, to be enabled by a `from __future__ import nested_scopes` directive. In 2.2 nested scopes no longer need to be specially enabled, and are now always present. The rest of this section is a copy of the description of nested scopes from my “What’s New in Python 2.1” document; if you read it when 2.1 came out, you can skip the rest of this section.

The largest change introduced in Python 2.1, and made complete in 2.2, is to Python’s scoping rules. In Python 2.0, at any given time there are at most three namespaces used to look up variable names: local, module-level, and the built-in namespace. This often surprised people because it didn’t match their intuitive expectations. For example, a nested recursive function definition doesn’t work:

```python
def f():
    ...
    def g(value):
        ...
        return g(value-1) + 1
    ...
```

The function `g()` will always raise a `NameError` exception, because the binding of the name `g` isn’t in either its local namespace or in the module-level namespace. This isn’t much of a problem in practice (how often do you recursively define interior functions like this?), but this also made using the `lambda` statement clumsier, and this was a problem in practice. In code which uses `lambda` you can often find local variables being copied by passing them as the default values of arguments.
```python
def find(self, name):
    """Return list of any entries equal to 'name'""
    L = filter(lambda x, name=name: x == name, self.list_attribute)
    return L
```

The readability of Python code written in a strongly functional style suffers greatly as a result.

The most significant change to Python 2.2 is that static scoping has been added to the language to fix this problem. As a first effect, the `name=name` default argument is now unnecessary in the above example. Put simply, when a given variable name is not assigned a value within a function (by an assignment, or the `def`, `class`, or `import` statements), references to the variable will be looked up in the local namespace of the enclosing scope. A more detailed explanation of the rules, and a dissection of the implementation, can be found in the PEP.

This change may cause some compatibility problems for code where the same variable name is used both at the module level and as a local variable within a function that contains further function definitions. This seems rather unlikely though, since such code would have been pretty confusing to read in the first place.

One side effect of the change is that the `from module import *` and `exec` statements have been made illegal inside a function scope under certain conditions. The Python reference manual has said all along that `from module import *` is only legal at the top level of a module, but the CPython interpreter has never enforced this before. As part of the implementation of nested scopes, the compiler which turns Python source into bytecodes has to generate different code to access variables in a containing scope. `from module import *`
and `exec` make it impossible for the compiler to figure this out, because they add names to the local namespace that are unknowable at compile time. Therefore, if a function contains function definitions or `lambda` expressions with free variables, the compiler will flag this by raising a `SyntaxError` exception.

To make the preceding explanation a bit clearer, here’s an example:

```python
x = 1
def f():
    # The next line is a syntax error
    exec 'x=2'
def g():
    return x
```

Line 4 containing the `exec` statement is a syntax error, since `exec` would define a new local variable named `x` whose value should be accessed by `g()`.

This shouldn’t be much of a limitation, since `exec` is rarely used in most Python code (and when it is used, it’s often a sign of a poor design anyway).

**PEP 227 - Statically Nested Scopes**
Written and implemented by Jeremy Hylton.
New and Improved Modules

- The `xmlrpclib` module was contributed to the standard library by Fredrik Lundh, providing support for writing XML-RPC clients. XML-RPC is a simple remote procedure call protocol built on top of HTTP and XML. For example, the following snippet retrieves a list of RSS channels from the O'Reilly Network, and then lists the recent headlines for one channel:

```python
import xmlrpclib
channels = s.meerkat.getChannels()
    # channels is a list of dictionaries, like this:
    # [{'id': 4, 'title': 'Freshmeat Daily News'},
    # {'id': 190, 'title': '32Bits Online'},
    # {'id': 4549, 'title': '3DGamers'}, ...

    # Get the items for one channel
    items = s.meerkat.getItems( {'channel': 4} )

    # 'items' is another list of dictionaries, like this:
    # [{'link': 'http://freshmeat.net/releases/52719/',
    # 'description': 'A utility which converts HTML to XSL FO.',
    # 'title': 'html2fo 0.3 (Default)'}, ...
```

The `SimpleXMLRPCServer` module makes it easy to create straightforward XML-RPC servers. See `http://www.xmlrpc.com/` for more information about XML-RPC.

- The new `hmac` module implements the HMAC algorithm described by `RFC 2104`. (Contributed by Gerhard Häring.)
• Several functions that originally returned lengthy tuples now return pseudo-sequences that still behave like tuples but also have mnemonic attributes such as memberst_mtime or tm_year. The enhanced functions include `stat()`, `fstat()`, `statvfs()`, and `fstatvfs()` in the `os` module, and `localtime()`, `gmtime()`, and `strptime()` in the `time` module.

For example, to obtain a file’s size using the old tuples, you’d end up writing something like `file_size = os.stat(filename)[stat.ST_SIZE]`, but now this can be written more clearly as `file_size = os.stat(filename).st_size`.

The original patch for this feature was contributed by Nick Mathewson.

• The Python profiler has been extensively reworked and various errors in its output have been corrected. (Contributed by Fred L. Drake, Jr. and Tim Peters.)

• The `socket` module can be compiled to support IPv6; specify the `--enable-ipv6` option to Python’s configure script. (Contributed by Jun-ichiro “itojun” Hagino.)

• Two new format characters were added to the `struct` module for 64-bit integers on platforms that support the C long long type. q is for a signed 64-bit integer, and Q is for an unsigned one. The value is returned in Python’s long integer type. (Contributed by Tim Peters.)

• In the interpreter’s interactive mode, there’s a new built-in function `help()` that uses the `pydoc` module introduced in Python 2.1 to provide interactive help. `help(object)` displays any available
help text about object. `help()` with no argument puts you in an online help utility, where you can enter the names of functions, classes, or modules to read their help text. (Contributed by Guido van Rossum, using Ka-Ping Yee’s `pydoc` module.)

- Various bugfixes and performance improvements have been made to the SRE engine underlying the `re` module. For example, the `re.sub()` and `re.split()` functions have been rewritten in C. Another contributed patch speeds up certain Unicode character ranges by a factor of two, and a new `finditer()` method that returns an iterator over all the non-overlapping matches in a given string. (SRE is maintained by Fredrik Lundh. The BIGCHARSET patch was contributed by Martin von Löwis.)

- The `smtplib` module now supports RFC 2487, “Secure SMTP over TLS”, so it’s now possible to encrypt the SMTP traffic between a Python program and the mail transport agent being handed a message. `smtplib` also supports SMTP authentication. (Contributed by Gerhard Häring.)

- The `imaplib` module, maintained by Piers Lauder, has support for several new extensions: the NAMESPACE extension defined in RFC 2342, SORT, GETACL and SETACL. (Contributed by Anthony Baxter and Michel Pelletier.)

- The `rfc822` module’s parsing of email addresses is now compliant with RFC 2822, an update to RFC 822. (The module’s name is not going to be changed to `rfc2822`.) A new package, `email`, has also been added for parsing and generating e-mail messages. (Contributed by Barry Warsaw, and arising out of his work on Mailman.)
The `difflib` module now contains a new Differ class for producing human-readable lists of changes (a “delta”) between two sequences of lines of text. There are also two generator functions, `ndiff()` and `restore()`, which respectively return a delta from two sequences, or one of the original sequences from a delta. (Grunt work contributed by David Goodger, from ndiff.py code by Tim Peters who then did the generatorization.)

New constants `ascii_letters`, `ascii_lowercase`, and `ascii_uppercase` were added to the `string` module. There were several modules in the standard library that used `string.letters` to mean the ranges A-Za-z, but that assumption is incorrect when locales are in use, because `string.letters` varies depending on the set of legal characters defined by the current locale. The buggy modules have all been fixed to use `ascii_letters` instead. (Reported by an unknown person; fixed by Fred L. Drake, Jr.)

The `mimetypes` module now makes it easier to use alternative MIME-type databases by the addition of a `MimeTypes` class, which takes a list of filenames to be parsed. (Contributed by Fred L. Drake, Jr.)

A Timer class was added to the `threading` module that allows scheduling an activity to happen at some future time. (Contributed by Itamar Shtull-Trauring.)
Interpreter Changes and Fixes

Some of the changes only affect people who deal with the Python interpreter at the C level because they're writing Python extension modules, embedding the interpreter, or just hacking on the interpreter itself. If you only write Python code, none of the changes described here will affect you very much.

- Profiling and tracing functions can now be implemented in C, which can operate at much higher speeds than Python-based functions and should reduce the overhead of profiling and tracing. This will be of interest to authors of development environments for Python. Two new C functions were added to Python’s API, `PyEval_SetProfile()` and `PyEval_SetTrace()`. The existing `sys.setprofile()` and `sys.settrace()` functions still exist, and have simply been changed to use the new C-level interface. (Contributed by Fred L. Drake, Jr.)

- Another low-level API, primarily of interest to implementors of Python debuggers and development tools, was added. `PyInterpreterState_Head()` and `PyInterpreterState_Next()` let a caller walk through all the existing interpreter objects; `PyInterpreterState_ThreadHead()` and `PyThreadState_Next()` allow looping over all the thread states for a given interpreter. (Contributed by David Beazley.)

- The C-level interface to the garbage collector has been changed to make it easier to write extension types that support garbage collection and to debug misuses of the functions. Various functions have slightly different semantics, so a bunch of functions
had to be renamed. Extensions that use the old API will still compile but will not participate in garbage collection, so updating them for 2.2 should be considered fairly high priority.

To upgrade an extension module to the new API, perform the following steps:

- Rename `Py_TPFLAGS_GC()` to `PyTPFLAGS_HAVE_GC()`.
- Use `PyObject_GC_New()` or `PyObject_GC_NewVar()` to allocate objects, and `PyObject_GC_Del()` to deallocate them.
- Rename `PyObject_GC_Init()` to `PyObject_GC_Track()` and `PyObject_GC_Fini()` to `PyObject_GC_UnTrack()`.
- Remove `PyGC_HEAD_SIZE()` from object size calculations.
- Remove calls to `PyObject_AS_GC()` and `PyObject_FROM_GC()`.
- A new `et` format sequence was added to `PyArg_ParseTuple()``; `et` takes both a parameter and an encoding name, and converts the parameter to the given encoding if the parameter turns out to be a Unicode string, or leaves it alone if it’s an 8-bit string, assuming it to already be in the desired encoding. This differs from the `es` format character, which assumes that 8-bit strings are in Python’s default ASCII encoding and converts them to the specified new encoding. (Contributed by M.-A. Lemburg, and used for the MBCS support on Windows described in the following section.)
- A different argument parsing function, `PyArg_UnpackTuple()`, has been added that's simpler and presumably faster. Instead of specifying a format string, the caller simply gives the minimum and maximum number of arguments expected, and a set of pointers to `PyObject*` variables that will be filled in with argument values.

- Two new flags `METH_NOARGS` and `METH_O` are available in method definition tables to simplify implementation of methods with no arguments or a single untyped argument. Calling such methods is more efficient than calling a corresponding method that uses `METH_VARARGS`. Also, the old `METH_OLDARGS` style of writing C methods is now officially deprecated.

- Two new wrapper functions, `PyOS_snprintf()` and `PyOS_vsnprintf()` were added to provide cross-platform implementations for the relatively new `snprintf()` and `vsnprintf()` C lib APIs. In contrast to the standard `sprintf()` and `vsprintf()` functions, the Python versions check the bounds of the buffer used to protect against buffer overruns. (Contributed by M.-A. Lemburg.)

- The `_PyTuple_Resize()` function has lost an unused parameter, so now it takes 2 parameters instead of 3. The third argument was never used, and can simply be discarded when porting code from earlier versions to Python 2.2.
Other Changes and Fixes

As usual there were a bunch of other improvements and bugfixes scattered throughout the source tree. A search through the CVS change logs finds there were 527 patches applied and 683 bugs fixed between Python 2.1 and 2.2; 2.2.1 applied 139 patches and fixed 143 bugs; 2.2.2 applied 106 patches and fixed 82 bugs. These figures are likely to be underestimates.

Some of the more notable changes are:

- The code for the MacOS port for Python, maintained by Jack Jansen, is now kept in the main Python CVS tree, and many changes have been made to support MacOS X.

The most significant change is the ability to build Python as a framework, enabled by supplying the `--enable-framework` option to the configure script when compiling Python. According to Jack Jansen, “This installs a self- contained Python installation plus the OS X framework “glue” into `/Library/Frameworks/Python.framework` (or another location of choice). For now there is little immediate added benefit to this (actually, there is the disadvantage that you have to change your PATH to be able to find Python), but it is the basis for creating a full-blown Python application, porting the MacPython IDE, possibly using Python as a standard OSA scripting language and much more.”

Most of the MacPython toolbox modules, which interface to MacOS APIs such as windowing, QuickTime, scripting, etc. have been ported to OS X, but they've been left commented out in `setup.py`. People who want to experiment with these modules
can uncomment them manually.

- Keyword arguments passed to built-in functions that don’t take them now cause a `TypeError` exception to be raised, with the message “*function* takes no keyword arguments”.

- Weak references, added in Python 2.1 as an extension module, are now part of the core because they’re used in the implementation of new-style classes. The `ReferenceError` exception has therefore moved from the `weakref` module to become a built-in exception.

- A new script, `Tools/scripts/cleanfuture.py` by Tim Peters, automatically removes obsolete `__future__` statements from Python source code.

- An additional `flags` argument has been added to the built-in function `compile()`, so the behaviour of `__future__` statements can now be correctly observed in simulated shells, such as those presented by IDLE and other development environments. This is described in PEP 264. (Contributed by Michael Hudson.)

- The new license introduced with Python 1.6 wasn’t GPL-compatible. This is fixed by some minor textual changes to the 2.2 license, so it’s now legal to embed Python inside a GPLed program again. Note that Python itself is not GPLed, but instead is under a license that’s essentially equivalent to the BSD license, same as it always was. The license changes were also applied to the Python 2.0.1 and 2.1.1 releases.

- When presented with a Unicode filename on Windows, Python will now convert it to an MBCS encoded string, as used by the
Microsoft file APIs. As MBCS is explicitly used by the file APIs, Python’s choice of ASCII as the default encoding turns out to be an annoyance. On Unix, the locale’s character set is used if `locale.nl_langinfo(CODESET)` is available. (Windows support was contributed by Mark Hammond with assistance from Marc-André Lemburg. Unix support was added by Martin von Löwis.)

- Large file support is now enabled on Windows. (Contributed by Tim Peters.)

- The `Tools/scripts/ftpmirror.py` script now parses a `.netrc` file, if you have one. (Contributed by Mike Romberg.)

- Some features of the object returned by the `xrange()` function are now deprecated, and trigger warnings when they’re accessed; they’ll disappear in Python 2.3. `xrange` objects tried to pretend they were full sequence types by supporting slicing, sequence multiplication, and the `in` operator, but these features were rarely used and therefore buggy. The `tolist()` method and the `start`, `stop`, and `step` attributes are also being deprecated. At the C level, the fourth argument to the `PyRange_New()` function, `repeat`, has also been deprecated.

- There were a bunch of patches to the dictionary implementation, mostly to fix potential core dumps if a dictionary contains objects that sneakily changed their hash value, or mutated the dictionary they were contained in. For a while python-dev fell into a gentle rhythm of Michael Hudson finding a case that dumped core, Tim Peters fixing the bug, Michael finding another case, and round and round it went.
• On Windows, Python can now be compiled with Borland C thanks to a number of patches contributed by Stephen Hansen, though the result isn't fully functional yet. (But this is progress...)

• Another Windows enhancement: Wise Solutions generously offered PythonLabs use of their InstallerMaster 8.1 system. Earlier PythonLabs Windows installers used Wise 5.0a, which was beginning to show its age. (Packaged up by Tim Peters.)

• Files ending in .pyw can now be imported on Windows. .pyw is a Windows-only thing, used to indicate that a script needs to be run using PYTHONW.EXE instead of PYTHON.EXE in order to prevent a DOS console from popping up to display the output. This patch makes it possible to import such scripts, in case they're also usable as modules. (Implemented by David Bolen.)

• On platforms where Python uses the C dllopen() function to load extension modules, it's now possible to set the flags used by dllopen() using the sys.getdlopenflags() and sys.setdlopenflags() functions. (Contributed by Bram Stolk.)

• The pow() built-in function no longer supports 3 arguments when floating-point numbers are supplied. pow(x, y, z) returns (x**y) % z, but this is never useful for floating point numbers, and the final result varies unpredictably depending on the platform. A call such as pow(2.0, 8.0, 7.0) will now raise a TypeError exception.

What’s New in Python 2.1

Author: A.M. Kuchling
Introduction

This article explains the new features in Python 2.1. While there aren’t as many changes in 2.1 as there were in Python 2.0, there are still some pleasant surprises in store. 2.1 is the first release to be steered through the use of Python Enhancement Proposals, or PEPs, so most of the sizable changes have accompanying PEPs that provide more complete documentation and a design rationale for the change. This article doesn’t attempt to document the new features completely, but simply provides an overview of the new features for Python programmers. Refer to the Python 2.1 documentation, or to the specific PEP, for more details about any new feature that particularly interests you.

One recent goal of the Python development team has been to accelerate the pace of new releases, with a new release coming every 6 to 9 months. 2.1 is the first release to come out at this faster pace, with the first alpha appearing in January, 3 months after the final version of 2.0 was released.

The final release of Python 2.1 was made on April 17, 2001.
PEP 227: Nested Scopes

The largest change in Python 2.1 is to Python's scoping rules. In Python 2.0, at any given time there are at most three namespaces used to look up variable names: local, module-level, and the built-in namespace. This often surprised people because it didn't match their intuitive expectations. For example, a nested recursive function definition doesn't work:

```python
def f():
    ...
def g(value):
    ...
    return g(value-1) + 1
...
```

The function `g()` will always raise a `NameError` exception, because the binding of the name `g` isn't in either its local namespace or in the module-level namespace. This isn't much of a problem in practice (how often do you recursively define interior functions like this?), but this also made using the `lambda` statement clumsier, and this was a problem in practice. In code which uses `lambda` you can often find local variables being copied by passing them as the default values of arguments.

```python
def find(self, name):
    "Return list of any entries equal to 'name'"
    L = filter(lambda x, name=name: x == name, self.list_attribute)
    return L
```

The readability of Python code written in a strongly functional style
suffers greatly as a result.

The most significant change to Python 2.1 is that static scoping has been added to the language to fix this problem. As a first effect, the `name=name` default argument is now unnecessary in the above example. Put simply, when a given variable name is not assigned a value within a function (by an assignment, or the `def`, `class`, or `import` statements), references to the variable will be looked up in the local namespace of the enclosing scope. A more detailed explanation of the rules, and a dissection of the implementation, can be found in the PEP.

This change may cause some compatibility problems for code where the same variable name is used both at the module level and as a local variable within a function that contains further function definitions. This seems rather unlikely though, since such code would have been pretty confusing to read in the first place.

One side effect of the change is that the `from module import *` and `exec` statements have been made illegal inside a function scope under certain conditions. The Python reference manual has said all along that `from module import *` is only legal at the top level of a module, but the CPython interpreter has never enforced this before. As part of the implementation of nested scopes, the compiler which turns Python source into bytecodes has to generate different code to access variables in a containing scope. `from module import *` and `exec` make it impossible for the compiler to figure this out, because they add names to the local namespace that are unknowable at compile time. Therefore, if a function contains function definitions or `lambda` expressions with free variables, the compiler will flag this by raising a `SyntaxError` exception.
To make the preceding explanation a bit clearer, here’s an example:

```python
x = 1
def f():
    # The next line is a syntax error
    exec 'x=2'
def g():
    return x
```

Line 4 containing the `exec` statement is a syntax error, since `exec` would define a new local variable named `x` whose value should be accessed by `g()`.

This shouldn’t be much of a limitation, since `exec` is rarely used in most Python code (and when it is used, it’s often a sign of a poor design anyway).

Compatibility concerns have led to nested scopes being introduced gradually; in Python 2.1, they aren’t enabled by default, but can be turned on within a module by using a future statement as described in PEP 236. (See the following section for further discussion of PEP 236.) In Python 2.2, nested scopes will become the default and there will be no way to turn them off, but users will have had all of 2.1’s lifetime to fix any breakage resulting from their introduction.

See also:

**PEP 227 - Statically Nested Scopes**

Written and implemented by Jeremy Hylton.
PEP 236: __future__ Directives

The reaction to nested scopes was widespread concern about the dangers of breaking code with the 2.1 release, and it was strong enough to make the Pythoneers take a more conservative approach. This approach consists of introducing a convention for enabling optional functionality in release N that will become compulsory in release N+1.

The syntax uses a `from __future__ import` statement using the reserved module name `__future__`. Nested scopes can be enabled by the following statement:

```python
from __future__ import nested_scopes
```

While it looks like a normal `import` statement, it's not; there are strict rules on where such a future statement can be put. They can only be at the top of a module, and must precede any Python code or regular `import` statements. This is because such statements can affect how the Python bytecode compiler parses code and generates bytecode, so they must precede any statement that will result in bytecodes being produced.

**PEP 236 - Back to the __future__**

Written by Tim Peters, and primarily implemented by Jeremy Hylton.
PEP 207: Rich Comparisons

In earlier versions, Python’s support for implementing comparisons on user-defined classes and extension types was quite simple. Classes could implement a `__cmp__( )` method that was given two instances of a class, and could only return 0 if they were equal or +1 or -1 if they weren’t; the method couldn’t raise an exception or return anything other than a Boolean value. Users of Numeric Python often found this model too weak and restrictive, because in the number-crunching programs that numeric Python is used for, it would be more useful to be able to perform elementwise comparisons of two matrices, returning a matrix containing the results of a given comparison for each element. If the two matrices are of different sizes, then the compare has to be able to raise an exception to signal the error.

In Python 2.1, rich comparisons were added in order to support this need. Python classes can now individually overload each of the `<`, `<=`, `>`, `>=`, `==`, and `!=` operations. The new magic method names are:

<table>
<thead>
<tr>
<th>Operation</th>
<th>Method name</th>
</tr>
</thead>
<tbody>
<tr>
<td><code>&lt;</code></td>
<td><code>__lt__( )</code></td>
</tr>
<tr>
<td><code>&lt;=</code></td>
<td><code>__le__( )</code></td>
</tr>
<tr>
<td><code>&gt;</code></td>
<td><code>__gt__( )</code></td>
</tr>
<tr>
<td><code>&gt;=</code></td>
<td><code>__ge__( )</code></td>
</tr>
<tr>
<td><code>==</code></td>
<td><code>__eq__( )</code></td>
</tr>
<tr>
<td><code>!=</code></td>
<td><code>__ne__( )</code></td>
</tr>
</tbody>
</table>

(The magic methods are named after the corresponding Fortran operators `LT`, `LE`, &c. Numeric programmers are almost certainly
quite familiar with these names and will find them easy to remember.)

Each of these magic methods is of the form `method(self, other)`, where `self` will be the object on the left-hand side of the operator, while `other` will be the object on the right-hand side. For example, the expression `A < B` will cause `A.__lt__(B)` to be called.

Each of these magic methods can return anything at all: a Boolean, a matrix, a list, or any other Python object. Alternatively they can raise an exception if the comparison is impossible, inconsistent, or otherwise meaningless.

The built-in `cmp(A, B)` function can use the rich comparison machinery, and now accepts an optional argument specifying which comparison operation to use; this is given as one of the strings `"<"`, `"<="`, `">"`, `">="`, `"=="`, or `"!="`. If called without the optional third argument, `cmp()` will only return -1, 0, or +1 as in previous versions of Python; otherwise it will call the appropriate method and can return any Python object.

There are also corresponding changes of interest to C programmers; there’s a new slot `tp_richcmp` in type objects and an API for performing a given rich comparison. I won’t cover the C API here, but will refer you to PEP 207, or to 2.1’s C API documentation, for the full list of related functions.

**See also:**

**PEP 207 - Rich Comparisons**

Written by Guido van Rossum, heavily based on earlier work by David Ascher, and implemented by Guido van Rossum.
PEP 230: Warning Framework

Over its 10 years of existence, Python has accumulated a certain number of obsolete modules and features along the way. It's difficult to know when a feature is safe to remove, since there's no way of knowing how much code uses it — perhaps no programs depend on the feature, or perhaps many do. To enable removing old features in a more structured way, a warning framework was added. When the Python developers want to get rid of a feature, it will first trigger a warning in the next version of Python. The following Python version can then drop the feature, and users will have had a full release cycle to remove uses of the old feature.

Python 2.1 adds the warning framework to be used in this scheme. It adds a `warnings` module that provide functions to issue warnings, and to filter out warnings that you don’t want to be displayed. Third-party modules can also use this framework to deprecate old features that they no longer wish to support.

For example, in Python 2.1 the `regex` module is deprecated, so importing it causes a warning to be printed:

```python
>>> import regex
__main__:1: DeprecationWarning: the regex module is deprecated; please use the re module
```

Warnings can be issued by calling the `warnings.warn()` function:

```python
warnings.warn("feature X no longer supported")
```

The first parameter is the warning message; an additional optional
parameters can be used to specify a particular warning category.

Filters can be added to disable certain warnings; a regular expression pattern can be applied to the message or to the module name in order to suppress a warning. For example, you may have a program that uses the regex module and not want to spare the time to convert it to use the re module right now. The warning can be suppressed by calling

```
import warnings
warnings.filterwarnings(action = 'ignore',
                        message='.*regex module is deprecated',
                        category=DeprecationWarning,
                        module = '__main__')
```

This adds a filter that will apply only to warnings of the class `DeprecationWarning` triggered in the `__main__` module, and applies a regular expression to only match the message about the regex module being deprecated, and will cause such warnings to be ignored. Warnings can also be printed only once, printed every time the offending code is executed, or turned into exceptions that will cause the program to stop (unless the exceptions are caught in the usual way, of course).

Functions were also added to Python's C API for issuing warnings; refer to PEP 230 or to Python's API documentation for the details.

See also:

**PEP 5 - Guidelines for Language Evolution**

Written by Paul Prescod, to specify procedures to be followed when removing old features from Python. The policy described in this PEP hasn’t been officially adopted, but the eventual policy
probably won’t be too different from Prescod's proposal.

**PEP 230 - Warning Framework**

Written and implemented by Guido van Rossum.
When compiling Python, the user had to go in and edit the Modules/Setup file in order to enable various additional modules; the default set is relatively small and limited to modules that compile on most Unix platforms. This means that on Unix platforms with many more features, most notably Linux, Python installations often don't contain all useful modules they could.

Python 2.0 added the Distutils, a set of modules for distributing and installing extensions. In Python 2.1, the Distutils are used to compile much of the standard library of extension modules, autodetecting which ones are supported on the current machine. It’s hoped that this will make Python installations easier and more featureful.

Instead of having to edit the Modules/Setup file in order to enable modules, a setup.py script in the top directory of the Python source distribution is run at build time, and attempts to discover which modules can be enabled by examining the modules and header files on the system. If a module is configured in Modules/Setup, the setup.py script won’t attempt to compile that module and will defer to the Modules/Setup file’s contents. This provides a way to specific any strange command-line flags or libraries that are required for a specific platform.

In another far-reaching change to the build mechanism, Neil Schemenauer restructured things so Python now uses a single makefile that isn’t recursive, instead of makefiles in the top directory and in each of the Python/, Parser/, Objects/, and Modules/ subdirectories. This makes building Python faster and also makes hacking the Makefiles clearer and simpler.

**PEP 229** - Using Distutils to Build Python

Written and implemented by A.M. Kuchling.
PEP 205: Weak References

Weak references, available through the `weakref` module, are a minor but useful new data type in the Python programmer’s toolbox.

Storing a reference to an object (say, in a dictionary or a list) has the side effect of keeping that object alive forever. There are a few specific cases where this behaviour is undesirable, object caches being the most common one, and another being circular references in data structures such as trees.

For example, consider a memoizing function that caches the results of another function $f(x)$ by storing the function’s argument and its result in a dictionary:

```python
_cache = {}
def memoize(x):
    if _cache.has_key(x):
        return _cache[x]

retval = f(x)

# Cache the returned object
_cache[x] = retval

return retval
```

This version works for simple things such as integers, but it has a side effect; the `_cache` dictionary holds a reference to the return values, so they’ll never be deallocated until the Python process exits and cleans up. This isn’t very noticeable for integers, but if $f()$ returns an object, or a data structure that takes up a lot of memory, this can be a problem.
Weak references provide a way to implement a cache that won’t keep objects alive beyond their time. If an object is only accessible through weak references, the object will be deallocated and the weak references will now indicate that the object it referred to no longer exists. A weak reference to an object `obj` is created by calling `wr = weakref.ref(obj)`. The object being referred to is returned by calling the weak reference as if it were a function: `wr()`. It will return the referenced object, or None if the object no longer exists.

This makes it possible to write a `memoize()` function whose cache doesn’t keep objects alive, by storing weak references in the cache.

```python
_cache = {}
def memoize(x):
    if _cache.has_key(x):
        obj = _cache[x]()
        # If weak reference object still exists,
        # return it
        if obj is not None: return obj

    retval = f(x)

    # Cache a weak reference
    _cache[x] = weakref.ref(retval)

    return retval
```

The `weakref` module also allows creating proxy objects which behave like weak references — an object referenced only by proxy objects is deallocated – but instead of requiring an explicit call to retrieve the object, the proxy transparently forwards all operations to the object as long as the object still exists. If the object is deallocated, attempting to use a proxy will cause a `weakref.ReferenceError` exception to be raised.
proxy = weakref.proxy(obj)
proxy.attr  # Equivalent to obj.attr
proxy.meth() # Equivalent to obj.meth()
\texttt{del} obj
proxy.attr  # raises weakref.ReferenceError

See also:

**PEP 205 - Weak References**

Written and implemented by Fred L. Drake, Jr.
PEP 232: Function Attributes

In Python 2.1, functions can now have arbitrary information attached to them. People were often using docstrings to hold information about functions and methods, because the __doc__ attribute was the only way of attaching any information to a function. For example, in the Zope Web application server, functions are marked as safe for public access by having a docstring, and in John Aycock’s SPARK parsing framework, docstrings hold parts of the BNF grammar to be parsed. This overloading is unfortunate, since docstrings are really intended to hold a function's documentation; for example, it means you can’t properly document functions intended for private use in Zope.

Arbitrary attributes can now be set and retrieved on functions using the regular Python syntax:

```python
def f(): pass
f.publish = 1
f.secure = 1
f.grammar = "A ::= B (C D)*"
```

The dictionary containing attributes can be accessed as the function’s __dict__. Unlike the __dict__ attribute of class instances, in functions you can actually assign a new dictionary to __dict__, though the new value is restricted to a regular Python dictionary; you can’t be tricky and set it to a UserDict instance, or any other random object that behaves like a mapping.

PEP 232 - Function Attributes
Written and implemented by Barry Warsaw.
PEP 235: Importing Modules on Case-Insensitive Platforms

Some operating systems have filesystems that are case-insensitive, MacOS and Windows being the primary examples; on these systems, it's impossible to distinguish the filenames FILE.PY and file.py, even though they do store the file's name in its original case (they're case-preserving, too).

In Python 2.1, the import statement will work to simulate case-sensitivity on case-insensitive platforms. Python will now search for the first case-sensitive match by default, raising an ImportError if no such file is found, so import file will not import a module named FILE.PY. Case-insensitive matching can be requested by setting the PYTHONCASEOK environment variable before starting the Python interpreter.
PEP 217: Interactive Display Hook

When using the Python interpreter interactively, the output of commands is displayed using the built-in `repr()` function. In Python 2.1, the variable `sys.displayhook()` can be set to a callable object which will be called instead of `repr()`. For example, you can set it to a special pretty-printing function:

```python
>>> # Create a recursive data structure
... L = [1, 2, 3]
>>> L.append(L)
>>> L # Show Python's default output
[1, 2, 3, [...]]
>>> # Use pprint.pprint() as the display function
... import sys, pprint
>>> sys.displayhook = pprint.pprint
>>> L
[1, 2, 3, <Recursion on list with id=135143996>]
```

Written and implemented by Moshe Zadka.
PEP 208: New Coercion Model

How numeric coercion is done at the C level was significantly modified. This will only affect the authors of C extensions to Python, allowing them more flexibility in writing extension types that support numeric operations.

Extension types can now set the type flag Py_TPFLAGS_CHECKTYPES in their PyTypeObject structure to indicate that they support the new coercion model. In such extension types, the numeric slot functions can no longer assume that they'll be passed two arguments of the same type; instead they may be passed two arguments of differing types, and can then perform their own internal coercion. If the slot function is passed a type it can't handle, it can indicate the failure by returning a reference to the Py_NotImplemented singleton value. The numeric functions of the other type will then be tried, and perhaps they can handle the operation; if the other type also returns Py_NotImplemented, then a TypeError will be raised. Numeric methods written in Python can also return Py_NotImplemented, causing the interpreter to act as if the method did not exist (perhaps raising a TypeError, perhaps trying another object's numeric methods).

**PEP 208 - Reworking the Coercion Model**

Written and implemented by Neil Schemenauer, heavily based upon earlier work by Marc-André Lemburg. Read this to understand the fine points of how numeric operations will now be processed at the C level.
PEP 241: Metadata in Python Packages

A common complaint from Python users is that there's no single catalog of all the Python modules in existence. T. Middleton's Vaults of Parnassus at http://www.vex.net/parnassus/ are the largest catalog of Python modules, but registering software at the Vaults is optional, and many people don't bother.

As a first small step toward fixing the problem, Python software packaged using the Distutils sdist command will include a file named PKG-INFO containing information about the package such as its name, version, and author (metadata, in cataloguing terminology). PEP 241 contains the full list of fields that can be present in the PKG-INFO file. As people began to package their software using Python 2.1, more and more packages will include metadata, making it possible to build automated cataloguing systems and experiment with them. With the result experience, perhaps it'll be possible to design a really good catalog and then build support for it into Python 2.2. For example, the Distutils sdist and bdist_* commands could support a upload option that would automatically upload your package to a catalog server.

You can start creating packages containing PKG-INFO even if you're not using Python 2.1, since a new release of the Distutils will be made for users of earlier Python versions. Version 1.0.2 of the Distutils includes the changes described in PEP 241, as well as various bugfixes and enhancements. It will be available from the Distutils SIG at http://www.python.org/sigs/distutils-sig/.

Written and implemented by A.M. Kuchling.

**PEP 243 - Module Repository Upload Mechanism**

Written by Sean Reifschneider, this draft PEP describes a proposed mechanism for uploading Python packages to a central server.
New and Improved Modules

- Ka-Ping Yee contributed two new modules: inspect.py, a module for getting information about live Python code, and pydoc.py, a module for interactively converting docstrings to HTML or text. As a bonus, Tools/scripts/pydoc, which is now automatically installed, uses pydoc.py to display documentation given a Python module, package, or class name. For example, `pydoc xml.dom` displays the following:

```
Pyhthon Library Documentation: package xml.dom

NAME
    xml.dom - W3C Document Object Model implementation

FILE
    /usr/local/lib/python2.1/xml/dom/__init__.pyc

DESCRIPTION
    The Python mapping of the Document Object Model
    Python Library Reference in the section on the

    This package contains the following modules:
    ...
```

`pydoc` also includes a Tk-based interactive help browser. `pydoc` quickly becomes addictive; try it out!

- Two different modules for unit testing were added to the standard library. The `doctest` module, contributed by Tim Peters, provides a testing framework based on running embedded examples in docstrings and comparing the results against the expected output.
PyUnit, contributed by Steve Purcell, is a unit testing framework inspired by JUnit, which was in turn an adaptation of Kent Beck's Smalltalk testing framework. See http://pyunit.sourceforge.net/ for more information about PyUnit.

- The `difflib` module contains a class, `SequenceMatcher`, which compares two sequences and computes the changes required to transform one sequence into the other. For example, this module can be used to write a tool similar to the Unix `diff` program, and in fact the sample program `Tools/scripts/ndiff.py` demonstrates how to write such a script.

- `curses.panel`, a wrapper for the panel library, part of `ncurses` and of `SYSV curses`, was contributed by Thomas Gellekum. The panel library provides windows with the additional feature of depth. Windows can be moved higher or lower in the depth ordering, and the panel library figures out where panels overlap and which sections are visible.

- The PyXML package has gone through a few releases since Python 2.0, and Python 2.1 includes an updated version of the `xml` package. Some of the noteworthy changes include support for Expat 1.2 and later versions, the ability for Expat parsers to handle files in any encoding supported by Python, and various bugfixes for SAX, DOM, and the `minidom` module.

- Ping also contributed another hook for handling uncaught exceptions. `sys.excepthook()` can be set to a callable object. When an exception isn’t caught by any `try...except` blocks, the exception will be passed to `sys.excepthook()`, which can then do whatever it likes. At the Ninth Python Conference, Ping
demonstrated an application for this hook: printing an extended traceback that not only lists the stack frames, but also lists the function arguments and the local variables for each frame.

- Various functions in the `time` module, such as `asctime()` and `localtime()`, require a floating point argument containing the time in seconds since the epoch. The most common use of these functions is to work with the current time, so the floating point argument has been made optional; when a value isn't provided, the current time will be used. For example, log file entries usually need a string containing the current time; in Python 2.1, `time.asctime()` can be used, instead of the lengthier `time.asctime(time.localtime(time.time()))` that was previously required.

  This change was proposed and implemented by Thomas Wouters.

- The `ftplib` module now defaults to retrieving files in passive mode, because passive mode is more likely to work from behind a firewall. This request came from the Debian bug tracking system, since other Debian packages use `ftplib` to retrieve files and then don’t work from behind a firewall. It’s deemed unlikely that this will cause problems for anyone, because Netscape defaults to passive mode and few people complain, but if passive mode is unsuitable for your application or network setup, call `set_pasv(0)` on FTP objects to disable passive mode.

- Support for raw socket access has been added to the `socket` module, contributed by Grant Edwards.

- The `pstats` module now contains a simple interactive statistics
browser for displaying timing profiles for Python programs, invoked when the module is run as a script. Contributed by Eric S. Raymond.

- A new implementation-dependent function, `sys._getframe([depth])`, has been added to return a given frame object from the current call stack. `sys._getframe()` returns the frame at the top of the call stack; if the optional integer argument `depth` is supplied, the function returns the frame that is `depth` calls below the top of the stack. For example, `sys._getframe(1)` returns the caller’s frame object.

This function is only present in CPython, not in Jython or the .NET implementation. Use it for debugging, and resist the temptation to put it into production code.
Other Changes and Fixes

There were relatively few smaller changes made in Python 2.1 due to the shorter release cycle. A search through the CVS change logs turns up 117 patches applied, and 136 bugs fixed; both figures are likely to be underestimates. Some of the more notable changes are:

- A specialized object allocator is now optionally available, that should be faster than the system `malloc()` and have less memory overhead. The allocator uses C’s `malloc()` function to get large pools of memory, and then fulfills smaller memory requests from these pools. It can be enabled by providing the `--with-pymalloc` option to the configure script; see `Objects/obmalloc.c` for the implementation details.

Authors of C extension modules should test their code with the object allocator enabled, because some incorrect code may break, causing core dumps at runtime. There are a bunch of memory allocation functions in Python’s C API that have previously been just aliases for the C library’s `malloc()` and `free()`, meaning that if you accidentally called mismatched functions, the error wouldn’t be noticeable. When the object allocator is enabled, these functions aren’t aliases of `malloc()` and `free()` any more, and calling the wrong function to free memory will get you a core dump. For example, if memory was allocated using `PyMem_New()`, it has to be freed using `PyMem_Del()`, not `free()`. A few modules included with Python fell afoul of this and had to be fixed; doubtless there are more third-party modules that will have the same problem.

The object allocator was contributed by Vladimir Marangozov.
The speed of line-oriented file I/O has been improved because people often complain about its lack of speed, and because it's often been used as a naïve benchmark. The `readline()` method of file objects has therefore been rewritten to be much faster. The exact amount of the speedup will vary from platform to platform depending on how slow the C library's getc() was, but is around 66%, and potentially much faster on some particular operating systems. Tim Peters did much of the benchmarking and coding for this change, motivated by a discussion in comp.lang.python.

A new module and method for file objects was also added, contributed by Jeff Epler. The new method, `xreadlines()`, is similar to the existing `xrange()` built-in. `xreadlines()` returns an opaque sequence object that only supports being iterated over, reading a line on every iteration but not reading the entire file into memory as the existing `readlines()` method does. You'd use it like this:

```python
for line in sys.stdin.xreadlines():
    # ... do something for each line ... 
...
```

A new method, `popitem()`, was added to dictionaries to enable destructively iterating through the contents of a dictionary; this can be faster for large dictionaries because there's no need to construct a list containing all the keys or values. `D.popitem()` removes a random (key, value) pair from the dictionary `D` and
returns it as a 2-tuple. This was implemented mostly by Tim Peters and Guido van Rossum, after a suggestion and preliminary patch by Moshe Zadka.

- Modules can now control which names are imported when `from module import *` is used, by defining an `__all__` attribute containing a list of names that will be imported. One common complaint is that if the module imports other modules such as `sys` or `string`, `from module import *` will add them to the importing module’s namespace. To fix this, simply list the public names in `__all__`:

```python
# List public names
__all__ = ['Database', 'open']
```

A stricter version of this patch was first suggested and implemented by Ben Wolfson, but after some python-dev discussion, a weaker final version was checked in.

- Applying `repr()` to strings previously used octal escapes for non-printable characters; for example, a newline was `'\012'`. This was a vestigial trace of Python’s C ancestry, but today octal is of very little practical use. Ka-Ping Yee suggested using hex escapes instead of octal ones, and using the `\n`, `\t`, `\r` escapes for the appropriate characters, and implemented this new formatting.

- Syntax errors detected at compile-time can now raise exceptions containing the filename and line number of the error, a pleasant side effect of the compiler reorganization done by Jeremy Hylton.

- C extensions which import other modules have been changed to use `PyImport_ImportModule()`, which means that they will
use any import hooks that have been installed. This is also encouraged for third-party extensions that need to import some other module from C code.

- The size of the Unicode character database was shrunk by another 340K thanks to Fredrik Lundh.

- Some new ports were contributed: MacOS X (by Steven Majewski), Cygwin (by Jason Tishler); RISCOS (by Dietmar Schwertberger); Unixware 7 (by Billy G. Allie).

And there’s the usual list of minor bugfixes, minor memory leaks, docstring edits, and other tweaks, too lengthy to be worth itemizing; see the CVS logs for the full details if you want them.

What’s New in Python 2.0

Author: A.M. Kuchling and Moshe Zadka
Introduction

A new release of Python, version 2.0, was released on October 16, 2000. This article covers the exciting new features in 2.0, highlights some other useful changes, and points out a few incompatible changes that may require rewriting code.

Python’s development never completely stops between releases, and a steady flow of bug fixes and improvements are always being submitted. A host of minor fixes, a few optimizations, additional docstrings, and better error messages went into 2.0; to list them all would be impossible, but they’re certainly significant. Consult the publicly-available CVS logs if you want to see the full list. This progress is due to the five developers working for PythonLabs are now getting paid to spend their days fixing bugs, and also due to the improved communication resulting from moving to SourceForge.
What About Python 1.6?

Python 1.6 can be thought of as the Contractual Obligations Python release. After the core development team left CNRI in May 2000, CNRI requested that a 1.6 release be created, containing all the work on Python that had been performed at CNRI. Python 1.6 therefore represents the state of the CVS tree as of May 2000, with the most significant new feature being Unicode support. Development continued after May, of course, so the 1.6 tree received a few fixes to ensure that it’s forward-compatible with Python 2.0. 1.6 is therefore part of Python’s evolution, and not a side branch.

So, should you take much interest in Python 1.6? Probably not. The 1.6final and 2.0beta1 releases were made on the same day (September 5, 2000), the plan being to finalize Python 2.0 within a month or so. If you have applications to maintain, there seems little point in breaking things by moving to 1.6, fixing them, and then having another round of breakage within a month by moving to 2.0; you’re better off just going straight to 2.0. Most of the really interesting features described in this document are only in 2.0, because a lot of work was done between May and September.
New Development Process

The most important change in Python 2.0 may not be to the code at all, but to how Python is developed: in May 2000 the Python developers began using the tools made available by SourceForge for storing source code, tracking bug reports, and managing the queue of patch submissions. To report bugs or submit patches for Python 2.0, use the bug tracking and patch manager tools available from Python's project page, located at http://sourceforge.net/projects/python/.

The most important of the services now hosted at SourceForge is the Python CVS tree, the version-controlled repository containing the source code for Python. Previously, there were roughly 7 or so people who had write access to the CVS tree, and all patches had to be inspected and checked in by one of the people on this short list. Obviously, this wasn’t very scalable. By moving the CVS tree to SourceForge, it became possible to grant write access to more people; as of September 2000 there were 27 people able to check in changes, a fourfold increase. This makes possible large-scale changes that wouldn’t be attempted if they’d have to be filtered through the small group of core developers. For example, one day Peter Schneider-Kamp took it into his head to drop K&R C compatibility and convert the C source for Python to ANSI C. After getting approval on the python-dev mailing list, he launched into a flurry of checkins that lasted about a week, other developers joined in to help, and the job was done. If there were only 5 people with write access, probably that task would have been viewed as “nice, but not worth the time and effort needed” and it would never have gotten done.

The shift to using SourceForge's services has resulted in a remarkable increase in the speed of development. Patches now get submitted,
commented on, revised by people other than the original submitter, and bounced back and forth between people until the patch is deemed worth checking in. Bugs are tracked in one central location and can be assigned to a specific person for fixing, and we can count the number of open bugs to measure progress. This didn’t come without a cost: developers now have more e-mail to deal with, more mailing lists to follow, and special tools had to be written for the new environment. For example, SourceForge sends default patch and bug notification e-mail messages that are completely unhelpful, so Ka-Ping Yee wrote an HTML screen-scraper that sends more useful messages.

The ease of adding code caused a few initial growing pains, such as code was checked in before it was ready or without getting clear agreement from the developer group. The approval process that has emerged is somewhat similar to that used by the Apache group. Developers can vote +1, +0, -0, or -1 on a patch; +1 and -1 denote acceptance or rejection, while +0 and -0 mean the developer is mostly indifferent to the change, though with a slight positive or negative slant. The most significant change from the Apache model is that the voting is essentially advisory, letting Guido van Rossum, who has Benevolent Dictator For Life status, know what the general opinion is. He can still ignore the result of a vote, and approve or reject a change even if the community disagrees with him.

Producing an actual patch is the last step in adding a new feature, and is usually easy compared to the earlier task of coming up with a good design. Discussions of new features can often explode into lengthy mailing list threads, making the discussion hard to follow, and no one can read every posting to python-dev. Therefore, a relatively formal process has been set up to write Python Enhancement Proposals (PEPs), modelled on the Internet RFC process. PEPs are draft documents that describe a proposed new feature, and are continually
revised until the community reaches a consensus, either accepting or rejecting the proposal. Quoting from the introduction to PEP 1, “PEP Purpose and Guidelines”:

PEP stands for Python Enhancement Proposal. A PEP is a design document providing information to the Python community, or describing a new feature for Python. The PEP should provide a concise technical specification of the feature and a rationale for the feature.

We intend PEPs to be the primary mechanisms for proposing new features, for collecting community input on an issue, and for documenting the design decisions that have gone into Python. The PEP author is responsible for building consensus within the community and documenting dissenting opinions.

Read the rest of PEP 1 for the details of the PEP editorial process, style, and format. PEPs are kept in the Python CVS tree on SourceForge, though they’re not part of the Python 2.0 distribution, and are also available in HTML form from http://www.python.org/peps/. As of September 2000, there are 25 PEPS, ranging from PEP 201, “Lockstep Iteration”, to PEP 225, “Elementwise/Objectwise Operators”.
Unicode

The largest new feature in Python 2.0 is a new fundamental data type: Unicode strings. Unicode uses 16-bit numbers to represent characters instead of the 8-bit number used by ASCII, meaning that 65,536 distinct characters can be supported.

The final interface for Unicode support was arrived at through countless often-stormy discussions on the python-dev mailing list, and mostly implemented by Marc-André Lemburg, based on a Unicode string type implementation by Fredrik Lundh. A detailed explanation of the interface was written up as PEP 100, “Python Unicode Integration”. This article will simply cover the most significant points about the Unicode interfaces.

In Python source code, Unicode strings are written as u"string". Arbitrary Unicode characters can be written using a new escape sequence, \uHHHH, where HHHH is a 4-digit hexadecimal number from 0000 to FFFF. The existing \xHHHH escape sequence can also be used, and octal escapes can be used for characters up to U+01FF, which is represented by \777.

Unicode strings, just like regular strings, are an immutable sequence type. They can be indexed and sliced, but not modified in place. Unicode strings have an encode( [encoding] ) method that returns an 8-bit string in the desired encoding. Encodings are named by strings, such as 'ascii', 'utf-8', 'iso-8859-1', or whatever. A codec API is defined for implementing and registering new encodings that are then available throughout a Python program. If an encoding isn’t specified, the default encoding is usually 7-bit ASCII, though it can be changed for your Python installation by calling the
sys.setdefaultencoding(encoding) function in a customised version of site.py.

Combining 8-bit and Unicode strings always coerces to Unicode, using the default ASCII encoding; the result of 'a' + u'bc' is u'abc'.

New built-in functions have been added, and existing built-ins modified to support Unicode:

- **unichr(ch)** returns a Unicode string 1 character long, containing the character `ch`.
- **ord(u)**, where `u` is a 1-character regular or Unicode string, returns the number of the character as an integer.
- **unicode(string [, encoding] [, errors])** creates a Unicode string from an 8-bit string. `encoding` is a string naming the encoding to use. The `errors` parameter specifies the treatment of characters that are invalid for the current encoding; passing 'strict' as the value causes an exception to be raised on any encoding error, while 'ignore' causes errors to be silently ignored and 'replace' uses U+FFFD, the official replacement character, in case of any problems.
- The **exec** statement, and various built-ins such as **eval()**, **getattr()**, and **setattr()** will also accept Unicode strings as well as regular strings. (It's possible that the process of fixing this missed some built-ins; if you find a built-in function that accepts strings but doesn't accept Unicode strings at all, please report it as a bug.)

A new module, **unicodedata**, provides an interface to Unicode character properties. For example, **unicodedata.category(u'A')** returns the 2-character string ‘Lu’, the ‘L’ denoting it’s a letter, and ‘u’ meaning it’s uppercase. **unicodedata.bidirectional(u'٠')** returns ‘AN’,
meaning that U+0660 is an Arabic number.

The `codecs` module contains functions to look up existing encodings and register new ones. Unless you want to implement a new encoding, you'll most often use the `codecs.lookup(encoding)` function, which returns a 4-element tuple: `(encode_func, decode_func, stream_reader, stream_writer).

- `encode_func` is a function that takes a Unicode string, and returns a 2-tuple `(string, length). `string` is an 8-bit string containing a portion (perhaps all) of the Unicode string converted into the given encoding, and `length` tells you how much of the Unicode string was converted.
- `decode_func` is the opposite of `encode_func`, taking an 8-bit string and returning a 2-tuple `(ustring, length), consisting of the resulting Unicode string `ustring` and the integer `length` telling how much of the 8-bit string was consumed.
- `stream_reader` is a class that supports decoding input from a stream. `stream_reader(file_obj)` returns an object that supports the `read()`, `readline()`, and `readlines()` methods. These methods will all translate from the given encoding and return Unicode strings.
- `stream_writer`, similarly, is a class that supports encoding output to a stream. `stream_writer(file_obj)` returns an object that supports the `write()` and `writelines()` methods. These methods expect Unicode strings, translating them to the given encoding on output.

For example, the following code writes a Unicode string into a file, encoding it as UTF-8:

```python
import codecs
unistr = u'\u0660\u2000ab ...
```
The following code would then read UTF-8 input from the file:

```python
input = UTF8_streamreader( open( '/tmp/output', 'rb' )
print repr(input.read())
input.close()
```

Unicode-aware regular expressions are available through the `re` module, which has a new underlying implementation called SRE written by Fredrik Lundh of Secret Labs AB.

A `-U` command line option was added which causes the Python compiler to interpret all string literals as Unicode string literals. This is intended to be used in testing and future-proofing your Python code, since some future version of Python may drop support for 8-bit strings and provide only Unicode strings.
List Comprehensions

Lists are a workhorse data type in Python, and many programs manipulate a list at some point. Two common operations on lists are to loop over them, and either pick out the elements that meet a certain criterion, or apply some function to each element. For example, given a list of strings, you might want to pull out all the strings containing a given substring, or strip off trailing whitespace from each line.

The existing map() and filter() functions can be used for this purpose, but they require a function as one of their arguments. This is fine if there's an existing built-in function that can be passed directly, but if there isn’t, you have to create a little function to do the required work, and Python’s scoping rules make the result ugly if the little function needs additional information. Take the first example in the previous paragraph, finding all the strings in the list containing a given substring. You could write the following to do it:

```
# Given the list L, make a list of all strings
# containing the substring S.
sublist = filter( lambda s, substring=S: string.find(s, substring) != -1, L)
```

Because of Python’s scoping rules, a default argument is used so that the anonymous function created by the lambda statement knows what substring is being searched for. List comprehensions make this cleaner:

```
sublist = [ s for s in L if string.find(s, S) != -1
```
List comprehensions have the form:

```
[ expression for expr in sequence1
  for expr2 in sequence2 ...
  for exprN in sequenceN
  if condition ]
```

The `for ... in` clauses contain the sequences to be iterated over. The sequences do not have to be the same length, because they are not iterated over in parallel, but from left to right; this is explained more clearly in the following paragraphs. The elements of the generated list will be the successive values of `expression`. The final `if` clause is optional; if present, `expression` is only evaluated and added to the result if `condition` is true.

To make the semantics very clear, a list comprehension is equivalent to the following Python code:

```
for expr1 in sequence1:
  for expr2 in sequence2:
    ...
  for exprN in sequenceN:
    if (condition):
      # Append the value of
      # the expression to the
      # resulting list.
```

This means that when there are multiple `for ... in` clauses, the resulting list will be equal to the product of the lengths of all the sequences. If you have two lists of length 3, the output list is 9 elements long:

```
seq1 = 'abc'
seq2 = (1,2,3)
```
To avoid introducing an ambiguity into Python’s grammar, if *expression* is creating a tuple, it must be surrounded with parentheses. The first list comprehension below is a syntax error, while the second one is correct:

```
# Syntax error
[ x,y for x in seq1 for y in seq2]
# Correct
[ (x,y) for x in seq1 for y in seq2]
```

The idea of list comprehensions originally comes from the functional programming language Haskell ([http://www.haskell.org](http://www.haskell.org)). Greg Ewing argued most effectively for adding them to Python and wrote the initial list comprehension patch, which was then discussed for a seemingly endless time on the python-dev mailing list and kept up-to-date by Skip Montanaro.
Augmented Assignment

Augmented assignment operators, another long-requested feature, have been added to Python 2.0. Augmented assignment operators include `+=`, `-=` , `*=` , and so forth. For example, the statement `a += 2` increments the value of the variable `a` by 2, equivalent to the slightly lengthier `a = a + 2`.

The full list of supported assignment operators is `+=`, `-=` , `*=` , `/=` , `%=` , `**=` , `&=` , `|=` , `^=` , `>>=` , and `<<=` . Python classes can override the augmented assignment operators by defining methods named `__iadd__()`, `__isub__()`, etc. For example, the following Number class stores a number and supports using `+=` to create a new instance with an incremented value.

```python
class Number:
    def __init__(self, value):
        self.value = value
    def __iadd__(self, increment):
        return Number( self.value + increment)

n = Number(5)
n += 3
print n.value
```

The `__iadd__()` special method is called with the value of the increment, and should return a new instance with an appropriately modified value; this return value is bound as the new value of the variable on the left-hand side.

Augmented assignment operators were first introduced in the C programming language, and most C-derived languages, such as `awk`,
C++, Java, Perl, and PHP also support them. The augmented assignment patch was implemented by Thomas Wouters.
String Methods

Until now string-manipulation functionality was in the string module, which was usually a front-end for the strop module written in C. The addition of Unicode posed a difficulty for the strop module, because the functions would all need to be rewritten in order to accept either 8-bit or Unicode strings. For functions such as string.replace(), which takes 3 string arguments, that means eight possible permutations, and correspondingly complicated code.

Instead, Python 2.0 pushes the problem onto the string type, making string manipulation functionality available through methods on both 8-bit strings and Unicode strings.

```python
>>> 'andrew'.capitalize()
'Andrew'
>>> 'hostname'.replace('os', 'linux')
'hlinuxtname'
>>> 'moshe'.find('sh')
2
```

One thing that hasn’t changed, a noteworthy April Fools’ joke notwithstanding, is that Python strings are immutable. Thus, the string methods return new strings, and do not modify the string on which they operate.

The old string module is still around for backwards compatibility, but it mostly acts as a front-end to the new string methods.

Two methods which have no parallel in pre-2.0 versions, although they did exist in JPython for quite some time, arestartswith() and endswith(). s.startswith(t) is equivalent to s[:len(t)] ==

```python
```
t, while `s.endswith(t)` is equivalent to `s[-len(t):] == t`.

One other method which deserves special mention is `join()`. The `join()` method of a string receives one parameter, a sequence of strings, and is equivalent to the `string.join()` function from the old `string` module, with the arguments reversed. In other words, `s.join(seq)` is equivalent to the old `string.join(seq, s)`. 
Garbage Collection of Cycles

The C implementation of Python uses reference counting to implement garbage collection. Every Python object maintains a count of the number of references pointing to itself, and adjusts the count as references are created or destroyed. Once the reference count reaches zero, the object is no longer accessible, since you need to have a reference to an object to access it, and if the count is zero, no references exist any longer.

Reference counting has some pleasant properties: it's easy to understand and implement, and the resulting implementation is portable, fairly fast, and reacts well with other libraries that implement their own memory handling schemes. The major problem with reference counting is that it sometimes doesn't realise that objects are no longer accessible, resulting in a memory leak. This happens when there are cycles of references.

Consider the simplest possible cycle, a class instance which has a reference to itself:

```python
instance = SomeClass()
instance.myself = instance
```

After the above two lines of code have been executed, the reference count of `instance` is 2; one reference is from the variable named 'instance', and the other is from the `myself` attribute of the instance.

If the next line of code is `del instance`, what happens? The reference count of `instance` is decreased by 1, so it has a reference count of 1; the reference in the `myself` attribute still exists. Yet the
instance is no longer accessible through Python code, and it could be deleted. Several objects can participate in a cycle if they have references to each other, causing all of the objects to be leaked.

Python 2.0 fixes this problem by periodically executing a cycle detection algorithm which looks for inaccessible cycles and deletes the objects involved. A new `gc` module provides functions to perform a garbage collection, obtain debugging statistics, and tuning the collector’s parameters.

Running the cycle detection algorithm takes some time, and therefore will result in some additional overhead. It is hoped that after we’ve gotten experience with the cycle collection from using 2.0, Python 2.1 will be able to minimize the overhead with careful tuning. It’s not yet obvious how much performance is lost, because benchmarking this is tricky and depends crucially on how often the program creates and destroys objects. The detection of cycles can be disabled when Python is compiled, if you can’t afford even a tiny speed penalty or suspect that the cycle collection is buggy, by specifying the `--without-cycle-gc` switch when running the `configure` script.

Several people tackled this problem and contributed to a solution. An early implementation of the cycle detection approach was written by Toby Kelsey. The current algorithm was suggested by Eric Tiedemann during a visit to CNRI, and Guido van Rossum and Neil Schemenauer wrote two different implementations, which were later integrated by Neil. Lots of other people offered suggestions along the way; the March 2000 archives of the python-dev mailing list contain most of the relevant discussion, especially in the threads titled “Reference cycle collection for Python” and “Finalization again”.

Other Core Changes

Various minor changes have been made to Python’s syntax and built-in functions. None of the changes are very far-reaching, but they’re handy conveniences.

Minor Language Changes

A new syntax makes it more convenient to call a given function with a tuple of arguments and/or a dictionary of keyword arguments. In Python 1.5 and earlier, you’d use the `apply()` built-in function: `apply(f, args, kw)` calls the function `f()` with the argument tuple `args` and the keyword arguments in the dictionary `kw`. `apply()` is the same in 2.0, but thanks to a patch from Greg Ewing, `f(*args, **kw)` as a shorter and clearer way to achieve the same effect. This syntax is symmetrical with the syntax for defining functions:

```python
def f(*args, **kw):
    # args is a tuple of positional args,
    # kw is a dictionary of keyword args
    ...
```

The `print` statement can now have its output directed to a file-like object by following the `print` with `>> file`, similar to the redirection operator in Unix shells. Previously you’d either have to use the `write()` method of the file-like object, which lacks the convenience and simplicity of `print`, or you could assign a new value to `sys.stdout` and then restore the old value. For sending output to standard error, it’s much easier to write this:

```python
print >> sys.stderr, "Warning: action field not supp"
Modules can now be renamed on importing them, using the syntax
\begin{verbatim}
import module as name or from module import name as othername.
\end{verbatim}
The patch was submitted by Thomas Wouters.

A new format style is available when using the \% operator; \texttt{%r} will
insert the \texttt{repr()} of its argument. This was also added from
symmetry considerations, this time for symmetry with the existing \texttt{%s}
format style, which inserts the \texttt{str()} of its argument. For example,
\texttt{%r %s} ('abc', 'abc') returns a string containing 'abc' abc.

Previously there was no way to implement a class that overrode
Python's built-in \texttt{in} operator and implemented a custom version. \texttt{obj in seq} returns true if \texttt{obj} is present in the sequence \texttt{seq}; Python
computes this by simply trying every index of the sequence until either
\texttt{obj} is found or an \texttt{IndexError} is encountered. Moshe Zadka
contributed a patch which adds a \texttt{__contains__()} magic method
for providing a custom implementation for \texttt{in}. Additionally, new built-in
objects written in C can define what \texttt{in} means for them via a new slot
in the sequence protocol.

Earlier versions of Python used a recursive algorithm for deleting
objects. Deeply nested data structures could cause the interpreter to
fill up the C stack and crash; Christian Tismer rewrote the deletion
logic to fix this problem. On a related note, comparing recursive
objects recursed infinitely and crashed; Jeremy Hylton rewrote the
code to no longer crash, producing a useful result instead. For
example, after this code:

\begin{verbatim}
a = []
b = []
\end{verbatim}
a.append(a)
b.append(b)

The comparison `a==b` returns true, because the two recursive data structures are isomorphic. See the thread “trashcan and PR#7” in the April 2000 archives of the python-dev mailing list for the discussion leading up to this implementation, and some useful relevant links. Note that comparisons can now also raise exceptions. In earlier versions of Python, a comparison operation such as `cmp(a, b)` would always produce an answer, even if a user-defined `__cmp__()` method encountered an error, since the resulting exception would simply be silently swallowed.

Work has been done on porting Python to 64-bit Windows on the Itanium processor, mostly by Trent Mick of ActiveState. (Confusingly, `sys.platform` is still 'win32' on Win64 because it seems that for ease of porting, MS Visual C++ treats code as 32 bit on Itanium.) PythonWin also supports Windows CE; see the Python CE page at http://pythonce.sourceforge.net/ for more information.

Another new platform is Darwin/MacOS X; initial support for it is in Python 2.0. Dynamic loading works, if you specify “configure –with-dyld –with-suffix=.x”. Consult the README in the Python source distribution for more instructions.

An attempt has been made to alleviate one of Python’s warts, the often-confusing `NameError` exception when code refers to a local variable before the variable has been assigned a value. For example, the following code raises an exception on the `print` statement in both 1.5.2 and 2.0; in 1.5.2 a `NameError` exception is raised, while 2.0 raises a new `UnboundLocalError` exception. `UnboundLocalError` is a subclass of `NameError`, so any existing
code that expects **NameError** to be raised should still work.

```python
def f():
    print "i=", i
    i = i + 1
f()
```

Two new exceptions, **TabError** and **IndentationError**, have been introduced. They're both subclasses of **SyntaxError**, and are raised when Python code is found to be improperly indented.

**Changes to Built-in Functions**

A new built-in, `zip(seq1, seq2, ...)`, has been added. `zip()` returns a list of tuples where each tuple contains the i-th element from each of the argument sequences. The difference between `zip()` and `map(None, seq1, seq2)` is that `map()` pads the sequences with None if the sequences aren't all of the same length, while `zip()` truncates the returned list to the length of the shortest argument sequence.

The `int()` and `long()` functions now accept an optional “base” parameter when the first argument is a string. `int('123', 10)` returns 123, while `int('123', 16)` returns 291. `int(123, 16)` raises a **TypeError** exception with the message “can’t convert non-string with explicit base”.

A new variable holding more detailed version information has been added to the `sys` module. `sys.version_info` is a tuple `(major, minor, micro, level, serial)` For example, in a hypothetical 2.0.1beta1, `sys.version_info` would be `(2, 0, 1, 'beta', 1). level is a string such as "alpha", "beta", or "final" for a
Dictionaries have an odd new method, `setdefault(key, default)`, which behaves similarly to the existing `get()` method. However, if the key is missing, `setdefault()` both returns the value of `default` as `get()` would do, and also inserts it into the dictionary as the value for `key`. Thus, the following lines of code:

```python
if dict.has_key(key):
    return dict[key]
else:
    dict[key] = []
    return dict[key]
```

can be reduced to a single `return dict.setdefault(key, [])` statement.

The interpreter sets a maximum recursion depth in order to catch runaway recursion before filling the C stack and causing a core dump or GPF. Previously this limit was fixed when you compiled Python, but in 2.0 the maximum recursion depth can be read and modified using `sys.getrecursionlimit()` and `sys.setrecursionlimit()`. The default value is 1000, and a rough maximum value for a given platform can be found by running a new script, `Misc/find_recursionlimit.py`. 
Porting to 2.0

New Python releases try hard to be compatible with previous releases, and the record has been pretty good. However, some changes are considered useful enough, usually because they fix initial design decisions that turned out to be actively mistaken, that breaking backward compatibility can't always be avoided. This section lists the changes in Python 2.0 that may cause old Python code to break.

The change which will probably break the most code is tightening up the arguments accepted by some methods. Some methods would take multiple arguments and treat them as a tuple, particularly various list methods such as append() and insert(). In earlier versions of Python, if L is a list, L.append( 1,2 ) appends the tuple (1,2) to the list. In Python 2.0 this causes a TypeError exception to be raised, with the message: ‘append requires exactly 1 argument; 2 given’. The fix is to simply add an extra set of parentheses to pass both values as a tuple: L.append( (1,2) ).

The earlier versions of these methods were more forgiving because they used an old function in Python's C interface to parse their arguments; 2.0 modernizes them to use PyArg_ParseTuple(), the current argument parsing function, which provides more helpful error messages and treats multi-argument calls as errors. If you absolutely must use 2.0 but can't fix your code, you can edit Objects/listobject.c and define the preprocessor symbol NO_STRICT_LIST_APPEND to preserve the old behaviour; this isn't recommended.

Some of the functions in the socket module are still forgiving in this way. For example, socket.connect( ( 'hostname', 25 ) )() is
the correct form, passing a tuple representing an IP address, but socket.connect( 'hostname', 25 )() also works. socket.connect_ex() and socket.bind() are similarly easy-going. 2.0alpha1 tightened these functions up, but because the documentation actually used the erroneous multiple argument form, many people wrote code which would break with the stricter argument checking. GvR backed out the changes in the face of public reaction, so for the socket module, the documentation was fixed and the multiple argument form is simply marked as deprecated; it will be tightened up again in a future Python version.

The \x escape in string literals now takes exactly 2 hex digits. Previously it would consume all the hex digits following the ‘x’ and take the lowest 8 bits of the result, so \x123456 was equivalent to \x56.

The AttributeError and NameError exceptions have a more friendly error message, whose text will be something like 'Spam' instance has no attribute 'eggs' or name 'eggs' is not defined. Previously the error message was just the missing attribute name eggs, and code written to take advantage of this fact will break in 2.0.

Some work has been done to make integers and long integers a bit more interchangeable. In 1.5.2, large-file support was added for Solaris, to allow reading files larger than 2 GiB; this made the tell() method of file objects return a long integer instead of a regular integer. Some code would subtract two file offsets and attempt to use the result to multiply a sequence or slice a string, but this raised a TypeError. In 2.0, long integers can be used to multiply or slice a sequence, and it'll behave as you'd intuitively expect it to; 3L * 'abc' produces 'abcabcabc', and (0,1,2,3)[2L:4L] produces (2,3). Long integers can also be used in various contexts where previously only integers
were accepted, such as in the seek() method of file objects, and in the formats supported by the % operator (%d, %i, %x, etc.). For example, "%d" % 2L**64 will produce the string 18446744073709551616.

The subtlest long integer change of all is that the str() of a long integer no longer has a trailing ‘L’ character, though repr() still includes it. The ‘L’ annoyed many people who wanted to print long integers that looked just like regular integers, since they had to go out of their way to chop off the character. This is no longer a problem in 2.0, but code which does str(longval)[::-1] and assumes the ‘L’ is there, will now lose the final digit.

Taking the repr() of a float now uses a different formatting precision than str(). repr() uses %.17g format string for C’s sprintf(), while str() uses %.12g as before. The effect is that repr() may occasionally show more decimal places than str(), for certain numbers. For example, the number 8.1 can’t be represented exactly in binary, so repr(8.1) is '8.0999999999999996', while str(8.1) is '8.1'.

The -X command-line option, which turned all standard exceptions into strings instead of classes, has been removed; the standard exceptions will now always be classes. The exceptions module containing the standard exceptions was translated from Python to a built-in C module, written by Barry Warsaw and Fredrik Lundh.
Extending/Embedding Changes

Some of the changes are under the covers, and will only be apparent to people writing C extension modules or embedding a Python interpreter in a larger application. If you aren’t dealing with Python's C API, you can safely skip this section.

The version number of the Python C API was incremented, so C extensions compiled for 1.5.2 must be recompiled in order to work with 2.0. On Windows, it’s not possible for Python 2.0 to import a third party extension built for Python 1.5.x due to how Windows DLLs work, so Python will raise an exception and the import will fail.

Users of Jim Fulton’s ExtensionClass module will be pleased to find out that hooks have been added so that ExtensionClasses are now supported by `isinstance()` and `issubclass()`. This means you no longer have to remember to write code such as `if type(obj) == myExtensionClass`, but can use the more natural `if isinstance(obj, myExtensionClass)`.

The `Python/importdl.c` file, which was a mass of #ifdefs to support dynamic loading on many different platforms, was cleaned up and reorganised by Greg Stein. `importdl.c` is now quite small, and platform-specific code has been moved into a bunch of `Python/dynload_*.c` files. Another cleanup: there were also a number of `my*.h` files in the `Include/` directory that held various portability hacks; they’ve been merged into a single file, `Include/pyport.h`.

Vladimir Marangozov’s long-awaited malloc restructuring was completed, to make it easy to have the Python interpreter use a
custom allocator instead of C's standard malloc(). For documentation, read the comments in Include/pymem.h and Include/objimpl.h. For the lengthy discussions during which the interface was hammered out, see the Web archives of the ‘patches’ and ‘python-dev’ lists at python.org.

Recent versions of the GUSI development environment for MacOS support POSIX threads. Therefore, Python's POSIX threading support now works on the Macintosh. Threading support using the user-space GNU pth library was also contributed.

Threading support on Windows was enhanced, too. Windows supports thread locks that use kernel objects only in case of contention; in the common case when there's no contention, they use simpler functions which are an order of magnitude faster. A threaded version of Python 1.5.2 on NT is twice as slow as an unthreaded version; with the 2.0 changes, the difference is only 10%. These improvements were contributed by Yakov Markovitch.

Python 2.0's source now uses only ANSI C prototypes, so compiling Python now requires an ANSI C compiler, and can no longer be done using a compiler that only supports K&R C.

Previously the Python virtual machine used 16-bit numbers in its bytecode, limiting the size of source files. In particular, this affected the maximum size of literal lists and dictionaries in Python source; occasionally people who are generating Python code would run into this limit. A patch by Charles G. Waldman raises the limit from $2^{16}$ to $2^{32}$.

Three new convenience functions intended for adding constants to a module's dictionary at module initialization time were added: PyModule_AddObject(), PyModule_AddIntConstant(), and
PyModule_AddStringConstant(). Each of these functions takes a module object, a null-terminated C string containing the name to be added, and a third argument for the value to be assigned to the name. This third argument is, respectively, a Python object, a C long, or a C string.

A wrapper API was added for Unix-style signal handlers. PyOS_getsig() gets a signal handler and PyOS_setsig() will set a new handler.
Distutils: Making Modules Easy to Install

Before Python 2.0, installing modules was a tedious affair – there was no way to figure out automatically where Python is installed, or what compiler options to use for extension modules. Software authors had to go through an arduous ritual of editing Makefiles and configuration files, which only really work on Unix and leave Windows and MacOS unsupported. Python users faced wildly differing installation instructions which varied between different extension packages, which made administering a Python installation something of a chore.

The SIG for distribution utilities, shepherded by Greg Ward, has created the Distutils, a system to make package installation much easier. They form the distutils package, a new part of Python's standard library. In the best case, installing a Python module from source will require the same steps: first you simply mean unpack the tarball or zip archive, and the run “python setup.py install”. The platform will be automatically detected, the compiler will be recognized, C extension modules will be compiled, and the distribution installed into the proper directory. Optional command-line arguments provide more control over the installation process, the distutils package offers many places to override defaults – separating the build from the install, building or installing in non-default directories, and more.

In order to use the Distutils, you need to write a setup.py script. For the simple case, when the software contains only .py files, a minimal setup.py can be just a few lines long:

```python
from distutils.core import setup
setup (name = "foo", version = "1.0",
       py_modules = ["module1", "module2"])
```
The setup.py file isn’t much more complicated if the software
consists of a few packages:
from distutils.core import setup
setup (name = "foo", version = "1.0",
packages = ["package", "package.subpackage"])

A C extension can be the most complicated case; here’s an example
taken from the PyXML package:
from distutils.core import setup, Extension
expat_extension = Extension('xml.parsers.pyexpat',
define_macros = [('XML_NS', None)],
include_dirs = [ 'extensions/expat/xmltok',
'extensions/expat/xmlparse' ],
sources = [ 'extensions/pyexpat.c',
'extensions/expat/xmltok/xmltok.c',
'extensions/expat/xmltok/xmlrole.c'
)
setup (name = "PyXML", version = "0.5.4",
ext_modules =[ expat_extension ] )

The Distutils can also take care of creating source and binary
distributions. The “sdist” command, run by “python setup.py
sdist‘, builds a source distribution such as foo-1.0.tar.gz.
Adding new commands isn’t difficult, “bdist_rpm” and “bdist_wininst”
commands have already been contributed to create an RPM
distribution and a Windows installer for the software, respectively.
Commands to create other distribution formats such as Debian
packages and Solaris .pkg files are in various stages of development.


All this is documented in a new manual, *Distributing Python Modules*, that joins the basic set of Python documentation.
XML Modules

Python 1.5.2 included a simple XML parser in the form of the xmllib module, contributed by Sjoerd Mullender. Since 1.5.2’s release, two different interfaces for processing XML have become common: SAX2 (version 2 of the Simple API for XML) provides an event-driven interface with some similarities to xmllib, and the DOM (Document Object Model) provides a tree-based interface, transforming an XML document into a tree of nodes that can be traversed and modified. Python 2.0 includes a SAX2 interface and a stripped-down DOM interface as part of the xml package. Here we will give a brief overview of these new interfaces; consult the Python documentation or the source code for complete details. The Python XML SIG is also working on improved documentation.

SAX2 Support

SAX defines an event-driven interface for parsing XML. To use SAX, you must write a SAX handler class. Handler classes inherit from various classes provided by SAX, and override various methods that will then be called by the XML parser. For example, the startElement() and endElement() methods are called for every starting and end tag encountered by the parser, the characters() method is called for every chunk of character data, and so forth.

The advantage of the event-driven approach is that the whole document doesn’t have to be resident in memory at any one time, which matters if you are processing really huge documents. However, writing the SAX handler class can get very complicated if you’re trying to modify the document structure in some elaborate way.
For example, this little example program defines a handler that prints a message for every starting and ending tag, and then parses the file `hamlet.xml` using it:

```python
from xml import sax

class SimpleHandler(sax.ContentHandler):
    def startElement(self, name, attrs):
        print 'Start of element:', name, attrs.keys()

    def endElement(self, name):
        print 'End of element:', name

# Create a parser object
parser = sax.make_parser()

# Tell it what handler to use
handler = SimpleHandler()
parser.setContentHandler( handler )

# Parse a file!
parser.parse( 'hamlet.xml' )
```

For more information, consult the Python documentation, or the XML HOWTO at [http://pyxml.sourceforge.net/topics/howto/xml-howto.html](http://pyxml.sourceforge.net/topics/howto/xml-howto.html).

**DOM Support**

The Document Object Model is a tree-based representation for an XML document. A top-level Document instance is the root of the tree, and has a single child which is the top-level Element instance. This Element has children nodes representing character data and any sub-elements, which may have further children of their own, and so
forth. Using the DOM you can traverse the resulting tree any way you like, access element and attribute values, insert and delete nodes, and convert the tree back into XML.

The DOM is useful for modifying XML documents, because you can create a DOM tree, modify it by adding new nodes or rearranging subtrees, and then produce a new XML document as output. You can also construct a DOM tree manually and convert it to XML, which can be a more flexible way of producing XML output than simply writing `<tag1>...</tag1>` to a file.

The DOM implementation included with Python lives in the `xml.dom.minidom` module. It's a lightweight implementation of the Level 1 DOM with support for XML namespaces. The `parse()` and `parseString()` convenience functions are provided for generating a DOM tree:

```
from xml.dom import minidom
doc = minidom.parse('hamlet.xml')
```

doc is a Document instance. Document, like all the other DOM classes such as Element and Text, is a subclass of the Node base class. All the nodes in a DOM tree therefore support certain common methods, such as `toxml()` which returns a string containing the XML representation of the node and its children. Each class also has special methods of its own; for example, Element and Document instances have a method to find all child elements with a given tag name. Continuing from the previous 2-line example:

```
perslist = doc.getElementsByTagName('PERSONA')
print perslist[0].toxml()
pprint perslist[1].toxml()
```
For the *Hamlet* XML file, the above few lines output:

```xml
<Persona>CLAUDIUS, king of Denmark. </Persona>
<Persona>HAMLET, son to the late, and nephew to the
```

The root element of the document is available as `doc.documentElement`, and its children can be easily modified by deleting, adding, or removing nodes:

```python
root = doc.documentElement

# Remove the first child
root.removeChild( root.childNodes[0] )

# Move the new first child to the end
root.appendChild( root.childNodes[0] )

# Insert the new first child (originally, # the third child) before the 20th child.
root.insertBefore( root.childNodes[0], root.childNodes[20] )
```

Again, I will refer you to the Python documentation for a complete listing of the different Node classes and their various methods.

**Relationship to PyXML**

The XML Special Interest Group has been working on XML-related Python code for a while. Its code distribution, called PyXML, is available from the SIG’s Web pages at [http://www.python.org/sigs/xml-sig/](http://www.python.org/sigs/xml-sig/). The PyXML distribution also used the package name `xml`. If you’ve written programs that used PyXML, you’re probably wondering about its compatibility with the 2.0 `xml` package.
The answer is that Python 2.0’s `xml` package isn’t compatible with PyXML, but can be made compatible by installing a recent version PyXML. Many applications can get by with the XML support that is included with Python 2.0, but more complicated applications will require that the full PyXML package will be installed. When installed, PyXML versions 0.6.0 or greater will replace the `xml` package shipped with Python, and will be a strict superset of the standard package, adding a bunch of additional features. Some of the additional features in PyXML include:

- 4DOM, a full DOM implementation from FourThought, Inc.
- The xmlproc validating parser, written by Lars Marius Garshol.
- The sgmlop parser accelerator module, written by Fredrik Lundh.
Module changes

Lots of improvements and bugfixes were made to Python’s extensive standard library; some of the affected modules include `readline`, ConfigParser, `cgi`, `calendar`, `posix`, `readline`, `xmllib`, `aifc`, `chunk`, `wave`, `random`, `shelve`, and `nnplib`. Consult the CVS logs for the exact patch-by-patch details.

Brian Gallew contributed OpenSSL support for the `socket` module. OpenSSL is an implementation of the Secure Socket Layer, which encrypts the data being sent over a socket. When compiling Python, you can edit `Modules/Setup` to include SSL support, which adds an additional function to the `socket` module: `socket.ssl(socket, keyfile, certfile)`, which takes a socket object and returns an SSL socket. The `httplib` and `urllib` modules were also changed to support `https://` URLs, though no one has implemented FTP or SMTP over SSL.

The `httplib` module has been rewritten by Greg Stein to support HTTP/1.1. Backward compatibility with the 1.5 version of `httplib` is provided, though using HTTP/1.1 features such as pipelining will require rewriting code to use a different set of interfaces.

The Tkinter module now supports Tcl/Tk version 8.1, 8.2, or 8.3, and support for the older 7.x versions has been dropped. The Tkinter module now supports displaying Unicode strings in Tk widgets. Also, Fredrik Lundh contributed an optimization which makes operations like `create_line` and `create_polygon` much faster, especially when using lots of coordinates.

The `curses` module has been greatly extended, starting from Oliver
Andrich’s enhanced version, to provide many additional functions from ncurses and SYSV curses, such as colour, alternative character set support, pads, and mouse support. This means the module is no longer compatible with operating systems that only have BSD curses, but there don’t seem to be any currently maintained OSes that fall into this category.

As mentioned in the earlier discussion of 2.0’s Unicode support, the underlying implementation of the regular expressions provided by the re module has been changed. SRE, a new regular expression engine written by Fredrik Lundh and partially funded by Hewlett Packard, supports matching against both 8-bit strings and Unicode strings.
New modules

A number of new modules were added. We'll simply list them with brief descriptions; consult the 2.0 documentation for the details of a particular module.

- **atexit**: For registering functions to be called before the Python interpreter exits. Code that currently sets `sys.exitfunc` directly should be changed to use the **atexit** module instead, importing `atexit` and calling `atexit.register()` with the function to be called on exit. (Contributed by Skip Montanaro.)
- **codecs**, **encodings**, **unicodedata**: Added as part of the new Unicode support.
- **filecmp**: Supersedes the old `cmp`, `cmpcache` and `dircmp` modules, which have now become deprecated. (Contributed by Gordon MacMillan and Moshe Zadka.)
- **gettext**: This module provides internationalization (I18N) and localization (L10N) support for Python programs by providing an interface to the GNU gettext message catalog library. (Integrated by Barry Warsaw, from separate contributions by Martin von Löwis, Peter Funk, and James Henstridge.)
- **linuxaudiodev**: Support for the `/dev/audio` device on Linux, a twin to the existing `sunaudiodev` module. (Contributed by Peter Bosch, with fixes by Jeremy Hylton.)
- **mmap**: An interface to memory-mapped files on both Windows and Unix. A file's contents can be mapped directly into memory, at which point it behaves like a mutable string, so its contents can be read and modified. They can even be passed to functions that expect ordinary strings, such as the **re** module. (Contributed by Sam Rushing, with some extensions by A.M. Kuchling.)
- **pyexpat**: An interface to the Expat XML parser. (Contributed by Paul Prescod.)
- **robotparser**: Parse a `robots.txt` file, which is used for writing Web spiders that politely avoid certain areas of a Web site. The parser accepts the contents of a `robots.txt` file, builds a set of rules from it, and can then answer questions about the fetchability of a given URL. (Contributed by Skip Montanaro.)
- **tabnanny**: A module/script to check Python source code for ambiguous indentation. (Contributed by Tim Peters.)
- **UserString**: A base class useful for deriving objects that behave like strings.
- **webbrowser**: A module that provides a platform independent way to launch a web browser on a specific URL. For each platform, various browsers are tried in a specific order. The user can alter which browser is launched by setting the `BROWSER` environment variable. (Originally inspired by Eric S. Raymond's patch to `urllib` which added similar functionality, but the final module comes from code originally implemented by Fred Drake as `Tools/idle/BrowserControl.py`, and adapted for the standard library by Fred.)
- **_winreg**: An interface to the Windows registry. `_winreg` is an adaptation of functions that have been part of PythonWin since 1995, but has now been added to the core distribution, and enhanced to support Unicode. `_winreg` was written by Bill Tutt and Mark Hammond.
- **zipfile**: A module for reading and writing ZIP-format archives. These are archives produced by `PKZIP` on DOS/Windows or `zip` on Unix, not to be confused with `gzip`-format files (which are supported by the `gzip` module) (Contributed by James C. Ahlstrom.)
- **imputil**: A module that provides a simpler way for writing customised import hooks, in comparison to the existing `ihooks` module. (Implemented by Greg Stein, with much discussion on python-dev along the way.)
IDLE Improvements

IDLE is the official Python cross-platform IDE, written using Tkinter. Python 2.0 includes IDLE 0.6, which adds a number of new features and improvements. A partial list:

- UI improvements and optimizations, especially in the area of syntax highlighting and auto-indentation.
- The class browser now shows more information, such as the top level functions in a module.
- Tab width is now a user settable option. When opening an existing Python file, IDLE automatically detects the indentation conventions, and adapts.
- There is now support for calling browsers on various platforms, used to open the Python documentation in a browser.
- IDLE now has a command line, which is largely similar to the vanilla Python interpreter.
- Call tips were added in many places.
- IDLE can now be installed as a package.
- In the editor window, there is now a line/column bar at the bottom.
- Three new keystroke commands: Check module (Alt-F5), Import module (F5) and Run script (Ctrl-F5).
Deleted and Deprecated Modules

A few modules have been dropped because they’re obsolete, or because there are now better ways to do the same thing. The `stdwin` module is gone; it was for a platform-independent windowing toolkit that’s no longer developed.

A number of modules have been moved to the `lib-old` subdirectory: `cmp`, `cmpcache`, `dircmp`, `dump`, `find`, `grep`, `packmail`, `poly`, `util`, `whatsound`, `zmod`. If you have code which relies on a module that’s been moved to `lib-old`, you can simply add that directory to `sys.path` to get them back, but you’re encouraged to update any code that uses these modules.
Acknowledgements

The authors would like to thank the following people for offering suggestions on various drafts of this article: David Bolen, Mark Hammond, Gregg Hauser, Jeremy Hylton, Fredrik Lundh, Detlef Lannert, Aahz Maruch, Skip Montanaro, Vladimir Marangozov, Tobias Polzin, Guido van Rossum, Neil Schemenauer, and Russ Schmidt.
Changelog
Python 3.3.3 release candidate 2?

Release date: 11-Nov-2013

Library

- **Issue #19227**: Any re-seeding of the OpenSSL RNG on fork has been removed; this should be handled by OpenSSL itself or by the application.
- **Issue #19435**: Fix directory traversal attack on CGIHttpRequestHandler.

Tests

- **Issue #18964**: Fix test_tcl when run with Tcl/Tk versions < 8.5.

Build

- **Issue #15663**: Revert OS X installer built-in Tcl/Tk support for 3.3.3. Some third-party projects, such as Matplotlib and PIL/Pillow, depended on being able to build with Tcl and Tk frameworks in /Library/Frameworks.
Python 3.3.3 release candidate 1?

Release date: 27-Oct-2013

Core and Builtins

- **Issue #18603**: Ensure that PyOS_mycstricmp and PyOS_mycstrnicmp are in the Python executable and not removed by the linker’s optimizer.
- **Issue #19279**: UTF-7 decoder no more produces illegal strings.
- Fix macro expansion of _PyErr_OCCURRED(), and make sure to use it in at least one place so as to avoid regressions.
- **Issue #19014**: memoryview.cast() is now allowed on zero-length views.
- **Issue #19098**: Prevent overflow in the compiler when the recursion limit is set absurdly high.
- **Issue #18942**: sys._debugmallocstats() output was damaged on Windows.
- **Issue #18667**: Add missing “HAVE_FCHOWNAT” symbol to posix._have_functions.
- **Issue #18368**: PyOS_StdioReadline() no longer leaks memory when realloc() fails.
- **Issue #16741**: Fix an error reporting in int().
- **Issue #17899**: Fix rare file descriptor leak in os.listdir().
- **Issue #18552**: Check return value of PyArena_AddPyObject() in obj2ast_object().
- **Issue #18560**: Fix potential NULL pointer dereference in sum().
- **Issue #15905**: Fix theoretical buffer overflow in handling of sys.argv[0], prefix and exec_prefix if the operation system does not obey MAXPATHLEN.
- **Issue #18344**: Fix potential ref-leaks in _bufferedreader_read_all().
- **Issue #17872**: Fix a segfault in marshal.load() when input stream
returns more bytes than requested.

- **Issue #18426**: Fix NULL pointer dereference in C extension import when `PyModule_GetDef()` returns an error.
- **Issue #18328**: Reorder ops in `PyThreadState_Delete*()` functions. Now the tstate is first removed from TLS and then deallocated.
- **Issue #18184**: `PyUnicode_FromFormat()` and `PyUnicode_FromFormatV()` now raise `OverflowError` when an argument of `%c` format is out of range.
- **Issue #18137**: Detect integer overflow on precision in `float.__format__()` and `complex.__format__()`.
- **Issue #18183**: Fix various unicode operations on strings with large unicode codepoints.
- **Issue #18180**: Fix ref leak in `_PyImport_GetDynLoadWindows()`.
- **Issue #18038**: `SyntaxError` raised during compilation sources with illegal encoding now always contains an encoding name.
- **Issue #17644**: Fix a crash in `str.format` when curly braces are used in square brackets.
- **Issue #17983**: Raise a `SyntaxError` for a `global __class__` statement in a class body.
- **Issue #17927**: Frame objects kept arguments alive if they had been copied into a cell, even if the cell was cleared.

**Library**

- **Issue #19227**: Try to fix deadlocks caused by re-seeding then OpenSSL pseudo-random number generator on `fork()`.
- **Issue #16037**: `HTTPMessage.readheaders()` raises an `HTTPException` when more than 100 headers are read. Adapted from patch by Jyrki Pulliainen.
- **Issue #16040**: CVE-2013-1752: nntplib: Limit maximum line lengths to 2048 to prevent `readline()` calls from consuming too much memory. Patch by Jyrki Pulliainen.
- **Issue #16041**: CVE-2013-1752: poplib: Limit maximum line lengths to 2048 to prevent `readline()` calls from consuming too
much memory. Patch by Jyrki Pulliainen.

- **Issue #17997**: Change behavior of `ssl.match_hostname()` to follow RFC 6125, for security reasons. It now doesn’t match multiple wildcards nor wildcards inside IDN fragments.
- **Issue #16039**: CVE-2013-1752: Change use of readline in imaplib module to limit line length. Patch by Emil Lind.
- **Issue #19393**: Fix `symtable.symtable` function to not be confused when there are functions or classes named “top”.
- **Issue #19339**: `telnetlib` module is now using `time.monotonic()` when available to compute timeout.
- **Issue #19288**: Fixed the “in” operator of `dbm.gnu` databases for string argument. Original patch by Arfrever Frehtes Taifersar Arahesis.
- **Issue #19287**: Fixed the “in” operator of `dbm.ndbm` databases for string argument. Original patch by Arfrever Frehtes Taifersar Arahesis.
- **Issue #19327**: Fixed the working of regular expressions with too big charset.
- **Issue #19350**: Increasing the test coverage of `macurl2path`. Patch by Colin Williams.
- **Issue #19352**: Fix unittest discovery when a module can be reached through several paths (e.g. under Debian/Ubuntu with virtualenv).
- **Issue #15207**: Fix mimetypes to read from correct part of Windows registry Original patch by Dave Chambers
- **Issue #8964**: fix `platform._sys_version` to handle IronPython 2.6+. Patch by Martin Matusiak.
- **Issue #16038**: CVE-2013-1752: `ftplib`: Limit amount of data read by limiting the call to `readline()`. Original patch by Michał Jastrzębski and Giampaolo Rodola.
- **Issue #18235**: Fix the `sysconfig` variables `LDLIBRARY` and `BLDLIBRARY` under AIX. Patch by David Edelsohn.
- **Issue #19276**: Fixed the `wave` module on 64-bit big-endian platforms.
- **Issue #18776**: atexit callbacks now display their full traceback when they raise an exception.
- **Issue #17827**: Add the missing documentation for `codecs.encode` and `codecs.decode`.
- **Issue #18458**: Prevent crashes with newer versions of libedit. Its readline emulation has changed from 0-based indexing to 1-based like gnu readline. Original patch by Ronald Oussoren.
- **Issue #18919**: If the close() method of a writer in the sunau or wave module failed, second invocation of close() and destructor no more raise an exception.
- **Issue #19131**: The aifc module now correctly reads and writes sampwidth of compressed streams.
- **Issue #19158**: a rare race in BoundedSemaphore could allow .release() too often.
- **Issue #18037**: 2to3 now escapes ‘u’ and ‘U’ in native strings.
- **Issue #19137**: The pprint module now correctly formats instances of set and frozenset subclasses.
- **Issue #19092**: `contextlib.ExitStack` now correctly reraises exceptions from the __exit__ callbacks of inner context managers (Patch by Hrvoje Nikšić)
- **Issue #12641**: Avoid passing “-mno-cygwin” to the mingw32 compiler, except when necessary. Patch by Oscar Benjamin.
- **Issue #18594**: The fast path for collections.Counter() was never taken due to an over-restrictive type check. And the fallback path did not implement the same algorithm as the pure python code.
- Properly initialize all fields of a SSL object after allocation.
- **Issue #4366**: Fix building extensions on all platforms when --enable-shared is used.
- **Issue #18950**: Fix miscellaneous bugs in the sunau module. `Au_read.readframes()` now updates current file position and reads correct number of frames from multichannel stream. `Au_write.writeframesraw()` now correctly updates current file position. `Au_read.getnframes()` now returns an integer (as in Python 2). `Au_read` and `Au_write` now correctly works with file
object if start file position is not a zero.

- **Issue #19053**: ZipExtFile.read1() with non-zero argument no more returns empty bytes until end of data.
- **Issue #19028**: Fixed tkinter.Tkapp.merge() for non-string arguments.
- **Issue #3015**: Fixed tkinter with wantobject=False. Any Tcl command call returned empty string.
- **Issue #18050**: Fixed an incompatibility of the re module with Python 3.3.0 binaries.
- **Issue #19037**: The mailbox module now makes all changes to maildir files before moving them into place, to avoid race conditions with other programs that may be accessing the maildir directory.
- **Issue #14984**: On POSIX systems, when netrc is called without a filename argument (and therefore is reading the user's $HOME/.netrc file), it now enforces the same security rules as typical ftp clients: the .netrc file must be owned by the user that owns the process and must not be readable by any other user.
- **Issue #18873**: The tokenize module now detects Python source code encoding only in comment lines.
- **Issue #17324**: Fix http.server's request handling case on trailing '/'. Patch contributed by Vajrasky Kok.
- **Issue #19018**: The heapq.merge() function no longer suppresses IndexError in the underlying iterables.
- **Issue #18784**: The uuid module no more attempts to load libc via ctypes.CDLL, if all necessary functions are already found in libuuid. Patch by Evgeny Sologubov.
- **Issue #18672**: Fixed format specifiers for Py_ssize_t in debugging output in the _sre module.
- **Issue #18830**: inspect.getclasstree() no more produces duplicated entries even when input list contains duplicates.
- **Issue #18909**: Fix _tkinter.tkapp.interpaddr() on Windows 64-bit, don't cast 64-bit pointer to long (32 bits).
- **Issue #18876**: The FileIO.mode attribute now better reflects the
actual mode under which the file was opened. Patch by Erik Bray.

- **Issue #18418**: After fork(), reinit all threads states, not only active ones. Patch by A. Jesse Jiryu Davis.
- **Issue #16611**: http.cookie now correctly parses the ‘secure’ and ‘httponly’ cookie flags.
- **Issue #11973**: Fix a problem in kevent. The flags and fflags fields are now properly handled as unsigned.
- **Issue #17702**: On error, os.environb now removes suppress the except context when raising a new KeyError with the original key.
- **Issue #18755**: Fixed the loader used in imp to allow get_data() to be called multiple times.
- **Issue #16809**: Fixed some tkinter incompabilities with Tcl/Tk 8.6.
- **Issue #16809**: Tkinter’s splitlist() and split() methods now accept Tcl_Obj argument.
- **Issue #18324**: set_payload now correctly handles binary input. This also supersedes the previous fixes for #14360, #1717, and #16564.
- **Issue #17119**: Fixed integer overflows when processing large strings and tuples in the tkinter module.
- **Issue #18747**: Re-seed OpenSSL’s pseudo-random number generator after fork. A pthread_atfork() parent handler is used to seed the PRNG with pid, time and some stack data.
- **Issue #8865**: Concurrent invocation of select.poll.poll() now raises a RuntimeError exception. Patch by Christian Schubert.
- **Issue #13461**: Fix a crash in the TextIOWrapper.tell method on 64-bit platforms. Patch by Yogesh Chaudhari.
- **Issue #18777**: The ssl module now uses the new CRYPTO_THREADID API of OpenSSL 1.0.0+ instead of the deprecated CRYPTO id callback function.
- **Issue #18768**: Correct doc string of RAND_edg(). Patch by Vajrasky Kok.
- **Issue #18178**: Fix ctypes on BSD. dlmalloc.c was compiled twice which broke malloc weak symbols.
- **Issue #18709**: Fix CVE-2013-4238. The SSL module now handles
NULL bytes inside subjectAltName correctly. Formerly the module has used OpenSSL's GENERAL_NAME_print() function to get the string representation of ASN.1 strings for rfc822Name (email), dNSName (DNS) and uniformResourceIdentifier (URI).

- **Issue #18756**: Improve error reporting in os.urandom() when the failure is due to something else than /dev/urandom not existing (for example, exhausting the file descriptor limit).
- **Issue #18405**: Improve the entropy of crypt.mksalt().
- **Issue #19151**: Fix docstring and use of _get_supported_file_loaders() to reflect 2-tuples.
- **Issue #18676**: Change ‘positive’ to ‘non-negative’ in queue.py put and get docstrings and ValueError messages. Patch by Zhongyue Luo
- **Issue #18681**: Fix a NameError in imp.reload() (noticed by Weizhao Li).
- **Issue #8112**: xmlrpc.server’s DocXMLRPCServer server no longer raises an error if methods have annotations; it now correctly displays the annotations.
- **Issue #17998**: Fix an internal error in regular expression engine.
- **Issue #17557**: Fix os.getgroups() to work with the modified behavior of getgroups(2) on OS X 10.8. Original patch by Mateusz Lenik.
- **Issue #18599**: Fix name attribute of _sha1.sha1() object. It now returns ‘SHA1’ instead of ‘SHA’.
- **Issue #18561**: Skip name in ctypes’ _build_callargs() if name is NULL.
- **Issue #18559**: Fix NULL pointer dereference error in _pickle module
- **Issue #18556**: Check the return value of a PyUnicode_AsWideChar() call in ctypes’ U_set().
- **Issue #18549**: Eliminate dead code in socket_ntohl()
- **Issue #18514**: Fix unreachable Py_DECREF() call in PyCData_FromBaseObj()
- **Issue #18513**: Fix behaviour of cmath.rect w.r.t. signed zeros on
OS X 10.8 + gcc.

- **Issue #18480**: Add missing call to PyType_Ready to the _elementtree extension.
- **Issue #17778**: Fix test discovery for test_multiprocessing. (Patch by Zachary Ware.)
- **Issue #18431**: The new email header parser now decodes RFC2047 encoded words in structured headers.
- **Issue #18432**: The sched module's queue method was incorrectly returning an iterator instead of a list.
- **Issue #18044**: The new email header parser was mis-parsing encoded words where an encoded character immediately followed the ‘?’ that follows the CTE character, resulting in a decoding failure. They are now decoded correctly.
- **Issue #18101**: Tcl.split() now process strings nested in a tuple as it do with byte strings.
- **Issue #17198**: Fix a NameError in the dbm module. Patch by Valentina Mukhamedzhanova.
- **Issue #18013**: Fix cgi.FieldStorage to parse the W3C sample form.
- **Issue #18347**: ElementTree's html serializer now preserves the case of closing tags.
- **Issue #17261**: Ensure multiprocessing's proxies use proper address.
- **Issue #18343**: faulthandler.register() now keeps the previous signal handler when the function is called twice, so faulthandler.unregister() restores correctly the original signal handler.
- **Issue #17097**: Make multiprocessing ignore EINTR.
- **Issue #18339**: Negative ints keys in unpickler.memo dict no longer cause a segfault inside the _pickle C extension.
- **Issue #18224**: Removed pydoc script from created venv, as it causes problems on Windows and adds no value over and above python -m pydoc ...
- **Issue #18155**: The csv module now correctly handles csv files
that use a delimiter character that has a special meaning in regexes, instead of throwing an exception.

- **Issue #14360**: encode_quopri can now be successfully used as an encoder when constructing a MIMEApplication object.
- **Issue #18135**: ssl.SSLSocket.write() now raises an OverflowError if the input string is longer than 2 gigabytes, and ssl.SSLContext.load_cert_chain() raises a ValueError if the password is longer than 2 gigabytes. The ssl module does not support partial write.
- **Issue #18248**: Fix libffi build on AIX.
- **Issue #18259**: Declare sethostname in socketmodule.c for AIX
- **Issue #18167**: cgi.FieldStorage no longer fails to handle multipart/form-data when \n appears at end of 65535 bytes without other newlines.
- **subprocess**: Prevent a possible double close of parent pipe fds when the subprocess exec runs into an error. Prevent a regular multi-close of the /dev/null fd when any of stdin, stdout and stderr was set to DEVNULL.

- **Issue #16102**: Make uuid._netbios_getnode() work again on Python 3.
- **Issue #18109**: os.uname() now decodes fields from the locale encoding, and socket.gethostname() now decodes the hostname from the locale encoding, instead of using the UTF-8 encoding in strict mode.
- **Issue #17403**: urllib.parse.robotparser normalizes the urls before adding to ruleline. This helps in handling certain types invalid urls in a conservative manner.
- **Issue #18025**: Fixed a segfault in io.BufferedIOBase.readinto() when raw stream’s read() returns more bytes than requested.
- **Issue #18011**: base64.b32decode() now raises a binascii.Error if there are non-alphabet characters present in the input string to conform a docstring. Updated the module documentation.
- **Issue #13772**: Restored directory detection of targets in os.symlink on Windows, which was temporarily removed in
Python 3.2.3 due to an incomplete implementation. The implementation now works even if the symlink is created in a location other than the current directory.

- **Issue #16986**: ElementTree now correctly parses a string input not only when an internal XML encoding is UTF-8 or US-ASCII.
- **Issue #17812**: Fixed quadratic complexity of base64.b32encode().
- **Issue #17980**: Fix possible abuse of ssl.match_hostname() for denial of service using certificates with many wildcards (CVE-2013-2099).
- **Issue #17981**: Closed socket on error in SysLogHandler.
- Fix typos in the multiprocessing module.
- **Issue #17754**: Make ctypes.util.find_library() independent of the locale.
- **Issue #17968**: Fix memory leak in os.listdir().
- **Issue #17269**: Workaround for socket.getaddrinfo crash on MacOS X with port None or “0” and flags AI_NUMERICSERV.
- **Issue #18698**: Ensure imp.reload() returns the module out of sys.modules.
- **Issue #18080**: When building a C extension module on OS X, if the compiler is overridden with the CC environment variable, use the new compiler as the default for linking if LDSHARED is not also overridden. This restores Distutils behavior introduced in 3.2.3 and inadvertently dropped in 3.3.0.
- **Issue #18113**: Fixed a refcount leak in the curses.panel module's set_userptr() method. Reported by Atsuo Ishimoto.
- **Issue #18849**: Fixed a Windows-specific tempfile bug where collision with an existing directory caused mkstemp and related APIs to fail instead of retrying. Report and fix by Vlad Shcherbina.
- **Issue #19400**: Prevent extension module build failures with Xcode 5 on OS X 10.8+ when using a universal Python that included a PPC architecture, such as with a python.org 32-bit-only binary installer.

**C API**
• **Issue #18351**: Fix various issues with a helper function in importlib used by PyImport_ExecCodeModuleWithPathnames() (and thus by extension PyImport_ExecCodeModule() and PyImport_ExecCodeModuleEx()).

**IDLE**

• **Issue #18873**: IDLE now detects Python source code encoding only in comment lines.
• **Issue #18988**: The “Tab” key now works when a word is already autocompleted.
• **Issue #18489**: Add tests for SearchEngine. Original patch by Phil Webster.
• **Issue #18429**: Format / Format Paragraph, now works when comment blocks are selected. As with text blocks, this works best when the selection only includes complete lines.
• **Issue #18226**: Add docstrings and unitests for FormatParagraph.py. Original patches by Todd Rovito and Phil Webster.
• **Issue #18279**: Format - Strip trailing whitespace no longer marks a file as changed when it has not been changed. This fix followed the addition of a test file originally written by Phil Webster (the issue’s main goal).
• **Issue #7136**: In the Idle File menu, “New Window” is renamed “New File”. Patch by Tal Einat, Roget Serwy, and Todd Rovito.
• Remove dead imports of imp.
• **Issue #18196**: Avoid displaying spurious SystemExit tracebacks.
• **Issue #5492**: Avoid traceback when exiting IDLE caused by a race condition.
• **Issue #17511**: Keep IDLE find dialog open after clicking “Find Next”. Original patch by Sarah K.
• **Issue #18055**: Move IDLE off of imp and on to importlib.
• **Issue #15392**: Create a unittest framework for IDLE. Initial patch
by Rajagoparasarma Jayakrishnan. See Lib/idlelib/idle_test/README.txt for how to run Idle tests.

- **Issue #14146**: Highlight source line while debugging on Windows.
- **Issue #17532**: Always include Options menu for IDLE on OS X. Patch by Guilherme Simões.

### Tests

- **Issue #14407**: Fix unittest test discovery in test_concurrent_futures.
- **Issue #18919**: Unified and extended tests for audio modules: aifc, sunau and wave.
- **Issue #18952**: Fix regression in support data downloads introduced when test.support was converted to a package. Regression noticed by Zachary Ware.
- **Issue #12037**: Fix test_email for desktop Windows.
- **Issue #15507**: test_subprocess's test_send_signal could fail if the test runner were run in an environment where the process inherited an ignore setting for SIGINT. Restore the SIGINT handler to the desired KeyboardInterrupt raising one during that test.
- **Issue #18792**: Use “127.0.0.1” or “::1” instead of “localhost” as much as possible, since “localhost” goes through a DNS lookup under recent Windows versions.
- **Issue #1666318**: Add a test that shutil.copytree() retains directory permissions. Patch by Catherine Devlin.
- **Issue #18357**: add tests for dictview set difference. Patch by Fraser Tweedale.
- **Issue #18273**: move the tests in Lib/test/json_tests to Lib/test/test_json and make them discoverable by unittest. Patch by Zachary Ware.
- Fix a fcntl test case on KFreeBSD, Debian #708653 (Petr Salinger).
- **Issue #18396**: Fix spurious test failure in test_signal on Windows.
when faulthandler is enabled (Patch by Jeremy Kloth)

- **Issue #17046**: Fix broken `test_executable_without_cwd` in `test_subprocess`.
- **Issue #15415**: Add new `temp_dir()` and `change_cwd()` context managers to test.support, and refactor `temp_cwd()` to use them. Patch by Chris Jerdonek.
- **Issue #15494**: `test.support` is now a package rather than a module (Initial patch by Indra Talip)
- **Issue #17944**: `test_zipfile` now discoverable and uses subclassing to generate tests for different compression types. Fixed a bug with skipping some tests due to use of exhausted iterators.
- **Issue #18266**: `test_largefile` now works with unittest test discovery and supports running only selected tests. Patch by Zachary Ware.
- **Issue #17767**: `test_locale` now works with unittest test discovery. Original patch by Zachary Ware.
- **Issue #18375**: Assume `–randomize` when `–randseed` is used for running the testsuite.
- **Issue #11185**: Fix `test_wait4` under AIX. Patch by Sébastien Sablé.
- **Issue #17691**: `test_univnewlines` now works with unittest test discovery. Patch by Zachary Ware.
- **Issue #18094**: `test_uuid` no more reports skipped tests as passed.
- **Issue #11995**: `test_pydoc` doesn’t import all `sys.path` modules anymore.

**Documentation**

- **Issue #19392**: Document that `imp.reload()` now also requires `__loader__` to be set on the module being reloaded.
- **Issue #18758**: Fixed and improved cross-references.
- **Issue #18743**: Fix references to non-existent “StringIO” module.
- **Issue #18783**: Removed existing mentions of Python long type in docstrings, error messages and comments.
- **Issue #17701**: Improving `strftime` documentation.
Issue #18440: Clarify that hash() can truncate the value returned from an object's custom __hash__() method.

Issue #17953: Mention that you shouldn't replace sys.modules and deleting key items will cause Python to not be happy.

Issue #17844: Add links to encoders and decoders for bytes-to-bytes codecs.

Issue #14097: improve the “introduction” page of the tutorial.

Issue #17977: The documentation for the cadefault argument's default value in urllib.request.urlopen() is fixed to match the code.

Tools/Demos

Issue #18873: 2to3 and the findnocoding.py script now detect Python source code encoding only in comment lines.

Issue #18817: Fix a resource warning in Lib/aifc.py demo.

Issue #18439: Make patchcheck work on Windows for ACKS, NEWS.

Issue #18448: Fix a typo in Tools/demo/eiffel.py.

Issue #18457: Fixed saving of formulas and complex numbers in Tools/demo/ss1.py.

Issue #18449: Make Tools/demo/ss1.py work again on Python 3.

Patch by Févry Thibault.

Issue #15239: Make mkstringprep.py work again on Python 3.

Issue #12990: The “Python Launcher” on OSX could not launch python scripts that have paths that include wide characters.

Build

Issue #19356: Avoid using a C variabled named “_self”, it's a reserved word in some C compilers.

Issue #19130: Correct PCbuild/readme.txt, Python 3.3 and 3.4 require VS 2010.

Issue #16067: Add description into MSI file to replace installer's
temporary name.

- **Issue #18256**: Compilation fix for recent AIX releases. Patch by David Edelsohn.
- **Issue #15172**: Document NASM 2.10+ as requirement for building OpenSSL 1.0.1 on Windows.
- **Issue #1584**: Provide options to override default search paths for Tcl and Tk when building _tkinter.
- **Issue #15663**: Tcl/Tk 8.5.15 is now included with the OS X 10.6+ 64-bit/32-bit installer for 10.6+. It is no longer necessary to install a third-party version of Tcl/Tk 8.5 to work around the problems in the Apple-supplied Tcl/Tk 8.5 shipped in OS X 10.6 and later releases.
- **Issue #19019**: Change the OS X installer build script to use CFLAGS instead of OPT for special build options. By setting OPT, some compiler-specific options like -fwrapv were overridden and thus not used, which could result in broken interpreters when building with clang.
Python 3.3.2?

Release date: 13-May-2013

Core and Builtins

- **Issue #17237**: Fix crash in the ASCII decoder on m68k.
- **Issue #17408**: Avoid using an obsolete instance of the copyreg module when the interpreter is shutdown and then started again.
- **Issue #17863**: In the interactive console, don’t loop forever if the encoding can’t be fetched from stdin.
- **Issue #17867**: Raise an ImportError if __import__ is not found in __builtins__.
- **Issue #17857**: Prevent build failures with pre-3.5.0 versions of sqlite3, such as was shipped with Centos 5 and Mac OS X 10.4.
- **Issue #17413**: sys.settrace callbacks were being passed a string instead of an exception instance for the ‘value’ element of the arg tuple if the exception originated from C code; now an exception instance is always provided.
- **Issue #17782**: Fix undefined behaviour on platforms where `struct timespec`’s “tv_nsec” member is not a C long.
- **Issue #17715**: Fix segmentation fault from raising an exception in a __trunc__ method.
- **Issue #16447**: Fixed potential segmentation fault when setting __name__ on a class.
- **Issue #17669**: Fix crash involving finalization of generators using yield from.
- **Issue #17619**: Make input() check for Ctrl-C correctly on Windows.
- **Issue #17610**: Don’t rely on non-standard behavior of the C qsort() function.
- **Issue #17357**: Add missing verbosity output when using -v/-vv.
Library

- **Issue #17606**: Fixed support of encoded byte strings in the XMLGenerator characters() and ignorableWhitespace() methods. Original patch by Sebastian Ortiz Vasquez.
- **Issue #17732**: Ignore distutils.cfg options pertaining to install paths if a virtual environment is active.
- **Issue #1159051**: Back out a fix for handling corrupted gzip files that broke backwards compatibility.
- **Issue #17915**: Fix interoperability of xml.sax with file objects returned by codecs.open().
- **Issue #16601**: Restarting iteration over tarfile no more continues from where it left off. Patch by Michael Birtwell.
- **Issue #17289**: The readline module now plays nicer with external modules or applications changing the rl_completer_word_break_characters global variable. Initial patch by Bradley Froehle.
- **Issue #12181**: select module: Fix struct kevent definition on OpenBSD 64-bit platforms. Patch by Federico Schwindt.
- **Issue #14173**: Avoid crashing when reading a signal handler during interpreter shutdown.
- **Issue #16316**: mimetypes now recognizes the .xz and .txz (.tar.xz) extensions.
- **Issue #15902**: Fix imp.load_module() accepting None as a file when loading an extension module.
- **Issue #17802**: Fix an UnboundLocalError in html.parser. Initial tests by Thomas Barlow.
- **Issue #15535**: Fix namedtuple pickles which were picking up the OrderedDict instead of just the underlying tuple.
- **Issue #17192**: Restore the patch for Issue #11729 which was ommitted in 3.3.1 when updating the bundled version of libffi used by ctypes. Update many libffi files that were missed in 3.3.1's update to libffi-3.0.13.
- **Issue #17358**: Modules loaded by imp.load_source() and
load_compiled() (and by extension load_module()) now have a better chance of working when reloaded.

- **Issue #17353**: Plistlib emitted empty data tags with deeply nested datastructures
- **Issue #11714**: Use ‘with’ statements to assure a Semaphore releases a condition variable. Original patch by Thomas Rachel.
- **Issue #17795**: Reverted backwards-incompatible change in SysLogHandler with Unix domain sockets.
- **Issue #17555**: Fix ForkAwareThreadLock so that size of after fork registry does not grow exponentially with generation of process.
- **Issue #17707**: multiprocessing.Queue’s get() method does not block for short timeouts.
- **Issue #17720**: Fix the Python implementation of pickle.Unpickler to correctly process the APPENDS opcode when it is used on non-list objects.
- **Issue #17012**: shutil.which() no longer fallbacks to the PATH environment variable if empty path argument is specified. Patch by Serhiy Storchaka.
- **Issue #17710**: Fix pickle raising a SystemError on bogus input.
- **Issue #17341**: Include the invalid name in the error messages from re about invalid group names.
- **Issue #17702**: os.environ now raises KeyError with the original environment variable name (str on UNIX), instead of using the encoded name (bytes on UNIX).
- **Issue #16163**: Make the importlib based version of pkgutil.iter_importers work for submodules. Initial patch by Berker Peksag.
- **Issue #16804**: Fix a bug in the ‘site’ module that caused running ‘python -S -m site’ to incorrectly throw an exception.
- **Issue #17016**: Get rid of possible pointer wraparounds and integer overflows in the re module. Patch by Nickolai Zeldovich.
- **Issue #16658**: add missing return to HTTPConnection.send() Patch by Jeff Knupp.
- **Issue #14971**: unittest test discovery no longer gets confused...
when a function has a different __name__ than its name in the TestCase class dictionary.

- **Issue #17678**: Fix DeprecationWarning in the http/cookiejar.py by changing the usage of get_origin_req_host() to origin_req_host.
- **Issue #17666**: Fix reading gzip files with an extra field.
- **Issue #17502**: Process DEFAULT values in mock side_effect that returns iterator. Patch by Michael Foord.
- **Issue #17572**: Avoid chained exceptions while passing bad directives to time.strptime(). Initial patch by Claudiu Popa.
- **Issue #17435**: threading.Timer’s __init__ method no longer uses mutable default values for the args and kwargs parameters.
- **Issue #17526**: Fix an IndexError raised while passing code without filename to inspect.findsource(). Initial patch by Tyler Doyle.
- **Issue #16550**: Update the opcode descriptions of pickletools to use unsigned integers where appropriate. Initial patch by Serhiy Storchaka.

**IDLE**

- **Issue #17838**: Allow sys.stdin to be reassigned.
- **Issue #13495**: Avoid loading the color delegator twice in IDLE.
- **Issue #17798**: Allow IDLE to edit new files when specified on command line.
- **Issue #14735**: Update IDLE docs to omit “Control-z on Windows”.
- **Issue #17585**: Fixed IDLE regression. Now closes when using exit() or quit().
- **Issue #17657**: Show full Tk version in IDLE’s about dialog. Patch by Todd Rovito.
- **Issue #17613**: Prevent traceback when removing syntax colorizer in IDLE.
- **Issue #1207589**: Backwards-compatibility patch for right-click menu in IDLE.
- **Issue #16887**: IDLE now accepts Cancel in tabify/untabify dialog box.
• **Issue #17625**: In IDLE, close the replace dialog after it is used.
• **Issue #14254**: IDLE now handles readline correctly across shell restarts.
• **Issue #17614**: IDLE no longer raises exception when quickly closing a file.
• **Issue #6698**: IDLE now opens just an editor window when configured to do so.
• **Issue #8900**: Using keyboard shortcuts in IDLE to open a file no longer raises an exception.
• **Issue #6649**: Fixed missing exit status in IDLE. Patch by Guilherme Polo.

Tests

• **Issue #17833**: Fix test_gdb failures seen on machines where debug symbols for glibc are available (seen on PPC64 Linux).
• **Issue #7855**: Add tests for ctypes/winreg for issues found in IronPython. Initial patch by Dino Viehland.
• **Issue #17712**: Fix test_gdb failures on Ubuntu 13.04.
• **Issue #17835**: Fix test_io when the default OS pipe buffer size is larger than one million bytes.
• **Issue #17065**: Use process-unique key for winreg tests to avoid failures if test is run multiple times in parallel (eg: on a buildbot host).
• **Issue #12820**: add tests for the xml.dom.minicompact module. Patch by John Chandler and Phil Connell.
• **Issue #17790**: test_set now works with unittest test discovery. Patch by Zachary Ware.
• **Issue #17789**: test_random now works with unittest test discovery. Patch by Zachary Ware.
• **Issue #17779**: test_osx_env now works with unittest test discovery. Patch by Zachary Ware.
• **Issue #17766**: test_iterlen now works with unittest test discovery. Patch by Zachary Ware.
• **Issue #17690:** test_time now works with unittest test discovery. Patch by Zachary Ware.

• **Issue #17692:** test_sqlite now works with unittest test discovery. Patch by Zachary Ware.

• **Issue #17843:** Removed bz2 test data file that was triggering false-positive virus warnings with certain antivirus software.

**Documentation**

• **Issue #15940:** Specify effect of locale on time functions.

• **Issue #6696:** add documentation for the Profile objects, and improve profile/cProfile docs. Patch by Tom Pinckney.

• **Issue #17915:** Fix interoperability of xml.sax with file objects returned by codecs.open().

**Build**

• **Issue #17547:** In configure, explicitly pass -Wformat for the benefit for GCC 4.8.

• **Issue #17962:** Build with OpenSSL 1.0.1e on Windows.
Python 3.3.1?

Release date: 07-Apr-2013

Build

- Issue #17550: Fix the –enable-profiling configure switch.

IDLE

- Issue #17625: In IDLE, close the replace dialog after it is used.
Python 3.3.1 release candidate 1?

Release date: 24-Mar-2013

Core and Builtins

- **Issue #17328**: Fix possible ref leak in dict.setdefault.
- **Issue #17223**: Fix PyUnicode_FromUnicode() for string of 1 character outside the range U+0000-U+10ffff.
- **Issue #1692335**: Move initial args assignment to BaseException.__new__ to help pickling of naive subclasses.
- **Issue #17275**: Corrected class name in init error messages of the C version of BufferedWriter and BufferedRandom.
- **Issue #7963**: Fixed misleading error message that issued when object is called without arguments.
- **Issue #5308**: Raise ValueError when marshalling too large object (a sequence with size >= 2**31), instead of producing illegal marshal data.
- **Issue #12983**: Bytes literals with invalid x escape now raise a SyntaxError and a full traceback including line number.
- **Issue #17173**: Remove uses of locale-dependent C functions (isalpha() etc.) in the interpreter.
- **Issue #17137**: When an Unicode string is resized, the internal wide character string (wstr) format is now cleared.
- **Issue #17043**: The unicode-internal decoder no longer read past the end of input buffer.
- **Issue #17098**: All modules now have __loader__ set even if they pre-exist the bootstrapping of importlib.
- **Issue #16979**: Fix error handling bugs in the unicode-escape-decode decoder.
- **Issue #10156**: In the interpreter’s initialization phase, unicode globals are now initialized dynamically as needed.
- **Issue #16980**: Fix processing of escaped non-ascii bytes in the
unicode-escape-decode decoder.

- **Issue #16975**: Fix error handling bug in the escape-decode bytes decoder.
- **Issue #14850**: Now a charmap decoder treats U+FFFE as “undefined mapping” in any mapping, not only in a string.
- **Issue #16730**: importlib.machinery.FileFinder now no longer raises an exception when trying to populate its cache and it finds out the directory is unreadable or has turned into a file. Reported and diagnosed by David Pritchard.
- **Issue #16906**: Fix a logic error that prevented most static strings from being cleared.
- **Issue #11461**: Fix the incremental UTF-16 decoder. Original patch by Amaury Forgeot d’Arc.
- **Issue #16856**: Fix a segmentation fault from calling repr() on a dict with a key whose repr raise an exception.
- **Issue #16367**: Fix FileIO.readall() on Windows for files larger than 2 GB.
- **Issue #16455**: On FreeBSD and Solaris, if the locale is C, the ASCII/surrogateescape codec is now used, instead of the locale encoding, to decode the command line arguments. This change fixes inconsistencies with os.fsencode() and os.fsdecode() because these operating systems announces an ASCII locale encoding, whereas the ISO-8859-1 encoding is used in practice.
- **Issue #16761**: Calling int() with base argument only now raises TypeError.
- **Issue #16759**: Support the full DWORD (unsigned long) range in Reg2Py when retrieving a REG_DWORD value. This corrects functions like winreg.QueryValueEx that may have been returning truncated values.
- **Issue #14420**: Support the full DWORD (unsigned long) range in Py2Reg when passed a REG_DWORD value. Fixes OverflowError in winreg.SetValueEx.
- **Issue #16597**: In buffered and text IO, call close() on the underlying stream if invoking flush() fails.
• **Issue #16722**: In the bytes() constructor, try to call __bytes__ on the argument before __index__.

• **Issue #16602**: When a weakref's target was part of a long deallocation chain, the object could remain reachable through its weakref even though its refcount had dropped to zero.

• **Issue #16416**: On Mac OS X, operating system data are now always encoded/decoded to/from UTF-8/surrogateescape, instead of the locale encoding (which may be ASCII if no locale environment variable is set), to avoid inconsistencies with os.fsencode() and os.fsdecode() functions which are already using UTF-8/surrogateescape.

• **Issue #16588**: Silence unused-but-set warnings in Python/thread_pthread

• **Issue #16546**: Fix: ast.YieldFrom argument is now mandatory.

• **Issue #16514**: Fix regression causing a traceback when sys.path[0] is None (actually, any non-string or non-bytes type).

• **Issue #16306**: Fix multiple error messages when unknown command line parameters where passed to the interpreter. Patch by Hieu Nguyen.

• **Issue #16215**: Fix potential double memory free in str.replace(). Patch by Serhiy Storchaka.

• **Issue #16453**: Fix equality testing of dead weakref objects.

• **Issue #9535**: Fix pending signals that have been received but not yet handled by Python to not persist after os.fork() in the child process.

• **Issue #15001**: fix segfault on “del sys.modules['__main__']”. Patch by Victor Stinner.

• **Issue #8271**: the utf-8 decoder now outputs the correct number of U+FFFD characters when used with the ‘replace’ error handler on invalid utf-8 sequences. Patch by Serhiy Storchaka, tests by Ezio Melotti.

• **Issue #5765**: Apply a hard recursion limit in the compiler instead of blowing the stack and segfaulting. Initial patch by Andrea Griffini.
- **Issue #16402:** When slicing a range, fix shadowing of exceptions from `__index__`.
- **Issue #16336:** fix input checking in the surrogatepass error handler. Patch by Serhiy Storchaka.
- **Issue #8401:** assigning an int to a bytearray slice (e.g. `b[3:4] = 5`) now raises an error.
- Fix segfaults on setting `__qualname__` on builtin types and attempting to delete it on any type.
- **Issue #16345:** Fix an infinite loop when `fromkeys` on a dict subclass received a nonempty dict from the constructor.
- **Issue #16271:** Fix strange bugs that resulted from `__qualname__` appearing in a class’s `__dict__` and on type.
- **Issue #6074:** Ensure cached bytecode files can always be updated by the user that created them, even when the source file is read-only.
- **Issue #14783:** Improve `int()` docstring and switch docstrings for `str()`, `range()`, and `slice()` to use multi-line signatures.
- **Issue #16160:** Subclass support now works for `types.SimpleNamespace`.
- **Issue #15379:** Fix passing of non-BMP characters as integers for the charmap decoder (already working as unicode strings). Patch by Serhiy Storchaka.
- **Issue #15144:** Fix possible integer overflow when handling pointers as integer values, by using `Py_uintptr_t` instead of `size_t`. Patch by Serhiy Storchaka.
- **Issue #15965:** Explicitly cast `AT_FDCWD` as `(int)`. Required on Solaris 10 (which defines `AT_FDCWD` as `0xffd19553`), harmless on other platforms.
- **Issue #15839:** Convert `SystemErrors` in `super()` to `RuntimeErrors`.
- **Issue #15846:** Fix `SystemError` which happened when using `ast.parse()` in an exception handler on code with syntax errors.
- **Issue #15801:** Make sure mappings passed to ‘%’ formatting are
• **Issue #15111**: `__import__` should let `ImportError` propagate when a module that is imported as a side-effect of using `fromlist` tries to import a module that cannot be found.

Library

• **Issue #17540**: Added style to formatter configuration by `dict`.
• **Issue #17536**: Add to webbrowser’s browser list: `www-browser`, `x-www-browser`, `iceweasel`, `iceape`.
• **Issue #17488**: Change the subprocess.Popen bufsize parameter default value from unbuffered (0) to buffering (-1) to match the behavior existing code expects and match the behavior of the subprocess module in Python 2 to avoid introducing hard to track down bugs.
• **Issue #17521**: Corrected non-enabling of logger following two calls to `fileConfig()`.
• **Issue #17508**: Corrected MemoryHandler configuration in `dictConfig()` where the target handler wasn’t configured first.
• **Issue #17209**: curses.window.get_wch() now handles correctly `KeyboardInterrupt` (CTRL+c).
• **Issue #5713**: `smtplib` now handles 421 (closing connection) error codes when sending mail by closing the socket and reporting the 421 error code via the exception appropriate to the command that received the error response.
• **Issue #17192**: Update the ctypes module’s `libffi` to v3.0.13. This specifically addresses a stack misalignment issue on x86 and issues on some more recent platforms.
• **Issue #8862**: Fixed curses cleanup when `getkey` is interrupted by a signal.
• **Issue #17443**: `imaplib.IMAP4_stream` was using the default unbuffered IO in subprocess, but the imap code assumes buffered IO. In Python2 this worked by accident. `IMAP4_stream` now explicitly uses buffered IO.
• **Issue #17476:** Fixed regression relative to Python2 in undocumented pydoc ‘allmethods’; it was missing unbound methods on the class.

• **Issue #16880:** Do not assume `_imp.load_dynamic()` is defined in the imp module.

• **Issue #16389:** Fixed a performance regression relative to Python 3.1 in the caching of compiled regular expressions.

• **Issue #17431:** Fix missing import of BytesFeedParser in email.parser.

• **Issue #1285086:** Get rid of the refcounting hack and speed up `urllib.parse.unquote()` and `urllib.parse.unquote_to_bytes()`.

• **Issue #17368:** Fix an off-by-one error in the Python JSON decoder that caused a failure while decoding empty object literals when `object_pairs_hook` was specified.

• **Issue #14645:** The email generator classes now produce output using the specified linesep throughout. Previously if the prolog, epilog, or body were stored with a different linesep, that linesep was used. This fix corrects an RFC non-compliance issue with `smtplib.send_message`.

• **Issue #17278:** Fix a crash in `heapq.heappush()` and `heapq.heappop()` when the list is being resized concurrently.

• **Issue #16962:** Use `getdents64` instead of the obsolete `getdents` syscall in the subprocess module on Linux.

• **Issue #17018:** Make `Process.join()` retry if `os.waitpid()` fails with EINTR.

• **Issue #17223:** array module: Fix a crasher when converting an array containing invalid characters (outside range `[U+0000; U+10ffff]`) to Unicode: `repr(array)`, `str(array)` and `array.tounicode()`. Patch written by Manuel Jacob.

• **Issue #14720:** sqlite3: Convert datetime microseconds correctly. Patch by Lowe Thiderman.

• **Issue #17225:** JSON decoder now counts columns in the first line starting with 1, as in other lines.

• **Issue #13700:** Fix byte/string handling in `imaplib` authentication
when an authobject is specified.

- **Issue #13153**: Tkinter functions now raise TclError instead of ValueError when a string argument contains non-BMP character.
- **Issue #9669**: Protect re against infinite loops on zero-width matching in non-greedy repeat. Patch by Matthew Barnett.
- **Issue #13169**: The maximal repetition number in a regular expression has been increased from 65534 to 2147483647 (on 32-bit platform) or 4294967294 (on 64-bit).
- **Issue #17143**: Fix a missing import in the trace module. Initial patch by Berker Peksag.
- **Issue #16743**: Fix mmap overflow check on 32 bit Windows.
- **Issue #16800**: tempfile.gettempdir() no longer left temporary files when the disk is full. Original patch by Amir Szekely.
- **Issue #16564**: Fixed regression relative to Python2 in the operation of email.encoders.encode_7or8bit when used with binary data.
- **Issue #17052**: unittest discovery should use self.testLoader.
- **Issue #4591**: Uid and gid values larger than 2**31 are supported now.
- **Issue #17141**: random.vonmisesvariate() no more hangs for large kappas.
- **Issue #17149**: Fix random.vonmisesvariate to always return results in [0, 2*math.pi].
- **Issue #1470548**: XMLGenerator now works with binary output streams.
- **Issue #6975**: os.path.realpath() now correctly resolves multiple nested symlinks on POSIX platforms.
- **Issue #16564**: Fixed regression relative to Python2 in the operation of email.encoders.encode_noop when used with binary data.
- **Issue #10355**: In SpooledTemporaryFile class mode, name, encoding and newlines properties now work for unrolled files. Obsoleted and never working on Python 3 xreadline method now removed.
- **Issue #16686**: Fixed a lot of bugs in audioop module. Fixed crashes in avgpp(), maxpp() and ratecv(). Fixed an integer overflow in add(), bias(), and ratecv(). reverse(), lin2lin() and ratecv() no more lose precision for 32-bit samples. max() and rms() no more returns a negative result and various other functions now work correctly with 32-bit sample -0x80000000.

- **Issue #17073**: Fix some integer overflows in sqlite3 module.

- **Issue #16723**: httplib.HTTPResponse no longer marked closed when the connection is automatically closed.

- **Issue #16948**: Fix quoted printable body encoding for non-latin1 character sets in the email package.

- **Issue #16811**: Fix folding of headers with no value in the provisional email policies.

- **Issue #17132**: Update symbol for “yield from” grammar changes.

- **Issue #17076**: Make copying of xattrs more permissive of missing FS support. Patch by Thomas Wouters.

- **Issue #17089**: Expat parser now correctly works with string input not only when an internal XML encoding is UTF-8 or US-ASCII. It now accepts bytes and strings larger than 2 GiB.

- **Issue #6083**: Fix multiple segmentation faults occurred when PyArg_ParseTuple parses nested mutating sequence.

- **Issue #5289**: Fix ctypes.util.find_library on Solaris.

- **Issue #17106**: Fix a segmentation fault in io.TextIOWrapper when an underlying stream or a decoder produces data of an unexpected type (i.e. when io.TextIOWrapper initialized with text stream or use bytes-to-bytes codec).

- **Issue #15633**: httplib.HTTPResponse is now marked closed when the server sends less than the advertised Content-Length.

- **Issue #12268**: The io module file object write methods no longer abort early when one of its write system calls is interrupted (EINTR).

- **Issue #6972**: The zipfile module no longer overwrites files outside of its destination path when extracting malicious zip files.

- **Issue #4844**: ZipFile now raises BadZipFile when opens a ZIP file
with an incomplete “End of Central Directory” record. Original patch by Guilherme Polo and Alan McIntyre.

- **Issue #17071**: Signature.bind() now works when one of the keyword arguments is named `self`.
- **Issue #12004**: Fix an internal error in PyZipFile when writing an invalid Python file. Patch by Ben Morgan.
- **Issue #1602133**: on Mac OS X a shared library build (`--enable-shared`) now fills the `os.environ` variable correctly.
- **Issue #15505**: `unittest.installHandler` no longer assumes SIGINT handler is set to a callable object.
- **Issue #13454**: Fix a crash when deleting an iterator created by `itertools.tee()` if all other iterators were very advanced before.
- **Issue #12411**: Fix to `cgi.parse_multipart` to correctly use bytes boundaries and bytes data. Patch by Jonas Wagner.
- **Issue #16957**: `shutil.which()` no longer searches a bare file name in the current directory on Unix and no longer searches a relative file path with a directory part in PATH directories. Patch by Thomas Kluyver.
- **Issue #16993**: `shutil.which()` now preserves the case of the path and extension on Windows.
- **Issue #16992**: On Windows in `signal.set_wakeup_fd`, validate the file descriptor argument.
- **Issue #16422**: For compatibility with the Python version, the C version of `decimal` now uses strings instead of integers for rounding mode constants.
- **Issue #15861**: `tkinter` now correctly works with lists and tuples containing strings with whitespaces, backslashes or unbalanced braces.
- **Issue #10527**: Use `poll()` instead of `select()` for multiprocessing pipes.
- **Issue #9720**: `zipfile` now writes correct local headers for files larger than 4 GiB.
- **Issue #16955**: Fix the `poll()` method for multiprocessing's socket connections on Windows.
- SSLContext.load_dh_params() now properly closes the input file.
- **Issue #16900**: Issue a ResourceWarning when an ssl socket is left unclosed.
- **Issue #13899**: A, Z, and B now correctly match the A, Z, and B literals when used inside character classes (e.g. `[A]`). Patch by Matthew Barnett.
- **Issue #15545**: Fix regression in sqlite3’s iterdump method where it was failing if the connection used a row factory (such as sqlite3.Row) that produced unsortable objects. (Regression was introduced by fix for 9750).
- **Issue #15972**: Fix error messages when os functions expecting a file name or file descriptor receive the incorrect type.
- **Issue #16828**: Fix error incorrectly raised by bz2.compress(b'') and bz2.BZ2Compressor.compress(b''). Initial patch by Martin Packman.
- **Issue #16541**: tk_setPalette() now works with keyword arguments.
- **Issue #16820**: In configparser, parser.popitem() no longer raises ValueError. This makes parser.clean() work correctly.
- **Issue #16820**: In configparser, parser['section'] = {} now preserves section order within the parser. This makes parser.update() preserve section order as well.
- **Issue #16820**: In configparser, parser['DEFAULT'] = {} now correctly clears previous values stored in the default section. Same goes for parser.update({'DEFAULT': {}}).
- **Issue #9586**: Redefine SEM_FAILED on MacOSX to keep compiler happy.
- **Issue #10527**: make multiprocessing use poll() instead of select() if available.
- **Issue #16688**: Now regexes contained backreferences correctly work with non-ASCII strings. Patch by Matthew Barnett.
- **Issue #16485**: Now file descriptors are closed if file header patching failed on closing an aifc file.
- **Issue #16165**: sched.scheduler.run() no longer blocks a scheduler
for other threads.

- **Issue #16641**: Default values of sched.scheduler.enter() are no longer modifiable.
- **Issue #16618**: Makeglob.glob match consistently across strings and bytes regarding leading dots. Patch by Serhiy Storchaka.
- **Issue #16713**: Parsing of 'tel' urls using urlparse separates params from path.
- **Issue #16443**: Add docstrings to regular expression match objects. Patch by Anton Kasyanov.
- **Issue #15701**: Fix HTTPError info method call to return the headers information.
- **Issue #16752**: Add a missing import to modulefinder. Patch by Berker Peksag.
- **Issue #16646**: ftplib.FTP.makeport() might lose socket error details. (patch by Serhiy Storchaka)
- **Issue #16626**: Fix infinite recursion in glob.glob() on Windows when the pattern contains a wildcard in the drive or UNC path. Patch by Serhiy Storchaka.
- **Issue #15783**: Except for the number methods, the C version of decimal now supports all None default values present in decimal.py. These values were largely undocumented.
- **Issue #16298**: In HTTPResponse.read(), close the socket when there is no Content-Length and the incoming stream is finished. Patch by Eran Rundstein.
- **Issue #15872**: Fix 3.3 regression introduced by the new fd-based shutil.rmtree that caused it to not ignore certain errors when ignore_errors was set. Patch by Alessandro Moura and Serhiy Storchaka.
- **Issue #16248**: Disable code execution from the user’s home directory by tkinter when the -E flag is passed to Python. Patch by Zachary Ware.
- **Issue #16628**: Fix a memory leak in ctypes.resize().
- **Issue #13614**: Fix setup.py register failure with invalid rst in description. Patch by Julien Courteau and Pierre Paul Lefebvre.
• **Issue #13512**: Create ~/.pypirc securely (CVE-2011-4944). Initial patch by Philip Jenvey, tested by Mageia and Debian.

• **Issue #7719**: Make distutils ignore .nfs* files instead of choking later on. Initial patch by SilentGhost and Jeff Ramnani.

• **Issue #13120**: Allow to call pdb.set_trace() from thread. Patch by Ilya Sandler.

• **Issue #16585**: Make CJK encoders support error handlers that return bytes per PEP 383.

• **Issue #10182**: The re module doesn’t truncate indices to 32 bits anymore. Patch by Serhiy Storchaka.

• **Issue #16573**: In 2to3, treat enumerate() like a consuming call, so superfluous list() calls aren’t added to filter(), map(), and zip() which are directly passed enumerate().

• **Issue #12848**: The pure Python pickle implementation now treats object lengths as unsigned 32-bit integers, like the C implementation does. Patch by Serhiy Storchaka.

• **Issue #16408**: Fix file descriptors not being closed in error conditions in the zipfile module. Patch by Serhiy Storchaka.

• **Issue #16481**: multiprocessing no longer leaks process handles on Windows.

• **Issue #16140**: The subprocess module no longer double closes its child subprocess.PIPE parent file descriptors on child error prior to exec().

• Remove a bare print to stdout from the subprocess module that could have happened if the child process wrote garbage to its pre-exec error pipe.

• **Issue #16327**: The subprocess module no longer leaks file descriptors used for stdin/stdout/stderr pipes to the child when fork() fails.

• **Issue #14396**: Handle the odd rare case of waitpid returning 0 when not expected in subprocess.Popen.wait().

• **Issue #16411**: Fix a bug where zlib.decompressobj().flush() might try to access previously-freed memory. Patch by Serhiy Storchaka.
• **Issue #16357**: fix calling accept() on a SSLSocket created through SSLContext.wrap_socket(). Original patch by Jeff McNeil.

• **Issue #16409**: The reporthook callback made by the legacy urllib.request.urlretrieve API now properly supplies a constant non-zero block_size as it did in Python 3.2 and 2.7. This matches the behavior of urllib.request.URLopener.retrieve.

• **Issue #16431**: Use the type information when constructing a Decimal subtype from a Decimal argument.

• **Issue #16350**: zlib.decompressobj().decompress() now accumulates data from successive calls after EOF in unused_data, instead of only saving the argument to the last call. decompressobj().flush() now correctly sets unused_data and unconsumed_tail. A bug in the handling of MemoryError when setting the unconsumed_tail attribute has also been fixed. Patch by Serhiy Storchaka.

• **Issue #12759**: sre_parse now raises a proper error when the name of the group is missing. Initial patch by Serhiy Storchaka.

• **Issue #16152**: fix tokenize to ignore whitespace at the end of the code when no newline is found. Patch by Ned Batchelder.

• **Issue #16230**: Fix a crash in select.select() when one the lists changes size while iterated on. Patch by Serhiy Storchaka.

• **Issue #16228**: Fix a crash in the json module where a list changes size while it is being encoded. Patch by Serhiy Storchaka.

• **Issue #14897**: Enhance error messages of struct.pack and struct.pack_into. Patch by Matti Mäki.

• **Issue #12890**: cgitb no longer prints spurious <p> tags in text mode when the logdir option is specified.

• **Issue #16307**: Fix multiprocessing.Pool.map_async not calling its callbacks. Patch by Janne Karila.

• **Issue #16250**: Fix URLError invocation with proper args.

• **Issue #16116**: Fix include and library paths to be correct when building C extensions in venvs.

• **Issue #16245**: Fix the value of a few entities in html.entities.html5.

• **Issue #14398**: Fix size truncation and overflow bugs in the bz2
module.

- **Issue #16220**: wsgiref now always calls close() on an iterable response. Patch by Brent Tubbs.
- **Issue #16270**: urllib may hang when used for retrieving files via FTP by using a context manager. Patch by Giampaolo Rodola'.
- **Issue #16461**: Wave library should be able to deal with 4GB wav files, and sample rate of 44100 Hz.
- **Issue #16176**: Properly identify Windows 8 via platform.platform().
- **Issue #16114**: The subprocess module no longer provides a misleading error message stating that args[0] did not exist when either the cwd or executable keyword arguments specified a path that did not exist.
- **Issue #16169**: Fix ctypes.WinError()’s confusion between errno and winerror.
- **Issue #16076**: Made _elementtree.Element pickleable in a way that is compatible with the Python Element. Pickling/unpickling of xml.etree.ElementTree.Element works again - this was a temporary regression from 3.2 where the by-default imported _elementtree had no pickling capability.
- **Issue #16089**: Allow ElementTree.TreeBuilder to work again with a non-Element element_factory (fixes a regression in SimpleTAL).
- **Issue #16913**: Fix Element.itertext()’s handling of text with XML entities.
- **Issue #16034**: Fix performance regressions in the new bz2.BZ2File implementation. Initial patch by Serhiy Storchaka.
- **Issue #16112**: platform.architecture does not correctly escape argument to /usr/bin/file. Patch by David Benjamin.
- **Issue #15756**: subprocess.poll() now properly handles errno.ECHILD to return a returncode of 0 when the child has already exited or cannot be waited on.
- **Issue #15323**: Improve failure message of Mock.assert_called_once_with().
- **Issue #16064**: unittest -m claims executable is “python”, not “python3”.
• **Issue #12376:** Pass on parameters in `TextTestResult.__init__()` super call.

• **Issue #15222:** Insert blank line after each message in `mbox` mailboxes.

• **Issue #16013:** Fix `csv.Reader` parsing issue with ending quote characters. Patch by Serhiy Storchaka.

• **Issue #15421:** Fix an `OverflowError` in `Calendar.itermonthdates()` after `datetime.MAXYEAR`. Patch by Cédric Krier.

• **Issue #15970:** `xml.etree.ElementTree` now serializes correctly the empty HTML elements ‘meta’ and ‘param’.

• **Issue #15842:** The `SocketIO.{readable,writable,seekable}` methods now raise `ValueError` when the file-like object is closed. Patch by Alessandro Moura.

• **Issue #15876:** Fix a refleak in the `curses` module:`window.encoding`.

• **Issue #15881:** Fix `atexit` hook in `multiprocessing`. Original patch by Chris McDonough.

• **Issue #15841:** The `readable()`, `writable()` and `seekable()` methods of `io.BytesIO` and `io.StringIO` objects now raise `ValueError` when the object has been closed. Patch by Alessandro Moura.

• **Issue #15447:** Use `subprocess.DEVNULL` in `webbrowser`, instead of opening `os.devnull` explicitly and leaving it open.

• **Issue #15509:** `webbrowser.UnixBrowser` no longer passes empty arguments to `Popen` when `%action` substitutions produce empty strings.

• **Issue #12776, issue #11839:** Call `argparse` type function (specified by `add_argument`) only once. Before, the type function was called twice in the case where the default was specified and the argument was given as well. This was especially problematic for the `FileType` type, as a default file would always be opened, even if a file argument was specified on the command line.
- **Issue #15906**: Fix a regression in `argparse` caused by the preceding change, when `action='append', type='str'` and `default=[]`.

**IDLE**

- **Issue #17114**: IDLE now uses non-strict config parser.
- **Issue #9290**: In IDLE the `sys.std*` streams now implement `io.TextIOBase` interface and support all mandatory methods and properties.
- **Issue #16829**: IDLE printing no longer fails if there are spaces or other special characters in the file path.
- **Issue #16491**: IDLE now prints chained exception tracebacks.
- **Issue #16819**: IDLE method completion now correctly works for bytes literals.
- **Issue #16504**: IDLE now catches `SyntaxErrors` raised by tokenizer. Patch by Roger Serwy.
- **Issue #16511**: Use default IDLE width and height if config param is not valid. Patch Serhiy Storchaka.
- **Issue #1207589**: Add Cut/Copy/Paste items to IDLE right click Context Menu. Patch by Todd Rovito.

**Tests**

- **Issue #17448**: `test_sax` now skips if there are no xml parsers available instead of raising an `ImportError`.
- **Issue #11420**: make test suite pass with `-B/DONTWRITEBYTECODE` set. Initial patch by Thomas Wouters.
- **Issue #10652**: make `tcl/tk` tests run after `__all__` test, patch by Zachary Ware.
- **Issue #11963**: remove human verification from `test_parser` and `test_subprocess`.
- **Issue #11732**: add a new `suppress_crash_popup()` context
manager to test.support that disables crash popups on Windows and use it in test_faulthandler and test_capi.

- **Issue #13898**: test_ssl no longer prints a spurious stack trace on Ubuntu.
- **Issue #17249**: convert a test in test_capi to use unittest and reap threads.
- **Issue #17041**: Fix testing when Python is configured with the –without-doc-strings.
- **Issue #16923**: Fix ResourceWarnings in test_ssl.
- **Issue #15539**: Added regression tests for Tools/scripts/pindent.py.
- **Issue #17479**: test_io now works with unittest test discovery. Patch by Zachary Ware.
- **Issue #17066**: test_robotparser now works with unittest test discovery. Patch by Zachary Ware.
- **Issue #17334**: test_index now works with unittest test discovery. Patch by Zachary Ware.
- **Issue #17333**: test_imaplib now works with unittest test discovery. Patch by Zachary Ware.
- **Issue #17082**: test_dbm* now work with unittest test discovery. Patch by Zachary Ware.
- **Issue #17079**: test_ctypes now works with unittest test discovery. Patch by Zachary Ware.
- **Issue #17304**: test_hash now works with unittest test discovery. Patch by Zachary Ware.
- **Issue #17303**: test_future* now work with unittest test discovery. Patch by Zachary Ware.
- **Issue #17163**: test_file now works with unittest test discovery. Patch by Zachary Ware.
- **Issue #16925**: test_configparser now works with unittest test discovery. Patch by Zachary Ware.
- **Issue #16918**: test_codecs now works with unittest test discovery. Patch by Zachary Ware.
- **Issue #16919**: test_crypt now works with unittest test discovery. Patch by Zachary Ware.
- **Issue #16910**: test_bytes, test_unicode, and test_userstring now work with unittest test discovery. Patch by Zachary Ware.
- **Issue #16905**: test_warnings now works with unittest test discovery. Initial patch by Berker Peksag.
- **Issue #16898**: test_bufio now works with unittest test discovery. Patch by Zachary Ware.
- **Issue #16888**: test_array now works with unittest test discovery. Patch by Zachary Ware.
- **Issue #16896**: test_asyncore now works with unittest test discovery. Patch by Zachary Ware.
- **Issue #16897**: test_bisect now works with unittest test discovery. Initial patch by Zachary Ware.
- **Issue #16852**: test_genericpath, test_posixpath, test_ntpath, and test_macpath now work with unittest test discovery. Patch by Zachary Ware.
- **Issue #16748**: test_heapq now works with unittest test discovery.
- **Issue #15324**: Fix regrtest parsing of –fromfile, –match, and –randomize options.
- **Issue #16702**: test_urllib2_localnet tests now correctly ignores proxies for localhost tests.
- **Issue #16664**: Add regression tests for glob’s behaviour concerning entries starting with a ".". Patch by Sebastian Kreft.
- **Issue #16559**: Add more tests for the json module, including some from the official test suite at json.org. Patch by Serhiy Storchaka.
- **Issue #16661**: Fix the os.getgrouplist() test by not assuming that it gives the same output as id -G.
- **Issue #16115**: Add some tests for the executable argument to subprocess.Popen(). Initial patch by Kushal Das.
- **Issue #16126**: PyErr_Format format mismatch in _testcapimodule.c. Patch by Serhiy Storchaka.
- **Issue #15304**: Fix warning message when os.chdir() fails inside test.support.temp_cwd(). Patch by Chris Jerdonek.
- **Issue #15802**: Fix test logic in TestMaildir.test_create_tmp(). Patch by Serhiy
- **Issue #15557**: Add a test suite for the `webbrowser` module, thanks to Anton Barkovsky.
- **Issue #16698**: Skip posix test_getgroups when built with OS X deployment target prior to 10.6.

Build

- **Issue #17550**: Fix the `–enable-profiling` configure switch.
- **Issue #17425**: Build with openssl 1.0.1d on Windows.
- **Issue #16754**: Fix the incorrect shared library extension on linux. Introduce two makefile macros `SHLIB_SUFFIX` and `EXT_SUFFIX`. SO now has the value of `SHLIB_SUFFIX` again (as in 2.x and 3.1). The SO macro is removed in 3.4.
- **Issue #5033**: Fix building of the sqlite3 extension module when the SQLite library version has “beta” in it. Patch by Andreas Pelme.
- **Issue #17228**: Fix building without pymalloc.
- **Issue #3718**: Use `AC_ARG_VAR` to set `MACHDEP` in `configure.ac`.
- **Issue #17031**: Fix running regen in cross builds.
- **Issue #3754**: fix typo in pthread `AC_CACHE_VAL`.
- **Issue #15484**: Fix `_PYTHON_PROJECT_BASE` for srchdir != builddir builds; use `_PYTHON_PROJECT_BASE` in `distutils/sysconfig.py`.
- **Issue #17029**: Let h2py search the multiarch system include directory.
- **Issue #16953**: Fix socket module compilation on platforms with `HAVE_BROKEN_POLL`. Patch by Jeffrey Armstrong.
- **Issue #16836**: Enable IPv6 support even if IPv6 is disabled on the build host.
- Cross compiling needs host and build settings. configure no longer creates a broken `PYTHON_FOR_BUILD` variable when – build is missing.
• Fix cross compiling issue in setup.py, ensure that lib_dirs and inc_dirs are defined in cross compiling mode, too.

  **Issue #16593**: Have BSD ‘make -s’ do the right thing, thanks to Daniel Shahaf

  **Issue #16262**: fix out-of-src-tree builds, if mercurial is not installed.

  **Issue #15298**: ensure _sysconfigdata is generated in build directory, not source directory.

  **Issue #15833**: Fix a regression in 3.3 that resulted in exceptions being raised if importlib failed to write byte-compiled files. This affected attempts to build Python out-of-tree from a read-only source directory.

  **Issue #15923**: Fix a mistake in asdl_c.py that resulted in a TypeError after 2801bf875a24 (see #15801).

  **Issue #15819**: Make sure we can build Python out-of-tree from a read-only source directory. (Somewhat related to issue #9860.)

  **Issue #15587**: Enable Tk high-resolution text rendering on Macs with Retina displays. Applies to Tkinter apps, such as IDLE, on OS X framework builds linked with Cocoa Tk 8.5.

  **Issue #17161**: make install now also installs a python3 man page.

**C-API**

- **Issue #16881**: Fix Py_ARRAY_LENGTH macro for GCC < 3.1.

**Documentation**

- **Issue 17538**: Document XML vulnerabilities
- **Issue #16642**: sched.scheduler timefunc initial default is time.monotonic. Patch by Ramchandra Apte
- **Issue #17047**: remove doubled words in docs and docstrings reported by Serhiy Storchaka and Matthew Barnett.
- **Issue #15465**: Document the versioning macros in the C API docs
rather than the standard library docs. Patch by Kushal Das.

- **Issue #16406**: Combine the pages for uploading and registering to PyPI.
- **Issue #16403**: Document how distutils uses the maintainer field in PKG-INFO. Patch by Jyrki Pulliainen.
- **Issue #16695**: Document how glob handles filenames starting with a dot. Initial patch by Jyrki Pulliainen.
- **Issue #8890**: Stop advertising an insecure practice by replacing uses of the /tmp directory with better alternatives in the documentation. Patch by Geoff Wilson.
- **Issue #17203**: add long option names to unittest discovery docs.
- **Issue #13094**: add “Why do lambdas defined in a loop with different values all return the same result?” programming FAQ.
- **Issue #14901**: Update portions of the Windows FAQ. Patch by Ashish Nitin Patil.
- **Issue #16267**: Better document the 3.3+ approach to combining @abstractmethod with @staticmethod, @classmethod and @property
- **Issue #15209**: Clarify exception chaining description in exceptions module documentation
- **Issue #15990**: Improve argument/parameter documentation.
- **Issue #16209**: Move the documentation for the str built-in function to a new str class entry in the “Text Sequence Type” section.
- **Issue #13538**: Improve str() and object.__str__() documentation.
- **Issue #16489**: Make it clearer that importlib.find_loader() requires any and all packages to be separately imported.
- **Issue #16400**: Update the description of which versions of a given package PyPI displays.
- **Issue #15677**: Document that zlib and gzip accept a compression level of 0 to mean ‘no compression’. Patch by Brian Brazil.
- **Issue #16197**: Update winreg docstrings and documentation to match code. Patch by Zachary Ware.
- **Issue #8040**: added a version switcher to the documentation. Patch by Yury Selivanov.
- **Issue #16241**: Document -X faulthandler command line option. Patch by Marek Šuppa.
- Additional comments and some style changes in the concurrent.futures URL retrieval example
- **Issue #16115**: Improve subprocess.Popen() documentation around args, shell, and executable arguments.
- **Issue #15533**: Clarify docs and add tests for subprocess.Popen()'s cwd argument.
- **Issue #15979**: Improve timeit documentation.
- **Issue #16036**: Improve documentation of built-in int()’s signature and arguments.
- **Issue #15935**: Clarification of argparse docs, re: add_argument() type and default arguments. Patch contributed by Chris Jerdonek.
- **Issue #11964**: Document a change in v3.2 to the behavior of the indent parameter of json encoding operations.
- **Issue #15116**: Remove references to appscript as it is no longer being supported.

**Tools/Demos**

- **Issue #17156**: pygettext.py now uses an encoding of source file and correctly writes and escapes non-ascii characters.
- **Issue #15539**: Fix a number of bugs in Tools/scripts/pindent.py. Now pindent.py works with a “with” statement. pindent.py no longer produces improper indentation. pindent.py now works with continued lines broken after “class” or “def” keywords and with continuations at the start of line.
- **Issue #15378**: Fix Tools/unicode/comparecodecs.py. Patch by Serhiy Storchaka.
- **Issue #16476**: Fix json.tool to avoid including trailing whitespace.
- **Issue #16549**: Make json.tool work again on Python 3 and add tests. Initial patch by Berker Peksag and Serhiy Storchaka.
• **Issue #13301**: use ast.literal_eval() instead of eval() in Tools/i18n/msgfmt.py Patch by Serhiy Storchaka.
Python 3.3.0?

Release date: 29-Sep-2012

Core and Builtins

- **Issue #16046**: Fix loading sourceless legacy .pyo files.
- **Issue #16060**: Fix refcounting bug when `__trunc__()` returns an object whose `__int__()` gives a non-integer. Patch by Serhiy Storchaka.

Extension Modules

- **Issue #16012**: Fix a regression in pyexpat. The parser's `UseForeignDTD()` method doesn't require an argument again.
Python 3.3.0 Release Candidate 3?

Release date: 23-Sep-2012

Core and Builtins

- **Issue #15900**: Fix reference leak in PyUnicode_TranslateCharmap().
- **Issue #15926**: Fix crash after multiple reinitializations of the interpreter.
- **Issue #15895**: Fix FILE pointer leak in one error branch of PyRun_SimpleFileExFlags() when filename points to a pyc/pyo file, closeit is false an and set_main_loader() fails.
- **Issue #15895**: Fix for a few crash and memory leak regressions found by Coverity.

Library

- **Issue #15882**: Change _decimal to accept any coefficient tuple when constructing infinities. This is done for backwards compatibility with decimal.py: Infinity coefficients are undefined in _decimal (in accordance with the specification).
- **Issue #15925**: Fix a regression in email.util where the parsedate() and parsedate_tz() functions did not return None anymore when the argument could not be parsed.

Extension Modules

- **Issue #15973**: Fix a segmentation fault when comparing datetime timezone objects.
- **Issue #15977**: Fix memory leak in Modules/_ssl.c when the
function _set_npn_protocols() is called multiple times, thanks to Daniel Sommermann.

- **Issue #15969**: `faulthandler` module: rename `dump_tracebacks_later()` to `dump_traceback_later()` and `cancel_dump_tracebacks_later()` to `cancel_dump_traceback_later()`.
- `_decimal` module: use only C 89 style comments.
Python 3.3.0 Release Candidate 2?

*Release date: 09-Sep-2012*

Core and Builtins

- **Issue #13992**: The trashcan mechanism is now thread-safe. This eliminates sporadic crashes in multi-thread programs when several long deallocator chains ran concurrently and involved subclasses of built-in container types.
- **Issue #15784**: Modify `OSError.__str__()` to better distinguish between errno error numbers and Windows error numbers.
- **Issue #15781**: Fix two small race conditions in import's module locking.

Library

- **Issue #15847**: Fix a regression in argparse, which did not accept tuples as argument lists anymore.
- **Issue #15828**: Restore support for C extensions in `imp.load_module()`.
- **Issue #15340**: Fix importing the random module when `/dev/urandom` cannot be opened. This was a regression caused by the hash randomization patch.
- **Issue #10650**: Deprecate the watchexp parameter of the `Decimal.quantize()` method.
- **Issue #15785**: Modify `window.get_wch()` API of the curses module: return a character for most keys, and an integer for special keys, instead of always returning an integer. So it is now possible to distinguish special keys like keypad keys.
- **Issue #14223**: Fix `window.addch()` of the curses module for special characters like `curses.ACS_HLINE`: the Python function
addch(int) and addch(bytes) is now calling the C function waddch()/mvwaddch() (as it was done in Python 3.2), instead of wadd_wch()/mvwadd_wch(). The Python function addch(str) is still calling the C function wadd_wch()/mvwadd_wch() if the Python curses is linked to libncursesw.

Build

- **Issue #15822**: Really ensure 2to3 grammar pickles are properly installed (replaces fixes for Issue #15645).

Documentation

- **Issue #15814**: The memoryview enhancements in 3.3.0 accidentally permitted the hashing of multi-dimensional memoryviews and memoryviews with multi-byte item formats. The intended restrictions have now been documented - they will be correctly enforced in 3.3.1.
Python 3.3.0 Release Candidate 1?

_Release date: 25-Aug-2012_

Core and Builtins

- **Issue #15573**: memoryview comparisons are now performed by value with full support for any valid struct module format definition.
- **Issue #15316**: When an item in the fromlist for `__import__()` doesn't exist, don't raise an error, but if an exception is raised as part of an import do let that propagate.
- **Issue #15778**: Ensure that `str(ImportError(msg))` returns a str even when msg isn’t a str.
- **Issue #2051**: Source file permission bits are once again correctly copied to the cached bytecode file. (The migration to importlib reintroduced this problem because these was no regression test. A test has been added as part of this patch)
- **Issue #15761**: Fix crash when `PYTHONEXECUTABLE` is set on Mac OS X.
- **Issue #15726**: Fix incorrect bounds checking in `PyState_FindModule`. Patch by Robin Schreiber.
- **Issue #15604**: Update uses of `PyObject_IsTrue()` to check for and handle errors correctly. Patch by Serhiy Storchaka.
- **Issue #14846**: `importlib.FileFinder` now handles the case where the directory being searched is removed after a previous import attempt.

Library

- **Issue #13370**: Ensure that ctypes works on Mac OS X when Python is compiled using the clang compiler.
- **Issue #13072**: The array module’s ‘u’ format code is now
deprecated and will be removed in Python 4.0.

- **Issue #15544**: Fix Decimal.__float__ to work with payload-carrying NaNs.
- **Issue #15776**: Allow pyvenv to work in existing directory with --clean.
- **Issue #15249**: email's BytesGenerator now correctly mangles From lines (when requested) even if the body contains undecodable bytes.
- **Issue #15777**: Fix a refleak in _posixsubprocess.
- Issue ##665194: Update `email.utils.localtime` to use `datetime.astimezone` and correctly handle historic changes in UTC offsets.
- **Issue #15199**: Fix JavaScript's default MIME type to application/javascript. Patch by Bohuslav Kabrdla.
- **Issue #12643**: `code.InteractiveConsole` now respects `sys.excepthook` when displaying exceptions. Patch by Aaron Iles.
- **Issue #13579**: `string.Formatter` now understands the ‘a’ conversion specifier.
- **Issue #15595**: Fix `subprocess.Popen(universal_newlines=True)` for certain locales (utf-16 and utf-32 family). Patch by Chris Jerdonek.
- **Issue #15477**: In cmath and math modules, add workaround for platforms whose system-supplied log1p function doesn’t respect signs of zeros.
- **Issue #15715**: `importlib.__import__()` will silence an ImportError when the use of fromlist leads to a failed import.
- **Issue #14669**: Fix pickling of connections and sockets on Mac OS X by sending/receiving an acknowledgment after file descriptor transfer. TestPicklingConnection has been reenabled for Mac OS X.
- **Issue #11062**: Fix adding a message from file to Babyl mailbox.
- **Issue #15646**: Prevent equivalent of a fork bomb when using `multiprocessing` on Windows without the `if __name__ ==`
'__main__' idiom.

IDLE

- **Issue #15678**: Fix IDLE menus when started from OS X command line (3.3.0b2 regression).

Documentation

- Touched up the Python 2 to 3 porting guide.
- **Issue #14674**: Add a discussion of the `json` module's standard compliance. Patch by Chris Rebert.
- Create a ‘Concurrent Execution’ section in the docs, and split up the ‘Optional Operating System Services’ section to use a more user-centric classification scheme (splitting them across the new CE section, IPC and text processing). Operating system limitations can be reflected with the Sphinx :platform: tag, it doesn’t make sense as part of the Table of Contents.
- **Issue #4966**: Bring the sequence docs up to date for the Py3k transition and the many language enhancements since they were original written.
- The “path importer” misnomer has been replaced with Eric Snow’s more-awkward-but-at-least-not-wrong suggestion of “path based finder” in the import system reference docs.
- **Issue #15640**: Document `importlib.abc.Finder` as deprecated.
- **Issue #15630**: Add an example for “continue” stmt in the tutorial. Patch by Daniel Ellis.

Tests

- **Issue #15747**: ZFS always returns EOPNOTSUPP when
attempting to set the UF_IMMUTABLE flag (via either chflags or lchflags); refactor affected tests in test_posix.py to account for this.

- **Issue #15285**: Refactor the approach for testing connect timeouts using two external hosts that have been configured specifically for this type of test.
- **Issue #15743**: Remove the deprecated method usage in *urllib* tests. Patch by Jeff Knupp.
- **Issue #15615**: Add some tests for the *json* module's handling of invalid input data. Patch by Kushal Das.

### Build

- Output lib files for PGO build into PGO directory.
- Pick up 32-bit launcher from PGO directory on 64-bit PGO build.
- Drop *PC\python_nt.h* as it’s not used. Add input dependency on custom build step.
- **Issue #15511**: Drop explicit dependency on *pythonxy.lib* from *_decimal* amd64 configuration.
- Add missing PGI/PGO configurations for *pywlauncher*.
- **Issue #15645**: Ensure 2to3 grammar pickles are properly installed.
Core and Builtins

- **Issue #15568**: Fix the return value of `yield from` when `StopIteration` is raised by a custom iterator.
- **Issue #13119**: `sys.stdout` and `sys.stderr` are now using “rn” newline on Windows, as Python 2.
- **Issue #15534**: Fix the fast-search function for non-ASCII Unicode strings.
- **Issue #15508**: Fix the docstring for `__import__()` to have the proper default value of 0 for ‘level’ and to not mention negative levels since they are not supported.
- **Issue #15425**: Eliminated traceback noise from more situations involving `importlib`.
- **Issue #14578**: Support modules registered in the Windows registry again.
- **Issue #15466**: Stop using `TYPE_INT64` in `marshal`, to make `importlib.h` (and other byte code files) equal between 32-bit and 64-bit systems.
- **Issue #1692335**: Move initial exception args assignment to `BaseException.__new__()` to help pickling of naive subclasses.
- **Issue #12834**: Fix `PyBuffer_ToContiguous()` for non-contiguous arrays.
- **Issue #15456**: Fix code `__sizeof__()` after #12399 change. Patch by Serhiy Storchaka.
- **Issue #15404**: Refleak in `PyMethodObject` repr.
- **Issue #15394**: An issue in `PyModule_Create()` that caused references to be leaked on some error paths has been fixed.
Patch by Julia Lawall.

- **Issue #15368**: An issue that caused bytecode generation to be non-deterministic has been fixed.
- **Issue #15202**: Consistently use the name “follow_symlinks” for new parameters in os and shutil functions.
- **Issue #15314**: `__main__.__loader__` is now set correctly during interpreter startup.
- **Issue #15111**: When a module imported using ‘from import’ has an ImportError inside itself, don’t mask that fact behind a generic ImportError for the module itself.
- **Issue #15293**: Add GC support to the AST base node type.
- **Issue #15291**: Fix a memory leak where AST nodes where not properly deallocated.
- **Issue #15110**: Fix the tracebacks generated by “import xxx” to not show the importlib stack frames.
- **Issue #16369**: Global PyTypeObjects not initialized with PyType_Ready(…).
- **Issue #15020**: The program name used to search for Python’s path is now “python3” under Unix, not “python”.
- **Issue #15897**: zipimport.c doesn’t check return value of fseek(). Patch by Felipe Cruz.
- **Issue #15033**: Fix the exit status bug when modules invoked using -m switch, return the proper failure return value (1). Patch contributed by Jeff Knupp.
- **Issue #15229**: An OSError subclass whose __init__ doesn’t call back OSError.__init__ could produce incomplete instances, leading to crashes when calling str() on them.

**Library**

- **Issue #14590**: configparser now correctly strips inline comments when delimiter occurs earlier without preceding space.
• **Issue #15424:** Add a `__sizeof__()` implementation for array objects. Patch by Ludwig Hähne.

• **Issue #15576:** Allow extension modules to act as a package's `__init__` module.

• **Issue #15502:** Have `importlib.invalidate_caches()` work on `sys.meta_path` instead of `sys.path_importer_cache`.

• **Issue #15163:** Pydoc shouldn't list `__loader__` as module data.

• **Issue #15471:** Do not use mutable objects as defaults for `importlib.__import__()`.  

• **Issue #15559:** To avoid a problematic failure mode when passed to the bytes constructor, objects in the ipaddress module no longer implement `__index__() (they still implement `__int__() as appropriate).` 

• **Issue #15546:** Fix handling of pathological input data in the `peek()` and `read1()` methods of the BZ2File, GzipFile and LZMAFile classes.

• **Issue #12655:** Instead of requiring a custom type, `os.sched_getaffinity()` and `os.sched_setaffinity()` now use regular sets of integers to represent the CPUs a process is restricted to.

• **Issue #15538:** Fix compilation of the `socket.getnameinfo()` / `socket.getaddrinfo()` emulation code. Patch by Philipp Hagemeister.

• **Issue #15519:** Properly expose WindowsRegistryFinder in importlib (and use the correct term for it). Original patch by Eric Snow.

• **Issue #15502:** Bring the importlib ABCs into line with the current state of the import protocols given PEP 420. Original patch by Eric Snow.

• **Issue #15499:** Launching a webbrowser in Unix used to sleep for a few seconds. Original patch by Anton Barkovsky.

• **Issue #15463:** The faulthandler module truncates strings to 500 characters, instead of 100, to be able to display long file paths.
• **Issue #6056**: Make `multiprocessing` use `setblocking(True)` on the sockets it uses. Original patch by J Derek Wilson.

• **Issue #15364**: Fix `sysconfig.get_config_var('srcdir')` to be an absolute path.

• **Issue #15413**: `os.times()` had disappeared under Windows.

• **Issue #15402**: An issue in the `struct` module that caused `sys.getsizeof()` to return incorrect results for `struct.Struct` instances has been fixed. Initial patch by Serhiy Storchaka.

• **Issue #15232**: When `mangle_from` is True, `email.Generator` now correctly mangles lines that start with ‘From ‘ that occur in a MIME preamble or epilogue.

• **Issue #15094**: Incorrectly placed `#endif` in `_tkinter.c`. Patch by Serhiy Storchaka.

• **Issue #13922**: `argparse` no longer incorrectly strips ‘–’s that appear after the first one.

• **Issue #12353**: `argparse` now correctly handles null argument values.

• **Issue #10017, issue #14998**: Fix TypeError using `pprint` on dictionaries with user-defined types as keys or other unorderable keys.

• **Issue #15397**: `inspect.getmodulename()` is now based directly on `importlib` via a new `importlib.machinery.all_suffixes()` API.

• **Issue #14635**: `telnetlib` will use `poll()` rather than `select()` when possible to avoid failing due to the `select()` file descriptor limit.

• **Issue #15180**: Clarify `posixpath.join()` error message when mixing str & bytes.

• **Issue #15343**: `pkgutil` now includes an `iter_importer_modules` implementation for `importlib.machinery.FileFinder` (similar to the way it already handled `zipimport.zipimporter`).

• **Issue #15314**: `runpy` now sets `__main__.loader___` correctly.

• **Issue #15357**: The import emulation in `pkgutil` is now deprecated.
pkgutil uses importlib internally rather than the emulation.

- **Issue #15233**: Python now guarantees that callables registered with the atexit module will be called in a deterministic order.
- **Issue #15238**: shutil.copystat() now copies Linux “extended attributes”.
- **Issue #15230**: runpy.run_path now correctly sets __package__ as described in the documentation.
- **Issue #15315**: Support VS 2010 in distutils cygwincompiler.
- **Issue #15294**: Fix a regression in pkgutil.extend_path()'s handling of nested namespace packages.
- **Issue #15056**: imp.cache_from_source() and imp.source_from_cache() raise NotImplementedError when sys.implementation.cache_tag is set to None.
- **Issue #15256**: Grammatical mistake in exception raised by imp.find_module().
- **Issue #5931**: wsgiref environ variable SERVER_SOFTWARE will specify an implementation specific term like CPython, Jython instead of generic “Python”.
- **Issue #13248**: Remove obsolete argument “max_buffer_size” of BufferedWriter and BufferedRWPair, from the io module.
- **Issue #13248**: Remove obsolete argument “version” of argparse.ArgumentParser.
- **Issue #14814**: Implement more consistent ordering and sorting behaviour for ipaddress objects.
- **Issue #14814**: ipaddress network objects correctly return NotImplemented when compared to arbitrary objects instead of raising TypeError.
- **Issue #14990**: Correctly fail with SyntaxError on invalid encoding declaration.
- **Issue #14814**: ipaddress now provides more informative error messages when constructing instances directly (changes permitted during beta due to provisional API status).
- **Issue #15247**: io.FileIO now raises an error when given a file
descriptor pointing to a directory.

- **Issue #15261**: Stop os.stat(fd) crashing on Windows when fd not open.
- **Issue #15166**: Implement `imp.get_tag()` using `sys.implementation.cache_tag`.
- **Issue #15210**: Catch KeyError when `importlib.__init__()` can’t find `_frozen_importlib` in `sys.modules`, not `ImportError`.
- **Issue #15030**: `importlib.abc.PyPycLoader` now supports the new source size header field in `.pyc` files.
- **Issue #15030**: Preserve permissions of mbox, MMDF and Babyl mailbox files on flush().
- **Issue #10571**: Fix the “–sign” option of distutils’ upload command. Patch by Jakub Wilk.
- **Issue #9559**: If messages were only added, a new file is no longer created and renamed over the old file when flush() is called on an mbox, MMDF or Babyl mailbox.
- **Issue #10924**: Fixed `crypt.mksalt()` to use a RNG that is suitable for cryptographic purpose.
- **Issue #15184**: Ensure consistent results of OS X configuration tailoring for universal builds by factoring out common OS X-specific customizations from `sysconfig`, `distutils.sysconfig`, `distutils.util`, and `distutils_unixccompiler` into a new module `_osx_support`.

**C API**

- **Issue #15610**: `PyImport_ImportModuleEx()` now uses a ‘level’ of 0 instead of -1.
- **Issue #15169, issue #14599**: Strip out the C implementation of `imp.source_from_cache()` used by `PyImport_ExecCodeModuleWithPathnames()` and used the Python code instead. Leads to `PyImport_ExecCodeModuleObject()` to not try to infer the source
path from the bytecode path as PyImport_ExecCodeModuleWithPathnames() does.

Extension Modules

- **Issue #6493**: An issue in ctypes on Windows that caused structure bitfields of type *ctypes.c_uint32* and width 32 to incorrectly be set has been fixed.
- **Issue #15194**: Update libffi to the 3.0.11 release.

IDLE

- **Issue #13052**: Fix IDLE crashing when replace string in Search/Replace dialog ended with `.` Patch by Roger Serwy.

Tools/Demos

- **Issue #15458**: python-config gets a new option –configdir to print the $LIBPL value.
- Move importlib.test.benchmark to Tools/importbench.
- **Issue #12605**: The gdb hooks for debugging CPython (within Tools/gdb) have been enhanced to show information on more C frames relevant to CPython within the “py-bt” and “py-bt-full” commands:
  - C frames that are waiting on the GIL
  - C frames that are garbage-collecting
  - C frames that are due to the invocation of a PyCFunction

Documentation

- **Issue #15041**: Update “see also” list in tkinter documentation.
- **Issue #15444**: Use proper spelling for non-ASCII contributor
names. Patch by Serhiy Storchaka.

- **Issue #15295**: Reorganize and rewrite the documentation on the import system.
- **Issue #15230**: Clearly document some of the limitations of the runpy module and nudge readers towards importlib when appropriate.
- **Issue #15053**: Copy Python 3.3 import lock change notice to all relevant functions in imp instead of just at the top of the relevant section.
- **Issue #15288**: Link to the term “loader” in notes in pkgutil about how things won’t work as expected in Python 3.3 and mark the requisite functions as “changed” since they will no longer work with modules directly imported by import itself.
- **Issue #13557**: Clarify effect of giving two different namespaces to `exec()` or `execfile()`.
- **Issue #15250**: Document that `filecmp.dircmp()` compares files shallowly. Patch contributed by Chris Jerdonek.

### Tests

- **Issue #15467**: Move helpers for `__sizeof__()` tests into `test_support`. Patch by Serhiy Storchaka.
- **Issue #15320**: Make iterating the list of tests thread-safe when running tests in multiprocess mode. Patch by Chris Jerdonek.
- **Issue #15168**: Move `importlib.test` to `test.test_importlib`.
- **Issue #15091**: Reactivate a test on UNIX which was failing thanks to a forgotten `importlib.invalidate_caches()` call.
- **Issue #15230**: Adopted a more systematic approach in the runpy tests.
- **Issue #15300**: Ensure the temporary test working directories are in the same parent folder when running tests in multiprocess mode from a Python build. Patch by Chris Jerdonek.
• **Issue #15284**: Skip `{send,recv}msg` tests in `test_socket` when IPv6 is not enabled. Patch by Brian Brazil.

• **Issue #15277**: Fix a resource leak in `support.py` when IPv6 is disabled. Patch by Brian Brazil.

## Build

• **Issue #11715**: Fix multiarch detection without having Debian development tools (dpkg-dev) installed.

• **Issue #15037**: Build OS X installers with local copy of ncurses 5.9 libraries to avoid curses.unget_wch bug present in older versions of ncurses such as those shipped with OS X.

• **Issue #15560**: Fix building `_sqlite3` extension on OS X with an SDK. Also, for OS X installers, ensure consistent sqlite3 behavior and feature availability by building a local copy of libsqlite3 rather than depending on the wide range of versions supplied with various OS X releases.

• **Issue #8847**: Disable COMDAT folding in Windows PGO builds.

• **Issue #14018**: Fix OS X Tcl/Tk framework checking when using OS X SDKs.

• **Issue #16256**: OS X installer now sets correct permissions for doc directory.

• **Issue #15431**: Add `_freeze_importlib` project to regenerate `importlib.h` on Windows. Patch by Kristján Valur Jónsson.

• **Issue #14197**: For OS X framework builds, ensure links to the shared library are created with the proper ABI suffix.

• **Issue #14330**: For cross builds, don’t use host python, use host search paths for host compiler.

• **Issue #15235**: Allow Berkley DB versions up to 5.3 to build the dbm module.

• **Issue #15268**: Search `curses.h` in `/usr/include/ncursesw`. 
Python 3.3.0 Beta 1?

Release date: 27-Jun-2012

Core and Builtins

- Fix a (most likely) very rare memory leak when calling main() and not being able to decode a command-line argument.
- **Issue #14815**: Use Py_ssize_t instead of long for the object hash, to preserve all 64 bits of hash on Win64.
- **Issue #12268**: File readline, readlines and read() or readall() methods no longer lose data when an underlying read system call is interrupted. IOError is no longer raised due to a read system call returning EINTR from within these methods.
- **Issue #11626**: Add _SizeT functions to stable ABI.
- **Issue #15142**: Fix reference leak when deallocating instances of types created using PyType_FromSpec().
- **Issue #10053**: Don’t close FDs when FileIO.__init__ fails. Loosely based on the work by Hirokazu Yamamoto.
- **Issue #15096**: Removed support for ur” as the raw notation isn’t compatible with Python 2.x’s raw unicode strings.
- **Issue #13783**: Generator objects now use the identifier APIs internally.
- **Issue #14874**: Restore charmap decoding speed to pre-PEP 393 levels. Patch by Serhiy Storchaka.
- **Issue #15026**: utf-16 encoding is now significantly faster (up to 10x). Patch by Serhiy Storchaka.
- **Issue #11022**: `open()` and `io.TextIOWrapper` are now calling `locale.getpreferredencoding(False)` instead of `locale.getpreferredencoding()` in text mode if the encoding is not specified. Don’t change temporary the locale encoding using `locale.setlocale()`, use the current locale encoding instead of the user preferred encoding.
• **Issue #14673**: Add Eric Snow’s `sys.implementation` implementation.
• **Issue #15038**: Optimize python Locks on Windows.

## Library

• **Issue #16305**: Fix a segmentation fault occurring when interrupting `math.factorial`.
• **Issue #12288**: Consider ‘0’ and ‘0.0’ as valid initial value for tkinter `SimpleDialog`.
• **Issue #15512**: Add a `__sizeof__` implementation for `parser`. Patch by Serhiy Storchaka.
• **Issue #15469**: Add a `__sizeof__` implementation for `deque` objects. Patch by Serhiy Storchaka.
• **Issue #15489**: Add a `__sizeof__` implementation for `BytesIO` objects. Patch by Serhiy Storchaka.
• **Issue #15487**: Add a `__sizeof__` implementation for buffered I/O objects. Patch by Serhiy Storchaka.
• **Issue #15514**: Correct `__sizeof__` support for `cpu_set`. Patch by Serhiy Storchaka.
• **Issue #15177**: Added `dir_fd` parameter to `os.fwalk()`.
• **Issue #15061**: Re-implemented `hmac.compare_digest()` in C to prevent further timing analysis and to support all buffer protocol aware objects as well as ASCII only str instances safely.
• **Issue #15164**: Change return value of `platform.uname()` from a plain tuple to a `collections.namedtuple`.
• Support Mageia Linux in the `platform` module.
• **Issue #11678**: Support Arch Linux in the `platform` module.
• **Issue #15118**: Change return value of `os.uname()` and `os.times()` from plain tuples to immutable iterable objects with named attributes (structseq objects).
• Speed up `_decimal` by another 10-15% by caching the thread local context that was last accessed. In the pi benchmark (64-bit platform, prec=9), `_decimal` is now only 1.5x slower than `float`. 
• Remove the packaging module, which is not ready for prime time.

**Issue #15154**: Add “dir_fd” parameter to os.rmdir, remove “rmdir” parameter from os.remove / os.unlink.

**Issue #4489**: Add a shutil.rmtree that isn’t susceptible to symlink attacks. It is used automatically on platforms supporting the necessary os.openat() and os.unlinkat() functions. Main code by Martin von Löwis.

**Issue #15156**: HTMLParser now uses the new “html.entities.html5” dictionary.

**Issue #11113**: add a new “html5” dictionary containing the named character references defined by the HTML5 standard and the equivalent Unicode character(s) to the html.entities module.

**Issue #15114**: the strict mode of HTMLParser and the HTMLParseError exception are deprecated now that the parser is able to parse invalid markup.

**Issue #3665**: u and U escapes are now supported in unicode regular expressions. Patch by Serhiy Storchaka.

**Issue #15153**: Added inspect.getgeneratorlocals to simplify white box testing of generator state updates

**Issue #13062**: Added inspect.getclosurevars to simplify testing stateful closures

**Issue #11024**: Fixes and additional tests for Time2Internaldate.

**Issue #14626**: Large refactoring of functions / parameters in the os module. Many functions now support “dir_fd” and “follow_symlinks” parameters; some also support accepting an open file descriptor in place of a path string. Added os.support_* collections as LBYL helpers. Removed many functions only previously seen in 3.3 alpha releases (often starting with “f” or “l”, or ending with “at”). Originally suggested by Serhiy Storchaka; implemented by Larry Hastings.

**Issue #15008**: Implement PEP 362 “Signature Objects”. Patch by Yury Selivanov.

**Issue**: #15138: base64.urlsafe_{en,de}code() are now 3-4x faster.

**Issue #444582**: Add shutil.which, for finding programs on the
system path. Original patch by Erik Demaine, with later iterations by Jan Killian and Brian Curtin.

- **Issue #14837**: SSL errors now have `library` and `reason` attributes describing precisely what happened and in which OpenSSL submodule. The `str()` of a SSLError is also enhanced accordingly.

- **Issue #9527**: `datetime.astimezone()` method will now supply a class timezone instance corresponding to the system local timezone when called with no arguments.

- **Issue #14653**: `email.utils.mktime_tz()` no longer relies on system `mktime()` when timezone offset is supplied.

- **Issue #14684**: `zlib.compressobj()` and `zlib.decompressobj()` now support the use of predefined compression dictionaries. Original patch by Sam Rushing.

- Fix `GzipFile`'s handling of filenames given as bytes objects.

- **Issue #14772**: Return destination values from some `shutil` functions.

- **Issue #15064**: Implement context manager protocol for multiprocessing types

- **Issue #15101**: Make pool finalizer avoid joining current thread.

- **Issue #14657**: The frozen instance of `importlib` used for bootstrap is now also the module imported as `importlib._bootstrap`.

- **Issue #14055**: Add `__sizeof__` support to `_elementtree`.

- **Issue #15054**: A bug in `tokenize.tokenize` that caused string literals with ‘b’ prefixes to be incorrectly tokenized has been fixed. Patch by Serhiy Storchaka.

- **Issue #15006**: Allow equality comparison between naive and aware time or datetime objects.

- **Issue #15036**: Mailbox no longer throws an error if a flush is done between operations when removing or changing multiple items in mbox, MMDF, or Babyl mailboxes.

- **Issue #14059**: Implement multiprocessing.Barrier.

- **Issue #15061**: The inappropriately named `hmac.secure_compare` has been renamed to `hmac.compare_digest`, restricted to
operating on bytes inputs only and had its documentation updated to more accurately reflect both its intent and its limitations.

- **Issue #13841**: Make child processes exit using `sys.exit()` on Windows.
- **Issue #14936**: `curses_panel` was converted to PEP 3121 and PEP 384 API. Patch by Robin Schreiber.
- **Issue #1667546**: On platforms supporting `tm_zone` and `tm_gmtoff` fields in `struct tm`, `time.struct_time` objects returned by `time.gmtime()`, `time.localtime()` and `time.strptime()` functions now have `tm_zone` and `tm_gmtoff` attributes. Original patch by Paul Boddie.
- Rename adjusted attribute to `adjustable` in `time.get_clock_info()` result.
- **Issue #3518**: Remove references to non-existent `BaseManager.from_address()` method.
- **Issue #13857**: Added `textwrap.indent()` function (initial patch by Ezra Berch)
- **Issue #2736**: Added `datetime.timestamp()` method.
- **Issue #13854**: Make multiprocessing properly handle non-integer non-string argument to `SystemExit`.
- **Issue #12157**: Make `pool.map()` empty iterables correctly. Initial patch by mouad.
- **Issue #11823**: disassembly now shows argument counts on calls with keyword args.
- **Issue #14711**: `os.stat_float_times()` has been deprecated.
- LZMAFile now accepts the modes “rb”/”wb”/”ab” as synonyms of “r”/”w”/”a”.
- The bz2 and lzma modules now each contain an `open()` function, allowing compressed files to readily be opened in text mode as well as binary mode.
- `BZ2File.__init__()` and `LZMAFile.__init__()` now accept a file object as their first argument, rather than requiring a separate “fileobj” argument.
- `gzip.open()` now accepts file objects as well as filenames.
- **Issue #14992**: `os.makedirs(path, exist_ok=True)` would raise an OSError when the path existed and had the S_ISGID mode bit set when it was not explicitly asked for. This is no longer an exception as mkdir cannot control if the OS sets that bit for it or not.
- **Issue #14989**: Make the CGI enable option to http.server available via command line.
- **Issue #14987**: Add a missing import statement to inspect.
- **Issue #1079**: `email.header.decode_header` now correctly parses all the examples in RFC2047. There is a necessary visible behavior change: the leading and/or trailing whitespace on ASCII parts is now preserved.
- **Issue #14969**: Better handling of exception chaining in `contextlib.ExitStack`
- **Issue #14963**: Convert `contextlib.ExitStack.__exit__` to use an iterative algorithm (Patch by Alon Horev)
- **Issue #14785**: Add `sys._debugmallocstats()` to help debug low-level memory allocation issues
- **Issue #14443**: Ensure that .py files are byte-compiled with the correct Python executable within `bdist_rpm` even on older versions of RPM

**C-API**

- **Issue #15146**: Add `PyType_FromSpecWithBases`. Patch by Robin Schreiber.
- **Issue #15042**: Add `PyState_AddModule` and `PyState_RemoveModule`. Add version guard for `Py_LIMITED_API` additions. Patch by Robin Schreiber.
- **Issue #13783**: Inadvertent additions to the public C API in the PEP 380 implementation have either been removed or marked as private interfaces.

**Extension Modules**
- **Issue #15000**: Support the “unique” x32 architecture in _posixsubprocess.c.

**IDLE**

- **Issue #9803**: Don’t close IDLE on saving if breakpoint is open. Patch by Roger Serwy.
- **Issue #14962**: Update text coloring in IDLE shell window after changing options. Patch by Roger Serwy.

**Documentation**

- **Issue #15176**: Clarified behavior, documentation, and implementation of os.listdir().
- **Issue #14982**: Document that pkgutil's iteration functions require the non-standard iter_modules() method to be defined by an importer (something the importlib importers do not define).
- **Issue #14814**: Added first draft of ipaddress module API reference

**Tests**

- **Issue #15187**: Bugfix: remove temporary directories test_shutil was leaving behind.
- **Issue #14769**: test_capi now has SkipitemTest, which cleverly checks for “parity” between PyArg_ParseTuple() and the Python/getargs.c static function skipitem() for all possible “format units”.
- test_nntplib now tolerates being run from behind NNTP gateways that add “X-Antivirus” headers to articles
- **Issue #15043**: test_gdb is now skipped entirely if gdb security settings block loading of the gdb hooks
• **Issue #14963**: Add test cases for exception handling behaviour in `contextlib.ExitStack` (Initial patch by Alon Horev)

**Build**

• **Issue #13590**: Improve support for OS X Xcode 4:
  ○ Try to avoid building Python or extension modules with problematic llvm-gcc compiler.
  ○ Since Xcode 4 removes ppc support, extension module builds now check for ppc compiler support and automatically remove ppc and ppc64 archs when not available.
  ○ Since Xcode 4 no longer install SDKs in default locations, extension module builds now revert to using installed headers and libs if the SDK used to build the interpreter is not available.
  ○ Update `./configure` to use better defaults for universal builds; in particular, `–enable-universalsdk=yes` uses the Xcode default SDK and `–with-universal-archs` now defaults to “intel” if ppc not available.

• **Issue #14225**: Fix Unicode support for curses (#12567) on OS X

• **Issue #14928**: Fix importlib bootstrap issues by using a custom executable (Modules/_freeze_importlib) to build Python/importlib.h.
Python 3.3.0 Alpha 4?

*Release date: 31-May-2012*

Core and Builtins

- **Issue #14835**: Make plistlib output empty arrays & dicts like OS X. Patch by Sidney San Martín.
- **Issue #14744**: Use the new _PyUnicodeWriter internal API to speed up str%args and str.format(args).
- **Issue #14930**: Make memoryview objects weakrefable.
- **Issue #14775**: Fix a potential quadratic dict build-up due to the garbage collector repeatedly trying to untrack dicts.
- **Issue #14857**: fix regression in references to PEP 3135 implicit __class__ closure variable (Reopens issue #12370)
- **Issue #14712** (PEP 405): Virtual environments. Implemented by Vinay Sajip.
- **Issue #14660** (PEP 420): Namespace packages. Implemented by Eric Smith.
- **Issue #14494**: Fix __future__.py and its documentation to note that absolute imports are the default behavior in 3.0 instead of 2.7. Patch by Sven Marnach.
- **Issue #9260**: A finer-grained import lock. Most of the import sequence now uses per-module locks rather than the global import lock, eliminating well-known issues with threads and imports.
- **Issue #14624**: UTF-16 decoding is now 3x to 4x faster on various inputs. Patch by Serhiy Storchaka.
- asdl_seq and asdl_int_seq are now Py_ssize_t sized.
- **Issue #14133** (PEP 415): Implement suppression of __context__ display with an attribute on BaseException. This replaces the original mechanism of PEP 409.
- **Issue #14417**: Mutating a dict during lookup now restarts the
lookup instead of raising a RuntimeError (undoes issue #14205).

- **Issue #14738**: Speed-up UTF-8 decoding on non-ASCII data. Patch by Serhiy Storchaka.
- **Issue #14700**: Fix two broken and undefined-behaviour-inducing overflow checks in old-style string formatting.

### Library

- **Issue #14690**: Use monotonic clock instead of system clock in the sched, subprocess and trace modules.
- **Issue #14443**: Tell rpmbuild to use the correct version of Python in bdist_rpm. Initial patch by Ross Lagerwall.
- **Issue #12515**: email now registers a defect if it gets to EOF while parsing a MIME part without seeing the closing MIME boundary.
- **Issue #1672568**: email now always decodes base64 payloads, adding padding and ignoring non-base64-alphabet characters if needed, and registering defects for any such problems.
- **Issue #14925**: email now registers a defect when the parser decides that there is a missing header/body separator line. MalformedHeaderDefect, which the existing code would never actually generate, is deprecated.
- **Issue #10365**: File open dialog now works instead of crashing even when the parent window is closed before the dialog. Patch by Roger Serwy.
- **Issue #8739**: Updated smtpd to support RFC 5321, and added support for the RFC 1870 SIZE extension.
- **Issue #665194**: Added a localtime function to email.utils to provide an aware local datetime for use in setting Date headers.
- **Issue #12586**: Added new provisional policies that implement convenient unicode support for email headers. See What’s New for details.
- **Issue #14731**: Refactored email Policy framework to support full backward compatibility with Python 3.2 by default yet allow for the introduction of new features through new policies. Note that
Policy.must_be_7bit is renamed to cte_type.

- **Issue #14876**: Use user-selected font for highlight configuration.
- **Issue #14920**: Fix the help(urslib.parse) failure on locale C on terminals. Have ascii characters in help.
- **Issue #14548**: Make multiprocessing finalizers check pid before running to cope with possibility of gc running just after fork.
- **Issue #14036**: Add an additional check to validate that port in urlparse does not go in illegal range and returns None.
- **Issue #14862**: Add missing names to os.__all__
- **Issue #14875**: Use float('inf') instead of float('1e66666') in the json module.
- **Issue #13585**: Added contextlib.ExitStack
- **PEP 3144, Issue #14814**: Added the ipaddress module
- **Issue #14426**: Correct the Date format in Expires attribute of Set-Cookie Header in Cookie.py.
- **Issue #14588**: The types module now provide new_class() and prepare_class() functions to support PEP 3115 compliant dynamic class creation. Patch by Daniel Urban and Nick Coghlan.
- **Issue #13152**: Allow to specify a custom tabsize for expanding tabs in textwrap. Patch by John Feuerstein.
- **Issue #14721**: Send the correct ‘Content-length: 0′ header when the body is an empty string ‘’. Initial Patch contributed by Arve Knudsen.
- **Issue #14072**: Fix parsing of ‘tel’ URIs in urlparse by making the check for ports stricter.
- **Issue #9374**: Generic parsing of query and fragment portions of url for any scheme. Supported both by RFC3986 and RFC2396.
- **Issue #14798**: Fix the functions in pyclbr to raise an ImportError when the first part of a dotted name is not a package. Patch by Xavier de Gaye.
- **Issue #12098**: multiprocessing on Windows now starts child processes using the same sys.flags as the current process. Initial patch by Sergey Mezentsev.
- **Issue #13031**: Small speed-up for tarfile when unzipping tarfiles.
Patch by Justin Peel.

- **Issue #14780**: `urllib.request.urlopen()` now has a `cadefault` argument to use the default certificate store. Initial patch by James Oakley.

- **Issue #14829**: Fix bisect and range() indexing with large indices (>= 2 ** 32) under 64-bit Windows.

- **Issue #14732**: The `_csv` module now uses PEP 3121 module initialization. Patch by Robin Schreiber.

- **Issue #14809**: Add HTTP status codes introduced by RFC 6585 to http.server and http.client. Patch by EungJun Yi.

- **Issue #14777**: `tkinter` may return undecoded UTF-8 bytes as a string when accessing the Tk clipboard. Modify clipboard_get() to first request type UTF8_STRING when no specific type is requested in an X11 windowing environment, falling back to the current default type STRING if that fails. Original patch by Thomas Kluyver.

- **Issue #14773**: Fix os.fwalk() failing on dangling symlinks.

- **Issue #12541**: Be lenient with quotes around Realm field of HTTP Basic Authorization in urllib2.

- **Issue #14807**: move undocumented `tarfile.filemode()` to `stat.filemode()` and add doc entry. Add `tarfile.filemode` alias with deprecation warning.

- **Issue #13815**: `TarFile.extractfile()` now returns `io.BufferedReader` objects.

- **Issue #14532**: Add a `secure_compare()` helper to the `hmac` module, to mitigate timing attacks. Patch by Jon Oberheide.

- Add `importlib.util.resolve_name()`.

- **Issue #14366**: Support lzma compression in zip files. Patch by Serhiy Storchaka.

- **Issue #13959**: Introduce `importlib.find_loader()` and document `imp.find_module/load_module` as deprecated.

- **Issue #14082**: `shutil.copy2()` now copies extended attributes, if possible. Patch by Hynek Schlawack.

- **Issue #13959**: Make
importlib.abc.FileLoader.load_module()/get_filename() and importlib.machinery.ExtensionFileLoader.load_module() have their single argument be optional. Allows for the replacement (and thus deprecation) of imp.load_source()/load_package()/load_compiled().

- **Issue #13959**: imp.get_suffixes() has been deprecated in favour of the new attributes on importlib.machinery: SOURCE_SUFFIXES, DEBUG_BYTECODE_SUFFIXES, OPTIMIZED_BYTECODE_SUFFIXES, BYTECODE_SUFFIXES, and EXTENSION_SUFFIXES. This led to an indirect deprecation of inspect.getmoduleinfo().
- **Issue #14662**: Prevent shutil failures on OS X when destination does not support chflag operations. Patch by Hynek Schlawack.
- **Issue #14157**: Fix time.strptime failing without a year on February 29th. Patch by Hynek Schlawack.
- **Issue #14753**: Make multiprocessing's handling of negative timeouts the same as it was in Python 3.2.
- **Issue #14583**: Fix importlib bug when a package's __init__.py would first import one of its modules then raise an error.
- **Issue #14741**: Fix missing support for Ellipsis ('...') in parser module.
- **Issue #14697**: Fix missing support for set displays and set comprehensions in parser module.
- **Issue #14701**: Fix missing support for ‘raise ... from’ in parser module.
- Add support for timeouts to the acquire() methods of multiprocessing's lock/semaphore/condition proxies.
- **Issue #13989**: Add support for text mode to gzip.open().
- **Issue #14127**: The os.stat() result object now provides three additional fields: st_ctime_ns, st_mtime_ns, and st_atime_ns, providing those times as an integer with nanosecond resolution. The functions os.utime(), os.lutimes(), and os.futimes() now accept a new parameter, ns, which accepts mtime and atime as integers with nanosecond resolution.
• **Issue #14127** and #10148: shutil.copystat now preserves exact mtime and atime on filesystems providing nanosecond resolution.

**IDLE**

• **Issue #14958**: Change IDLE syntax highlighting to recognize all string and byte literals supported in Python 3.3.

• **Issue #10997**: Prevent a duplicate entry in IDLE’s “Recent Files” menu.

• **Issue #14929**: Stop IDLE 3.x from closing on Unicode decode errors when grepping. Patch by Roger Serwy.

• **Issue #12510**: Attempting to get invalid tooltip no longer closes IDLE. Other tooltips have been corrected or improved and the number of tests has been tripled. Original patch by Roger Serwy.

**Tools/Demos**

• **Issue #14695**: Bring Tools/parser/unparse.py support up to date with the Python 3.3 Grammar.

**Build**

• **Issue #14472**: Update .gitignore. Patch by Matej Cepl.

• Upgrade Windows library versions: bzip 1.0.6, OpenSSL 1.0.1c.

• **Issue #14693**: Under non-Windows platforms, hashlib’s fallback modules are always compiled, even if OpenSSL is present at build time.

• **Issue #13210**: Windows build now uses VS2010, ported from VS2008.

**C-API**
• **Issue #14705:** The PyArg_Parse() family of functions now support the ‘p’ format unit, which accepts a “boolean predicate” argument. It converts any Python value into an integer—0 if it is “false”, and 1 otherwise.

**Documentation**

• **Issue #14863:** Update the documentation of os.fdopen() to reflect the fact that it’s only a thin wrapper around open() anymore.
• **Issue #14588:** The language reference now accurately documents the Python 3 class definition process. Patch by Nick Coghlan.
• **Issue #14943:** Correct a default argument value for winreg.OpenKey and correctly list the argument names in the function’s explanation.
Python 3.3.0 Alpha 3?

Release date: 01-May-2012

Core and Builtins

- **Issue #14699**: Fix calling the classmethod descriptor directly.
- **Issue #14433**: Prevent msvcrt crash in interactive prompt when stdin is closed.
- **Issue #14521**: Make result of float('nan') and float('-nan') more consistent across platforms.
- **Issue #14646**: __import__() sets __loader__ if the loader did not.
- **Issue #14605**: No longer have implicit entries in sys.meta_path. If sys.meta_path is found to be empty, raise ImportWarning.
- **Issue #14605**: No longer have implicit entries in sys.path_hooks. If sys.path_hooks is found to be empty, a warning will be raised. None is now inserted into sys.path_importer_cache if no finder was discovered. This also means imp.NullImporter is no longer implicitly used.
- **Issue #13903**: Implement PEP 412. Individual dictionary instances can now share their keys with other dictionaries. Classes take advantage of this to share their instance dictionary keys for improved memory and performance.
- **Issue #11603** (again): Setting __repr__ to __str__ now raises a RuntimeError when repr() or str() is called on such an object.
- **Issue #14658**: Fix binding a special method to a builtin implementation of a special method with a different name.
- **Issue #14630**: Fix a memory access bug for instances of a subclass of int with value 0.
- **Issue #14339**: Speed improvements to bin, oct and hex functions. Patch by Serhiy Storchaka.
- **Issue #14385**: It is now possible to use a custom type for the __builtins__ namespace, instead of a dict. It can be used for
sandboxing for example. Raise also a NameError instead of ImportError if __build_class__ name if not found in __builtins__.

- **Issue #12599**: Be more strict in accepting None compared to a false-like object for importlib.util.module_for_loader and importlib.machinery.PathFinder.
- **Issue #14612**: Fix jumping around with blocks by setting f_lineno.
- **Issue #14592**: Attempting a relative import w/o __package__ or __name__ set in globals raises a KeyError.
- **Issue #14607**: Fix keyword-only arguments which started with __.
- **Issue #10854**: The ImportError raised when an extension module on Windows fails to import now uses the new path and name attributes from Issue #1559549.
- **Issue #13889**: Check and (if necessary) set FPU control word before calling any of the dtoa.c string <-> float conversion functions, on MSVC builds of Python. This fixes issues when embedding Python in a Delphi app.
- **__import__()** now matches PEP 328 and documentation by defaulting ‘index’ to 0 instead of -1 and removing support for negative values.
- **Issue #2377**: Make importlib the implementation of __import__().
- **Issue #1559549**: ImportError now has ‘name’ and ‘path’ attributes that are set using keyword arguments to its constructor. They are currently not set by import as they are meant for use by importlib.
- **Issue #14474**: Save and restore exception state in thread.start_new_thread() while writing error message if the thread leaves an unhandled exception.
- **Issue #13019**: Fix potential reference leaks in bytearray.extend(). Patch by Suman Saha.

### Library

- **Issue #14768**: os.path.expanduser(‘~/a’) doesn’t works correctly when HOME is ‘/’.
- **Issue #14371**: Support bzip2 in zipfile module. Patch by Serhiy
Issue #13183: Fix pdb skipping frames after hitting a breakpoint and running step. Patch by Xavier de Gaye.

Issue #14696: Fix parser module to understand ‘nonlocal’ declarations.

Issue #10941: Fix imaplib.Internaldate2tuple to produce correct result near the DST transition. Patch by Joe Peterson.

Issue #9154: Fix parser module to understand function annotations.

Issue #6085: In http.server.py SimpleHTTPServer.address_string returns the client ip address instead client hostname. Patch by Charles-François Natali.

Issue #14309: Deprecate time.clock(), use time.perf_counter() or time.process_time() instead.

Issue #14428: Implement the PEP 418. Add time.get_clock_info(), time.perf_counter() and time.process_time() functions, and rename time.steady() to time.monotonic().

Issue #14646: importlib.util.module_for_loader() now sets __loader__ and __package__ (when possible).

Issue #14664: It is now possible to use @unittest.skip{If,Unless} on a test class that doesn't inherit from TestCase (i.e. a mixin).

Issue #4892: multiprocessing Connections can now be transferred over multiprocessing Connections. Patch by Richard Oudkerk (sbt).

Issue #14160: TarFile.extractfile() failed to resolve symbolic links when the links were not located in an archive subdirectory.

Issue #14638: pydoc now treats non-string __name__ values as if they were missing, instead of raising an error.

Issue #13684: Fix httplib tunnel issue of infinite loops for certain sites which send EOF without trailing rn.

Issue #13959: imp.cache_from_source()/source_from_cache()
now follow os.path.join()/split() semantics for path manipulation instead of its prior, custom semantics of caring the right-most path separator forward in path joining.

- **Issue #2193**: Allow ":" character in Cookie NAME values.
- **Issue #14629**: tokenizer.detect_encoding will specify the filename in the SyntaxError exception if found at readline.__self__.__name__.
- **Issue #14629**: Raise SyntaxError in tokenizer.detect_encoding if the first two lines have non-UTF-8 characters without an encoding declaration.
- **Issue #14308**: Fix an exception when a “dummy” thread is in the threading module’s active list after a fork().
- **Issue #11750**: The Windows API functions scattered in the _subprocess and _multiprocessing.win32 modules now live in a single module “_winapi”. Patch by sbt.
- **Issue #14087**: multiprocessing: add Condition.wait_for(). Patch by sbt.
- **Issue #14538**: HTMLParser can now parse correctly start tags that contain a bare ‘/’.  
- **Issue #14452**: SysLogHandler no longer inserts a UTF-8 BOM into the message.
- **Issue #14386**: Expose the dict_proxy internal type as types.MappingProxyType.
- **Issue #13959**: Make imp.reload() always use a module’s __loader__ to perform the reload.
- **Issue #13959**: Add imp.py and rename the built-in module to __imp, allowing for re-implementing parts of the module in pure Python.
- **Issue #13496**: Fix potential overflow in bisect.bisect algorithm when applied to a collection of size > sys.maxsize / 2.
- Have importlib take advantage of ImportError’s new ‘name’ and ‘path’ attributes.
- **Issue #14399**: zipfile now recognizes that the archive has been modified even if only the comment is changed. In addition, the TypeError that results from trying to set a non-binary value as a
comment is now raised at the time the comment is set rather than at the time the zipfile is written.

- `trace.CoverageResults.is_ignored_filename()` now ignores any name that starts with “<” and ends with “>” instead of special-casing “<string>” and “<doctest ”.

- **Issue #12537**: The mailbox module no longer depends on knowledge of internal implementation details of the email package Message object.

- **Issue #7978**: `socketserver` now restarts the select() call when EINTR is returned. This avoids crashing the server loop when a signal is received. Patch by Jerzy Kozera.

- **Issue #14522**: Avoid duplicating socket handles in `multiprocessing.connection`. Patch by sbt.

- Don’t `Py_DECREF` NULL variable in `io.IncrementalNewlineDecoder`.

- **Issue #3033**: Add display of parameter to `tkinter` font. Patch by Guilherme Polo.

- **Issue #14482**: Raise a `ValueError`, not a `NameError`, when trying to create a `multiprocessing` Client or Listener with an AF_UNIX type address under Windows. Patch by Popa Claudiu.

- **Issue #802310**: Generate always unique `tkinter` font names if not directly passed.

- **Issue #14151**: Raise a `ValueError`, not a `NameError`, when trying to create a `multiprocessing` Client or Listener with an AF_PIPE type address under non-Windows platforms. Patch by Popa Claudiu.

- **Issue #14493**: Use `gvfs-open` or `xdg-open` in `webbrowser`.

### Build

- “make touch” will now touch generated files that are checked into Mercurial, after a “hg update” which failed to bring the timestamps into the right order.
Tests

- **Issue #14026**: In test_cmd_line_script, check that sys.argv is populated correctly for the various invocation approaches (Patch by Jason Yeo)
- **Issue #14032**: Fix incorrect variable name in test_cmd_line_script debugging message (Patch by Jason Yeo)
- **Issue #14589**: Update certificate chain for sha256.tbs-internet.com, fixing a test failure in test_ssl.
- **Issue #14355**: Regrtest now supports the standard unittest test loading, and will use it if a test file contains no test_main method.

IDLE

- **Issue #8515**: Set __file__ when run file in IDLE. Initial patch by Bruce Frederiksen.
- **Issue #14496**: Fix wrong name in idlelib/tabbedpages.py. Patch by Popa Claudiu.

Tools / Demos

- **Issue #3561**: The Windows installer now has an option, off by default, for placing the Python installation into the system “Path” environment variable.
- **Issue #13165**: stringbench is now available in the Tools/stringbench folder. It used to live in its own SVN project.

C-API

- **Issue #14098**: New functions PyErr_GetExcInfo and PyErr_SetExcInfo. Patch by Stefan Behnel.
Python 3.3.0 Alpha 2?

Release date: 01-Apr-2012

Core and Builtins

- **Issue #1683368**: object.__new__ and object.__init__ raise a TypeError if they are passed arguments and their complementary method is not overridden.
- **Issue #14378**: Fix compiling ast.ImportFrom nodes with a “__future__” string as the module name that was not interned.
- **Issue #14331**: Use significantly less stack space when importing modules by allocating path buffers on the heap instead of the stack.
- **Issue #14334**: Prevent in a segfault in type.__getattribute__ when it was not passed strings.
- **Issue #1469629**: Allow cycles through an object’s __dict__ slot to be collected. (For example if x.__dict__ is x).
- **Issue #14205**: dict lookup raises a RuntimeError if the dict is modified during a lookup.
- **Issue #14220**: When a generator is delegating to another iterator with the yield from syntax, it needs to have its gi_running flag set to True.
- **Issue #14435**: Remove dedicated block allocator from floatobject.c and rely on the PyObject_Malloc() api like all other objects.
- **Issue #14471**: Fix a possible buffer overrun in the winreg module.
- **Issue #14288**: Allow the serialization of builtin iterators

Library

- **Issue #14300**: Under Windows, sockets created using
socket.dup() now allow overlapped I/O. Patch by sbt.

- **Issue #13872**: socket.detach() now marks the socket closed (as mirrored in the socket repr()). Patch by Matt Joiner.
- **Issue #14406**: Fix a race condition when using `concurrent.futures.wait(return_when=ALL_COMPLETED)`. Patch by Matt Joiner.
- **Issue #5136**: deprecate old, unused functions from tkinter.
- **Issue #14416**: syslog now defines the LOG_ODELAY and LOG_AUTHPRIV constants if they are defined in `<syslog.h>`.
- **Issue #14295**: Add unittest.mock
- **Issue #7652**: Add -with-system-libmpdec option to configure for linking the _decimal module against an installed libmpdec.
- **Issue #14380**: MIMETText now defaults to utf-8 when passed non-ASCII unicode with no charset specified.
- **Issue #10340**: asyncore - properly handle EINVAL in dispatcher constructor on OSX; avoid to call handle_connect in case of a disconnected socket which was not meant to connect.
- **Issue #14204**: The ssl module now has support for the Next Protocol Negotiation extension, if available in the underlying OpenSSL library. Patch by Colin Marc.
- **Issue #3035**: Unused functions from tkinter are marked as pending deprecated.
- **Issue #12757**: Fix the skipping of doctests when python is run with -OO so that it works in unittest's verbose mode as well as non-verbose mode.
- **Issue #7652**: Integrate the decimal floating point libmpdec library to speed up the decimal module. Performance gains of the new C implementation are between 10x and 100x, depending on the application.
- **Issue #14269**: SMTPD now conforms to the RFC and requires a HELO command before MAIL, RCPT, or DATA.
- **Issue #13694**: asynchronous connect in asyncore.dispatcher does not set addr attribute.
- **Issue #14344**: fixed the repr of email.policy objects.
- **Issue #11686**: Added missing entries to email package `__all__` lists (mostly the new Bytes classes).
- **Issue #14335**: multiprocessing’s custom Pickler subclass now inherits from the C-accelerated implementation. Patch by sbt.
- **Issue #10484**: Fix the CGIHTTPServer’s `PATH_INFO` handling problem.
- **Issue #11199**: Fix the with urllib which hangs on particular ftp urls.
- **Issue #14222**: Use the new `time.steady()` function instead of `time.time()` for timeout in queue and threading modules to not be affected of system time update.
- **Issue #13248**: Remove `lib2to3.pytree.Base.get_prefix/set_prefix`.
- **Issue #14234**: CVE-2012-0876: Randomize hashes of xml attributes in the hash table internal to the pyexpat module’s copy of the expat library to avoid a denial of service due to hash collisions. Patch by David Malcolm with some modifications by the expat project.
- **Issue #12818**: format address no longer needlessly escapes ()s in names when the name ends up being quoted.
- **Issue #14062**: BytesGenerator now correctly folds Header objects, including using linesep when folding.
- **Issue #13839**: When invoked on the command-line, the `pstats` module now accepts several filenames of profile stat files and merges them all. Patch by Matt Joiner.
- **Issue #14291**: Email now defaults to utf-8 for non-ASCII unicode headers instead of raising an error. This fixes a regression relative to 2.7.
- **Issue #989712**: Support using Tk without a mainloop.
- **Issue #3835**: Refuse to use unthreaded Tcl in threaded Python.
- **Issue #2843**: Add new Tk API to Tkinter.
- **Issue #14184**: Increase the default stack size for secondary threads on Mac OS X to avoid interpreter crashes when using threads on 10.7.
- **Issue #14180**: `datetime.date.fromtimestamp()`,
datetime.datetime.fromtimestamp() and datetime.datetime.utcfromtimestamp() now raise an OSError instead of ValueError if localtime() or gmtime() failed.

**Issue #14180:** time.ctime(), gmtime(), time.localtime(), datetime.date.fromtimestamp(),
datetime.datetime.fromtimestamp() and
datetime.datetime.utcfromtimestamp() now raises an OverflowError, instead of a ValueError, if the timestamp does not fit in time_t.

**Issue #14180:** datetime.datetime.fromtimestamp() and
datetime.datetime.utcfromtimestamp() now round microseconds towards zero instead of rounding to nearest with ties going away from zero.

**Issue #10543:** Fix unittest test discovery with Jython bytecode files.

**Issue #1178863:** Separate initialisation from setting when initializing Tkinter.Variables; harmonize exceptions to ValueError; only delete variables that have not been deleted; assert that variable names are strings.

**Issue #14104:** Implement time.monotonic() on Mac OS X, patch written by Nicholas Riley.

**Issue #13394:** the aifc module now uses warnings.warn() to signal warnings.

**Issue #14252:** Fix subprocess.Popen.terminate() to not raise an error under Windows when the child process has already exited.

**Issue #14223:** curses.addch() is no more limited to the range 0-255 when the Python curses is not linked to libncursesw. It was a regression introduced in Python 3.3a1.

**Issue #14168:** Check for presence of Element._attrs in minidom before accessing it.

**Issue #12328:** Fix multiprocessing's use of overlapped I/O on Windows. Also, add a multiprocessing.connection.wait(rlist, timeout=None) function for polling multiple objects at once. Patch by sbt.
- **Issue #14007**: Accept incomplete TreeBuilder objects (missing start, end, data or close method) for the Python implementation as well. Drop the no-op TreeBuilder().xml() method from the C implementation.
- **Issue #14210**: pdb now has tab-completion not only for command names, but also for their arguments, wherever possible.
- **Issue #14310**: Sockets can now be with other processes on Windows using the api socket.socket.share() and socket.fromshare().
- **Issue #10576**: The gc module now has a ‘callbacks’ member that will get called when garbage collection takes place.

**Build**

- **Issue #14557**: Fix extensions build on HP-UX. Patch by Adi Roiban.
- **Issue #14387**: Do not include accu.h from Python.h.
- **Issue #14359**: Only use O_CLOEXEC in _posixmodule.c if it is defined. Based on patch from Hervé Coatanhay.
- **Issue #14321**: Do not run pgen during the build if files are up to date.

**Documentation**

- **Issue #14034**: added the argparse tutorial.
- **Issue #14324**: Fix configure tests for cross builds.
- **Issue #14327**: Call AC_CANONICAL_HOST in configure.ac and check in config.{guess,sub}. Don’t use uname calls for cross builds.

**Extension Modules**

- **Issue #9041**: An issue in ctypes.c_longdouble, ctypes.c_double,
and ctypes.c_float that caused an incorrect exception to be returned in the case of overflow has been fixed.

- **Issue #14212**: The re module didn’t retain a reference to buffers it was scanning, resulting in segfaults.
- **Issue #14259**: The finditer() method of re objects did not take any keyword arguments, contrary to the documentation.
- **Issue #10142**: Support for SEEK_HOLE/SEEK_DATA (for example, under ZFS).

**Tests**

- **Issue #14442**: Add missing errno import in test_smtplib.
- **Issue #8315**: (partial fix) python -m unittest test.test_email now works.
Python 3.3.0 Alpha 1?

Release date: 05-Mar-2012

Core and Builtins

- **Issue #14172**: Fix reference leak when marshalling a buffer-like object (other than a bytes object).

- **Issue #13521**: `dict.setdefault()` now does only one lookup for the given key, making it “atomic” for many purposes. Patch by Filip Gruszczyński.

- PEP 409, **Issue #6210**: “raise X from None” is now supported as a means of suppressing the display of the chained exception context. The chained context still remains available as the `__context__` attribute.

- **Issue #10181**: New memoryview implementation fixes multiple ownership and lifetime issues of dynamically allocated `Py_buffer` members (#9990) as well as crashes (#8305, #7433). Many new features have been added (See whatsnew/3.3), and the documentation has been updated extensively. The `ndarray` test object from `_testbuffer.c` implements all aspects of PEP-3118, so further development towards the complete implementation of the PEP can proceed in a test-driven manner.

Thanks to Nick Coghlan, Antoine Pitrou and Pauli Virtanen for review and many ideas.

- **Issue #12834**: Fix incorrect results of `memoryview.tobytes()` for non-contiguous arrays.
• **Issue #5231**: Introduce `memoryview.cast()` method that allows changing format and shape without making a copy of the underlying memory.

• **Issue #14084**: Fix a file descriptor leak when importing a module with a bad encoding.

• Upgrade Unicode data to Unicode 6.1.

• **Issue #14040**: Remove rarely used file name suffixes for C extensions (under POSIX mainly).

• **Issue #14051**: Allow arbitrary attributes to be set of classmethod and staticmethod.

• **Issue #13703**: oCERT-2011-003: Randomize hashes of str and bytes to protect against denial of service attacks due to hash collisions within the dict and set types. Patch by David Malcolm, based on work by Victor Stinner.

• **Issue #13020**: Fix a reference leak when allocating a structsequence object fails. Patch by Suman Saha.

• **Issue #13908**: Ready types returned from `PyType_FromSpec`.

• **Issue #11235**: Fix `OverflowError` when trying to import a source file whose modification time doesn't fit in a 32-bit timestamp.

• **Issue #12705**: A `SyntaxError` exception is now raised when attempting to compile multiple statements as a single interactive statement.

• Fix the builtin module initialization code to store the init function for future reinitialization.
- **Issue #8052**: The posix subprocess module would take a long time closing all possible file descriptors in the child process rather than just open file descriptors. It now closes only the open fds if possible for the default close_fds=True behavior.

- **Issue #13629**: Renumber the tokens in token.h so that they match the indexes into _PyParser_TokenNames.

- **Issue #13752**: Add a casefold() method to str.

- **Issue #13761**: Add a “flush” keyword argument to the print() function, used to ensure flushing the output stream.

- **Issue #13645**: pyc files now contain the size of the corresponding source code, to avoid timestamp collisions (especially on filesystems with a low timestamp resolution) when checking for freshness of the bytecode.

- **PEP 380, Issue #11682**: Add “yield from <x>” to support easy delegation to subgenerators (initial patch by Greg Ewing, integration into 3.3 by Renaud Blanch, Ryan Kelly, Zbigniew Jędrzejewski-Szmek and Nick Coghlan)

- **Issue #13748**: Raw bytes literals can now be written with the `rb` prefix as well as `br`.

- **Issue #12736**: Use full unicode case mappings for upper, lower, and title case.

- **Issue #12760**: Add a create mode to open(). Patch by David Townshend.

- **Issue #13738**: Simplify implementation of bytes.lower() and bytes.upper().
• **Issue #13577**: Built-in methods and functions now have a __qualname__. Patch by sbt.

• **Issue #6695**: Full garbage collection runs now clear the freelist of set objects. Initial patch by Matthias Troffaes.

• Fix OSError.__init__ and OSError.__new__ so that each of them can be overridden and take additional arguments (followup to issue #12555).

• Fix the fix for issue #12149: it was incorrect, although it had the side effect of appearing to resolve the issue. Thanks to Mark Shannon for noticing.

• **Issue #13505**: Pickle bytes objects in a way that is compatible with Python 2 when using protocols <= 2.

• **Issue #11147**: Fix an unused argument in _Py_ANNOTATE_MEMORY_ORDER. (Fix given by Campbell Barton).

• **Issue #13503**: Use a more efficient reduction format for bytearrays with pickle protocol >= 3. The old reduction format is kept with older protocols in order to allow unpickling under Python 2. Patch by Irmen de Jong.

• **Issue #7111**: Python can now be run without a stdin, stdout or stderr stream. It was already the case with Python 2. However, the corresponding sys module entries are now set to None (instead of an unusable file object).

• **Issue #11849**: Ensure that free()d memory arenas are really released on POSIX systems supporting anonymous memory mappings. Patch by Charles-François Natali.
- PEP 3155 / issue #13448: Qualified name for classes and functions.

- Issue #13436: Fix a bogus error message when an AST object was passed an invalid integer value.

- Issue #13411: memoryview objects are now hashable when the underlying object is hashable.

- Issue #13338: Handle all enumerations in _Py_ANNOTATE_MEMORY_ORDER to allow compiling extension modules with -Wswitch-enum on gcc. Initial patch by Floris Bruynooghe.

- Issue #10227: Add an allocation cache for a single slice object. Patch by Stefan Behnel.

- Issue #13393: BufferedReader.read1() now asks the full requested size to the raw stream instead of limiting itself to the buffer size.

- Issue #13392: Writing a pyc file should now be atomic under Windows as well.

- Issue #13333: The UTF-7 decoder now accepts lone surrogates (the encoder already accepts them).

- Issue #13389: Full garbage collection passes now clear the freelists for list and dict objects. They already cleared other freelists in the interpreter.

- Issue #13327: Remove the need for an explicit None as the second argument to os.utime, os.lutimes, os.futimes, os.futimens, os.futimesat, in order to update to the current time. Also added
keyword argument handling to os.utimensat in order to remove the need for explicit None.

- **Issue #13350**: Simplify some C code by replacing most usages of PyUnicode_Format by PyUnicode_FromFormat.

- **Issue #13342**: input() used to ignore sys.stdin’s and sys.stdout’s unicode error handler in interactive mode (when calling into PyOS_Readline()).

- **Issue #9896**: Add start, stop, and step attributes to range objects.

- **Issue #13343**: Fix a SystemError when a lambda expression uses a global variable in the default value of a keyword-only argument:

  ```python
  lambda *, arg=GLOBAL_NAME: None
  ```

- **Issue #12797**: Added custom opener parameter to builtin open() and FileIO.open().

- **Issue #10519**: Avoid unnecessary recursive function calls in setobject.c.

- **Issue #10363**: Deallocate global locks in Py_Finalize().

- **Issue #13018**: Fix reference leaks in error paths in dictobject.c. Patch by Suman Saha.

- **Issue #13201**: Define ‘==’ and ‘!=' to compare range objects based on the sequence of values they define (instead of comparing based on object identity).

- **Issue #1294232**: In a few cases involving metaclass inheritance, the interpreter would sometimes invoke the wrong metaclass when building a new class object. These cases now behave correctly. Patch by Daniel Urban.
• **Issue #12753**: Add support for Unicode name aliases and named sequences. Both `unicodedata.lookup()` and `‘N{...}'` now resolve aliases, and `unicodedata.lookup()` resolves named sequences too.

• **Issue #12170**: The `count()`, `find()`, `rfind()`, `index()` and `rindex()` methods of bytes and bytearray objects now accept an integer between 0 and 255 as their first argument. Patch by Petri Lehtinen.

• **Issue #12604**: VTRACE macro expanded to no-op in `_sre.c` to avoid compiler warnings. Patch by Josh Triplett and Petri Lehtinen.

• **Issue #12281**: Rewrite the MBCS codec to handle correctly replace and ignore error handlers on all Windows versions. The MBCS codec is now supporting all error handlers, instead of only replace to encode and ignore to decode.

• **Issue #13188**: When called without an explicit traceback argument, `generator.throw()` now gets the traceback from the passed exception's `__traceback__` attribute. Patch by Petri Lehtinen.

• **Issue #13146**: Writing a pyc file is now atomic under POSIX.

• **Issue #7833**: Extension modules built using distutils on Windows will no longer include a “manifest” to prevent them failing at import time in some embedded situations.

• PEP 3151 / issue #12555: reworking the OS and IO exception hierarchy.
• Add internal API for static strings (Py_identifier et al.).

• **Issue #13063**: the Windows error ERROR_NO_DATA (numbered 232 and described as “The pipe is being closed”) is now mapped to POSIX errno EPIPE (previously EINVAL).

• **Issue #12911**: Fix memory consumption when calculating the repr() of huge tuples or lists.

• PEP 393: flexible string representation. Thanks to Torsten Becker for the initial implementation, and Victor Stinner for various bug fixes.

• **Issue #14081**: The ‘sep’ and ‘maxsplit’ parameter to str.split, bytes.split, and bytearray.split may now be passed as keyword arguments.

• **Issue #13012**: The ‘keepends’ parameter to str.splitlines may now be passed as a keyword argument: “my_string.splitlines(keepends=True)”. The same change also applies to bytes.splitlines and bytearray.splitlines.

• **Issue #7732**: Don’t open a directory as a file anymore while importing a module. Ignore the directory if its name matches the module name (e.g. “__init__.py”) and raise a ImportError instead.

• **Issue #13021**: Missing decref on an error path. Thanks to Suman Saha for finding the bug and providing a patch.

• **Issue #12973**: Fix overflow checks that relied on undefined behaviour in list_repeat (listobject.c) and islice_next (itertoolsmodule.c). These bugs caused test failures with recent versions of Clang.
- **Issue #12904**: os.uptime, os.futimes, os.lutimes, and os.futimesat now write atime and mtime with nanosecond precision on modern POSIX platforms.

- **Issue #12802**: the Windows error ERROR_DIRECTORY (numbered 267) is now mapped to POSIX errno ENOTDIR (previously EINVAL).

- **Issue #9200**: The str.is* methods now work with strings that contain non-BMP characters even in narrow Unicode builds.

- **Issue #12791**: Break reference cycles early when a generator exits with an exception.

- **Issue #12773**: Make __doc__ mutable on user-defined classes.

- **Issue #12766**: Raise a ValueError when creating a class with a class variable that conflicts with a name in __slots__.

- **Issue #12266**: Fix str.capitalize() to correctly uppercase/lowercase titlecased and cased non-letter characters.

- **Issue #12732**: In narrow unicode builds, allow Unicode identifiers which fall outside the BMP.

- **Issue #12575**: Validate user-generated AST before it is compiled.

- Make type(None), type(Ellipsis), and type(NotImplemented) callable. They return the respective singleton instances.

- Forbid summing bytes with sum().

- Verify the types of AST strings and identifiers provided by the user before compiling them.
- **Issue #12647**: The None object now has a `__bool__()` method that returns False. Formerly, bool(None) returned False only because of special case logic in PyObject_IsTrue().

- **Issue #12579**: str.format_map() now raises a ValueError if used on a format string that contains positional fields. Initial patch by Julian Berman.

- **Issue #10271**: Allow warnings.showwarning() be any callable.

- **Issue #11627**: Fix segfault when `__new__` on a exception returns a non-exception class.

- **Issue #12149**: Update the method cache after a type’s dictionary gets cleared by the garbage collector. This fixes a segfault when an instance and its type get caught in a reference cycle, and the instance's deallocator calls one of the methods on the type (e.g. when subclassing IOBase). Diagnosis and patch by Davide Rizzo.

- **Issue #9611, #9015**: FileIO.read() clamps the length to INT_MAX on Windows.

- **Issue #9642**: Uniformize the tests on the availability of the mbcs codec, add a new HAVE_MBCS define.

- **Issue #9642**: Fix filesystem encoding initialization: use the ANSI code page on Windows if the mbcs codec is not available, and fail with a fatal error if we cannot get the locale encoding (if nl_langinfo(CODESET) is not available) instead of using UTF-8.

- When a generator yields, do not retain the caller’s exception state on the generator.

- **Issue #12475**: Prevent generators from leaking their exception
state into the caller’s frame as they return for the last time.

- **Issue #12291**: You can now load multiple marshalled objects from a stream, with other data interleaved between marshalled objects.

- **Issue #12356**: When required positional or keyword-only arguments are not given, produce a informative error message which includes the name(s) of the missing arguments.

- **Issue #12370**: Fix super with no arguments when __class__ is overridden in the class body.

- **Issue #12084**: os.stat on Windows now works properly with relative symbolic links when called from any directory.

- Loosen type restrictions on the __dir__ method. __dir__ can now return any sequence, which will be converted to a list and sorted by dir().

- **Issue #12265**: Make error messages produced by passing an invalid set of arguments to a function more informative.

- **Issue #12225**: Still allow Python to build if Python is not in its hg repo or mercurial is not installed.

- **Issue #1195**: my_fgets() now always clears errors before calling fgets(). Fix the following case: sys.stdin.read() stopped with CTRL+d (end of file), raw_input() interrupted by CTRL+c.

- **Issue #12216**: Allow unexpected EOF errors to happen on any line of the file.

- **Issue #12199**: The TryExcept and TryFinally and AST nodes have been unified into a Try node.
• **Issue #9670**: Increase the default stack size for secondary threads on Mac OS X and FreeBSD to reduce the chances of a crash instead of a “maximum recursion depth” RuntimeError exception. (patch by Ronald Oussoren)

• **Issue #12106**: The use of the multiple-with shorthand syntax is now reflected in the AST.

• **Issue #12190**: Try to use the same filename object when compiling unmarshalling a code objects in the same file.

• **Issue #12166**: Move implementations of dir() specialized for various types into the __dir__() methods of those types.

• **Issue #5715**: In socketserver, close the server socket in the child process.

• Correct lookup of __dir__ on objects. Among other things, this causes errors besides AttributeError found on lookup to be propagated.

• **Issue #12060**: Use sig_atomic_t type and volatile keyword in the signal module. Patch written by Charles-François Natali.

• **Issue #174656**: Added the if_nameindex, if_indextoname, if_nametoindex methods to the socket module.

• **Issue #12044**: Fixed subprocess.Popen when used as a context manager to wait for the process to end when exiting the context to avoid unintentionally leaving zombie processes around.

• **Issue #1195**: Fix input() if it is interrupted by CTRL+d and then CTRL+c, clear the end-of-file indicator after CTRL+d.

• **Issue #1856**: Avoid crashes and lockups when daemon threads
run while the interpreter is shutting down; instead, these threads are now killed when they try to take the GIL.

- **Issue #9756**: When calling a method descriptor or a slot wrapper descriptor, the check of the object type doesn't read the `__class__` attribute anymore. Fix a crash if a class override its `__class__` attribute (e.g. a proxy of the str type). Patch written by Andreas Stührk.

- **Issue #10517**: After fork(), reinitialize the TLS used by the PyGILState_* APIs, to avoid a crash with the pthread implementation in RHEL 5. Patch by Charles-François Natali.

- **Issue #10914**: Initialize correctly the filesystem codec when creating a new subinterpreter to fix a bootstrap issue with codecs implemented in Python, as the ISO-8859-15 codec.

- **Issue #11918**: OS/2 and VMS are no more supported because of the lack of maintainer.

- **Issue #6780**: fix starts/endswith error message to mention that tuples are accepted too.

- **Issue #5057**: fix a bug in the peepholer that led to non-portable pyc files between narrow and wide builds while optimizing BINARY_SUBSCR on non-BMP chars (e.g. “U00012345”[0]).

- **Issue #11845**: Fix typo in rangeobject.c that caused a crash in compute_slice_indices. Patch by Daniel Urban.

- **Issue #5673**: Added a `timeout` keyword argument to subprocess.Popen.wait, subprocess.Popen.communicated, subprocess.call, subprocess.check_call, and subprocess.check_output. If the blocking operation takes more
than timeout seconds, the `subprocess.TimeoutExpired` exception is raised.

- **Issue #11650**: `PyOS_StdioReadline()` retries `fgets()` if it was interrupted (EINTR), for example if the program is stopped with CTRL+z on Mac OS X. Patch written by Charles-Francois Natali.

- **Issue #9319**: Include the filename in “Non-UTF8 code ...” syntax error.

- **Issue #10785**: Store the filename as Unicode in the Python parser.

- **Issue #11619**: `_PyImport_LoadDynamicModule()` doesn’t encode the path to bytes on Windows.

- **Issue #10998**: Remove mentions of -Q, `sys.flags.division_warning` and `Py_DivisionWarningFlag` left over from Python 2.

- **Issue #11244**: Remove an unnecessary peepholer check that was preventing negative zeros from being constant-folded properly.

- **Issue #11395**: `io.FileIO().write()` clamps the data length to 32,767 bytes on Windows if the file is a TTY to workaround a Windows bug. The Windows console returns an error (12: not enough space error) on writing into stdout if stdout mode is binary and the length is greater than 66,000 bytes (or less, depending on heap usage).

- **Issue #11320**: fix bogus memory management in `Modules/getpath.c`, leading to a possible crash when calling `Py_SetPath()`.

- **Issue #11432**: A bug was introduced in `subprocess.Popen()` on
posix systems with 3.2.0 where the stdout or stderr file descriptor being the same as the stdin file descriptor would raise an exception. webbrowser.open would fail. fixed.

- **Issue #9856**: Change object.__format__ with a non-empty format string to be a DeprecationWarning. In 3.2 it was a PendingDeprecationWarning. In 3.4 it will be a TypeError.

- **Issue #11244**: The peephole optimizer is now able to constant-fold arbitrarily complex expressions. This also fixes a 3.2 regression where operations involving negative numbers were not constant-folded.

- **Issue #11450**: Don’t truncate hg version info in Py_GetBuildInfo() when there are many tags (e.g. when using mq). Patch by Nadeem Vawda.

- **Issue #11335**: Fixed a memory leak in list.sort when the key function throws an exception.

- **Issue #8923**: When a string is encoded to UTF-8 in strict mode, the result is cached into the object. Examples: str.encode(), str.encode(‘utf-8’), PyUnicode_AsUTF8String() and PyUnicode_AsEncodedString(unicode, “utf-8”, NULL).

- **Issue #10829**: Refactor PyUnicode_FromFormat(), use the same function to parse the format string in the 3 steps, fix crashes on invalid format strings.

- **Issue #13007**: whichdb should recognize gdbm 1.9 magic numbers.

- **Issue #11286**: Raise a ValueError from calling PyMemoryView_FromBuffer with a buffer struct having a NULL
data pointer.

- **Issue #11272**: On Windows, input() strips ‘r’ (and not only ‘n’), and sys.stdin uses universal newline (replace ‘m’ by ‘n’).

- **Issue #11828**: startswith and endswith now accept None as slice index. Patch by Torsten Becker.

- **Issue #11168**: Remove filename debug variable from PyEval_EvalFrameEx(). It encoded the Unicode filename to UTF-8, but the encoding fails on undecodable filename (on surrogate characters) which raises an unexpected UnicodeEncodeError on recursion limit.

- **Issue #11187**: Remove bootstrap code (use ASCII) of PyUnicode_AsEncodedString(), it was replaced by a better fallback (use the locale encoding) in PyUnicode_EncodeFSDefault().

- Check for NULL result in PyType_FromSpec.

- **Issue #10516**: New copy() and clear() methods for lists and bytearrays.

- **Issue #11386**: bytearray.pop() now throws IndexError when the bytearray is empty, instead of OverflowError.

- **Issue #12380**: The rjust, ljust and center methods of bytes and bytearray now accept a bytearray argument.

**Library**

- **Issue #14195**: An issue that caused weakref.WeakSet instances to incorrectly return True for a WeakSet instance ‘a’ in both ‘a < a’
and ‘a > a’ has been fixed.

- **Issue #14166**: Pickler objects now have an optional `dispatch_table` attribute which allows to set custom per-pickler reduction functions. Patch by sbt.
- **Issue #14177**: `marshal.loads()` now raises `TypeError` when given an unicode string. Patch by Guilherme Gonçalves.
- **Issue #13550**: Remove the debug machinery from the threading module: remove verbose arguments from all threading classes and functions.
- **Issue #14159**: Fix the `len()` of weak containers (`WeakSet`, `WeakKeyDictionary`, `WeakValueDictionary`) to return a better approximation when some objects are dead or dying. Moreover, the implementation is now O(1) rather than O(n).
- **Issue #11841**: Fix comparison bug with ‘rc’ versions in `packaging.version`. Patch by Filip Gruszczyński.
- **Issue #6884**: Fix long-standing bugs with `MANIFEST.in` parsing in distutils on Windows. Also fixed in packaging.
- **Issue #8033**: `sqlite3`: Fix 64-bit integer handling in user functions on 32-bit architectures. Initial patch by Philippe Devalkeneer.
- **Issue #13641**: Decoding functions in the `base64` module now accept ASCII-only unicode strings. Patch by Catalin Iacob.
- **Issue #14043**: Speed up `importlib`'s `__FileFinder` by at least 8x, and add a new `importlib.invalidate_caches()` function.
- **Issue #14001**: CVE-2012-0845: `xmlrpc`: Fix an endless loop in `SimpleXMLRPCServer` upon malformed POST request.
- **Issue #13961**: Move `importlib` over to using `os.replace()` for atomic renaming.
- **Issue #2489**: `pty.spawn` could consume 100% cpu when it encountered an EOF.
- **Issue #13014**: Fix a possible reference leak in `SSLSocket.getpeercert()`.
• **Issue #13777**: Add PF_SYSTEM sockets on OS X. Patch by Michael Goderbauer.

• **Issue #13015**: Fix a possible reference leak in defaultdict.__repr__. Patch by Suman Saha.

• **Issue #1326113**: distutils' and packaging's build_ext commands option now correctly parses multiple values (separated by whitespace or commas) given to their --libraries option.

• **Issue #10287**: nntplib now queries the server's CAPABILITIES first before sending MODE READER, and only sends it if not already in READER mode. Patch by Hynek Schlawack.

• **Issue #13993**: HTMLParser is now able to handle broken end tags when strict=False.

• **Issue #13930**: lib2to3 now supports writing converted output files to another directory tree as well as copying unchanged files and altering the file suffix.

• **Issue #9750**: Fix sqlite3.Connection.iterdump on tables and fields with a name that is a keyword or contains quotes. Patch by Marko Kohtala.

• **Issue #10287**: nntplib now queries the server's CAPABILITIES again after authenticating (since the result may change, according to RFC 4643). Patch by Hynek Schlawack.

• **Issue #13590**: On OS X 10.7 and 10.6 with Xcode 4.2, building Distutils-based packages with C extension modules may fail because Apple has removed gcc-4.2, the version used to build python.org 64-bit/32-bit Pythons. If the user does not explicitly override the default C compiler by setting the CC environment variable, Distutils will now attempt to compile extension modules with clang if gcc-4.2 is required but not found. Also as a convenience, if the user does explicitly set CC, substitute its value as the default compiler in the Distutils LDSHARED configuration variable for OS X. (Note, the python.org 32-bit-only Pythons use gcc-4.0 and the 10.4u SDK, neither of which are available in Xcode 4. This change does not attempt to override settings to support their use with Xcode 4.)
- **Issue #13960**: HTMLParser is now able to handle broken comments when strict=False.
- When " is a path (e.g. in sys.path), make sure __file__ uses the current working directory instead of " in importlib.
- **Issue #13609**: Add two functions to query the terminal size: os.get_terminal_size (low level) and shutil.get_terminal_size (high level). Patch by Zbigniew Jędrzejewski-Szmek.
- **Issue #13845**: On Windows, time.time() now uses GetSystemTimeAsFileTime() instead of ftime() to have a resolution of 100 ns instead of 1 ms (the clock accuracy is between 0.5 ms and 15 ms).
- **Issue #13846**: Add time.monotonic(), monotonic clock.
- **Issue #8184**: multiprocessing: On Windows, don’t set SO_REUSEADDR on Connection sockets, and set FILE_FLAG_FIRST_PIPE_INSTANCE on named pipes, to make sure two listeners can’t bind to the same socket/pipe (or any existing socket/pipe).
- **Issue #10811**: Fix recursive usage of cursors. Instead of crashing, raise a ProgrammingError now.
- **Issue #13734**: Add os.fwalk(), a directory walking function yielding file descriptors.
- **Issue #2945**: Make the distutils upload command aware of bdist_rpm products.
- **Issue #13712**: pysetup create should not convert package_data to extra_files.
- **Issue #11805**: package_data in setup.cfg should allow more than one value.
- **Issue #13676**: Handle strings with embedded zeros correctly in sqlite3.
- **Issue #8828**: Add new function os.replace(), for cross-platform renaming with overwriting.
- **Issue #13848**: open() and the FileIO constructor now check for NUL characters in the file name. Patch by Hynek Schlawack.
- **Issue #13806**: The size check in audioop decompression
functions was too strict and could reject valid compressed data. Patch by Oleg Plakhotnyuk.

- **Issue #13812**: When a multiprocessing Process child raises an exception, flush stderr after printing the exception traceback.
- **Issue #13885**: CVE-2011-3389: the _ssl module would always disable the CBC IV attack countermeasure.
- **Issue #13847**: time.localtime() and time.gmtime() now raise an OSErrror instead of ValueError on failure. time.ctime() and time.asctime() now raises an OSErrror if localtime() failed. time.clock() now raises a RuntimeError if the processor time used is not available or its value cannot be represented.
- **Issue #13772**: In os.symlink() under Windows, do not try to guess the link target's type (file or directory). The detection was buggy and made the call non-atomic (therefore prone to race conditions).
- **Issue #6631**: Disallow relative file paths in urllib urlopen methods.
- **Issue #13722**: Avoid silencing ImportErrors when initializing the codecs registry.
- **Issue #13781**: Fix GzipFile bug that caused an exception to be raised when opening for writing using a fileobj returned by os.fdopen().
- **Issue #13803**: Under Solaris, distutils doesn't include bitness in the directory name.
- **Issue #10278**: Add time.wallclock() function, monotonic clock.
- **Issue #13809**: Fix regression where bz2 module wouldn't work when threads are disabled. Original patch by Amaury Forgeot d'Arc.
- **Issue #13589**: Fix some serialization primitives in the aifc module. Patch by Oleg Plakhotnyuk.
- **Issue #13642**: Unquote before b64encoding `user:password` during Basic Authentication. Patch contributed by Joonas Kuorilehto.
- **Issue #12364**: Fix a hang in concurrent.futures.ProcessPoolExecutor. The hang would occur when retrieving the result of a scheduled future after the executor
had been shut down.

- **Issue #13502**: threading: Fix a race condition in Event.wait() that made it return False when the event was set and cleared right after.
- **Issue #9993**: When the source and destination are on different filesystems, and the source is a symlink, shutil.move() now recreates a symlink on the destination instead of copying the file contents. Patch by Jonathan Niehof and Hynek Schlawack.
- **Issue #12926**: Fix a bug in tarfile’s link extraction.
- **Issue #13696**: Fix the 302 Relative URL Redirection problem.
- **Issue #13636**: Weak ciphers are now disabled by default in the ssl module (except when SSLv2 is explicitly asked for).
- **Issue #12715**: Add an optional symlinks argument to shutil functions (copyfile, copypmode, copystat, copy, copy2). When that parameter is true, symlinks aren’t dereferenced and the operation instead acts on the symlink itself (or creates one, if relevant). Patch by Hynek Schlawack.
- **Issue #13626**: Add support for SSL Diffie-Hellman key exchange, through the SSLContext.load_dh_params() method and the ssl.OP_SINGLE_DH_USE option.
- **Issue #11006**: Don’t issue low level warning in subprocess when pipe2() fails.
- **Issue #13620**: Support for Chrome browser in webbrowser. Patch contributed by Arnaud Calmettes.
- **Issue #11829**: Fix code execution holes in inspect.getattr_static for metaclasses with metaclasses. Patch by Andreas Stührk.
- **Issue #12708**: Add starmap() and starmap_async() methods (similar to itertools.starmap()) to multiprocessing.Pool. Patch by Hynek Schlawack.
- **Issue #1785**: Fix inspect and pydoc with misbehaving descriptors.
- **Issue #13637**: “a2b” functions in the binascii module now accept ASCII-only unicode strings.
- **Issue #13634**: Add support for querying and disabling SSL
compression.

- **Issue #13627**: Add support for SSL Elliptic Curve-based Diffie-Hellman key exchange, through the `SSLContext.set_ecdh_curve()` method and the `ssl.OP_SINGLE_ECDH_USE` option.

- **Issue #13635**: Add `ssl.OP_CIPHER_SERVER_PREFERENCE`, so that SSL servers choose the cipher based on their own preferences, rather than on the client’s.

- **Issue #11813**: Fix `inspect.getattr_static` for modules. Patch by Andreas Stührk.

- **Issue #7502**: Fix equality comparison for `DocTestSuite` instances. Patch by Cédric Krier.

- **Issue #11870**: threading: Properly reinitialize threads internal locks and condition variables to avoid deadlocks in child processes.

- **Issue #8035**: `urllib`: Fix a bug where the client could remain stuck after a redirection or an error.

- **Issue #13560**: `os.strerror()` now uses the current locale encoding instead of UTF-8.

- **Issue #8373**: The filesystem path of AF_UNIX sockets now uses the filesystem encoding and the surrogateescape error handler, rather than UTF-8. Patch by David Watson.

- **Issue #10350**: Read and save `errno` before calling a function which might overwrite it. Original patch by Hallvard B Furuseth.

- **Issue #11610**: Introduce a more general way to declare abstract properties.

- **Issue #13591**: A bug in `importlib` has been fixed that caused `import_module` to load a module twice.

- **Issue #13449** `sched.scheduler.run()` method has a new “blocking” parameter which when set to False makes `run()` execute the scheduled events due to expire soonest (if any) and then return. Patch by Giampaolo Rodolà.

- **Issue #8684** `sched.scheduler` class can be safely used in multi-threaded environments. Patch by Josiah Carlson and Giampaolo
Rodolà.

- Alias resource.error to OSError ala PEP 3151.
- **Issue #5689**: Add support for lzma compression to the tarfile module.
- **Issue #5905, #13560**: time.strftime() is now using the current locale encoding, instead of UTF-8, if the wcsftime() function is not available.
- **Issue #13464**: Add a readinto() method to http.client.HTTPResponse. Patch by Jon Kuhn.
- tarfile.py: Correctly detect bzip2 compressed streams with blocksizes other than 900k.
- **Issue #13439**: Fix many errors in turtle docstrings.
- **Issue #6715**: Add a module ‘lzma’ for compression using the LZMA algorithm. Thanks to Per Øyvind Karlsen for the initial implementation.
- **Issue #13487**: Make inspect.getmodule robust against changes done to sys.modules while it is iterating over it.
- **Issue #12618**: Fix a bug that prevented py_compile from creating byte compiled files in the current directory. Initial patch by Sjoerd de Vries.
- **Issue #13444**: When stdout has been closed explicitly, we should not attempt to flush it at shutdown and print an error.
- **Issue #12567**: The curses module uses Unicode functions for Unicode arguments when it is linked to the ncurses library. It encodes also Unicode strings to the locale encoding instead of UTF-8.
- **Issue #12856**: Ensure child processes do not inherit the parent’s random seed for filename generation in the tempfile module. Patch by Brian Harring.
- **Issue #9957**: SpooledTemporaryFile.truncate() now accepts an optional size parameter, as other file-like objects. Patch by Ryan Kelly.
- **Issue #13458**: Fix a memory leak in the ssl module when decoding a certificate with a subjectAltName. Patch by Robert Xiao.
- **Issue #13415**: os.unsetenv() doesn’t ignore errors anymore.
- **Issue #13245**: sched.scheduler class constructor’s timefunc and delayfunc parameters are now optional. scheduler.enter and scheduler.enterabs methods gained a new kwargs parameter. Patch contributed by Chris Clark.
- **Issue #12328**: Under Windows, refactor handling of Ctrl-C events and make _multiprocessing.win32.WaitForMultipleObjects interruptible when the wait_flag parameter is false. Patch by sbt.
- **Issue #13322**: Fix BufferedWriter.write() to ensure that BlockingIOError is raised when the wrapped raw file is non-blocking and the write would block. Previous code assumed that the raw write() would raise BlockingIOError, but RawIOBase.write() is defined to returned None when the call would block. Patch by sbt.
- **Issue #13358**: HTMLParser now calls handle_data only once for each CDATA.
- **Issue #4147**: minidom’s toprettyxml no longer adds whitespace around a text node when it is the only child of an element. Initial patch by Dan Kenigsberg.
- **Issue #13374**: The Windows bytes API has been deprecated in the os module. Use Unicode filenames instead of bytes filenames to not depend on the ANSI code page anymore and to support any filename.
- **Issue #13297**: Use bytes type to send and receive binary data through XMLRPC.
- **Issue #6397**: Support “/dev/poll” polling objects in select module, under Solaris & derivatives.
- Issues #1745761, #755670, #13357, #12629, #1200313:
HTMLParser now correctly handles non-valid attributes, including adjacent and unquoted attributes.

- **Issue #13193**: Fix distutils.filelist.FileList and packaging.manifest.Manifest under Windows.
- **Issue #13384**: Remove unnecessary __future__ import in Lib/random.py
- **Issue #13149**: Speed up append-only StringIO objects.
- **Issue #13373**: multiprocessing.Queue.get() could sometimes block indefinitely when called with a timeout. Patch by Arnaud Ysmal.
- **Issue #13254**: Fix Maildir initialization so that maildir contents are read correctly.
- **Issue #3067**: locale.setlocale() now raises TypeError if the second argument is an invalid iterable. Its documentation and docstring were also updated. Initial patch by Jyrki Pulliainen.
- **Issue #13140**: Fix the daemon_threads attribute of ThreadingMixIn.
- **Issue #13339**: Fix compile error in posixmodule.c due to missing semicolon. Thanks to Robert Xiao.
- Byte compilation in packaging is now isolated from the calling Python -B or -O options, instead of being disallowed under -B or buggy under -O.
- **Issue #10570**: curses.putp() and curses.tparm() are now expecting a byte string, instead of a Unicode string.
- **Issue #13295**: http.server now produces valid HTML 4.01 strict.
- **Issue #2892**: preserve iterparse events in case of SyntaxError.
- **Issue #13287**: urllib.request and urllib.error now contains an __all__ attribute to expose only relevant classes and functions. Patch by Florent Xicluna.
- **Issue #670664**: Fix HTMLParser to correctly handle the content of <script>...</script> and <style>...</style>.
- **Issue #10817**: Fix urlretrieve function to raise ContentTooShortError even when reporthook is None. Patch by Jyrki Pulliainen.
• Fix the xmlrpc.client user agent to return something similar to urllib.request user agent: “Python-xmlrpc/3.3”.
• Issue #13293: Better error message when trying to marshal bytes using xmlrpc.client.
• Issue #13291: NameError in xmlrpc package.
• Issue #13258: Use callable() built-in in the standard library.
• Issue #13273: fix a bug that prevented HTMLParser to properly detect some tags when strict=False.
• Issue #11183: Add finer-grained exceptions to the ssl module, so that you don’t have to inspect the exception’s attributes in the common case.
• Issue #13216: Add cp65001 codec, the Windows UTF-8 (CP_UTF8).
• Issue #13226: Add RTLD_xxx constants to the os module. These constants can be used with sys.setdlopenflags().
• Issue #10278: Add clock_getres(), clock_gettime() and CLOCK_xxx constants to the time module. time.clock_gettime(time.CLOCK_MONOTONIC) provides a monotonic clock
• Issue #10332: multiprocessing: fix a race condition when a Pool is closed before all tasks have completed.
• Issue #13255: wrong docstrings in array module.
• Issue #8540: Remove deprecated Context._clamp attribute in Decimal module.
• Issue #13235: Added DeprecationWarning to logging.warn() method and function.
• Issue #9168: now smtpd is able to bind privileged port.
• Issue #12529: fix cgi.parse_header issue on strings with double-quotes and semicolons together. Patch by Ben Darnell and Petri Lehtinen.
• Issue #13227: functools.lru_cache() now has a option to distinguish calls with different argument types.
• Issue #6090: zipfile raises a ValueError when a document with a timestamp earlier than 1980 is provided. Patch contributed by
Petri Lehtinen.

- **Issue #13150**: sysconfig no longer parses the Makefile and config.h files when imported, instead doing it at build time. This makes importing sysconfig faster and reduces Python startup time by 20%.

- **Issue #12448**: smtplib now flushes stdout while running `python -m smtplib` in order to display the prompt correctly.

- **Issue #12454**: The mailbox module is now using ASCII, instead of the locale encoding, to read and write .mh_sequences files.

- **Issue #13194**: `zlib.compressobj().copy()` and `zlib.decompressobj().copy()` are now available on Windows.

- **Issue #1673007**: urllib.request now supports HEAD request via new method argument. Patch contributions by David Stanek, Patrick Westerhoff and Ezio Melotti.

- **Issue #12386**: packaging does not fail anymore when writing the RESOURCES file.

- **Issue #13158**: Fix decoding and encoding of GNU tar specific base-256 number fields in tarfile.

- **Issue #13025**: mimetypes is now reading MIME types using the UTF-8 encoding, instead of the locale encoding.

- **Issue #10653**: On Windows, use `strftime()` instead of `wcsftime()` because `wcsftime()` doesn’t format time zone correctly.

- **Issue #13150**: The tokenize module doesn’t compile large regular expressions at startup anymore.

- **Issue #11171**: Fix distutils.sysconfig.get_makefile_filename when Python was configured with different prefix and exec-prefix.

- **Issue #11254**: Teach distutils and packaging to compile .pyc and .pyo files in PEP 3147-compliant __pycache__ directories.

- **Issue #7367**: Fix pkgutil.walk_paths to skip directories whose contents cannot be read.

- **Issue #3163**: The struct module gets new format characters ‘n’ and ‘N’ supporting C integer types ssize_t and size_t, respectively.

- **Issue #13099**: Fix sqlite3.Cursor.lastrowid under a Turkish locale.
Reported and diagnosed by Thomas Kluyver.

- **Issue #13087**: BufferedReader.seek() now always raises UnsupportedOperation if the underlying raw stream is unseekable, even if the seek could be satisfied using the internal buffer. Patch by John O’Connor.

- **Issue #7689**: Allow pickling of dynamically created classes when their metaclass is registered with copyreg. Patch by Nicolas M. Thiéry and Craig Citro.

- **Issue #13034**: When decoding some SSL certificates, the subjectAltName extension could be unreported.

- **Issue #12306**: Expose the runtime version of the zlib C library as a constant, ZLIB_RUNTIME_VERSION, in the zlib module. Patch by Torsten Landschoff.

- **Issue #12959**: Add collections.ChainMap to collections.__all__.

- **Issue #8933**: distutils’ PKG-INFO files and packaging’s METADATA files will now correctly report Metadata-Version: 1.1 instead of 1.0 if a Classifier or Download-URL field is present.

- **Issue #12567**: Add curses.unget_wch() function. Push a character so the next get_wch() will return it.

- **Issue #9561**: distutils and packaging now writes egg-info files using UTF-8, instead of the locale encoding.

- **Issue #8286**: The distutils command sdist will print a warning message instead of crashing when an invalid path is given in the manifest template.

- **Issue #12841**: tarfile unnecessarily checked the existence of numerical user and group ids on extraction. If one of them did not exist the respective id of the current user (i.e. root) was used for the file and ownership information was lost.

- **Issue #12888**: Fix a bug in HTMLParser.unescape that prevented it to escape more than 128 entities. Patch by Peter Otten.

- **Issue #12878**: Expose a __dict__ attribute on io.IOBase and its subclasses.

- **Issue #12494**: On error, call(), check_call(), check_output() and getstatusoutput() functions of the subprocess module now kill the
process, read its status (to avoid zombis) and close pipes.

- **Issue #12720**: Expose low-level Linux extended file attribute functions in os.
- **Issue #10946**: The distutils commands bdist_dumb, bdist_wininst and bdist_msi now respect a --skip-build option given to bdist. The packaging commands were fixed too.
- **Issue #12847**: Fix a crash with negative PUT and LONG_BINPUT arguments in the C pickle implementation.
- **Issue #11564**: Avoid crashes when trying to pickle huge objects or containers (more than 2**31 items). Instead, in most cases, an OverflowError is raised.
- **Issue #12287**: Fix a stack corruption in ossaudiodev module when the FD is greater than FD_SETSIZE.
- **Issue #12839**: Fix crash in zlib module due to version mismatch. Fix by Richard M. Tew.
- **Issue #9923**: The mailcap module now correctly uses the platform path separator for the MAILCAP environment variable on non-POSIX platforms.
- **Issue #12835**: Follow up to #6560 that unconditionally prevents use of the unencrypted sendmsg/recvmsg APIs on SSL wrapped sockets. Patch by David Watson.
- **Issue #12803**: SSLContext.load_cert_chain() now accepts a password argument to be used if the private key is encrypted. Patch by Adam Simpkins.
- **Issue #11657**: Fix sending file descriptors over 255 over a multiprocessing Pipe.
- **Issue #12811**: tabnanny.check() now promptly closes checked files. Patch by Anthony Briggs.
- **Issue #6560**: The sendmsg/recvmsg API is now exposed by the socket module when provided by the underlying platform, supporting processing of ancillary data in pure Python code. Patch by David Watson and Heiko Wundram.
- **Issue #12326**: On Linux, sys.platform doesn’t contain the major version anymore. It is now always ‘linux’, instead of ‘linux2’ or
‘linux3’ depending on the Linux version used to build Python.

- **Issue #12213**: Fix a buffering bug with interleaved reads and writes that could appear on BufferedRandom streams.
- **Issue #12778**: Reduce memory consumption when JSON-encoding a large container of many small objects.
- **Issue #12650**: Fix a race condition where a subprocess.Popen could leak resources (FD/zombie) when killed at the wrong time.
- **Issue #12744**: Fix inefficient representation of integers between $2^{31}$ and $2^{63}$ on systems with a 64-bit C “long”.
- **Issue #12646**: Add an ‘eof’ attribute to zlib.Decompress, to make it easier to detect truncated input streams.
- **Issue #11513**: Fix exception handling of `tarfile.TarFile.gzopen()` when the file cannot be opened.
- **Issue #12687**: Fix a possible buffering bug when unpickling text mode (protocol 0, mostly) pickles.
- **Issue #10087**: Fix the html output format of the calendar module.
- **Issue #13121**: add support for inplace math operators to collections.Counter.
- Add support for unary plus and unary minus to collections.Counter.
- **Issue #12683**: urlparse updated to include svn as schemes that uses relative paths. (svn from 1.5 onwards support relative path).
- **Issue #12655**: Expose functions from sched.h in the os module: `sched_yield()`, `sched_setscheduler()`, `sched_getscheduler()`, `sched_setparam()`, `sched_get_min_priority()`, `sched_get_max_priority()`, `sched_rr_get_interval()`, `sched_getaffinity()`, `sched_setaffinity()`.
- Add ThreadError to threading.__all__.
- Issues #11104, #8688: Fix the behavior of distutils’ sdist command with manually-maintained MANIFEST files.
- **Issue #11281**: smtplib.SMTP gets source_address parameter, which adds the ability to bind to specific source address on a machine with multiple interfaces. Patch by Paulo Scardine.
- **Issue #12464**: tempfile.TemporaryDirectory.cleanup() should not
follow symlinks: fix it. Patch by Petri Lehtinen.

- **Issue #8887**: "pydoc somebuiltin.somemethod" (or help('somebuiltin.somemethod') in Python code) now finds the doc of the method.
- **Issue #10968**: Remove indirection in threading. The public names (Event, Condition, etc.) used to be factory functions returning instances of hidden classes (_Event, _Condition, etc.), because (if Guido recalls correctly) this code pre-dates the ability to subclass extension types. It is now possible to inherit from these classes, without having to import the private underscored names like multiprocessing did.
- **Issue #9723**: Add shlex.quote functions, to escape filenames and command lines.
- **Issue #12603**: Fix pydoc.synopsis() on files with non-negative st_mtime.
- **Issue #12514**: Use try/finally to assure the timeit module restores garbage collections when it is done.
- **Issue #12607**: In subprocess, fix issue where if stdin, stdout or stderr is given as a low fd, it gets overwritten.
- **Issue #12576**: Fix urlopen behavior on sites which do not send (or obfuscate) a `Connection: close` header.
- **Issue #12560**: Build libpython.so on OpenBSD. Patch by Stefan Sperling.
- **Issue #1813**: Fix codec lookup under Turkish locales.
- **Issue #12591**: Improve support of “universal newlines” in the subprocess module: the piped streams can now be properly read from or written to.
- **Issue #12591**: Allow io.TextIOWrapper to work with raw IO objects (without a read1() method), and add a `write_through` parameter to mandate unbuffered writes.
- **Issue #10883**: Fix socket leaks in urllib.request when using FTP.
- **Issue #12592**: Make Python build on OpenBSD 5 (and future major releases).
- **Issue #12372**: POSIX semaphores are broken on AIX: don't use
them.

- **Issue #12551**: Provide a `get_channel_binding()` method on SSL sockets so as to get channel binding data for the current SSL session (only the “tls-unique” channel binding is implemented). This allows the implementation of certain authentication mechanisms such as SCRAM-SHA-1-PLUS. Patch by Jacek Konieczny.
- **Issue #665194**: `email.utils` now has `format_datetime` and `parsedate_to_datetime` functions, allowing for round tripping of RFC2822 format dates.
- **Issue #12571**: Add a `plat-linux3` directory mirroring the `plat-linux2` directory, so that “import DLFCN” and other similar imports work on Linux 3.0.
- **Issue #7484**: `smtplib` no longer puts <> around addresses in `VRFY` and `EXPN` commands; they aren’t required and in fact postfix doesn’t support that form.
- **Issue #12273**: Remove `ast.__version__`. AST changes can be accounted for by checking `sys.version_info` or `sys._mercurial`.
- Silence spurious “broken pipe” tracebacks when shutting down a `ProcessPoolExecutor`.
- Fix potential resource leaks in `concurrent.futures.ProcessPoolExecutor` by joining all queues and processes when `shutdown()` is called.
- **Issue #11603**: Fix a crash when `__str__` is rebound as `__repr__`. Patch by Andreas Stührk.
- **Issue #11321**: Fix a crash with multiple imports of the `_pickle` module when embedding Python. Patch by Andreas Stührk.
- **Issue #6755**: Add `get_wch()` method to `curses.window` class. Patch by Iñigo Serna.
- Add `cgi.closelog()` function to close the log file.
- **Issue #12502**: `asyncore`: fix polling loop with AF_UNIX sockets.
- **Issue #4376**: `ctypes` now supports nested structures in a endian different than the parent structure. Patch by Vlad Riscutia.
- Raise `ValueError` when attempting to set the `_CHUNK_SIZE`
attribute of a TextIOWrapper to a huge value, not TypeError.

- **Issue #12504**: Close file handles in a timely manner in packaging.database. This fixes a bug with the remove (uninstall) feature on Windows.
- **Issues #12169 and #10510**: Factor out code used by various packaging commands to make HTTP POST requests, and make sure it uses CRLF.
- **Issue #12016**: Multibyte CJK decoders now resynchronize faster. They only ignore the first byte of an invalid byte sequence. For example, b'xffn'.decode('gb2312', 'replace') gives ‘ufffdn' instead of ‘ufffd'.
- **Issue #12459**: time.sleep() now raises a ValueError if the sleep length is negative, instead of an infinite sleep on Windows or raising an IOError on Linux for example, to have the same behaviour on all platforms.
- **Issue #12451**: pydoc: html_getfile() now uses tokenize.open() to support Python scripts using a encoding different than UTF-8 (read the coding cookie of the script).
- **Issue #12493**: subprocess: Popen.communicate() now also handles EINTR errors if the process has only one pipe.
- **Issue #12467**: warnings: fix a race condition if a warning is emitted at shutdown, if globals()['__file__'] is None.
- **Issue #12451**: pydoc: importfile() now opens the Python script in binary mode, instead of text mode using the locale encoding, to avoid encoding issues.
- **Issue #12451**: runpy: run_path() now opens the Python script in binary mode, instead of text mode using the locale encoding, to support other encodings than UTF-8 (scripts using the coding cookie).
- **Issue #12451**: xml.dom.pulldom: parse() now opens files in binary mode instead of the text mode (using the locale encoding) to avoid encoding issues.
- **Issue #12147**: Adjust the new-in-3.2 smtplib.send_message method for better conformance to the RFCs: correctly handle
Sender and Resent- headers.

- **Issue #12352**: Fix a deadlock in multiprocessing.Heap when a block is freed by the garbage collector while the Heap lock is held.
- **Issue #12462**: `time.sleep()` now immediately calls the (Python) signal handler if it is interrupted by a signal, instead of having to wait until the next instruction.
- **Issue #12442**: new `shutil.disk_usage` function, providing total, used and free disk space statistics.
- **Issue #12451**: The XInclude default loader of `xml.etree` now decodes files from UTF-8 instead of the locale encoding if the encoding is not specified. It now also opens XML files for the parser in binary mode instead of the text mode to avoid encoding issues.
- **Issue #12451**: `doctest.debug_script()` doesn’t create a temporary file anymore to avoid encoding issues.
- **Issue #12451**: `pydoc.synopsis()` now reads the encoding cookie if available, to read the Python script from the right encoding.
- **Issue #12451**: `distutils` now opens the setup script in binary mode to read the encoding cookie, instead of opening it in UTF-8.
- **Issue #9516**: On Mac OS X, change Distutils to no longer globally attempt to check or set the MACOSX_DEPLOYMENT_TARGET environment variable for the interpreter process. This could cause failures in non-Distutils subprocesses and was unreliable since tests or user programs could modify the interpreter environment after Distutils set it. Instead, have Distutils set the deployment target only in the environment of each build subprocess. It is still possible to globally override the default by setting MACOSX_DEPLOYMENT_TARGET before launching the interpreter; its value must be greater or equal to the default value, the value with which the interpreter was built. Also, implement the same handling in packaging.
- **Issue #12422**: In the copy module, don’t store objects that are their own copy in the memo dict.
- **Issue #12303**: Add `sigwaitinfo()` and `sigtimedwait()` to the signal
module.
- **Issue #12404**: Remove C89 incompatible code from mmap module. Patch by Akira Kitada.
- **Issue #1874**: email now detects and reports as a defect the presence of any CTE other than 7bit, 8bit, or binary on a multipart.
- **Issue #12383**: Fix subprocess module with env={}: don’t copy the environment variables, start with an empty environment.
- **Issue #11637**: Fix support for importing packaging setup hooks from the project directory.
- **Issue #6771**: Moved the curses.wrapper function from the single-function wrapper module into __init__, eliminating the module. Since __init__ was already importing the function to curses.wrapper, there is no API change.
- **Issue #11584**: email.header.decode_header no longer fails if the header passed to it is a Header object, and Header/make_header no longer fail if given binary unknown-8bit input.
- **Issue #11700**: mailbox proxy object close methods can now be called multiple times without error.
- **Issue #11767**: Correct file descriptor leak in mailbox’s __getitem__ method.
- **Issue #12133**: AbstractHTTPHandler.do_open() of urllib.request closes the HTTP connection if its getresponse() method fails with a socket error. Patch written by Ezio Melotti.
- **Issue #12240**: Allow multiple setup hooks in packaging’s setup.cfg files. Original patch by Erik Bray.
- **Issue #9284**: Allow inspect.findsource() to find the source of doctest functions.
- **Issue #11595**: Fix assorted bugs in packaging.util.cfg_to_args, a compatibility helper for the distutils-packaging transition. Original patch by Erik Bray.
- **Issue #12287**: In ossaudiodev, check that the device isn’t closed in several methods.
- **Issue #12009**: Fixed regression in netrc file comment handling.
- **Issue #12246**: Warn and fail when trying to install a third-party
project from an uninstalled Python (built in a source checkout). Original patch by Tshepang Lekhonkhobe.

- **Issue #10694**: zipfile now ignores garbage at the end of a zipfile.
- **Issue #12283**: Fixed regression in smtplib quoting of leading dots in DATA.
- **Issue #10424**: Argparse now includes the names of the missing required arguments in the missing arguments error message.
- **Issue #12168**: SysLogHandler now allows NUL termination to be controlled using a new ‘append_nul’ attribute on the handler.
- **Issue #11583**: Speed up os.path.isdir on Windows by using GetFileAttributes instead of os.stat.
- **Issue #12021**: Make mmap's read() method argument optional. Patch by Petri Lehtinen.
- **Issue #9205**: concurrent.futures.ProcessPoolExecutor now detects killed children and raises BrokenProcessPool in such a situation. Previously it would reliably freeze/deadlock.
- **Issue #12040**: Expose a new attribute `sentinel` on instances of `multiprocessing.Process`. Also, fix `Process.join()` to not use polling anymore, when given a timeout.
- **Issue #11893**: Remove obsolete internal wrapper class `SSLFakeFile` in the smtplib module. Patch by Catalin Iacob.
- **Issue #12080**: Fix a Decimal.power() case that took an unreasonably long time to compute.
- **Issue #12221**: Remove `__version__` attributes from pyexpat, pickle, tarfile, pydoc, tkinter, and xml.parsers.expat. This were useless version constants left over from the Mercurial transition
- Named tuples now work correctly with vars().
- **Issue #12085**: Fix an attribute error in subprocess.Popen destructor if the constructor has failed, e.g. because of an undeclared keyword argument. Patch written by Oleg Oshmyan.
- **Issue #12028**: Make threading._get_ident() public, rename it to threading.get_ident() and document it. This function was already used using _thread.get_ident().
- **Issue #12171**: IncrementalEncoder.reset() of CJK codecs
(multibytecodec) calls encreset() instead of decreset().

- **Issue #12218**: Removed wsgiref.egg-info.
- **Issue #12196**: Add pipe2() to the os module.
- **Issue #985064**: Make plistlib more resilient to faulty input plists. Patch by Mher Movsisyan.
- **Issue #1625**: BZ2File and bz2.decompress() now support multi-stream files. Initial patch by Nir Aides.
- **Issue #12175**: BufferedReader.read(-1) now calls raw.readall() if available.
- **Issue #12175**: FileIO.readall() now only reads the file position and size once.
- **Issue #12175**: RawIOBase.readall() now returns None if read() returns None.
- **Issue #12175**: FileIO.readall() now raises a ValueError instead of an IOError if the file is closed.
- **Issue #11109**: New service_action method for BaseServer, used by ForkingMixin class for cleanup. Initial Patch by Justin Warkentin.
- **Issue #12045**: Avoid duplicate execution of command in ctypes.util._get_soname(). Patch by Sijin Joseph.
- **Issue #10818**: Remove the Tk GUI and the serve() function of the pydoc module, pydoc -g has been deprecated in Python 3.2 and it has a new enhanced web server.
- **Issue #1441530**: In imaplib, read the data in one chunk to speed up large reads and simplify code.
- **Issue #12070**: Fix the Makefile parser of the sysconfig module to handle correctly references to “bogus variable” (e.g. “prefix=/opt/python”).
- **Issue #12100**: Don’t reset incremental encoders of CJK codecs at each call to their encode() method anymore, but continue to call the reset() method if the final argument is True.
- **Issue #12049**: Add RAND_bytes() and RAND_pseudo_bytes() functions to the ssl module.
- **Issue #6501**: os.device_encoding() returns None on Windows if
the application has no console.

- **Issue #12105**: Add O_CLOEXEC to the os module.
- **Issue #12079**: `Decimal('Infinity').fma(Decimal('0'), (3.91224318126786e+19+0j))` now raises TypeError (reflecting the invalid type of the 3rd argument) rather than `Decimal.InvalidOperation`.
- **Issue #12124**: zipimport doesn’t keep a reference to `zlib.decompress()` anymore to be able to unload the module.
- **Issue #12065**: `connect_ex()` on an SSL socket now returns the original errno when the socket’s timeout expires (it used to return None).
- **Issue #8809**: The SMTP_SSL constructor and SMTP.starttls() now support passing a `context` argument pointing to an `ssl.SSLContext` instance. Patch by Kasun Herath.
- **Issue #9516**: avoid errors in sysconfig when `MACOSX_DEPLOYMENT_TARGET` is set in shell.
- **Issue #8650**: Make zlib module 64-bit clean. `compress()`, `decompress()` and their incremental counterparts now raise `OverflowError` if given an input larger than 4GB, instead of silently truncating the input and returning an incorrect result.
- **Issue #12050**: `zlib.decompressobj().decompress()` now clears the unconsumed_tail attribute when called without a `max_length` argument.
- **Issue #12062**: Fix a flushing bug when doing a certain type of I/O sequence on a file opened in read+write mode (namely: reading, seeking a bit forward, writing, then seeking before the previous write but still within buffered data, and writing again).
- **Issue #9971**: Write an optimized implementation of `BufferedReader.readinto()`. Patch by John O'Connor.
- **Issue #11799**: `urllib.request Authentication Handlers` will raise a `ValueError` when presented with an unsupported Authentication Scheme. Patch contributed by Yuval Greenfield.
• **Issue #10419**, #6011: build_scripts command of distutils handles correctly non-ASCII path (path to the Python executable). Open and write the script in binary mode, but ensure that the shebang is decodable from UTF-8 and from the encoding of the script.

• **Issue #8498**: In socket.accept(), allow to specify 0 as a backlog value in order to accept exactly one connection. Patch by Daniel Evers.

• **Issue #12011**: signal.signal() and signal.siginterrupt() raise an OSError, instead of a RuntimeError: OSError has an errno attribute.

• **Issue #3709**: add a flush_headers method to BaseHTTPRequestHandler, which manages the sending of headers to output stream and flushing the internal headers buffer. Patch contribution by Andrew Schaaf

• **Issue #11743**: Rewrite multiprocessing connection classes in pure Python.

• **Issue #11164**: Stop trying to use _xmlplus in the xml module.

• **Issue #11888**: Add log2 function to math module. Patch written by Mark Dickinson.

• **Issue #12012**: ssl.PROTOCOL_SSLv2 becomes optional.

• **Issue #8407**: The signal handler writes the signal number as a single byte instead of a nul byte into the wakeup file descriptor. So it is possible to wait more than one signal and know which signals were raised.

• **Issue #8407**: Add pthread_kill(), sigpending() and sigwait() functions to the signal module.

• **Issue #11927**: SMTP_SSL now uses port 465 by default as documented. Patch by Kasun Herath.

• **Issue #12002**: ftplib’s abort() method raises TypeError.

• **Issue #11916**: Add a number of MacOSX specific definitions to the errno module. Patch by Pierre Carrier.

• **Issue #11999**: fixed sporadic sync failure mailbox.Maildir due to its trying to detect mtime changes by comparing to the system clock instead of to the previous value of the mtime.
- Issue #11072: added MLSD command (RFC-3659) support to ftplib.
- Issue #8808: The IMAP4_SSL constructor now allows passing an SSLContext parameter to control parameters of the secure channel. Patch by Sijin Joseph.
- ntpath.samefile failed to notice that “a.txt” and “A.TXT” refer to the same file on Windows XP. As noticed in issue #10684.
- Issue #12000: When a SSL certificate has a subjectAltName without any dNSName entry, ssl.match_hostname() should use the subject’s commonName. Patch by Nicolas Bareil.
- Issue #10775: assertRaises, assertRaisesRegex, assertWarns, and assertWarnsRegex now accept a keyword argument ‘msg’ when used as context managers. Initial patch by Winston Ewert.
- Issue #10684: shutil.move used to delete a folder on case insensitive filesystems when the source and destination name where the same except for the case.
- Issue #11647: objects created using contextlib.contextmanager now support more than one call to the function when used as a decorator. Initial patch by Ysj Ray.
- Issue #11930: Removed deprecated time.accept2dyear variable. Removed year >= 1000 restriction from datetime.strftime.
- logging: don’t define QueueListener if Python has no thread support.
- functools.cmp_to_key() now works with collections.Hashable().
- Issue #11277: mmap.mmap() calls fcntl(fd, F_FULLFSYNC) on Mac OS X to get around a mmap bug with sparse files. Patch written by Steffen Daode Nurpmeso.
- Issue #8407: Add signal.pthread_sigmask() function to fetch and/or change the signal mask of the calling thread.
- Issue #11858: configparser.ExtendedInterpolation expected lowercase section names.
- Issue #11324: ConfigParser(interpolation=None) now works correctly.
- Issue #11811: ssl.get_server_certificate() is now IPv6-compatible.
Patch by Charles-François Natali.

- **Issue #11763**: don't use difflib in `TestCase.assertMultiLineEqual` if the strings are too long.
- **Issue #11236**: `getpass.getpass` responds to ctrl-c or ctrl-z on terminal.
- **Issue #11856**: Speed up parsing of JSON numbers.
- **Issue #11005**: `threading.RLock()._release_save()` raises a `RuntimeError` if the lock was not acquired.
- **Issue #11258**: Speed up `ctypes.util.find_library()` under Linux by a factor of 5 to 10. Initial patch by Jonas H.
- **Issue #11382**: Trivial system calls, such as `dup()` or `pipe()`, needn't release the GIL. Patch by Charles-François Natali.
- **Issue #11223**: Add `threading._info()` function providing informations about the thread implementation.
- **Issue #11731**: simplify/enhance email parser/generator API by introducing policy objects.
- **Issue #11768**: The signal handler of the signal module only calls `Py_AddPendingCall()` for the first signal to fix a deadlock on reentrant or parallel calls. `PyErr_SetInterrupt()` writes also into the wake up file.
- **Issue #11492**: fix several issues with header folding in the email package.
- **Issue #11852**: Add missing imports and update tests.
- **Issue #11875**: `collections.OrderedDict.__reduce__` was temporarily mutating the object instead of just working on a copy.
- **Issue #11467**: Fix `urlparse` behavior when handling urls which contains scheme specific part only digits. Patch by Santoso Wijaya.
- `collections.Counter().copy()` now works correctly for subclasses.
- **Issue #11474**: Fix the bug with `url2pathname()` handling of `'\C\'` on Windows. Patch by Santoso Wijaya.
- **Issue #11684**: complete `email.parser` bytes API by adding `BytesHeaderParser`.
- The `bz2` module now handles 4GiB+ input buffers correctly.
• **Issue #9233**: Fix `json.loads('{}')` to return a dict (instead of a list), when `_json` is not available.
• **Issue #11830**: Remove unnecessary introspection code in the decimal module.
• **Issue #11703**: `urlib2.geturl()` does not return correct url when the original url contains `#fragment`.
• **Issue #10019**: Fixed regression in `json` module where an indent of 0 stopped adding newlines and acted instead like ‘None’.
• **Issue #11186**: `pydoc` ignores a module if its name contains a surrogate character in the index of modules.
• **Issue #11815**: Use a light-weight `SimpleQueue` for the result queue in `concurrent.futures.ProcessPoolExecutor`.
• **Issue #5162**: Treat services like frozen executables to allow child spawning from multiprocessing.forking on Windows.
• `logging.basicConfig` now supports an optional ‘handlers’ argument taking an iterable of handlers to be added to the root logger. Additional parameter checks were also added to `basicConfig`.
• **Issue #11814**: Fix likely typo in `multiprocessing.Pool._terminate()`.
• **Issue #11747**: Fix range formatting in `difflib.context_diff()` and `difflib.unified_diff()`.
• **Issue #8428**: Fix a race condition in `multiprocessing.Pool` when terminating worker processes: new processes would be spawned while the pool is being shut down. Patch by Charles-François Natali.
• **Issue #2650**: `re.escape()` no longer escapes the ‘_’.
• **Issue #11757**: `select.select()` now raises `ValueError` when a negative timeout is passed (previously, a `select.error` with EINVAL would be raised). Patch by Charles-François Natali.
• **Issue #7311**: fix `html.parser` to accept non-ASCII attribute values.
• **Issue #11605**: `email.parser.BytesFeedParser` was incorrectly converting multipart subparts with an 8-bit CTE into unicode instead of preserving the bytes.
• **Issue #1690608**: `email.util.formataddr` is now RFC 2047 aware: it now has a charset parameter that defaults to utf-8 and is used as
the charset for RFC 2047 encoding when the realname contains non-ASCII characters.

- **Issue #10963**: Ensure that subprocess.communicate() never raises EPIPE.
- **Issue #10791**: Implement missing method GzipFile.read1(), allowing GzipFile to be wrapped in a TextIOWrapper. Patch by Nadeem Vawda.
- **Issue #11707**: Added a fast C version of functools.cmp_to_key(). Patch by Filip Gruszczynski.
- **Issue #11688**: Add sqlite3.Connection.set_trace_callback(). Patch by Torsten Landschoff.
- **Issue #11746**: Fix SSLContext.load_cert_chain() to accept elliptic curve private keys.
- **Issue #5863**: Rewrite BZ2File in pure Python, and allow it to accept file-like objects using a new fileobj constructor argument. Patch by Nadeem Vawda.
- unittest.TestCase.assertSameElements has been removed.
- sys.getfilesystemencoding() raises a RuntimeError if initfsencoding() was not called yet: detect bootstrap (startup) issues earlier.
- **Issue #11393**: Add the new faulthandler module.
- **Issue #11618**: Fix the timeout logic in threading.Lock.acquire() under Windows.
- Removed the ‘strict’ argument to email.parser.Parser, which has been deprecated since Python 2.4.
- **Issue #11256**: Fix inspect.getcallargs on functions that take only keyword arguments.
- **Issue #11696**: Fix ID generation in msilib.
- itertools.accumulate now supports an optional func argument for a user-supplied binary function.
- **Issue #11692**: Remove unnecessary demo functions in subprocess module.
- **Issue #9696**: Fix exception incorrectly raised by xdrlib.Packer.pack_int when trying to pack a negative (in-range)
• **Issue #11675**: multiprocessing. Array objects created from an integer size are now zeroed on creation. This matches the behaviour specified by the documentation.

• **Issue #7639**: Fix short file name generation in bdist_msi

• **Issue #11635**: Don’t use polling in worker threads and processes launched by concurrent.futures.

• **Issue #6811**: Allow importlib to change a code object’s co_filename attribute to match the path to where the source code currently is, not where the code object originally came from.

• **Issue #8754**: Have importlib use the repr of a module name in error messages.

• **Issue #11591**: Prevent “import site” from modifying sys.path when python was started with -S.

• **collections.namedtuple()** now adds a _source attribute to the generated class. This make the source more accessible than the outdated “verbose” option which prints to stdout but doesn’t make the source string available.

• **Issue #11371**: Mark getopt error messages as localizable. Patch by Filip Gruszczynski.

• **Issue #11333**: Add __slots__ to collections ABCs.

• **Issue #11628**: cmp_to_key generated class should use __slots__.

• **Issue #11666**: let help() display named tuple attributes and methods that start with a leading underscore.

• **Issue #11662**: Make urllib and urllib2 ignore redirections if the scheme is not HTTP, HTTPS or FTP (CVE-2011-1521).

• **Issue #5537**: Fix time2isoz() and time2netscape() functions of httplib.cookiejar for expiration year greater than 2038 on 32-bit systems.

• **Issue #4391**: Use proper gettext plural forms in optparse.

• **Issue #11127**: Raise a TypeError when trying to pickle a socket object.

• **Issue #11563**: **Connection: close** header is sent by requests using URLopener class which helps in closing of sockets after
connection is over. Patch contributions by Jeff McNeil and Nadeem Vawda.

- **Issue #11459**: A `bufsize` value of 0 in subprocess.Popen() really creates unbuffered pipes, such that select() works properly on them.
- **Issue #5421**: Fix misleading error message when one of socket.sendto()'s arguments has the wrong type. Patch by Nikita Vetoshkin.
- **Issue #10812**: Add some extra posix functions to the os module.
- **Issue #10979**: unittest stdout buffering now works with class and module setup and teardown.
- **Issue #11243**: fix the parameter querying methods of Message to work if the headers contain un-encoded non-ASCII data.
- **Issue #11401**: fix handling of headers with no value; this fixes a regression relative to Python2 and the result is now the same as it was in Python2.
- **Issue #9298**: base64 bodies weren’t being folded to line lengths less than 78, which was a regression relative to Python2. Unlike Python2, the last line of the folded body now ends with a carriage return.
- **Issue #11560**: shutil.unpack_archive now correctly handles the format parameter. Patch by Evan Dandrea.
- **Issue #5870**: Add `subprocess.DEVNULL` constant.
- **Issue #11133**: fix two cases where inspect.getattr_static can trigger code execution. Patch by Andreas Stührk.
- **Issue #11569**: use absolute path to the sysctl command in multiprocessing to ensure that it will be found regardless of the shell PATH. This ensures that multiprocessing.cpu_count works on default installs of MacOSX.
- **Issue #11501**: disutils.archive_utils.make_zipfile no longer fails if zlib is not installed. Instead, the zipfile.ZIP_STORED compression is used to create the ZipFile. Patch by Natalia B. Bidart.
- **Issue #11289**: smtp.SMTP class is now a context manager so it can be used in a with statement. Contributed by Giampaolo
Rodola.

- **Issue #11554**: Fixed support for Japanese codecs; previously the body output encoding was not done if euc-jp or shift-jis was specified as the charset.
- **Issue #11407**: `TestCase.run` returns the result object used or created. Contributed by Janathan Hartley.
- **Issue #11500**: Fixed a bug in the OS X proxy bypass code for fully qualified IP addresses in the proxy exception list.
- **Issue #11491**: `dbm.error` is no longer raised when `dbm.open` is called with the “n” as the flag argument and the file exists. The behavior matches the documentation and general logic.
- **Issue #1162477**: Postel Principle adjustment to email date parsing: handle the fact that some non-compliant MUAs use ‘.’ instead of ‘:’ in time specs.
- **Issue #11131**: Fix sign of zero in `decimal.Decimal` plus and minus operations when the rounding mode is ROUND_FLOOR.
- **Issue #9935**: Speed up pickling of instances of user-defined classes.
- **Issue #5622**: Fix curses.wrapper to raise correct exception if curses initialization fails.
- **Issue #11408**: In `threading.Lock.acquire()`, only call `gettimeofday()` when really necessary. Patch by Charles-François Natali.
- **Issue #11391**: Writing to a `mmap` object created with `mmap.PROT_READ|mmap.PROT_EXEC` would segfault instead of raising a `TypeError`. Patch by Charles-François Natali.
- **Issue #9795**: Add context manager protocol support for `nntplib.NNTP` class.
- **Issue #11306**: Mailbox in certain cases adapts to an inability to open certain files in read-write mode. Previously it detected this by checking for EACCES, now it also checks for EROFS.
- **Issue #11265**: asyncore now correctly handles EPIPE, EBADF and EAGAIN errors on `accept()`, `send()` and `recv()`.
- **Issue #11377**: Deprecate `platform.popen()` and reimplement it with `os.popen()`.
- **Issue #8513**: On UNIX, subprocess supports bytes command string.
- **Issue #10866**: Add socket.sethostname(). Initial patch by Ross Lagerwall.
- **Issue #11140**: Lock.release() now raises a RuntimeError when attempting to release an unacquired lock, as claimed in the threading documentation. The _thread.error exception is now an alias of RuntimeError. Patch by Filip Gruszczyński. Patch for _dummy_thread by Aymeric Augustin.
- **Issue #8594**: ftplib now provides a source_address parameter to specify which (address, port) to bind to before connecting.
- **Issue #11326**: Add the missing connect_ex() implementation for SSL sockets, and make it work for non-blocking connects.
- **Issue #11297**: Add collections.ChainMap().
- **Issue #10755**: Add the posix.flistdir() function. Patch by Ross Lagerwall.
- **Issue #4761**: Add the *at() family of functions (openat(), etc.) to the posix module. Patch by Ross Lagerwall.
- **Issue #7322**: Trying to read from a socket’s file-like object after a timeout occurred now raises an error instead of silently losing data.
- **Issue #11291**: poplib.POP no longer suppresses errors on quit().
- **Issue #11177**: asyncore’s create_socket() arguments can now be omitted.
- **Issue #6064**: Add a daemon keyword argument to the threading.Thread and multiprocessing.Process constructors in order to override the default behaviour of inheriting the daemonic property from the current thread/process.
- **Issue #10956**: Buffered I/O classes retry reading or writing after a signal has arrived and the handler returned successfully.
- **Issue #10784**: New os.getpriority() and os.setpriority() functions.
- **Issue #11114**: Fix catastrophic performance of tell() on text files (up to 1000x faster in some cases). It is still one to two order of magnitudes slower than binary tell().
- **Issue #10882**: Add os.sendfile function.
- **Issue #10868**: Allow usage of the register method of an ABC as a class decorator.
- **Issue #11224**: Fixed a regression in tarfile that affected the file-like objects returned by TarFile.extractfile() regarding performance, memory consumption and failures with the stream interface.
- **Issue #10924**: Adding salt and Modular Crypt Format to crypt library. Moved old C wrapper to _crypt, and added a Python wrapper with enhanced salt generation and simpler API for password generation.
- **Issue #11074**: Make ‘tokenize’ so it can be reloaded.
- **Issue #11085**: Moved collections abstract base classes into a separate module called collections.abc, following the pattern used by importlib.abc. For backwards compatibility, the names are imported into the collections module.
- **Issue #4681**: Allow mmap() to work on file sizes and offsets larger than 4GB, even on 32-bit builds. Initial patch by Ross Lagerwall, adapted for 32-bit Windows.
- **Issue #11169**: compileall module uses repr() to format filenames and paths to escape surrogate characters and show spaces.
- **Issue #11089**: Fix performance issue limiting the use of ConfigParser() with large config files.
- **Issue #10276**: Fix the results of zlibcrc32() and zlib.adler32() on buffers larger than 4GB. Patch by Nadeem Vawda.
- **Issue #11388**: Added a clear() method to MutableSequence
- **Issue #11174**: Add argparse.MetavarTypeHelpFormatter, which uses type names for the names of optional and positional arguments in help messages.
- **Issue #9348**: Raise an early error if argparse nargs and metavar don't match.
- **Issue #9026**: Fix order of argparse sub-commands in help messages.
- **Issue #9347**: Fix formatting for tuples in argparse type= error messages.
• **Issue #12191**: Added shutil.chown() to change user and/or group owner of a given path also specifying their names.

• **Issue #13988**: The _elementtree accelerator is used whenever available. Now xml.etree.cElementTree becomes a deprecated alias to ElementTree.

### Build

• **Issue #6807**: Run msisupport.mak earlier.

• **Issue #10580**: Minor grammar change in Windows installer.

• **Issue #13326**: Clean __pycache__ directories correctly on OpenBSD.

• PEP 393: the configure option –with-wide-unicode is removed.

• **Issue #12852**: Set _XOPEN_SOURCE to 700, instead of 600, to get POSIX 2008 functions on OpenBSD (e.g. fdopendir).

• **Issue #11863**: Remove support for legacy systems deprecated in Python 3.2 (following PEP 11). These systems are systems using Mach C Threads, SunOS lightweight processes, GNU pth threads and IRIX threads.

• **Issue #8746**: Correct faulty configure checks so that os.chflags() and os.lchflags() are once again built on systems that support these functions (BSD and OS X). Also add new stat file flags for OS X (UF_HIDDEN and UF_COMPRESSED).

• **Issue #10645**: Installing Python no longer creates a Python-X.Y.Z- pyX.Y.egg-info file in the lib-dynload directory.

• Do not accidentally include the directory containing sqlite.h twice when building sqlite3.

• **Issue #11217**: For 64-bit/32-bit Mac OS X universal framework builds, ensure “make install” creates symlinks in –prefix bin for the “-32” files in the framework bin directory like the installer does.

• **Issue #11347**: Use –no-as-needed when linking libpython3.so.

• **Issue #11411**: Fix ‘make DESTDIR=' with a relative destination.

• **Issue #11268**: Prevent Mac OS X Installer failure if Documentation package had previously been installed.
• **Issue #11495**: OSF support is eliminated. It was deprecated in Python 3.2.

**IDLE**

• **Issue #14409**: IDLE now properly executes commands in the Shell window when it cannot read the normal config files on startup and has to use the built-in default key bindings. There was previously a bug in one of the defaults.
• IDLE can be launched as python -m idlelib
• **Issue #3573**: IDLE hangs when passing invalid command line args (directory(ies) instead of file(s)) (Patch by Guilherme Polo)
• **Issue #14200**: IDLE shell crash on printing non-BMP unicode character.
• **Issue #5219**: Prevent event handler cascade in IDLE.
• **Issue #964437**: Make IDLE help window non-modal. Patch by Guilherme Polo and Roger Serwy.
• **Issue #13933**: IDLE auto-complete did not work with some imported module, like hashlib. (Patch by Roger Serwy)
• **Issue #13506**: Add ‘” to path for IDLE Shell when started and restarted with Restart Shell. Original patches by Marco Scataglini and Roger Serwy.
• **Issue #4625**: If IDLE cannot write to its recent file or breakpoint files, display a message popup and continue rather than crash. Original patch by Roger Serwy.
• **Issue #8641**: Update IDLE 3 syntax coloring to recognize b”..” and not u”..”. Patch by Tal Einat.
• **Issue #13296**: Fix IDLE to clear compile __future__ flags on shell restart. (Patch by Roger Serwy)
• **Issue #9871**: Prevent IDLE 3 crash when given byte stings with invalid hex escape sequences, like b’x0’. (Original patch by Claudiu Popa.)
• **Issue #12636**: IDLE reads the coding cookie when executing a Python script.
• Issue #12540: Prevent zombie IDLE processes on Windows due to changes in os.kill().

• Issue #12590: IDLE editor window now always displays the first line when opening a long file. With Tk 8.5, the first line was hidden.

• Issue #11088: don’t crash when using F5 to run a script in IDLE on MacOSX with Tk 8.5.

• Issue #1028: Tk returns invalid Unicode null in %A: UnicodeDecodeError. With Tk < 8.5 _tkinter.c:PythonCmd() raised UnicodeDecodeError, caused IDLE to exit. Converted to valid Unicode null in PythonCmd().

• Issue #11718: IDLE's open module dialog couldn't find the __init__.py file in a package.

Tools/Demos

• Issue #14053: patchcheck.py (“make patchcheck”) now works with MQ patches. Patch by Francisco Martín Brugué.

• Issue #13930: 2to3 is now able to write its converted output files to another directory tree as well as copying unchanged files and altering the file suffix. See its new -o, -W and –add-suffix options. This makes it more useful in many automated code translation workflows.

• Issue #13628: python-gdb.py is now able to retrieve more frames in the Python traceback if Python is optimized.

• Issue #11996: libpython (gdb), replace “py-bt” command by “py-bt-full” and add a smarter “py-bt” command printing a classic Python traceback.

• Issue #11179: Make ccbench work under Python 3.1 and 2.7 again.

• Issue #10639: reindent.py no longer converts newlines and will raise an error if attempting to convert a file with mixed newlines. “–newline” option added to specify new line character.
Extension Modules

- **Issue #16847**: Fixed improper use of `_PyUnicode_CheckConsistency()` in non-pydebug builds. Several extension modules now compile cleanly when assert()s are enabled in standard builds (-DDEBUG flag).
- **Issue #13840**: The error message produced by ctypes.create_string_buffer when given a Unicode string has been fixed.
- **Issue #9975**: socket: Fix incorrect use of flowinfo and scope_id. Patch by Vilmos Nebehaj.
- **Issue #7777**: socket: Add Reliable Datagram Sockets (PF_RDS) support.
- **Issue #13159**: FileIO and BZ2Compressor/BZ2Decompressor now use a linear-time buffer growth strategy instead of a quadratic-time one.
- **Issue #10141**: socket: Add SocketCAN (PF_CAN) support. Initial patch by Matthias Fuchs, updated by Tiago Gonçalves.
- **Issue #13070**: Fix a crash when a TextIOWrapper caught in a reference cycle would be finalized after the reference to its underlying BufferedRWPair’s writer got cleared by the GC.
- **Issue #12881**: ctypes: Fix segfault with large structure field names.
- **Issue #13058**: ossaudiodev: fix a file descriptor leak on error. Patch by Thomas Jarosch.
- **Issue #13013**: ctypes: Fix a reference leak in PyCArrayType_from_ctype. Thanks to Suman Saha for finding the bug and providing a patch.
- **Issue #13022**: Fix: `_multiprocessing.recvfd()` doesn’t check that file descriptor was actually received.
- **Issue #1172711**: Add ‘long long’ support to the array module. Initial patch by Oren Tirosh and Hirokazu Yamamoto.
- **Issue #12483**: ctypes: Fix a crash when the destruction of a
callback object triggers the garbage collector.

- **Issue #12950**: Fix passing file descriptors in multiprocessing, under OpenIndiana/Illumos.
- **Issue #12764**: Fix a crash in ctypes when the name of a Structure field is not a string.
- **Issue #11241**: subclasses of ctypes.Array can now be subclassed.
- **Issue #9651**: Fix a crash when ctypes.create_string_buffer(0) was passed to some functions like file.write().
- **Issue #10309**: Define _GNU_SOURCE so that mremap() gets the proper signature. Without this, architectures where sizeof void* != sizeof int are broken. Patch given by Hallvard B Furuseth.
- **Issue #12051**: Fix segfault in json.dumps() while encoding highly-nested objects using the C accelerations.
- **Issue #12017**: Fix segfault in json.loads() while decoding highly-nested objects using the C accelerations.
- **Issue #1838**: Prevent segfault in ctypes, when _as_parameter_ on a class is set to an instance of the class.

Tests

- **Issue #13125**: Silence spurious test_lib2to3 output when in non-verbose mode. Patch by Mikhail Novikov.
- **Issue #13447**: Add a test file to host regression tests for bugs in the scripts found in the Tools directory.
- **Issue #10881**: Fix test_site failure with OS X framework builds.
- **Issue #13901**: Prevent test_distutils failures on OS X with –enable-shared.
- **Issue #13862**: Fix spurious failure in test_zlib due to runtime/compile time minor versions not matching.
- **Issue #12804**: Fix test_socket and test_urllib2net failures when running tests on a system without internet access.
- **Issue #13726**: Fix the ambiguous -S flag in regtest. It is -o/–slow for slow tests.
- **Issue #11659**: Fix ResourceWarning in test_subprocess introduced by #11459. Patch by Ben Hayden.
- **Issue #11577**: fix ResourceWarning triggered by improved binhex test coverage
- **Issue #11509**: Significantly increase test coverage of fileinput. Patch by Denver Coneybeare at PyCon 2011 Sprints.
- **Issue #11689**: Fix a variable scoping error in an sqlite3 test
- **Issue #13786**: Remove unimplemented ‘trace’ long option from regrtest.py.
- **Issue #13725**: Fix regrtest to recognize the documented -d flag. Patch by Erno Tukia.
- **Issue #13304**: Skip test case if user site-packages disabled (-s or PYTHONNOUSERSITE). (Patch by Carl Meyer)
- **Issue #5661**: Add a test for ECONNRESET/EPIPE handling to test_asyncore. Patch by Xavier de Gaye.
- **Issue #13218**: Fix test_ssl failures on Debian/Ubuntu.
- Re-enable lib2to3’s test_parser.py tests, though with an expected failure (see issue 13125).
- **Issue #12656**: Add tests for IPv6 and Unix sockets to test_asyncore.
- **Issue #6484**: Add unit tests for mailcap module (patch by Gregory Nofi)
- **Issue #11651**: Improve the Makefile test targets to run more of the test suite more quickly. The –multiprocess option is now enabled by default, reducing the amount of time needed to run the tests. “make test” and “make quicktest” now include some resource-intensive tests, but no longer run the test suite twice to check for bugs in .pyc generation. Tools/scripts/run_test.py provides an easy platform-independent way to run test suite with sensible defaults.
- **Issue #12331**: The test suite for the packaging module can now run from an installed Python.
- **Issue #12331**: The test suite for lib2to3 can now run from an installed Python.
- **Issue #12626**: In regrttest, allow to filter tests using a glob filter with the `-m` (or `--match`) option. This works with all test cases using the unittest module. This is useful with long test suites such as test_io or test_subprocess.
- **Issue #12624**: It is now possible to fail after the first failure when running in verbose mode (`-v` or `-W`), by using the `--failfast` (or `-G`) option to regrttest. This is useful with long test suites such as test_io or test_subprocess.
- **Issue #12587**: Correct faulty test file and reference in `test_tokenize`. (Patch by Robert Xiao)
- **Issue #12573**: Add resource checks for dangling Thread and Process objects.
- **Issue #12549**: Correct test_platform to not fail when OS X returns ‘x86_64’ as the processor type on some Mac systems.
- Skip network tests when `getaddrinfo()` returns EAI_AGAIN, meaning a temporary failure in name resolution.
- **Issue #11812**: Solve transient socket failure to connect to ‘localhost’ in `test_telnetlib.py`.
- Solved a potential deadlock in `test_telnetlib.py`. Related to [issue #11812](#).
- Avoid failing in `test_robotparser` when mueblesmoraleda.com is flaky and an overzealous DNS service (e.g. OpenDNS) redirects to a placeholder Web site.
- Avoid failing in `test_urlibnet.test_bad_address` when some overzealous DNS service (e.g. OpenDNS) resolves a non-existent domain name. The test is now skipped instead.
- **Issue #12440**: When testing whether some bits in `SSLContext.options` can be reset, check the version of the OpenSSL headers Python was compiled against, rather than the runtime version of the OpenSSL library.
- **Issue #11512**: Add a test suite for the cgitb module. Patch by Robbie Clemons.
- **Issue #12497**: Install test/data to prevent failures of the various codecmaps tests.
• **Issue #12496**: Install test/capath directory to prevent test_connect_capath testcase failure in test_ssl.

• **Issue #12469**: Run wakeup and pending signal tests in a subprocess to run the test in a fresh process with only one thread and to not change signal handling of the parent process.

• **Issue #8716**: Avoid crashes caused by Aqua Tk on OSX when attempting to run test_tk or test_ttk_guionly under a username that is not currently logged in to the console windowserver (as may be the case under buildbot or ssh).

• **Issue #12407**: Explicitly skip test_capi.EmbeddingTest under Windows.

• **Issue #12400**: regrttest -W doesn’t rerun the tests twice anymore, but captures the output and displays it on failure instead. regrttest -v doesn’t print the error twice anymore if there is only one error.

• **Issue #12141**: Install copies of template C module file so that test_build_ext of test_distutils and test_command_build_ext of test_packaging are no longer silently skipped when run outside of a build directory.

• **Issue #8746**: Add additional tests for os.chflags() and os.lchflags(). Patch by Garrett Cooper.

• **Issue #10736**: Fix test_tk test_widgets failures with Cocoa Tk 8.5.9 2.8 + on Mac OS X. (Patch by Ronald Oussoren)

• **Issue #12057**: Add tests for ISO 2022 codecs (iso2022_jp, iso2022_jp_2, iso2022_kr).

• **Issue #12096**: Fix a race condition in test_threading.test_waitfor(). Patch written by Charles-François Natali.

• **Issue #11614**: import __hello__ prints “Hello World!”. Patch written by Andreas Stührk.

• **Issue #5723**: Improve json tests to be executed with and without accelerations.

• **Issue #12041**: Make test_wait3 more robust.

• **Issue #11873**: Change regex in test_compileall to fix occasional failures when when the randomly generated temporary path happened to match the regex.
- **Issue #11958**: Fix FTP tests for IPv6, bind to ":1" instead of "localhost". Patch written by Charles-Francois Natali.
- **Issue #8407, #11859**: Fix tests of test_io using threads and an alarm: use `pthread_sigmask()` to ensure that the SIGALRM signal is received by the main thread.
- **Issue #11811**: Factor out detection of IPv6 support on the current host and make it available as `test.support.IPV6_ENABLED`. Patch by Charles-François Natali.
- **Issue #10914**: Add a minimal embedding test to `test_capi`.
- **Issue #11223**: Skip `test_lock_acquire_interruption()` and `test_rlock_acquire_interruption()` of `test_threadsignals` if a thread lock is implemented using a POSIX mutex and a POSIX condition variable. A POSIX condition variable cannot be interrupted by a signal (e.g. on Linux, the futex system call is restarted).
- **Issue #11790**: Fix sporadic failures in `test_multiprocessing.WithProcessesTestCondition`.
- Fix possible "file already exists" error when running the tests in parallel.
- **Issue #11719**: Fix message about unexpected `test_msilib` skip on non-Windows platforms. Patch by Nadeem Vawda.
- **Issue #11727**: Add a –timeout option to regrtest: if a test takes more than TIMEOUT seconds, dumps the traceback of all threads and exits.
- **Issue #11653**: fix -W with -j in regrtest.
- The email test suite now lives in the Lib/test/test_email package. The test harness code has also been modernized to allow use of new unittest features.
- regrtest now discovers test packages as well as test modules.
- **Issue #11577**: improve test coverage of binhex.py. Patch by Arkady Koplyarov.
- New test_crashers added to exercise the scripts in the Lib/test/crashers directory and confirm they fail as expected
- **Issue #11578**: added test for the timeit module. Patch by Michael Henry.
• **Issue #11503**: improve test coverage of posixpath.py. Patch by Evan Dandrea.

• **Issue #11505**: improves test coverage of string.py, increases granularity of string.Formatter tests. Initial patch by Alicia Arlen.

• **Issue #11548**: Improve test coverage of the shutil module. Patch by Evan Dandrea.

• **Issue #11554**: Reactivated test_email_codecs.

• **Issue #11505**: improves test coverage of string.py. Patch by Alicia Arlen

• **Issue #11490**: test_subprocess.test_leaking_fds_on_error no longer gives a false positive if the last directory in the path is inaccessible.

• **Issue #11223**: Fix test_threads signals to fail, not hang, when the non-semaphore implementation of locks is used under POSIX.

• **Issue #10911**: Add tests on CGI with non-ASCII characters. Patch written by Pierre Quentel.

• **Issue #9931**: Fix hangs in GUI tests under Windows in certain conditions. Patch by Hirokazu Yamamoto.

• **Issue #10512**: Properly close sockets under test.test_cgi.

• **Issue #10992**: Make tests pass under coverage.

• **Issue #10826**: Prevent sporadic failure in test_subprocess on Solaris due to open door files.

• **Issue #10990**: Prevent tests from clobbering a set trace function.

**C-API**

• **Issue #13452**: PyUnicode_EncodeDecimal() doesn’t support error handlers different than “strict” anymore. The caller was unable to compute the size of the output buffer: it depends on the error handler.

• **Issue #13560**: Add PyUnicode_DecodeLocale(), PyUnicode_DecodeLocaleAndSize() and PyUnicode_EncodeLocale() functions to the C API to decode/encode from/to the current locale encoding.
- **Issue #10831**: PyUnicode_FromFormat() supports %li, %lli and %zi formats.
- **Issue #11246**: Fix PyUnicode_FromFormat(“%V”) to decode the byte string from UTF-8 (with replace error handler) instead of ISO-8859-1 (in strict mode). Patch written by Ray Allen.
- **Issue #10830**: Fix PyUnicode_FromFormatV(“%c”) for non-BMP characters on narrow build.
- Add PyObject_GenericGetDict and PyObject_GenericSetDict. They are generic implementations for the getter and setter of a __dict__ descriptor of C types.
- **Issue #13727**: Add 3 macros to access PyDateTime_Delta members: PyDateTime_DELTA_GET_DAYS, PyDateTime_DELTA_GET_SECONDS, PyDateTime_DELTA_GET_MICROSECONDS.
- **Issue #10542**: Add 4 macros to work with surrogates: Py_UNICODE_IS_SURROGATE, Py_UNICODE_IS_HIGH_SURROGATE, Py_UNICODE_IS_LOW_SURROGATE, Py_UNICODE_JOIN_SURROGATES.
- **Issue #12724**: Add Py_RETURN_NOTIMPLEMENTED macro for returning NotImplemented.
- PY_PATCHLEVEL_REVISION has been removed, since it's meaningless with Mercurial.
- **Issue #12173**: The first argument of PyImport_ImportModuleLevel is now const char * instead of char *.
- **Issue #12380**: PyArg_ParseTuple now accepts a bytearray for the ‘c’ format.

**Documentation**

- **Issue #13989**: Document that GzipFile does not support text mode, and give a more helpful error message when opened with an invalid mode string.
- **Issue #13921**: Undocument and clean up
sqlite3.OptimizedUnicode, which is obsolete in Python 3.x. It’s now aliased to str for backwards compatibility.

- **Issue #12102**: Document that buffered files must be flushed before being used with mmap. Patch by Steffen Daode Nurpmeso.
- **Issue #8982**: Improve the documentation for the argparse Namespace object.
- **Issue #9343**: Document that argparse parent parsers must be configured before their children.
- **Issue #13498**: Clarify docs of os.makedirs()'s exist_ok argument. Done with great native-speaker help from R. David Murray.
- **Issues #13491 and #13995**: Fix many errors in sqlite3 documentation. Initial patch for #13491 by Johannes Vogel.
- **Issue #13402**: Document absoluteness of sys.executable.
- **Issue #13883**: PYTHONCASEOK also works on OS X.
- **Issue #9021**: Add an introduction to the copy module documentation.
- **Issue #6005**: Examples in the socket library documentation use sendall, where relevant, instead send method.
- **Issue #12798**: Updated the mimetypes documentation.
- **Issue #12949**: Document the kwonlyargcount argument for the PyCode_New C API function.
- **Issue #13513**: Fix io.IOBase documentation to correctly link to the io.IOBase.readline method instead of the readline module.
- **Issue #13237**: Reorganise subprocess documentation to emphasise convenience functions and the most commonly needed arguments to Popen.
- **Issue #13141**: Demonstrate recommended style for socketserver examples.
- **Issue #11818**: Fix tempfile examples for Python 3.

*(For information about older versions, consult the HISTORY file.)*
1. Whetting Your Appetite

If you do much work on computers, eventually you find that there’s some task you’d like to automate. For example, you may wish to perform a search-and-replace over a large number of text files, or rename and rearrange a bunch of photo files in a complicated way. Perhaps you’d like to write a small custom database, or a specialized GUI application, or a simple game.

If you’re a professional software developer, you may have to work with several C/C++/Java libraries but find the usual write/compile/test/re-compile cycle is too slow. Perhaps you’re writing a test suite for such a library and find writing the testing code a tedious task. Or maybe you’ve written a program that could use an extension language, and you don’t want to design and implement a whole new language for your application.

Python is just the language for you.

You could write a Unix shell script or Windows batch files for some of these tasks, but shell scripts are best at moving around files and changing text data, not well-suited for GUI applications or games. You could write a C/C++/Java program, but it can take a lot of development time to get even a first-draft program. Python is simpler to use, available on Windows, Mac OS X, and Unix operating systems, and will help you get the job done more quickly.

Python is simple to use, but it is a real programming language, offering much more structure and support for large programs than shell scripts or batch files can offer. On the other hand, Python also offers much more error checking than C, and, being a very-high-level language, it has high-level data types built in, such as flexible arrays and
dictionaries. Because of its more general data types Python is applicable to a much larger problem domain than Awk or even Perl, yet many things are at least as easy in Python as in those languages.

Python allows you to split your program into modules that can be reused in other Python programs. It comes with a large collection of standard modules that you can use as the basis of your programs — or as examples to start learning to program in Python. Some of these modules provide things like file I/O, system calls, sockets, and even interfaces to graphical user interface toolkits like Tk.

Python is an interpreted language, which can save you considerable time during program development because no compilation and linking is necessary. The interpreter can be used interactively, which makes it easy to experiment with features of the language, to write throw-away programs, or to test functions during bottom-up program development. It is also a handy desk calculator.

Python enables programs to be written compactly and readably. Programs written in Python are typically much shorter than equivalent C, C++, or Java programs, for several reasons:

- the high-level data types allow you to express complex operations in a single statement;
- statement grouping is done by indentation instead of beginning and ending brackets;
- no variable or argument declarations are necessary.

Python is extensible: if you know how to program in C it is easy to add a new built-in function or module to the interpreter, either to perform critical operations at maximum speed, or to link Python programs to libraries that may only be available in binary form (such as a vendor-specific graphics library). Once you are really hooked, you can link the
Python interpreter into an application written in C and use it as an extension or command language for that application.

By the way, the language is named after the BBC show “Monty Python’s Flying Circus” and has nothing to do with reptiles. Making references to Monty Python skits in documentation is not only allowed, it is encouraged!

Now that you are all excited about Python, you'll want to examine it in some more detail. Since the best way to learn a language is to use it, the tutorial invites you to play with the Python interpreter as you read.

In the next chapter, the mechanics of using the interpreter are explained. This is rather mundane information, but essential for trying out the examples shown later.

The rest of the tutorial introduces various features of the Python language and system through examples, beginning with simple expressions, statements and data types, through functions and modules, and finally touching upon advanced concepts like exceptions and user-defined classes.
2. Using the Python Interpreter
2.1. Invoking the Interpreter

The Python interpreter is usually installed as `/usr/local/bin/python3.3` on those machines where it is available; putting `/usr/local/bin` in your Unix shell's search path makes it possible to start it by typing the command:

```
python3.3
```

to the shell. [1] Since the choice of the directory where the interpreter lives is an installation option, other places are possible; check with your local Python guru or system administrator. (E.g., `/usr/local/python` is a popular alternative location.)

On Windows machines, the Python installation is usually placed in `C:\Python33`, though you can change this when you're running the installer. To add this directory to your path, you can type the following command into the command prompt in a DOS box:

```
set path=%path%;C:\python33
```

Typing an end-of-file character (`Control-D` on Unix, `Control-Z` on Windows) at the primary prompt causes the interpreter to exit with a zero exit status. If that doesn't work, you can exit the interpreter by typing the following command: `quit()`.

The interpreter's line-editing features usually aren't very sophisticated. On Unix, whoever installed the interpreter may have enabled support for the GNU readline library, which adds more elaborate interactive editing and history features. Perhaps the quickest check to see whether command line editing is supported is typing `Control-P` to the first Python prompt you get. If it beeps, you have command line
editing; see Appendix Interactive Input Editing and History Substitution for an introduction to the keys. If nothing appears to happen, or if ^P is echoed, command line editing isn’t available; you’ll only be able to use backspace to remove characters from the current line.

The interpreter operates somewhat like the Unix shell: when called with standard input connected to a tty device, it reads and executes commands interactively; when called with a file name argument or with a file as standard input, it reads and executes a script from that file.

A second way of starting the interpreter is python -c command [arg] ..., which executes the statement(s) in command, analogous to the shell’s -c option. Since Python statements often contain spaces or other characters that are special to the shell, it is usually advised to quote command in its entirety with single quotes.

Some Python modules are also useful as scripts. These can be invoked using python -m module [arg] ..., which executes the source file for module as if you had spelled out its full name on the command line.

When a script file is used, it is sometimes useful to be able to run the script and enter interactive mode afterwards. This can be done by passing -i before the script.

2.1.1. Argument Passing

When known to the interpreter, the script name and additional arguments thereafter are turned into a list of strings and assigned to the argv variable in the sys module. You can access this list by executing import sys. The length of the list is at least one; when no script and no arguments are given, sys.argv[0] is an empty string.
When the script name is given as ' - ' (meaning standard input), sys.argv[0] is set to ' - '. When -c command is used, sys.argv[0] is set to '-c'. When -m module is used, sys.argv[0] is set to the full name of the located module. Options found after -c command or -m module are not consumed by the Python interpreter’s option processing but left in sys.argv for the command or module to handle.

2.1.2. Interactive Mode

When commands are read from a tty, the interpreter is said to be in interactive mode. In this mode it prompts for the next command with the primary prompt, usually three greater-than signs (>>>); for continuation lines it prompts with the secondary prompt, by default three dots (...). The interpreter prints a welcome message stating its version number and a copyright notice before printing the first prompt:

```
$ python3.3
Python 3.3 (default, Sep 24 2012, 09:25:04)
[GCC 4.6.3] on linux2
Type "help", "copyright", "credits" or "license" for more information.

>>> the_world_is_flat = 1
>>> if the_world_is_flat:
...     print("Be careful not to fall off!")
... Be careful not to fall off!
```
2.2. The Interpreter and Its Environment

2.2.1. Error Handling

When an error occurs, the interpreter prints an error message and a stack trace. In interactive mode, it then returns to the primary prompt; when input came from a file, it exits with a nonzero exit status after printing the stack trace. (Exceptions handled by an `except` clause in a `try` statement are not errors in this context.) Some errors are unconditionally fatal and cause an exit with a nonzero exit; this applies to internal inconsistencies and some cases of running out of memory. All error messages are written to the standard error stream; normal output from executed commands is written to standard output.

Typing the interrupt character (usually Control-C or DEL) to the primary or secondary prompt cancels the input and returns to the primary prompt. [2] Typing an interrupt while a command is executing raises the `KeyboardInterrupt` exception, which may be handled by a `try` statement.

2.2.2. Executable Python Scripts

On BSD’ish Unix systems, Python scripts can be made directly executable, like shell scripts, by putting the line

```
#!/usr/bin/env python3.3
```

(assuming that the interpreter is on the user’s PATH) at the beginning of the script and giving the file an executable mode. The `#!` must be the first two characters of the file. On some platforms, this first line must end with a Unix-style line ending (`\n`), not a Windows
Note that the hash, or pound, character, '#', is used to start a comment in Python.

The script can be given an executable mode, or permission, using the `chmod` command:

```bash
$ chmod +x myscript.py
```

On Windows systems, there is no notion of an “executable mode”. The Python installer automatically associates `.py` files with `python.exe` so that a double-click on a Python file will run it as a script. The extension can also be `.pyw`, in that case, the console window that normally appears is suppressed.

### 2.2.3. Source Code Encoding

By default, Python source files are treated as encoded in UTF-8. In that encoding, characters of most languages in the world can be used simultaneously in string literals, identifiers and comments — although the standard library only uses ASCII characters for identifiers, a convention that any portable code should follow. To display all these characters properly, your editor must recognize that the file is UTF-8, and it must use a font that supports all the characters in the file.

It is also possible to specify a different encoding for source files. In order to do this, put one more special comment line right after the `#!` line to define the source file encoding:

```bash
# -*- coding: encoding -*-
```

With that declaration, everything in the source file will be treated as having the encoding `encoding` instead of UTF-8. The list of possible
encodings can be found in the Python Library Reference, in the section on `codecs`.

For example, if your editor of choice does not support UTF-8 encoded files and insists on using some other encoding, say Windows-1252, you can write:

```
# -*- coding: cp-1252 -*-
```

and still use all characters in the Windows-1252 character set in the source files. The special encoding comment must be in the first or second line within the file.

### 2.2.4. The Interactive Startup File

When you use Python interactively, it is frequently handy to have some standard commands executed every time the interpreter is started. You can do this by setting an environment variable named `PYTHONSTARTUP` to the name of a file containing your start-up commands. This is similar to the `.profile` feature of the Unix shells.

This file is only read in interactive sessions, not when Python reads commands from a script, and not when `/dev/tty` is given as the explicit source of commands (which otherwise behaves like an interactive session). It is executed in the same namespace where interactive commands are executed, so that objects that it defines or imports can be used without qualification in the interactive session. You can also change the prompts `sys.ps1` and `sys.ps2` in this file.

If you want to read an additional start-up file from the current directory, you can program this in the global start-up file using code like `if os.path.isfile('./.pythonrc.py'):`
exec(open('.pythonrc.py').read()). If you want to use the startup file in a script, you must do this explicitly in the script:

```python
import os
filename = os.environ.get('PYTHONSTARTUP')
if filename and os.path.isfile(filename):
    exec(open(filename).read())
```

2.2.5. The Customization Modules

Python provides two hooks to let you customize it: sitecustomize and usercustomize. To see how it works, you need first to find the location of your user site-packages directory. Start Python and run this code:

```python
>>> import site
>>> site.getusersitepackages()
'/home/user/.local/lib/python3.2/site-packages'
```

Now you can create a file named `usercustomize.py` in that directory and put anything you want in it. It will affect every invocation of Python, unless it is started with the `-s` option to disable the automatic import.

`sitestatecustomize` works in the same way, but is typically created by an administrator of the computer in the global site-packages directory, and is imported before usercustomize. See the documentation of the `site` module for more details.

Footnotes

On Unix, the Python 3.x interpreter is by default not installed with the executable named `python`, so that it does not conflict
with a simultaneously installed Python 2.x executable.

[2] A problem with the GNU Readline package may prevent this.
3. An Informal Introduction to Python

In the following examples, input and output are distinguished by the presence or absence of prompts (>>> and ...): to repeat the example, you must type everything after the prompt, when the prompt appears; lines that do not begin with a prompt are output from the interpreter. Note that a secondary prompt on a line by itself in an example means you must type a blank line; this is used to end a multi-line command.

Many of the examples in this manual, even those entered at the interactive prompt, include comments. Comments in Python start with the hash character, #, and extend to the end of the physical line. A comment may appear at the start of a line or following whitespace or code, but not within a string literal. A hash character within a string literal is just a hash character. Since comments are to clarify code and are not interpreted by Python, they may be omitted when typing in examples.

Some examples:

```python
# this is the first comment
spam = 1  # and this is the second comment
    # ... and now a third!
# text = "# This is not a comment because it's inside
```
3.1. Using Python as a Calculator

Let's try some simple Python commands. Start the interpreter and wait for the primary prompt, `>>>`. (It shouldn't take long.)

3.1.1. Numbers

The interpreter acts as a simple calculator: you can type an expression at it and it will write the value. Expression syntax is straightforward: the operators `+`, `-`, `*` and `/` work just like in most other languages (for example, Pascal or C); parentheses `()` can be used for grouping. For example:

```
>>> 2 + 2
4
>>> 50 - 5*6
20
>>> (50 - 5*6) / 4
5.0
>>> 8 / 5  # division always returns a floating point
1.6
```

The integer numbers (e.g. 2, 4, 20) have type `int`, the ones with a fractional part (e.g. 5.0, 1.6) have type `float`. We will see more about numeric types later in the tutorial.

Division `/` always returns a float. To do floor division and get an integer result (discarding any fractional result) you can use the `//` operator; to calculate the remainder you can use `%:

```
>>> 17 / 3  # classic division returns a float
```

With Python is possible to use the ** operator to calculate powers [1]:

```
>>> 5 ** 2  # 5 squared
25
>>> 2 ** 7  # 2 to the power of 7
128
```

The equal sign (=) is used to assign a value to a variable. Afterwards, no result is displayed before the next interactive prompt:

```
>>> width = 20
>>> height = 5 * 9
>>> width * height
900
```

If a variable is not “defined” (assigned a value), trying to use it will give you an error:

```
>>> n  # try to access an undefined variable
Traceback (most recent call last):
  File "<stdin>", line 1, in <module>
NameError: name 'n' is not defined
```

There is full support for floating point; operators with mixed type operands convert the integer operand to floating point:
In interactive mode, the last printed expression is assigned to the variable `_`. This means that when you are using Python as a desk calculator, it is somewhat easier to continue calculations, for example:

```
>>> 3 * 3.75 / 1.5
7.5
>>> 7.0 / 2
3.5
```

This variable should be treated as read-only by the user. Don’t explicitly assign a value to it — you would create an independent local variable with the same name masking the built-in variable with its magic behavior.

In addition to `int` and `float`, Python supports other types of numbers, such as `Decimal` and `Fraction`. Python also has built-in support for `complex numbers`, and uses the `j` or `J` suffix to indicate the imaginary part (e.g. `3+5j`).

### 3.1.2. Strings

Besides numbers, Python can also manipulate strings, which can be expressed in several ways. They can be enclosed in single quotes (`'...'`) or double quotes (`"..."`) with the same result [2]. \ can be
used to escape quotes:

```
>>> 'spam eggs'  # single quotes
'spam eggs'
>>> 'doesn\'t'  # use \' to escape the single quote.
'doesn't'
>>> "doesn't"  # ...or use double quotes instead
'doesn't'
>>> '"Yes," he said.'
'"Yes," he said.'
>>> '"Yes,\" he said.'
'"Yes," he said.'
>>> '"Isn\'t," she said.'
'"Isn\'t," she said.'
```

In the interactive interpreter, the output string is enclosed in quotes and special characters are escaped with backslashes. While this might sometimes look different from the input (the enclosing quotes could change), the two strings are equivalent. The string is enclosed in double quotes if the string contains a single quote and no double quotes, otherwise it is enclosed in single quotes. The `print()` function produces a more readable output, by omitting the enclosing quotes and by printing escaped and special characters:

```
>>> '"Isn\'t," she said.'
'"Isn\'t," she said.'
>>> print('"Isn\'t," she said.')
'Isn\'t," she said.
>>> s = 'First line.\nSecond line.'  # \n means new line
>>> s  # without print(), \n is included in the output
'First line.\nSecond line.'
>>> print(s)  # with print(), \n produces a new line
First line.
Second line.
```
If you don’t want characters prefaced by `\` to be interpreted as special characters, you can use *raw strings* by adding an `r` before the first quote:

```python
>>> print('C:\some\name') # here \n means newline!
C:some
ame
>>> print(r'C:\some\name') # note the r before the quote
C:\some\name
```

String literals can span multiple lines. One way is using triple-quotes: """..."""" or '''...'''. End of lines are automatically included in the string, but it’s possible to prevent this by adding a `\` at the end of the line. The following example:

```python
print(""
Usage: thingy [OPTIONS]
    -h                          Display this usage message
    -H hostname                Hostname to connect to
"")
```

produces the following output (note that the initial newline is not included):

```
Usage: thingy [OPTIONS]
    -h                          Display this usage message
    -H hostname                Hostname to connect to
```

Strings can be concatenated (glued together) with the `+` operator, and repeated with `*`:

```python
>>> # 3 times 'un', followed by 'ium'
```
Two or more string literals (i.e. the ones enclosed between quotes) next to each other are automatically concatenated.

```
>>> 3 * 'un' + 'ium'
'unununium'
```

This only works with two literals though, not with variables or expressions:

```
>>> prefix = 'Py'
>>> prefix 'thon'  # can't concatenate a variable and a literal
... SyntaxError: invalid syntax
>>> ('un' * 3) 'ium'
... SyntaxError: invalid syntax
```

If you want to concatenate variables or a variable and a literal, use +:

```
>>> prefix + 'thon'
'Python'
```

This feature is particularly useful when you want to break long strings:

```
>>> text = ('Put several strings within parentheses to have them joined together.')
>>> text
'Put several strings within parentheses to have them joined together.'
```

Strings can be indexed (subscripted), with the first character having index 0. There is no separate character type; a character is simply a
string of size one:

```python
>>> word = 'Python'
>>> word[0]  # character in position 0
'P'
>>> word[5]  # character in position 5
'n'
```

Indices may also be negative numbers, to start counting from the right:

```python
>>> word[-1]  # last character
'n'
>>> word[-2]  # second-last character
'o'
>>> word[-6]  #
'P'
```

Note that since -0 is the same as 0, negative indices start from -1.

In addition to indexing, *slicing* is also supported. While indexing is used to obtain individual characters, *slicing* allows you to obtain substring:

```python
>>> word[0:2]  # characters from position 0 (inclusive)
'Py'
>>> word[2:5]  # characters from position 2 (inclusive)
'tho'
```

Note how the start is always included, and the end always excluded. This makes sure that `s[:i] + s[i:]` is always equal to `s`:

```python
>>> word[:2] + word[2:]
'Python'
>>> word[:4] + word[4:]
'Python'
```
Slice indices have useful defaults; an omitted first index defaults to zero, an omitted second index defaults to the size of the string being sliced.

```python
>>> word[:2]  # character from the beginning to position 2
'Py'
>>> word[4:]  # characters from position 4 (included)
'on'
>>> word[-2:] # characters from the second-last (inclusive)
'on'
```

One way to remember how slices work is to think of the indices as pointing between characters, with the left edge of the first character numbered 0. Then the right edge of the last character of a string of $n$ characters has index $n$, for example:

```
+---+---+---+---+---+---+
| P | y | t | h | o | n |
+---+---+---+---+---+---+
   0  1  2  3  4  5  6
-6  -5  -4  -3  -2  -1
```

The first row of numbers gives the position of the indices 0...6 in the string; the second row gives the corresponding negative indices. The slice from $i$ to $j$ consists of all characters between the edges labeled $i$ and $j$, respectively.

For non-negative indices, the length of a slice is the difference of the indices, if both are within bounds. For example, the length of `word[1:3]` is 2.

Attempting to use a index that is too large will result in an error:
However, out of range slice indexes are handled gracefully when used for slicing:

```python
>>> word[4:42]
'on'
>>> word[42:]
''
```

Python strings cannot be changed — they are immutable. Therefore, assigning to an indexed position in the string results in an error:

```python
>>> word[0] = 'J'
...
TypeError: 'str' object does not support item assignment
>>> word[2:] = 'py'
...
TypeError: 'str' object does not support item assignment
```

If you need a different string, you should create a new one:

```python
>>> 'J' + word[1:]  
'Jython'
>>> word[:2] + 'py'
'Pypy'
```

The built-in function `len()` returns the length of a string:

```python
>>> s = 'supercalifragilisticexpialidocious'
>>> len(s)
```

```python
Output: 44
```

**Text Sequence Type — str**

Strings are examples of sequence types, and support the common operations supported by such types.

**String Methods**

Strings support a large number of methods for basic transformations and searching.

**String Formatting**

Information about string formatting with `str.format()` is described here.

**printf-style String Formatting**

The old formatting operations invoked when strings and Unicode strings are the left operand of the `%` operator are described in more detail here.

### 3.1.3. Lists

Python knows a number of compound data types, used to group together other values. The most versatile is the `list`, which can be written as a list of comma-separated values (items) between square brackets. Lists might contain items of different types, but usually the items all have the same type.

```python
>>> squares = [1, 2, 4, 9, 16, 25]
>>> squares
[1, 2, 4, 9, 16, 25]
```

Like strings (and all other built-in sequence type), lists can be indexed and sliced:
All slice operations return a new list containing the requested elements. This means that the following slice returns a new (shallow) copy of the list:

```
>>> squares[:]
[1, 2, 4, 9, 16, 25]
```

Lists also support operations like concatenation:

```
>>> squares + [36, 49, 64, 81, 100]
[1, 2, 4, 9, 16, 25, 36, 49, 64, 81, 100]
```

Unlike strings, which are immutable, lists are a mutable type, i.e. it is possible to change their content:

```
>>> cubes = [1, 8, 27, 65, 125]  # something's wrong
>>> 4 ** 3  # the cube of 4 is 64, not 65!
64
>>> cubes[3] = 64  # replace the wrong value
>>> cubes
[1, 8, 27, 64, 125]
```

You can also add new items at the end of the list, by using the `append()` method (we will see more about methods later):

```
>>> cubes.append(216)  # add the cube of 6
>>> cubes.append(7 ** 3)  # and the cube of 7
```
Assignment to slices is also possible, and this can even change the size of the list or clear it entirely:

```python
>>> letters = ['a', 'b', 'c', 'd', 'e', 'f', 'g']
>>> letters
['a', 'b', 'c', 'd', 'e', 'f', 'g']
>>> # replace some values
>>> letters
['a', 'b', 'C', 'D', 'E', 'f', 'g']
>>> # now remove them
>>> letters[2:5] = []
>>> letters
['a', 'b', 'f', 'g']
>>> # clear the list by replacing all the elements with an empty list
>>> letters[:]=[]
>>> letters
[]
```

The built-in function `len()` also applies to lists:

```python
>>> letters = ['a', 'b', 'c', 'd']
>>> len(letters)
4
```

It is possible to nest lists (create lists containing other lists), for example:

```python
>>> a = ['a', 'b', 'c']
>>> n = [1, 2, 3]
>>> x = [a, n]
>>> x
```
[[['a', 'b', 'c'], [1, 2, 3]]

```python
>>> x[0]
['a', 'b', 'c']
```

```python
>>> x[0][1]
'b'
```
3.2. First Steps Towards Programming

Of course, we can use Python for more complicated tasks than adding two and two together. For instance, we can write an initial sub-sequence of the Fibonacci series as follows:

```python
>>> # Fibonacci series:
... # the sum of two elements defines the next
... a, b = 0, 1
>>> while b < 10:
...     print(b)
...     a, b = b, a+b
...
1
1
2
3
5
8
```

This example introduces several new features.

- The first line contains a *multiple assignment*: the variables `a` and `b` simultaneously get the new values 0 and 1. On the last line this is used again, demonstrating that the expressions on the right-hand side are all evaluated first before any of the assignments take place. The right-hand side expressions are evaluated from the left to the right.

- The `while` loop executes as long as the condition (here: `b < 10`) remains true. In Python, like in C, any non-zero integer value is true; zero is false. The condition may also be a string or list value, in fact any sequence; anything with a non-zero length is
true, empty sequences are false. The test used in the example is a simple comparison. The standard comparison operators are written the same as in C: `<` (less than), `>` (greater than), `==` (equal to), `<=` (less than or equal to), `>=` (greater than or equal to) and `!=` (not equal to).

- The body of the loop is *indented*: indentation is Python's way of grouping statements. At the interactive prompt, you have to type a tab or space(s) for each indented line. In practice you will prepare more complicated input for Python with a text editor; all decent text editors have an auto-indent facility. When a compound statement is entered interactively, it must be followed by a blank line to indicate completion (since the parser cannot guess when you have typed the last line). Note that each line within a basic block must be indented by the same amount.

- The `print()` function writes the value of the argument(s) it is given. It differs from just writing the expression you want to write (as we did earlier in the calculator examples) in the way it handles multiple arguments, floating point quantities, and strings. Strings are printed without quotes, and a space is inserted between items, so you can format things nicely, like this:

```python
>>> i = 256*256
>>> print('The value of i is', i)
The value of i is 65536
```

The keyword argument *end* can be used to avoid the newline after the output, or end the output with a different string:

```python
>>> a, b = 0, 1
>>> while b < 1000:
...    print(b, end=',')
```
... a, b = b, a+b
...
1, 1, 2, 3, 5, 8, 13, 21, 34, 55, 89, 144, 233, 377, 610, 987,

Footnotes

Since ** has higher precedence than -, -3**2 will be interpreted as -(3**2) and thus result in -9. To avoid this and get 9, you can use (-3)**2.

Unlike other languages, special characters such as \n have the same meaning with both single (' . . ') and double (" . . ") quotes. The only difference between the two is that within single quotes you don't need to escape " (but you have to escape \ ) and vice versa.
4. More Control Flow Tools

Besides the \texttt{while} statement just introduced, Python knows the usual control flow statements known from other languages, with some twists.
4.1. **if** Statements

Perhaps the most well-known statement type is the **if** statement. For example:

```python
>>> x = int(input("Please enter an integer: "))
Please enter an integer: 42
>>> if x < 0:
...     x = 0
...     print('Negative changed to zero')
... elif x == 0:
...     print('Zero')
... elif x == 1:
...     print('Single')
... else:
...     print('More')
More
```

There can be zero or more **elif** parts, and the **else** part is optional. The keyword `'elif'` is short for 'else if', and is useful to avoid excessive indentation. An **if** ... **elif** ... **elif** ... sequence is a substitute for the **switch** or **case** statements found in other languages.
4.2. **for** Statements

The **for** statement in Python differs a bit from what you may be used to in C or Pascal. Rather than always iterating over an arithmetic progression of numbers (like in Pascal), or giving the user the ability to define both the iteration step and halting condition (as C), Python’s **for** statement iterates over the items of any sequence (a list or a string), in the order that they appear in the sequence. For example (no pun intended):

```python
>>> # Measure some strings:
... words = ['cat', 'window', 'defenestrate']
>>> for w in words:
...     print(w, len(w))
... cat 3
window 6
defenestrate 12
```

If you need to modify the sequence you are iterating over while inside the loop (for example to duplicate selected items), it is recommended that you first make a copy. Iterating over a sequence does not implicitly make a copy. The slice notation makes this especially convenient:

```python
>>> for w in words[:]: # Loop over a slice copy of
...     if len(w) > 6:
...         words.insert(0, w)
... >>> words
['defenestrate', 'cat', 'window', 'defenestrate']
```
4.3. The `range()` Function

If you do need to iterate over a sequence of numbers, the built-in function `range()` comes in handy. It generates arithmetic progressions:

```python
>>> for i in range(5):
...     print(i)
... 0 1 2 3 4
```

The given end point is never part of the generated sequence; `range(10)` generates 10 values, the legal indices for items of a sequence of length 10. It is possible to let the range start at another number, or to specify a different increment (even negative; sometimes this is called the 'step'):

```python
range(5, 10)  
  5 through 9
range(0, 10, 3)  
  0, 3, 6, 9
range(-10, -100, -30)  
  -10, -40, -70
```

To iterate over the indices of a sequence, you can combine `range()` and `len()` as follows:
```python
>>> a = ['Mary', 'had', 'a', 'little', 'lamb']
>>> for i in range(len(a)):
...     print(i, a[i])
... 0 Mary
   1 had
   2 a
   3 little
   4 lamb
```

In most such cases, however, it is convenient to use the `enumerate()` function, see *Looping Techniques*.

A strange thing happens if you just print a range:

```python
>>> print(range(10))
range(0, 10)
```

In many ways the object returned by `range()` behaves as if it is a list, but in fact it isn’t. It is an object which returns the successive items of the desired sequence when you iterate over it, but it doesn’t really make the list, thus saving space.

We say such an object is *iterable*, that is, suitable as a target for functions and constructs that expect something from which they can obtain successive items until the supply is exhausted. We have seen that the `for` statement is such an *iterator*. The function `list()` is another; it creates lists from iterables:

```python
>>> list(range(5))
[0, 1, 2, 3, 4]
```

Later we will see more functions that return iterables and take iterables as argument.
4.4. break and continue Statements, and else Clauses on Loops

The break statement, like in C, breaks out of the smallest enclosing for or while loop.

Loop statements may have an else clause; it is executed when the loop terminates through exhaustion of the list (with for) or when the condition becomes false (with while), but not when the loop is terminated by a break statement. This is exemplified by the following loop, which searches for prime numbers:

```python
>>> for n in range(2, 10):
...     for x in range(2, n):
...         if n % x == 0:
...             print(n, 'equals', x, '*', n//x)
...             break
...     else:
...         # loop fell through without finding a factor
...         print(n, 'is a prime number')
...
2 is a prime number
3 is a prime number
4 equals 2 * 2
5 is a prime number
6 equals 2 * 3
7 is a prime number
8 equals 2 * 4
9 equals 3 * 3
```

(Yes, this is the correct code. Look closely: the else clause belongs to the for loop, not the if statement.)
When used with a loop, the `else` clause has more in common with the `else` clause of a `try` statement than it does that of `if` statements: a `try` statement’s `else` clause runs when no exception occurs, and a loop’s `else` clause runs when no `break` occurs. For more on the `try` statement and exceptions, see *Handling Exceptions*.

The `continue` statement, also borrowed from C, continues with the next iteration of the loop:

```python
>>> for num in range(2, 10):
...     if num % 2 == 0:
...         print("Found an even number", num)
...         continue
...     print("Found a number", num)
Found an even number 2
Found a number 3
Found an even number 4
Found a number 5
Found an even number 6
Found a number 7
Found an even number 8
Found a number 9
```
4.5. **pass** Statements

The **pass** statement does nothing. It can be used when a statement is required syntactically but the program requires no action. For example:

```python
>>> while True:
...    pass  # Busy-wait for keyboard interrupt (Ctrl+C)
...
```

This is commonly used for creating minimal classes:

```python
>>> class MyEmptyClass:
...    pass
...
```

Another place **pass** can be used is as a place-holder for a function or conditional body when you are working on new code, allowing you to keep thinking at a more abstract level. The **pass** is silently ignored:

```python
>>> def initlog(*args):
...    pass  # Remember to implement this!
...
```
4.6. Defining Functions

We can create a function that writes the Fibonacci series to an arbitrary boundary:

```python
def fib(n):
    # write Fibonacci series up to n
    '''Print a Fibonacci series up to n.'''
    a, b = 0, 1
    while a < n:
        print(a, end=' ')
        a, b = b, a+b
    print()
```

>>> # Now call the function we just defined:
... fib(2000)
0 1 1 2 3 5 8 13 21 34 55 89 144 233 377 610 987 1597
```

The keyword `def` introduces a function definition. It must be followed by the function name and the parenthesized list of formal parameters. The statements that form the body of the function start at the next line, and must be indented.

The first statement of the function body can optionally be a string literal; this string literal is the function's documentation string, or docstring. (More about docstrings can be found in the section Documentation Strings.) There are tools which use docstrings to automatically produce online or printed documentation, or to let the user interactively browse through code; it's good practice to include docstrings in code that you write, so make a habit of it.

The execution of a function introduces a new symbol table used for the local variables of the function. More precisely, all variable assignments
in a function store the value in the local symbol table; whereas variable references first look in the local symbol table, then in the local symbol tables of enclosing functions, then in the global symbol table, and finally in the table of built-in names. Thus, global variables cannot be directly assigned a value within a function (unless named in a `global` statement), although they may be referenced.

The actual parameters (arguments) to a function call are introduced in the local symbol table of the called function when it is called; thus, arguments are passed using *call by value* (where the *value* is always an object *reference*, not the value of the object). [1] When a function calls another function, a new local symbol table is created for that call.

A function definition introduces the function name in the current symbol table. The value of the function name has a type that is recognized by the interpreter as a user-defined function. This value can be assigned to another name which can then also be used as a function. This serves as a general renaming mechanism:

```python
>>> fib
<function fib at 10042ed0>
>>> f = fib
>>> f(100)
0 1 1 2 3 5 8 13 21 34 55 89
```

Coming from other languages, you might object that `fib` is not a function but a procedure since it doesn’t return a value. In fact, even functions without a `return` statement do return a value, albeit a rather boring one. This value is called None (it’s a built-in name). Writing the value None is normally suppressed by the interpreter if it would be the only value written. You can see it if you really want to using `print()`:
It is simple to write a function that returns a list of the numbers of the Fibonacci series, instead of printing it:

```python
>>> def fib2(n): # return Fibonacci series up to n ...
...     """Return a list containing the Fibonacci series up to n."""
...     result = []
...     a, b = 0, 1
...     while a < n:
...         result.append(a)  # see below
...         a, b = b, a+b
...     return result

>>> f100 = fib2(100)  # call it
>>> f100
[0, 1, 1, 2, 3, 5, 8, 13, 21, 34, 55, 89]
```

This example, as usual, demonstrates some new Python features:

- The `return` statement returns with a value from a function. `return` without an expression argument returns None. Falling off the end of a function also returns None.
- The statement `result.append(a)` calls a `method` of the list object `result`. A method is a function that 'belongs' to an object and is named `obj.methodname`, where `obj` is some object (this may be an expression), and `methodname` is the name of a method that is defined by the object's type. Different types define different methods. Methods of different types may have the same name without causing ambiguity. (It is possible to define your own object types and methods, using classes, see Classes) The method `append()` shown in the example is defined for list
objects; it adds a new element at the end of the list. In this example it is equivalent to \texttt{result = result + [a]}, but more efficient.
4.7. More on Defining Functions

It is also possible to define functions with a variable number of arguments. There are three forms, which can be combined.

4.7.1. Default Argument Values

The most useful form is to specify a default value for one or more arguments. This creates a function that can be called with fewer arguments than it is defined to allow. For example:

```python
def ask_ok(prompt, retries=4, complaint='Yes or no, please!'):
    ok = input(prompt)
    if ok in ('y', 'ye', 'yes'):
        return True
    if ok in ('n', 'no', 'nop', 'nope'):
        return False
    retries = retries - 1
    if retries < 0:
        raise IOError('refusenik user')
    print(complaint)
```

This function can be called in several ways:

- giving only the mandatory argument: `ask_ok('Do you really want to quit?')`
- giving one of the optional arguments: `ask_ok('OK to overwrite the file?', 2)`
- or even giving all arguments: `ask_ok('OK to overwrite the file?', 2, 'Come on, only yes or no!')`
This example also introduces the `in` keyword. This tests whether or not a sequence contains a certain value.

The default values are evaluated at the point of function definition in the defining scope, so that

```python
i = 5
def f(arg=i):
    print(arg)
i = 6
f()
```

will print 5.

**Important warning:** The default value is evaluated only once. This makes a difference when the default is a mutable object such as a list, dictionary, or instances of most classes. For example, the following function accumulates the arguments passed to it on subsequent calls:

```python
def f(a, L=[]):
    L.append(a)
    return L

print(f(1))
print(f(2))
print(f(3))
```

This will print

```
[1]
[1, 2]
[1, 2, 3]
```
If you don’t want the default to be shared between subsequent calls, you can write the function like this instead:

```python
def f(a, L=None):
    if L is None:
        L = []
    L.append(a)
    return L
```

### 4.7.2. Keyword Arguments

Functions can also be called using *keyword arguments* of the form `kwarg=value`. For instance, the following function:

```python
def parrot(voltage, state='a stiff', action='vroom',
           print("-- This parrot wouldn't", action, end='\n"
           print("if you put", voltage, "volts through it."
           print("-- Lovely plumage, the", type)
           print("-- It's", state, "!")
```

accepts one required argument (`voltage`) and three optional arguments (`state`, `action`, and `type`). This function can be called in any of the following ways:

```
parrot(1000)
parrot(voltage=1000)
parrot(voltage=1000000, action='V00000M')
parrot(action='V00000M', voltage=1000000)
parrot('a million', 'bereft of life', 'jump')
parrot('a thousand', state='pushing up the daisies')
```

but all the following calls would be invalid:
In a function call, keyword arguments must follow positional arguments. All the keyword arguments passed must match one of the arguments accepted by the function (e.g. `actor` is not a valid argument for the `parrot` function), and their order is not important. This also includes non-optional arguments (e.g. `parrot(voltage=1000)` is valid too). No argument may receive a value more than once. Here’s an example that fails due to this restriction:

```python
>>> def function(a):
...     pass
... >>> function(0, a=0)
Traceback (most recent call last):
  File "<stdin>", line 1, in ?
TypeError: function() got multiple values for keyword argument 'a'
```

When a final formal parameter of the form `**name` is present, it receives a dictionary (see `Mapping Types — dict`) containing all keyword arguments except for those corresponding to a formal parameter. This may be combined with a formal parameter of the form `*name` (described in the next subsection) which receives a tuple containing the positional arguments beyond the formal parameter list. (*name must occur before `**name`. ) For example, if we define a function like this:

```python
def cheeseshop(kind, *arguments, **keywords):
```
print("-- Do you have any", kind, "?")
print("-- I'm sorry, we're all out of", kind)
for arg in arguments:
    print(arg)
print("-" * 40)
keys = sorted(keywords.keys())
for kw in keys:
    print(kw, ":", keywords[kw])

It could be called like this:

cheeseshop("Limburger", "It's very runny, sir.",
           "It's really very, VERY runny, sir.",
           shopkeeper="Michael Palin",
           client="John Cleese",
           sketch="Cheese Shop Sketch")

and of course it would print:

-- Do you have any Limburger ?
-- I'm sorry, we're all out of Limburger
It's very runny, sir.
It's really very, VERY runny, sir.
----------------------------------------
client : John Cleese
shopkeeper : Michael Palin
sketch : Cheese Shop Sketch

Note that the list of keyword argument names is created by sorting the result of the keywords dictionary's keys() method before printing its contents; if this is not done, the order in which the arguments are printed is undefined.

4.7.3. Arbitrary Argument Lists
Finally, the least frequently used option is to specify that a function can be called with an arbitrary number of arguments. These arguments will be wrapped up in a tuple (see *Tuples and Sequences*). Before the variable number of arguments, zero or more normal arguments may occur.

```python
def write_multiple_items(file, separator, *args):
    file.write(separator.join(args))
```

Normally, these variadic arguments will be last in the list of formal parameters, because they scoop up all remaining input arguments that are passed to the function. Any formal parameters which occur after the `*args` parameter are 'keyword-only' arguments, meaning that they can only be used as keywords rather than positional arguments.

```python
>>> def concat(*args, sep="/ "):
...       return sep.join(args)
...
>>> concat("earth", "mars", "venus")
'earth/mars/venus'
>>> concat("earth", "mars", "venus", sep=". ")
'earth.mars.venus'
```

### 4.7.4. Unpacking Argument Lists

The reverse situation occurs when the arguments are already in a list or tuple but need to be unpacked for a function call requiring separate positional arguments. For instance, the built-in `range()` function expects separate `start` and `stop` arguments. If they are not available separately, write the function call with the `*`-operator to unpack the arguments out of a list or tuple:

```python
>>> list(range(3, 6))          # normal call with
```
In the same fashion, dictionaries can deliver keyword arguments with the **-operator:

4.7.5. Lambda Expressions

Small anonymous functions can be created with the lambda keyword. This function returns the sum of its two arguments: lambda a, b: a+b. Lambda functions can be used wherever function objects are required. They are syntactically restricted to a single expression. Semantically, they are just syntactic sugar for a normal function definition. Like nested function definitions, lambda functions can reference variables from the containing scope:
The above example uses a lambda expression to return a function. Another use is to pass a small function as an argument:

```python
>>> pairs = [(1, 'one'), (2, 'two'), (3, 'three'), (4, 'four')]
>>> pairs.sort(key=lambda pair: pair[1])
>>> pairs
[(1, 'one'), (2, 'two'), (3, 'three'), (4, 'four')]
```

4.7.6. Documentation Strings

Here are some conventions about the content and formatting of documentation strings.

The first line should always be a short, concise summary of the object’s purpose. For brevity, it should not explicitly state the object’s name or type, since these are available by other means (except if the name happens to be a verb describing a function’s operation). This line should begin with a capital letter and end with a period.

If there are more lines in the documentation string, the second line should be blank, visually separating the summary from the rest of the description. The following lines should be one or more paragraphs describing the object’s calling conventions, its side effects, etc.

The Python parser does not strip indentation from multi-line string literals in Python, so tools that process documentation have to strip indentation if desired. This is done using the following convention. The first non-blank line after the first line of the string determines the amount of indentation for the entire documentation string. (We can't use the first line since it is generally adjacent to the string's opening
quotes so its indentation is not apparent in the string literal.)
Whitespace “equivalent” to this indentation is then stripped from the
start of all lines of the string. Lines that are indented less should not
occur, but if they occur all their leading whitespace should be stripped.
Equivalence of whitespace should be tested after expansion of tabs (to
8 spaces, normally).

Here is an example of a multi-line docstring:

```python
>>> def my_function():
...     """Do nothing, but document it.
...     """
...     No, really, it doesn't do anything.
...     """
...     pass
... >>> print(my_function.__doc__)
Do nothing, but document it.

    No, really, it doesn't do anything.
```

4.7.7. Function Annotations

*Function annotations* are completely optional, arbitrary metadata
information about user-defined functions. Neither Python itself nor the
standard library use function annotations in any way; this section just
shows the syntax. Third-party projects are free to use function
annotations for documentation, type checking, and other uses.

Annotations are stored in the `__annotations__` attribute of the
function as a dictionary and have no effect on any other part of the
function. Parameter annotations are defined by a colon after the
parameter name, followed by an expression evaluating to the value of
the annotation. Return annotations are defined by a literal \(-\rightarrow\), followed by an expression, between the parameter list and the colon denoting the end of the \texttt{def} statement. The following example has a positional argument, a keyword argument, and the return value annotated with nonsense:

```python
>>> def f(ham: 42, eggs: int = 'spam') -> "Nothing to see there":
...     print("Annotations:", f.__annotations__)
...     print("Arguments:", ham, eggs)
... >>> f('wonderful')
Annotations: {'eggs': <class 'int'>, 'return': 'Nothing to see there'}
Arguments: wonderful spam
```
4.8. Intermezzo: Coding Style

Now that you are about to write longer, more complex pieces of Python, it is a good time to talk about coding style. Most languages can be written (or more concise, formatted) in different styles; some are more readable than others. Making it easy for others to read your code is always a good idea, and adopting a nice coding style helps tremendously for that.

For Python, PEP 8 has emerged as the style guide that most projects adhere to; it promotes a very readable and eye-pleasing coding style. Every Python developer should read it at some point; here are the most important points extracted for you:

- Use 4-space indentation, and no tabs.
  
  4 spaces are a good compromise between small indentation (allows greater nesting depth) and large indentation (easier to read). Tabs introduce confusion, and are best left out.

- Wrap lines so that they don’t exceed 79 characters.
  
  This helps users with small displays and makes it possible to have several code files side-by-side on larger displays.

- Use blank lines to separate functions and classes, and larger blocks of code inside functions.

- When possible, put comments on a line of their own.

- Use docstrings.

- Use spaces around operators and after commas, but not directly
inside bracketing constructs: \( a = f(1, 2) + g(3, 4) \).

- Name your classes and functions consistently; the convention is to use CamelCase for classes and lower_case_with_underscores for functions and methods. Always use `self` as the name for the first method argument (see *A First Look at Classes* for more on classes and methods).

- Don’t use fancy encodings if your code is meant to be used in international environments. Python’s default, UTF-8, or even plain ASCII work best in any case.

- Likewise, don’t use non-ASCII characters in identifiers if there is only the slightest chance people speaking a different language will read or maintain the code.

**Footnotes**

Actually, *call by object reference* would be a better description, since if a mutable object is passed, the caller will see any changes the callee makes to it (items inserted into a list).
5. Data Structures

This chapter describes some things you’ve learned about already in more detail, and adds some new things as well.
5.1. More on Lists

The list data type has some more methods. Here are all of the methods of list objects:

- **list.append(x)**
  Add an item to the end of the list. Equivalent to `a[len(a):] = [x]`.

- **list.extend(L)**
  Extend the list by appending all the items in the given list. Equivalent to `a[len(a):] = L`.

- **list.insert(i, x)**
  Insert an item at a given position. The first argument is the index of the element before which to insert, so `a.insert(0, x)` inserts at the front of the list, and `a.insert(len(a), x)` is equivalent to `a.append(x)`.

- **list.remove(x)**
  Remove the first item from the list whose value is `x`. It is an error if there is no such item.

- **list.pop([i])**
  Remove the item at the given position in the list, and return it. If no index is specified, `a.pop()` removes and returns the last item in the list. (The square brackets around the `i` in the method signature denote that the parameter is optional, not that you should type square brackets at that position. You will see this notation frequently in the Python Library Reference.)
list. `clear()`
Remove all items from the list. Equivalent to `del a[:]`.

list. `index(x)`
Return the index in the list of the first item whose value is `x`. It is an error if there is no such item.

list. `count(x)`
Return the number of times `x` appears in the list.

list. `sort()`
Sort the items of the list in place.

list. `reverse()`
Reverse the elements of the list in place.

list. `copy()`
Return a shallow copy of the list. Equivalent to `a[:]`.

An example that uses most of the list methods:

```python
>>> a = [66.25, 333, 333, 1, 1234.5]
>>> print(a.count(333), a.count(66.25), a.count('x'))
2 1 0
>>> a.insert(2, -1)
>>> a.append(333)
>>> a
[66.25, 333, -1, 333, 1, 1234.5, 333]
>>> a.index(333)
1
>>> a.remove(333)
>>> a
[66.25, -1, 333, 1, 1234.5, 333]
>>> a.reverse()
```
You might have noticed that methods like `insert`, `remove` or `sort` that modify the list have no return value printed – they return `None`. [1] This is a design principle for all mutable data structures in Python.

5.1.1. Using Lists as Stacks

The list methods make it very easy to use a list as a stack, where the last element added is the first element retrieved (“last-in, first-out”). To add an item to the top of the stack, use `append()` . To retrieve an item from the top of the stack, use `pop()` without an explicit index. For example:

```python
>>> stack = [3, 4, 5]
>>> stack.append(6)
>>> stack.append(7)
>>> stack
[3, 4, 5, 6, 7]
>>> stack.pop()
7
>>> stack
[3, 4, 5, 6]
>>> stack.pop()
6
>>> stack.pop()
5
>>> stack
[3, 4]
```
5.1.2. Using Lists as Queues

It is also possible to use a list as a queue, where the first element added is the first element retrieved (“first-in, first-out”); however, lists are not efficient for this purpose. While appends and pops from the end of list are fast, doing inserts or pops from the beginning of a list is slow (because all of the other elements have to be shifted by one).

To implement a queue, use `collections.deque` which was designed to have fast appends and pops from both ends. For example:

```python
>>> from collections import deque
>>> queue = deque(["Eric", "John", "Michael"])
>>> queue.append("Terry")  # Terry arrives
>>> queue.append("Graham")  # Graham arrives
>>> queue.popleft()  # The first to arrive now leaves
'Eric'
>>> queue.popleft()  # The second to arrive now leaves
'John'
>>> queue  # Remaining queue
deque(['Michael', 'Terry', 'Graham'])
```

5.1.3. List Comprehensions

List comprehensions provide a concise way to create lists. Common applications are to make new lists where each element is the result of some operations applied to each member of another sequence or iterable, or to create a subsequence of those elements that satisfy a certain condition.

For example, assume we want to create a list of squares, like:
>>> squares = []
>>> for x in range(10):
...     squares.append(x**2)
...
>>> squares
[0, 1, 4, 9, 16, 25, 36, 49, 64, 81]

We can obtain the same result with:

```
squares = [x**2 for x in range(10)]
```

This is also equivalent to `squares = list(map(lambda x: x**2, range(10)))`, but it's more concise and readable.

A list comprehension consists of brackets containing an expression followed by a `for` clause, then zero or more `for` or `if` clauses. The result will be a new list resulting from evaluating the expression in the context of the `for` and `if` clauses which follow it. For example, this listcomp combines the elements of two lists if they are not equal:

```
>>> [(x, y) for x in [1, 2, 3] for y in [3, 1, 4] if x != y]
[(1, 3), (1, 4), (2, 3), (2, 1), (2, 4), (3, 1), (3, 4)]
```

and it's equivalent to:

```
>>> combs = []
>>> for x in [1, 2, 3]:
...     for y in [3, 1, 4]:
...         if x != y:
...             combs.append((x, y))
...
>>> combs
[(1, 3), (1, 4), (2, 3), (2, 1), (2, 4), (3, 1), (3, 4)]
```
Note how the order of the `for` and `if` statements is the same in both these snippets.

If the expression is a tuple (e.g. the \((x, y)\) in the previous example), it must be parenthesized.

```python
>>> vec = [-4, -2, 0, 2, 4]
>>> # create a new list with the values doubled
>>> [x*2 for x in vec]
[-8, -4, 0, 4, 8]
>>> # filter the list to exclude negative numbers
>>> [x for x in vec if x >= 0]
[0, 2, 4]
>>> # apply a function to all the elements
>>> [abs(x) for x in vec]
[4, 2, 0, 2, 4]
>>> # call a method on each element
>>> freshfruit = ['banana', 'loganberry', 'passion fruit']
>>> [weapon.strip() for weapon in freshfruit]
['banana', 'loganberry', 'passion fruit']
>>> # create a list of 2-tuples like (number, square)
>>> [(x, x**2) for x in range(6)]
[(0, 0), (1, 1), (2, 4), (3, 9), (4, 16), (5, 25)]
>>> # the tuple must be parenthesized, otherwise an error is raised
>>> [x, x**2 for x in range(6)]
File "<stdin>"", line 1, in ?
    [x, x**2 for x in range(6)]
    ^
SyntaxError: invalid syntax
>>> # flatten a list using a listcomp with two 'for'
>>> vec = [[1,2,3], [4,5,6], [7,8,9]]
>>> [num for elem in vec for num in elem]
[1, 2, 3, 4, 5, 6, 7, 8, 9]
```

List comprehensions can contain complex expressions and nested
functions:

```python
>>> from math import pi
>>> [str(round(pi, i)) for i in range(1, 6)]
['3.1', '3.14', '3.142', '3.1416', '3.14159']
```

5.1.4. Nested List Comprehensions

The initial expression in a list comprehension can be any arbitrary expression, including another list comprehension.

Consider the following example of a 3x4 matrix implemented as a list of 3 lists of length 4:

```python
>>> matrix = [
... [1, 2, 3, 4],
... [5, 6, 7, 8],
... [9, 10, 11, 12],
... ]
```

The following list comprehension will transpose rows and columns:

```python
>>> [[row[i] for row in matrix] for i in range(4)]
[[1, 5, 9], [2, 6, 10], [3, 7, 11], [4, 8, 12]]
```

As we saw in the previous section, the nested listcomp is evaluated in the context of the `for` that follows it, so this example is equivalent to:

```python
>>> transposed = []
>>> for i in range(4):
...    transposed.append([row[i] for row in matrix])
... >>> transposed
[[1, 5, 9], [2, 6, 10], [3, 7, 11], [4, 8, 12]]
```
which, in turn, is the same as:

```python
>>> transposed = []
>>> for i in range(4):
...     transposed_row = []
...     for row in matrix:
...         transposed_row.append(row[i])
...     transposed.append(transposed_row)

>>> transposed
[[[1, 5, 9], [2, 6, 10], [3, 7, 11], [4, 8, 12]]
```

In the real world, you should prefer built-in functions to complex flow statements. The `zip()` function would do a great job for this use case:

```python
>>> list(zip(*matrix))
[(1, 5, 9), (2, 6, 10), (3, 7, 11), (4, 8, 12)]
```

See *Unpacking Argument Lists* for details on the asterisk in this line.
5.2. The `del` statement

There is a way to remove an item from a list given its index instead of its value: the `del` statement. This differs from the `pop()` method which returns a value. The `del` statement can also be used to remove slices from a list or clear the entire list (which we did earlier by assignment of an empty list to the slice). For example:

```python
>>> a = [-1, 1, 66.25, 333, 333, 1234.5]
>>> del a[0]
>>> a
[1, 66.25, 333, 333, 1234.5]
>>> del a[2:4]
>>> a
[1, 66.25, 1234.5]
>>> del a[:]
>>> a
[]
```

`del` can also be used to delete entire variables:

```python
>>> del a
```

Referencing the name `a` hereafter is an error (at least until another value is assigned to it). We'll find other uses for `del` later.
5.3. Tuples and Sequences

We saw that lists and strings have many common properties, such as indexing and slicing operations. They are two examples of sequence data types (see Sequence Types — list, tuple, range). Since Python is an evolving language, other sequence data types may be added. There is also another standard sequence data type: the tuple.

A tuple consists of a number of values separated by commas, for instance:

```python
>>> t = 12345, 54321, 'hello!
>>> t[0]
12345
>>> t
(12345, 54321, 'hello!')
>>> # Tuples may be nested:
... u = t, (1, 2, 3, 4, 5)
>>> u
((12345, 54321, 'hello!'), (1, 2, 3, 4, 5))
>>> # Tuples are immutable:
... t[0] = 88888
Traceback (most recent call last):
  File "<stdin>", line 1, in <module>
TypeError: 'tuple' object does not support item assignment
>>> # but they can contain mutable objects:
... v = ([1, 2, 3], [3, 2, 1])
>>> v
([1, 2, 3], [3, 2, 1])
```

As you see, on output tuples are always enclosed in parentheses, so that nested tuples are interpreted correctly; they may be input with or without surrounding parentheses, although often parentheses are
necessary anyway (if the tuple is part of a larger expression). It is not possible to assign to the individual items of a tuple, however it is possible to create tuples which contain mutable objects, such as lists.

Though tuples may seem similar to lists, they are often used in different situations and for different purposes. Tuples are immutable, and usually contain an heterogeneous sequence of elements that are accessed via unpacking (see later in this section) or indexing (or even by attribute in the case of namedtuples). Lists are mutable, and their elements are usually homogeneous and are accessed by iterating over the list.

A special problem is the construction of tuples containing 0 or 1 items: the syntax has some extra quirks to accommodate these. Empty tuples are constructed by an empty pair of parentheses; a tuple with one item is constructed by following a value with a comma (it is not sufficient to enclose a single value in parentheses). Ugly, but effective. For example:

```python
>>> empty = ()
>>> singleton = 'hello',    # <-- note trailing comma
>>> len(empty)
0
>>> len(singleton)
1
>>> singleton
('hello',)
```

The statement `t = 12345, 54321, 'hello!'` is an example of tuple packing: the values 12345, 54321 and 'hello!' are packed together in a tuple. The reverse operation is also possible:

```python
>>> x, y, z = t
```
This is called, appropriately enough, *sequence unpacking* and works for any sequence on the right-hand side. Sequence unpacking requires that there are as many variables on the left side of the equals sign as there are elements in the sequence. Note that multiple assignment is really just a combination of tuple packing and sequence unpacking.
5.4. Sets

Python also includes a data type for sets. A set is an unordered collection with no duplicate elements. Basic uses include membership testing and eliminating duplicate entries. Set objects also support mathematical operations like union, intersection, difference, and symmetric difference.

Curly braces or the `set()` function can be used to create sets. Note: to create an empty set you have to use `set()`, not `{}`; the latter creates an empty dictionary, a data structure that we discuss in the next section.

Here is a brief demonstration:

```python
>>> basket = {'apple', 'orange', 'apple', 'pear', 'c'}
>>> print(basket)  # show that duplicates have been removed
{'orange', 'banana', 'pear', 'apple'}
>>> 'orange' in basket  # fast membership testing
True
>>> 'crabgrass' in basket
False

>>> # Demonstrate set operations on unique letters from two words...
>>> a = set('abracadabra')
>>> b = set('alacazam')
>>> a  # unique letters in a
{'a', 'r', 'b', 'c', 'd'}
>>> a - b  # letters in a but not b
{'r', 'd', 'b'}
>>> a | b  # letters in either a or b
{'a', 'c', 'r', 'd', 'b', 'm', 'z', 'l'}
>>> a & b  # letters in both a and b
```

```python
>>> a ^ b
{'r', 'd', 'b', 'm', 'z', 'l'}

# letters in

Similarly to *list comprehensions*, set comprehensions are also supported:

```python
>>> a = {x for x in 'abracadabra' if x not in 'abc'}
>>> a
{'r', 'd'}
```
5.5. Dictionaries

Another useful data type built into Python is the *dictionary* (see *Mapping Types — dict*). Dictionaries are sometimes found in other languages as “associative memories” or “associative arrays”. Unlike sequences, which are indexed by a range of numbers, dictionaries are indexed by *keys*, which can be any immutable type; strings and numbers can always be keys. Tuples can be used as keys if they contain only strings, numbers, or tuples; if a tuple contains any mutable object either directly or indirectly, it cannot be used as a key. You can’t use lists as keys, since lists can be modified in place using index assignments, slice assignments, or methods like `append()` and `extend()`.

It is best to think of a dictionary as an unordered set of *key: value* pairs, with the requirement that the keys are unique (within one dictionary). A pair of braces creates an empty dictionary: `{}`. Placing a comma-separated list of key:value pairs within the braces adds initial key:value pairs to the dictionary; this is also the way dictionaries are written on output.

The main operations on a dictionary are storing a value with some key and extracting the value given the key. It is also possible to delete a key:value pair with `del`. If you store using a key that is already in use, the old value associated with that key is forgotten. It is an error to extract a value using a non-existent key.

Performing `list(d.keys())` on a dictionary returns a list of all the keys used in the dictionary, in arbitrary order (if you want it sorted, just use `sorted(d.keys())` instead). [2] To check whether a single key is in the dictionary, use the *in* keyword.
Here is a small example using a dictionary:

```python
>>> tel = {'jack': 4098, 'sape': 4139}
>>> tel['guido'] = 4127
>>> tel
{'sape': 4139, 'guido': 4127, 'jack': 4098}
>>> tel['jack']
4098
>>> del tel['sape']
>>> tel['irv'] = 4127
>>> tel
{'guido': 4127, 'irv': 4127, 'jack': 4098}
>>> list(tel.keys())
['irv', 'guido', 'jack']
>>> sorted(tel.keys())
['guido', 'irv', 'jack']
>>> 'guido' in tel
True
>>> 'jack' not in tel
False
```

The `dict()` constructor builds dictionaries directly from sequences of key-value pairs:

```python
>>> dict([('sape', 4139), ('guido', 4127), ('jack',

{ 'sape': 4139, 'jack': 4098, 'guido': 4127}
```

In addition, dict comprehensions can be used to create dictionaries from arbitrary key and value expressions:

```python
>>> {x: x**2 for x in (2, 4, 6)}
{2: 4, 4: 16, 6: 36}
```

When the keys are simple strings, it is sometimes easier to specify pairs using keyword arguments:
```python
>>> dict(sape=4139, guido=4127, jack=4098)
{'sape': 4139, 'jack': 4098, 'guido': 4127}
```
5.6. Looping Techniques

When looping through dictionaries, the key and corresponding value can be retrieved at the same time using the `items()` method.

```python
>>> knights = {'gallahad': 'the pure', 'robin': 'the brave'}
>>> for k, v in knights.items():
    print(k, v)
...   print(k, v)
...gallahad the pure
robin the brave
```

When looping through a sequence, the position index and corresponding value can be retrieved at the same time using the `enumerate()` function.

```python
>>> for i, v in enumerate(['tic', 'tac', 'toe']):
    print(i, v)
...  print(i, v)
...0 tic
1 tac
2 toe
```

To loop over two or more sequences at the same time, the entries can be paired with the `zip()` function.

```python
>>> questions = ['name', 'quest', 'favorite color']
>>> answers = ['lancelot', 'the holy grail', 'blue']
>>> for q, a in zip(questions, answers):
    print('What is your {0}?' It is {1}'.format...
...  print('What is your name? It is lancelot.
What is your quest? It is the holy grail.'
What is your favorite color? It is blue.

To loop over a sequence in reverse, first specify the sequence in a forward direction and then call the `reversed()` function.

```python
>>> for i in reversed(range(1, 10, 2)):
    ...
    print(i)
...
9
7
5
3
1
```

To loop over a sequence in sorted order, use the `sorted()` function which returns a new sorted list while leaving the source unaltered.

```python
>>> basket = ['apple', 'orange', 'apple', 'pear', 'cherry', 'cherry', 'cherry']
>>> for f in sorted(set(basket)):
    ...
    print(f)
...
apple
banana
orange
pear
```

To change a sequence you are iterating over while inside the loop (for example to duplicate certain items), it is recommended that you first make a copy. Looping over a sequence does not implicitly make a copy. The slice notation makes this especially convenient:

```python
>>> words = ['cat', 'window', 'defenestrate']
>>> for w in words[:]:  # Loop over a slice copy of...
    ...
    if len(w) > 6:
```
... words.insert(0, w)
...

>>> words
['defenestrate', 'cat', 'window', 'defenestrate']
5.7. More on Conditions

The conditions used in `while` and `if` statements can contain any operators, not just comparisons.

The comparison operators `in` and `not in` check whether a value occurs (does not occur) in a sequence. The operators `is` and `is not` compare whether two objects are really the same object; this only matters for mutable objects like lists. All comparison operators have the same priority, which is lower than that of all numerical operators.

Comparisons can be chained. For example, `a < b == c` tests whether `a` is less than `b` and moreover `b` equals `c`.

Comparisons may be combined using the Boolean operators `and` and `or`, and the outcome of a comparison (or of any other Boolean expression) may be negated with `not`. These have lower priorities than comparison operators; between them, `not` has the highest priority and `or` the lowest, so that `A and not B or C` is equivalent to `(A and (not B)) or C`. As always, parentheses can be used to express the desired composition.

The Boolean operators `and` and `or` are so-called *short-circuit* operators: their arguments are evaluated from left to right, and evaluation stops as soon as the outcome is determined. For example, if `A` and `C` are true but `B` is false, `A and B and C` does not evaluate the expression `C`. When used as a general value and not as a Boolean, the return value of a short-circuit operator is the last evaluated argument.

It is possible to assign the result of a comparison or other Boolean
expression to a variable. For example,

```python
>>> string1, string2, string3 = '', 'Trondheim', 'Hammer Dance'
>>> non_null = string1 or string2 or string3
>>> non_null
'Trondheim'
```

Note that in Python, unlike C, assignment cannot occur inside expressions. C programmers may grumble about this, but it avoids a common class of problems encountered in C programs: typing `=` in an expression when `==` was intended.
5.8. Comparing Sequences and Other Types

Sequence objects may be compared to other objects with the same sequence type. The comparison uses lexicographical ordering: first the first two items are compared, and if they differ this determines the outcome of the comparison; if they are equal, the next two items are compared, and so on, until either sequence is exhausted. If two items to be compared are themselves sequences of the same type, the lexicographical comparison is carried out recursively. If all items of two sequences compare equal, the sequences are considered equal. If one sequence is an initial sub-sequence of the other, the shorter sequence is the smaller (lesser) one. Lexicographical ordering for strings uses the Unicode codepoint number to order individual characters. Some examples of comparisons between sequences of the same type:

\[
(1, 2, 3) < (1, 2, 4) \\
[1, 2, 3] < [1, 2, 4] \\
'ABC' < 'C' < 'Pascal' < 'Python' \\
(1, 2, 3, 4) < (1, 2, 4) \\
(1, 2) < (1, 2, -1) \\
(1, 2, 3) == (1.0, 2.0, 3.0) \\
(1, 2, ('aa', 'ab')) < (1, 2, ('abc', 'a'), 4)
\]

Note that comparing objects of different types with `<` or `>` is legal provided that the objects have appropriate comparison methods. For example, mixed numeric types are compared according to their numeric value, so 0 equals 0.0, etc. Otherwise, rather than providing an arbitrary ordering, the interpreter will raise a `TypeError` exception.
Other languages may return the mutated object, which allows method chaining, such as `d->insert("a")- >remove("b")->sort();`.

Calling `d.keys()` will return a dictionary view object. It supports operations like membership test and iteration, but its contents are not independent of the original dictionary – it is only a view.
6. Modules

If you quit from the Python interpreter and enter it again, the definitions you have made (functions and variables) are lost. Therefore, if you want to write a somewhat longer program, you are better off using a text editor to prepare the input for the interpreter and running it with that file as input instead. This is known as creating a script. As your program gets longer, you may want to split it into several files for easier maintenance. You may also want to use a handy function that you've written in several programs without copying its definition into each program.

To support this, Python has a way to put definitions in a file and use them in a script or in an interactive instance of the interpreter. Such a file is called a module; definitions from a module can be imported into other modules or into the main module (the collection of variables that you have access to in a script executed at the top level and in calculator mode).

A module is a file containing Python definitions and statements. The file name is the module name with the suffix .py appended. Within a module, the module's name (as a string) is available as the value of the global variable __name__. For instance, use your favorite text editor to create a file called fibo.py in the current directory with the following contents:

```python
# Fibonacci numbers module

def fib(n):   # write Fibonacci series up to n
    a, b = 0, 1
    while b < n:
        print(b, end=' ')
```

```python
    a, b = b, a+b
print()

def fib2(n):
    # return Fibonacci series up to n
    result = []
    a, b = 0, 1
    while b < n:
        result.append(b)
        a, b = b, a+b
    return result
```

Now enter the Python interpreter and import this module with the following command:

```python
>>> import fibo
```

This does not enter the names of the functions defined in `fibo` directly in the current symbol table; it only enters the module name `fibo` there. Using the module name you can access the functions:

```python
>>> fibo.fib(1000)
1 1 2 3 5 8 13 21 34 55 89 144 233 377 610 987
>>> fibo.fib2(100)
[1, 1, 2, 3, 5, 8, 13, 21, 34, 55, 89]
>>> fibo.__name__
'fibo'
```

If you intend to use a function often you can assign it to a local name:

```python
>>> fib = fibo.fib
>>> fib(500)
1 1 2 3 5 8 13 21 34 55 89 144 233 377
```
6.1. More on Modules

A module can contain executable statements as well as function definitions. These statements are intended to initialize the module. They are executed only the first time the module name is encountered in an import statement. [1] (They are also run if the file is executed as a script.)

Each module has its own private symbol table, which is used as the global symbol table by all functions defined in the module. Thus, the author of a module can use global variables in the module without worrying about accidental clashes with a user’s global variables. On the other hand, if you know what you are doing you can touch a module's global variables with the same notation used to refer to its functions, modname.itemname.

Modules can import other modules. It is customary but not required to place all import statements at the beginning of a module (or script, for that matter). The imported module names are placed in the importing module’s global symbol table.

There is a variant of the import statement that imports names from a module directly into the importing module’s symbol table. For example:

```python
>>> from fibo import fib, fib2
>>> fib(500)
1 1 2 3 5 8 13 21 34 55 89 144 233 377
```

This does not introduce the module name from which the imports are taken in the local symbol table (so in the example, fibo is not defined).
There is even a variant to import all names that a module defines:

```python
>>> from fibo import *
>>> fib(500)
1 1 2 3 5 8 13 21 34 55 89 144 233 377
```

This imports all names except those beginning with an underscore (_). In most cases Python programmers do not use this facility since it introduces an unknown set of names into the interpreter, possibly hiding some things you have already defined.

Note that in general the practice of importing * from a module or package is frowned upon, since it often causes poorly readable code. However, it is okay to use it to save typing in interactive sessions.

**Note:** For efficiency reasons, each module is only imported once per interpreter session. Therefore, if you change your modules, you must restart the interpreter – or, if it’s just one module you want to test interactively, use `imp.reload()`, e.g. `import imp; imp.reload(modulename)`.

### 6.1.1. Executing modules as scripts

When you run a Python module with

```bash
python fibo.py <arguments>
```

the code in the module will be executed, just as if you imported it, but with the `__name__` set to `"__main__"`. That means that by adding this code at the end of your module:

```python
if __name__ == "__main__":
    import sys
```
you can make the file usable as a script as well as an importable module, because the code that parses the command line only runs if the module is executed as the “main” file:

```python
def fib(n):
    a, b = 0, 1
    while a < n:
        yield a
        a, b = b, a + b
    return
```

```bash
$ python fibo.py 50
1 1 2 3 5 8 13 21 34
```

If the module is imported, the code is not run:

```python
>>> import fibo

This is often used either to provide a convenient user interface to a module, or for testing purposes (running the module as a script executes a test suite).

6.1.2. The Module Search Path

When a module named spam is imported, the interpreter first searches for a built-in module with that name. If not found, it then searches for a file named spam.py in a list of directories given by the variable sys.path. sys.path is initialized from these locations:

- the directory containing the input script (or the current directory).
- PYTHONPATH (a list of directory names, with the same syntax as the shell variable PATH).
- the installation-dependent default.

After initialization, Python programs can modify sys.path. The directory containing the script being run is placed at the beginning of the search path, ahead of the standard library path. This means that
scripts in that directory will be loaded instead of modules of the same name in the library directory. This is an error unless the replacement is intended. See section *Standard Modules* for more information.

### 6.1.3. “Compiled” Python files

To speed up loading modules, Python caches the compiled version of each module in the `__pycache__` directory under the name `module.version.pyc`, where the version encodes the format of the compiled file; it generally contains the Python version number. For example, in CPython release 3.3 the compiled version of spam.py would be cached as `__pycache__/spam.cpython-33.pyc`. This naming convention allows compiled modules from different releases and different versions of Python to coexist.

Python checks the modification date of the source against the compiled version to see if it’s out of date and needs to be recompiled. This is a completely automatic process. Also, the compiled modules are platform-independent, so the same library can be shared among systems with different architectures.

Python does not check the cache in two circumstances. First, it always recompiles and does not store the result for the module that’s loaded directly from the command line. Second, it does not check the cache if there is no source module. To support a non-source (compiled only) distribution, the compiled module must be in the source directory, and there must not be a source module.

Some tips for experts:

- You can use the `-O` or `-OO` switches on the Python command to reduce the size of a compiled module. The `-O` switch removes
assert statements, the `-00` switch removes both assert statements and `__doc__` strings. Since some programs may rely on having these available, you should only use this option if you know what you're doing. “Optimized” modules have a .pyo rather than a .pyc suffix and are usually smaller. Future releases may change the effects of optimization.

- A program doesn’t run any faster when it is read from a .pyc or .pyo file than when it is read from a .py file; the only thing that’s faster about .pyc or .pyo files is the speed with which they are loaded.
- The module `compileall` can create .pyc files (or .pyo files when `-O` is used) for all modules in a directory.
- There is more detail on this process, including a flow chart of the decisions, in PEP 3147.
6.2. Standard Modules

Python comes with a library of standard modules, described in a separate document, the Python Library Reference (“Library Reference” hereafter). Some modules are built into the interpreter; these provide access to operations that are not part of the core of the language but are nevertheless built in, either for efficiency or to provide access to operating system primitives such as system calls. The set of such modules is a configuration option which also depends on the underlying platform. For example, the `winreg` module is only provided on Windows systems. One particular module deserves some attention: `sys`, which is built into every Python interpreter. The variables `sys.ps1` and `sys.ps2` define the strings used as primary and secondary prompts:

```python
>>> import sys
>>> sys.ps1
'>>>
>>> sys.ps2
'...
>>> sys.ps1 = 'C> '
C> print('Yuck!')
Yuck!
C>
```

These two variables are only defined if the interpreter is in interactive mode.

The variable `sys.path` is a list of strings that determines the interpreter’s search path for modules. It is initialized to a default path taken from the environment variable `PYTHONPATH`, or from a built-in default if `PYTHONPATH` is not set. You can modify it using standard list
operations:

```python
>>> import sys
>>> sys.path.append('/ufs/guido/lib/python')
```
6.3. The \texttt{dir()} Function

The built-in function \texttt{dir()} is used to find out which names a module defines. It returns a sorted list of strings:

```python
>>> import fibo, sys
>>> dir(fibo)
['__name__', 'fib', 'fib2']
>>> dir(sys)
['__displayhook__', '__doc__', '__egginsrt', '__exc',
 '__loader__', '__name__', '__package__', '__plen',
 '__stdin__', '__stdout__', '__clear_type_cache', '__debugmallocstats',
 '__getframe__', '__home', '__mercurial', 'abiflags',
 'api_version', 'argv', 'base_exec_prefix',
 'builtin_module_names', 'byteorder', 'call_trace',
 'copyright', 'displayhook', 'dont_write_bytecode',
 'excepthook', 'exec_prefix', 'executable', 'exit',
 'float_repr_style', 'getcheckinterval', 'getdefault',
 'getdlopenflags', 'getfilesystemencoding', 'getobje',
 'getrecursionlimit', 'getrefcount', 'getsizeof', 'get',
 'gettotalrefcount', 'gettrace', 'hash_info', 'hexver',
 'implementation', 'int_info', 'intern', 'maxsize',
 'meta_path', 'modules', 'path', 'path_hooks', 'path',
 'platform', 'prefix', 'ps1', 'setcheckinterval', 'set',
 'setprofile', 'setrecursionlimit', 'setswitchinterval',
 'stderr', 'stdin', 'stdout', 'thread_info', 'version',
 'warnoptions']
```

Without arguments, \texttt{dir()} lists the names you have defined currently:

```python
>>> a = [1, 2, 3, 4, 5]
>>> import fibo
>>> fib = fibo.fib
>>> dir()
```
Note that it lists all types of names: variables, modules, functions, etc.

dir() does not list the names of built-in functions and variables. If you want a list of those, they are defined in the standard module `builtins`:

```python
>>> import builtins

>>> dir(builtins)
```
['quit', 'range', 'repr', 'reversed', 'round', 'set', 'sorted', 'staticmethod', 'str', 'sum', 'super', 'tuple', 'type', 'vars', 'zip']
6.4. Packages

Packages are a way of structuring Python’s module namespace by using “dotted module names”. For example, the module name A.B designates a submodule named B in a package named A. Just like the use of modules saves the authors of different modules from having to worry about each other’s global variable names, the use of dotted module names saves the authors of multi-module packages like NumPy or the Python Imaging Library from having to worry about each other’s module names.

Suppose you want to design a collection of modules (a “package”) for the uniform handling of sound files and sound data. There are many different sound file formats (usually recognized by their extension, for example: .wav, .aiff, .au), so you may need to create and maintain a growing collection of modules for the conversion between the various file formats. There are also many different operations you might want to perform on sound data (such as mixing, adding echo, applying an equalizer function, creating an artificial stereo effect), so in addition you will be writing a never-ending stream of modules to perform these operations. Here’s a possible structure for your package (expressed in terms of a hierarchical filesystem):

```
sound/
  __init__.py
  formats/
    __init__.py
    wavread.py
    wavwrite.py
    aiffread.py
    aiffwrite.py
    auread.py

Top-level package
Initialize the sound package
Subpackage for file format conversions
```
When importing the package, Python searches through the directories on `sys.path` looking for the package subdirectory.

The `__init__.py` files are required to make Python treat the directories as containing packages; this is done to prevent directories with a common name, such as `string`, from unintentionally hiding valid modules that occur later on the module search path. In the simplest case, `__init__.py` can just be an empty file, but it can also execute initialization code for the package or set the `__all__` variable, described later.

Users of the package can import individual modules from the package, for example:

```
import sound.effects.echo
```

This loads the submodule `sound.effects.echo`. It must be referenced with its full name.
An alternative way of importing the submodule is:

```python
from sound.effects import echo
```

This also loads the submodule echo, and makes it available without its package prefix, so it can be used as follows:

```python
echo.echofilter(input, output, delay=0.7, atten=4)
```

Yet another variation is to import the desired function or variable directly:

```python
from sound.effects.echo import echofilter
```

Again, this loads the submodule echo, but this makes its function `echofilter()` directly available:

```python
echofilter(input, output, delay=0.7, atten=4)
```

Note that when using `from package import item`, the item can be either a submodule (or subpackage) of the package, or some other name defined in the package, like a function, class or variable. The `import` statement first tests whether the item is defined in the package; if not, it assumes it is a module and attempts to load it. If it fails to find it, an `ImportError` exception is raised.

Contrarily, when using syntax like `import item.subitem.subsubitem`, each item except for the last must be a package; the last item can be a module or a package but can’t be a class or function or variable defined in the previous item.
6.4.1. Importing * From a Package

Now what happens when the user writes `from sound.effects import *`? Ideally, one would hope that this somehow goes out to the filesystem, finds which submodules are present in the package, and imports them all. This could take a long time and importing submodules might have unwanted side-effects that should only happen when the sub-module is explicitly imported.

The only solution is for the package author to provide an explicit index of the package. The `import` statement uses the following convention: if a package's `__init__.py` code defines a list named `__all__`, it is taken to be the list of module names that should be imported when `from package import *` is encountered. It is up to the package author to keep this list up-to-date when a new version of the package is released. Package authors may also decide not to support it, if they don't see a use for importing * from their package. For example, the file `sound/effects/__init__.py` could contain the following code:

```python
__all__ = ["echo", "surround", "reverse"]
```

This would mean that `from sound.effects import *` would import the three named submodules of the sound package.

If `__all__` is not defined, the statement `from sound.effects import *` does not import all submodules from the package `sound.effects` into the current namespace; it only ensures that the package `sound.effects` has been imported (possibly running any initialization code in `__init__.py`) and then imports whatever names are defined in the package. This includes any names defined (and
submodules explicitly loaded) by __init__.py. It also includes any submodules of the package that were explicitly loaded by previous import statements. Consider this code:

```python
import sound.effects.echo
import sound.effects.surround
from sound.effects import *
```

In this example, the echo and surround modules are imported in the current namespace because they are defined in the sound.effects package when the from...import statement is executed. (This also works when __all__ is defined.)

Although certain modules are designed to export only names that follow certain patterns when you use import *, it is still considered bad practice in production code.

Remember, there is nothing wrong with using from Package import specific_submodule! In fact, this is the recommended notation unless the importing module needs to use submodules with the same name from different packages.

### 6.4.2. Intra-package References

When packages are structured into subpackages (as with the sound package in the example), you can use absolute imports to refer to submodules of siblings packages. For example, if the module sound.filters.vocoder needs to use the echo module in the sound.effects package, it can use from sound.effects import echo.

You can also write relative imports, with the from module import
name form of import statement. These imports use leading dots to indicate the current and parent packages involved in the relative import. From the surround module for example, you might use:

```python
from . import echo
from .. import formats
from ..filters import equalizer
```

Note that relative imports are based on the name of the current module. Since the name of the main module is always "__main__", modules intended for use as the main module of a Python application must always use absolute imports.

### 6.4.3. Packages in Multiple Directories

Packages support one more special attribute, __path__. This is initialized to be a list containing the name of the directory holding the package's __init__.py before the code in that file is executed. This variable can be modified; doing so affects future searches for modules and subpackages contained in the package.

While this feature is not often needed, it can be used to extend the set of modules found in a package.

**Footnotes**

[1] In fact function definitions are also ‘statements’ that are ‘executed’; the execution of a module-level function definition enters the function name in the module’s global symbol table.

7. Input and Output

There are several ways to present the output of a program; data can be printed in a human-readable form, or written to a file for future use. This chapter will discuss some of the possibilities.
7.1. Fancier Output Formatting

So far we've encountered two ways of writing values: *expression statements* and the `print()` function. (A third way is using the `write()` method of file objects; the standard output file can be referenced as `sys.stdout`. See the Library Reference for more information on this.)

Often you'll want more control over the formatting of your output than simply printing space-separated values. There are two ways to format your output; the first way is to do all the string handling yourself; using string slicing and concatenation operations you can create any layout you can imagine. The string type has some methods that perform useful operations for padding strings to a given column width; these will be discussed shortly. The second way is to use the `str.format()` method.

The `string` module contains a `Template` class which offers yet another way to substitute values into strings.

One question remains, of course: how do you convert values to strings? Luckily, Python has ways to convert any value to a string: pass it to the `repr()` or `str()` functions.

The `str()` function is meant to return representations of values which are fairly human-readable, while `repr()` is meant to generate representations which can be read by the interpreter (or will force a `SyntaxError` if there is no equivalent syntax). For objects which don't have a particular representation for human consumption, `str()` will return the same value as `repr()`. Many values, such as numbers or structures like lists and dictionaries, have the same representation
using either function. Strings, in particular, have two distinct representations.

Some examples:

```python
>>> s = 'Hello, world.'
>>> str(s)
'Hello, world.'
>>> repr(s)
''Hello, world.'''
>>> str(1/7)
'0.14285714285714285'
>>> x = 10 * 3.25
>>> y = 200 * 200
>>> s = 'The value of x is ' + repr(x) + ', and y is
>>> print(s)
The value of x is 32.5, and y is 40000...
>>> # The repr() of a string adds string quotes and
... hello = 'hello, world\n'
>>> hellos = repr(hello)
>>> print(hellos)
'hello, world\n'
>>> # The argument to repr() may be any Python object
... repr((x, y, ('spam', 'eggs')))
'(32.5, 40000, ('spam', 'eggs'))'
```

Here are two ways to write a table of squares and cubes:

```python
>>> for x in range(1, 11):
...     print(repr(x).rjust(2), repr(x*x).rjust(3),
...     # Note use of 'end' on previous line
...     print(repr(x*x*x).rjust(4))
...     print('1  1  1
2  4  8
3  9  27')
```
(Note that in the first example, one space between each column was added by the way print() works: it always adds spaces between its arguments.)

This example demonstrates the str.rjust() method of string objects, which right-justifies a string in a field of a given width by padding it with spaces on the left. There are similar methods str.ljust() and str.center(). These methods do not write anything, they just return a new string. If the input string is too long, they don’t truncate it, but return it unchanged; this will mess up your column lay-out but that’s usually better than the alternative, which would be lying about a value. (If you really want truncation you can
always add a slice operation, as in `x.ljust(n)[:-n].`

There is another method, `str.zfill()`, which pads a numeric string on the left with zeros. It understands about plus and minus signs:

```python
>>> '12'.zfill(5)
'00012'
>>> '-3.14'.zfill(7)
'-003.14'
>>> '3.14159265359'.zfill(5)
'3.14159265359'
```

Basic usage of the `str.format()` method looks like this:

```python
>>> print('We are the {} who say "{}!"'.format('knights', 'Ni!'))
We are the knights who say "Ni!"
```

The brackets and characters within them (called format fields) are replaced with the objects passed into the `str.format()` method. A number in the brackets can be used to refer to the position of the object passed into the `str.format()` method.

```python
>>> print('{0} and {1}'.format('spam', 'eggs'))
spam and eggs
>>> print('{1} and {0}'.format('spam', 'eggs'))
eggs and spam
```

If keyword arguments are used in the `str.format()` method, their values are referred to by using the name of the argument.

```python
>>> print('This {food} is {adjective}.'.format(...
...     food='spam', adjective='absolutely horrible'))
This spam is absolutely horrible.
```
Positional and keyword arguments can be arbitrarily combined:

```python
>>> print('The story of {0}, {1}, and {other}.'.format('Bill', 'Manfred', other='Georg'))
The story of Bill, Manfred, and Georg.
```

'!a' (apply `ascii()`), '!s' (apply `str()`) and '!r' (apply `repr()`) can be used to convert the value before it is formatted:

```python
>>> import math
>>> print('The value of PI is approximately {}.'.format(math.pi))
The value of PI is approximately 3.14159265359.
>>> print('The value of PI is approximately {!r}.'.format(math.pi))
The value of PI is approximately 3.141592653589793.
```

An optional `:` and format specifier can follow the field name. This allows greater control over how the value is formatted. The following example rounds Pi to three places after the decimal.

```python
>>> import math
>>> print('The value of PI is approximately {0:.3f}.'.format(math.pi))
The value of PI is approximately 3.142.
```

Passing an integer after the `:` will cause that field to be a minimum number of characters wide. This is useful for making tables pretty.

```python
>>> table = {'Sjoerd': 4127, 'Jack': 4098, 'Dcab': 7678}
>>> for name, phone in table.items():
...     print('{0:10} == > {1:10d}'.format(name, phone))
...     print('Jack	==>	4098
Dcab	==>	7678
Sjoerd	==>	4127
```
If you have a really long format string that you don’t want to split up, it would be nice if you could reference the variables to be formatted by name instead of by position. This can be done by simply passing the dict and using square brackets \[\] to access the keys.

```python
>>> table = {'Sjoerd': 4127, 'Jack': 4098, 'Dcab': 8637678}
>>> print('Jack: {0[Jack]:d}; Sjoerd: {0[Sjoerd]:d};
...   'Dcab: {0[Dcab]:d}'.format(table))
Jack: 4098; Sjoerd: 4127; Dcab: 8637678
```

This could also be done by passing the table as keyword arguments with the ‘**’ notation.

```python
>>> table = {'Sjoerd': 4127, 'Jack': 4098, 'Dcab': 8637678}
Jack: 4098; Sjoerd: 4127; Dcab: 8637678
```

This is particularly useful in combination with the built-in function `vars()` which returns a dictionary containing all local variables.

For a complete overview of string formatting with `str.format()`, see *Format String Syntax*.

### 7.1.1. Old string formatting

The `%` operator can also be used for string formatting. It interprets the left argument much like a `printf()-`style format string to be applied to the right argument, and returns the string resulting from this formatting operation. For example:
>>> import math
>>> print('The value of PI is approximately %5.3f.'
The value of PI is approximately 3.142.

More information can be found in the *printf-style String Formatting* section.
7.2. Reading and Writing Files

`open()` returns a file object, and is most commonly used with two arguments: `open(filename, mode)`. 

```python
>>> f = open('workfile', 'w')
```

The first argument is a string containing the filename. The second argument is another string containing a few characters describing the way in which the file will be used. `mode` can be `'r'` when the file will only be read, `'w'` for only writing (an existing file with the same name will be erased), and `'a'` opens the file for appending; any data written to the file is automatically added to the end. `'r+'` opens the file for both reading and writing. The `mode` argument is optional; `'r'` will be assumed if it’s omitted.

Normally, files are opened in text mode, that means, you read and write strings from and to the file, which are encoded in a specific encoding (the default being UTF-8). `'b'` appended to the mode opens the file in binary mode: now the data is read and written in the form of bytes objects. This mode should be used for all files that don’t contain text.

In text mode, the default when reading is to convert platform-specific line endings (\n on Unix, \r\n on Windows) to just \n. When writing in text mode, the default is to convert occurrences of \n back to platform-specific line endings. This behind-the-scenes modification to file data is fine for text files, but will corrupt binary data like that in JPEG or EXE files. Be very careful to use binary mode when reading and writing such files.
7.2.1. Methods of File Objects

The rest of the examples in this section will assume that a file object called `f` has already been created.

To read a file's contents, call `f.read(size)`, which reads some quantity of data and returns it as a string or bytes object. `size` is an optional numeric argument. When `size` is omitted or negative, the entire contents of the file will be read and returned; it's your problem if the file is twice as large as your machine's memory. Otherwise, at most `size` bytes are read and returned. If the end of the file has been reached, `f.read()` will return an empty string (`''`).

```python
>>> f.read()
'This is the entire file.\n'
```

`f.readline()` reads a single line from the file; a newline character (`\n`) is left at the end of the string, and is only omitted on the last line of the file if the file doesn't end in a newline. This makes the return value unambiguous; if `f.readline()` returns an empty string, the end of the file has been reached, while a blank line is represented by `''`, a string containing only a single newline.

```python
>>> f.readline()
'This is the first line of the file.\n'
```

For reading lines from a file, you can loop over the file object. This is
memory efficient, fast, and leads to simple code:

```python
>>> for line in f:
...     print(line, end=''
...
This is the first line of the file.
Second line of the file
```

If you want to read all the lines of a file in a list you can also use `list(f)` or `f.readlines()`.

`f.write(string)` writes the contents of `string` to the file, returning the number of characters written.

```python
>>> f.write('This is a test\n')
15
```

To write something other than a string, it needs to be converted to a string first:

```python
>>> value = ('the answer', 42)
>>> s = str(value)
>>> f.write(s)
18
```

`f.tell()` returns an integer giving the file object’s current position in the file represented as number of bytes from the beginning of the file when in `binary mode` and an opaque number when in `text mode`.

To change the file object’s position, use `f.seek(offset, from_what)`.

The position is computed from adding `offset` to a reference point; the reference point is selected by the `from_what` argument. A `from_what` value of 0 measures from the beginning of the file, 1 uses the current file position, and 2 uses the end of the file as
the reference point. from_what can be omitted and defaults to 0, using the beginning of the file as the reference point.

```
>>> f = open('workfile', 'rb+')
>>> f.write(b'0123456789abcdef')
16
>>> f.seek(5)        # Go to the 6th byte in the file
5
>>> f.read(1)
'b'5'
>>> f.seek(-3, 2)   # Go to the 3rd byte before the end
13
>>> f.read(1)
'b'd'
```

In text files (those opened without a b in the mode string), only seeks relative to the beginning of the file are allowed (the exception being seeking to the very file end with `seek(0, 2)` and the only valid offset values are those returned from the `f.tell()`, or zero. Any other offset value produces undefined behaviour.

When you're done with a file, call `f.close()` to close it and free up any system resources taken up by the open file. After calling `f.close()`, attempts to use the file object will automatically fail.

```
>>> f.close()
>>> f.read()
Traceback (most recent call last):
  File "<stdin>", line 1, in ?
ValueError: I/O operation on closed file
```

It is good practice to use the `with` keyword when dealing with file objects. This has the advantage that the file is properly closed after its suite finishes, even if an exception is raised on the way. It is also much
shorter than writing equivalent `try-finally` blocks:

```python
>>> with open('workfile', 'r') as f:
...     read_data = f.read()
>>> f.closed
True
```

File objects have some additional methods, such as `isatty()` and `truncate()` which are less frequently used; consult the Library Reference for a complete guide to file objects.

### 7.2.2. The `pickle` Module

Strings can easily be written to and read from a file. Numbers take a bit more effort, since the `read()` method only returns strings, which will have to be passed to a function like `int()`, which takes a string like `'123'` and returns its numeric value 123. However, when you want to save more complex data types like lists, dictionaries, or class instances, things get a lot more complicated.

Rather than have users be constantly writing and debugging code to save complicated data types, Python provides a standard module called `pickle`. This is an amazing module that can take almost any Python object (even some forms of Python code!), and convert it to a string representation; this process is called `pickling`. Reconstructing the object from the string representation is called `unpickling`. Between pickling and unpickling, the string representing the object may have been stored in a file or data, or sent over a network connection to some distant machine.

If you have an object `x`, and a file object `f` that’s been opened for writing, the simplest way to pickle the object takes only one line of
code:

```python
pickle.dump(x, f)
```

To unpickle the object again, if `f` is a file object which has been opened for reading:

```python
x = pickle.load(f)
```

(There are other variants of this, used when pickling many objects or when you don’t want to write the pickled data to a file; consult the complete documentation for `pickle` in the Python Library Reference.)

`pickle` is the standard way to make Python objects which can be stored and reused by other programs or by a future invocation of the same program; the technical term for this is a *persistent* object. Because `pickle` is so widely used, many authors who write Python extensions take care to ensure that new data types such as matrices can be properly pickled and unpickled.
8. Errors and Exceptions

Until now error messages haven't been more than mentioned, but if you have tried out the examples you have probably seen some. There are (at least) two distinguishable kinds of errors: syntax errors and exceptions.
8.1. Syntax Errors

Syntax errors, also known as parsing errors, are perhaps the most common kind of complaint you get while you are still learning Python:

```python
>>> while True print('Hello world')
File "<stdin>", line 1, in ?
    while True print('Hello world')
    ^
SyntaxError: invalid syntax
```

The parser repeats the offending line and displays a little ‘arrow’ pointing at the earliest point in the line where the error was detected. The error is caused by (or at least detected at) the token preceding the arrow: in the example, the error is detected at the function `print()`, since a colon (`:`) is missing before it. File name and line number are printed so you know where to look in case the input came from a script.
8.2. Exceptions

Even if a statement or expression is syntactically correct, it may cause an error when an attempt is made to execute it. Errors detected during execution are called exceptions and are not unconditionally fatal: you will soon learn how to handle them in Python programs. Most exceptions are not handled by programs, however, and result in error messages as shown here:

```python
>>> 10 * (1/0)
ZeroDivisionError: division by zero
>>> 4 + spam*3
NameError: name 'spam' is not defined
>>> '2' + 2
TypeError: Can't convert 'int' object to str implicitly
```

The last line of the error message indicates what happened. Exceptions come in different types, and the type is printed as part of the message: the types in the example are `ZeroDivisionError`, `NameError` and `TypeError`. The string printed as the exception type is the name of the built-in exception that occurred. This is true for all built-in exceptions, but need not be true for user-defined exceptions (although it is a useful convention). Standard exception names are built-in identifiers (not reserved keywords).

The rest of the line provides detail based on the type of exception and
what caused it.

The preceding part of the error message shows the context where the exception happened, in the form of a stack traceback. In general it contains a stack traceback listing source lines; however, it will not display lines read from standard input.

*Built-in Exceptions* lists the built-in exceptions and their meanings.
8.3. Handling Exceptions

It is possible to write programs that handle selected exceptions. Look at the following example, which asks the user for input until a valid integer has been entered, but allows the user to interrupt the program (using `Control-C` or whatever the operating system supports); note that a user-generated interruption is signalled by raising the `KeyboardInterrupt` exception.

```
>>> while True:
    ...   try:
    ...     x = int(input("Please enter a number: "))
    ...     break
    ...   except ValueError:
    ...     print("Oops! That was no valid number.")
    ...
```

The `try` statement works as follows.

- First, the `try clause` (the statement(s) between the `try` and `except` keywords) is executed.
- If no exception occurs, the `except clause` is skipped and execution of the `try` statement is finished.
- If an exception occurs during execution of the try clause, the rest of the clause is skipped. Then if its type matches the exception named after the `except` keyword, the except clause is executed, and then execution continues after the `try` statement.
- If an exception occurs which does not match the exception named in the except clause, it is passed on to outer `try` statements; if no handler is found, it is an `unhandled exception` and execution stops with a message as shown above.
A try statement may have more than one except clause, to specify handlers for different exceptions. At most one handler will be executed. Handlers only handle exceptions that occur in the corresponding try clause, not in other handlers of the same try statement. An except clause may name multiple exceptions as a parenthesized tuple, for example:

```python
... except (RuntimeError, TypeError, NameError):
    ...   pass
```

The last except clause may omit the exception name(s), to serve as a wildcard. Use this with extreme caution, since it is easy to mask a real programming error in this way! It can also be used to print an error message and then re-raise the exception (allowing a caller to handle the exception as well):

```python
import sys

try:
    f = open('myfile.txt')
    s = f.readline()
    i = int(s.strip())
except IOError as err:
    print("I/O error: \{0\}".format(err))
except ValueError:
    print("Could not convert data to an integer.")
except:
    print("Unexpected error: ", sys.exc_info()[0])
raise
```

The try ... except statement has an optional else clause, which, when present, must follow all except clauses. It is useful for code that must be executed if the try clause does not raise an exception. For example:
for arg in sys.argv[1:]:
    try:
        f = open(arg, 'r')
    except IOError:
        print('cannot open', arg)
    else:
        print(arg, 'has', len(f.readlines()), 'lines')
        f.close()

The use of the else clause is better than adding additional code to the try clause because it avoids accidentally catching an exception that wasn't raised by the code being protected by the try ... except statement.

When an exception occurs, it may have an associated value, also known as the exception's argument. The presence and type of the argument depend on the exception type.

The except clause may specify a variable after the exception name. The variable is bound to an exception instance with the arguments stored in instance.args. For convenience, the exception instance defines __str__() so the arguments can be printed directly without having to reference .args. One may also instantiate an exception first before raising it and add any attributes to it as desired.

>>> try:
    ...     raise Exception('spam', 'eggs')
    ... except Exception as inst:
    ...     print(type(inst))  # the exception instance
    ...     print(inst.args)   # arguments stored in .args
    ...     print(inst)        # __str__ allows args to be printed directly
    ...     x, y = inst.args   # unpack args
    ...     print('x =', x)
If an exception has arguments, they are printed as the last part ('detail') of the message for unhandled exceptions.

Exception handlers don’t just handle exceptions if they occur immediately in the try clause, but also if they occur inside functions that are called (even indirectly) in the try clause. For example:

```python
>>> def this_fails():
...     x = 1/0
... >>> try:
...     this_fails()
...     except ZeroDivisionError as err:
...         print('Handling run-time error:', err)
... Handling run-time error: int division or modulo by zero
```
8.4. Raising Exceptions

The `raise` statement allows the programmer to force a specified exception to occur. For example:

```python
>>> raise NameError('HiThere')
Traceback (most recent call last):
  File "<stdin>", line 1, in ?
NameError: HiThere
```

The sole argument to `raise` indicates the exception to be raised. This must be either an exception instance or an exception class (a class that derives from `Exception`).

If you need to determine whether an exception was raised but don't intend to handle it, a simpler form of the `raise` statement allows you to re-raise the exception:

```python
>>> try:
...    raise NameError('HiThere')
... except NameError:
...    print('An exception flew by!')
...    raise
...
An exception flew by!
Traceback (most recent call last):
  File "<stdin>", line 2, in ?
NameError: HiThere
```
8.5. User-defined Exceptions

Programs may name their own exceptions by creating a new exception class (see *Classes* for more about Python classes). Exceptions should typically be derived from the `Exception` class, either directly or indirectly. For example:

```python
>>> class MyError(Exception):
...     def __init__(self, value):
...         self.value = value
...     def __str__(self):
...         return repr(self.value)
...
>>> try:
...     raise MyError(2*2)
... except MyError as e:
...     print('My exception occurred, value:', e.value)
My exception occurred, value: 4
>>> raise MyError('oops!')
Traceback (most recent call last):
  File "<stdin>", line 1, in ?
__main__.MyError: 'oops!'
```

In this example, the default `__init__()` of `Exception` has been overridden. The new behavior simply creates the `value` attribute. This replaces the default behavior of creating the `args` attribute.

Exception classes can be defined which do anything any other class can do, but are usually kept simple, often only offering a number of attributes that allow information about the error to be extracted by handlers for the exception. When creating a module that can raise several distinct errors, a common practice is to create a base class for
exceptions defined by that module, and subclass that to create specific exception classes for different error conditions:

```python
class Error(Exception):
    """Base class for exceptions in this module.""
    pass

class InputError(Error):
    """Exception raised for errors in the input.

    Attributes:
    expression -- input expression in which the error occurred
    message -- explanation of the error
    ""

    def __init__(self, expression, message):
        self.expression = expression
        self.message = message

class TransitionError(Error):
    """Raised when an operation attempts a state transition that's not allowed.

    Attributes:
    previous -- state at beginning of transition
    next -- attempted new state
    message -- explanation of why the specific transition is not allowed
    ""

    def __init__(self, previous, next, message):
        self.previous = previous
        self.next = next
        self.message = message
```

Most exceptions are defined with names that end in “Error,” similar to the naming of the standard exceptions.
Many standard modules define their own exceptions to report errors that may occur in functions they define. More information on classes is presented in chapter *Classes*. 
8.6. Defining Clean-up Actions

The `try` statement has another optional clause which is intended to define clean-up actions that must be executed under all circumstances. For example:

```python
>>> try:
...     raise KeyboardInterrupt
... finally:
...     print('Goodbye, world!')
...
Goodbye, world!
KeyboardInterrupt
```

A `finally clause` is always executed before leaving the `try` statement, whether an exception has occurred or not. When an exception has occurred in the `try` clause and has not been handled by an `except` clause (or it has occurred in a `except` or `else` clause), it is re-raised after the `finally` clause has been executed. The `finally` clause is also executed “on the way out” when any other clause of the `try` statement is left via a `break`, `continue` or `return` statement. A more complicated example:

```python
>>> def divide(x, y):
...     try:
...         result = x / y
...     except ZeroDivisionError:
...         print("division by zero!")
...     else:
...         print("result is", result)
... finally:
...     print("executing finally clause")
... ```
As you can see, the `finally` clause is executed in any event. The `TypeError` raised by dividing two strings is not handled by the `except` clause and therefore re-raised after the `finally` clause has been executed.

In real world applications, the `finally` clause is useful for releasing external resources (such as files or network connections), regardless of whether the use of the resource was successful.
8.7. Predefined Clean-up Actions

Some objects define standard clean-up actions to be undertaken when the object is no longer needed, regardless of whether or not the operation using the object succeeded or failed. Look at the following example, which tries to open a file and print its contents to the screen.

```
for line in open("myfile.txt"):  
    print(line, end="")
```

The problem with this code is that it leaves the file open for an indeterminate amount of time after this part of the code has finished executing. This is not an issue in simple scripts, but can be a problem for larger applications. The `with` statement allows objects like files to be used in a way that ensures they are always cleaned up promptly and correctly.

```
with open("myfile.txt") as f:  
    for line in f:  
        print(line, end="")
```

After the statement is executed, the file `f` is always closed, even if a problem was encountered while processing the lines. Objects which, like files, provide predefined clean-up actions will indicate this in their documentation.
9. Classes

Compared with other programming languages, Python’s class mechanism adds classes with a minimum of new syntax and semantics. It is a mixture of the class mechanisms found in C++ and Modula-3. Python classes provide all the standard features of Object Oriented Programming: the class inheritance mechanism allows multiple base classes, a derived class can override any methods of its base class or classes, and a method can call the method of a base class with the same name. Objects can contain arbitrary amounts and kinds of data. As is true for modules, classes partake of the dynamic nature of Python: they are created at runtime, and can be modified further after creation.

In C++ terminology, normally class members (including the data members) are public (except see below Private Variables), and all member functions are virtual. As in Modula-3, there are no shorthands for referencing the object’s members from its methods: the method function is declared with an explicit first argument representing the object, which is provided implicitly by the call. As in Smalltalk, classes themselves are objects. This provides semantics for importing and renaming. Unlike C++ and Modula-3, built-in types can be used as base classes for extension by the user. Also, like in C++, most built-in operators with special syntax (arithmetic operators, subscripting etc.) can be redefined for class instances.

(Lacking universally accepted terminology to talk about classes, I will make occasional use of Smalltalk and C++ terms. I would use Modula-3 terms, since its object-oriented semantics are closer to those of Python than C++, but I expect that few readers have heard of it.)
9.1. A Word About Names and Objects

Objects have individuality, and multiple names (in multiple scopes) can be bound to the same object. This is known as aliasing in other languages. This is usually not appreciated on a first glance at Python, and can be safely ignored when dealing with immutable basic types (numbers, strings, tuples). However, aliasing has a possibly surprising effect on the semantics of Python code involving mutable objects such as lists, dictionaries, and most other types. This is usually used to the benefit of the program, since aliases behave like pointers in some respects. For example, passing an object is cheap since only a pointer is passed by the implementation; and if a function modifies an object passed as an argument, the caller will see the change — this eliminates the need for two different argument passing mechanisms as in Pascal.
9.2. Python Scopes and Namespaces

Before introducing classes, I first have to tell you something about Python’s scope rules. Class definitions play some neat tricks with namespaces, and you need to know how scopes and namespaces work to fully understand what’s going on. Incidentally, knowledge about this subject is useful for any advanced Python programmer.

Let’s begin with some definitions.

A namespace is a mapping from names to objects. Most namespaces are currently implemented as Python dictionaries, but that’s normally not noticeable in any way (except for performance), and it may change in the future. Examples of namespaces are: the set of built-in names (containing functions such as \texttt{abs()}, and built-in exception names); the global names in a module; and the local names in a function invocation. In a sense the set of attributes of an object also form a namespace. The important thing to know about namespaces is that there is absolutely no relation between names in different namespaces; for instance, two different modules may both define a function \texttt{maximize} without confusion — users of the modules must prefix it with the module name.

By the way, I use the word \textit{attribute} for any name following a dot — for example, in the expression \texttt{z.real}, \texttt{real} is an attribute of the object \texttt{z}. Strictly speaking, references to names in modules are attribute references: in the expression \texttt{modname.funcname}, \texttt{modname} is a module object and \texttt{funcname} is an attribute of it. In this case there happens to be a straightforward mapping between the module’s attributes and the global names defined in the module: they share the same namespace! [1]
Attributes may be read-only or writable. In the latter case, assignment to attributes is possible. Module attributes are writable: you can write `modname.the_answer = 42`. Writable attributes may also be deleted with the `del` statement. For example, `del modname.the_answer` will remove the attribute `the_answer` from the object named by `modname`.

Namespaces are created at different moments and have different lifetimes. The namespace containing the built-in names is created when the Python interpreter starts up, and is never deleted. The global namespace for a module is created when the module definition is read in; normally, module namespaces also last until the interpreter quits. The statements executed by the top-level invocation of the interpreter, either read from a script file or interactively, are considered part of a module called `__main__`, so they have their own global namespace. (The built-in names actually also live in a module; this is called `builtins`.)

The local namespace for a function is created when the function is called, and deleted when the function returns or raises an exception that is not handled within the function. (Actually, forgetting would be a better way to describe what actually happens.) Of course, recursive invocations each have their own local namespace.

A scope is a textual region of a Python program where a namespace is directly accessible. “Directly accessible” here means that an unqualified reference to a name attempts to find the name in the namespace.

Although scopes are determined statically, they are used dynamically. At any time during execution, there are at least three nested scopes whose namespaces are directly accessible:
- the innermost scope, which is searched first, contains the local names
- the scopes of any enclosing functions, which are searched starting with the nearest enclosing scope, contains non-local, but also non-global names
- the next-to-last scope contains the current module’s global names
- the outermost scope (searched last) is the namespace containing built-in names

If a name is declared global, then all references and assignments go directly to the middle scope containing the module's global names. To rebind variables found outside of the innermost scope, the `nonlocal` statement can be used; if not declared nonlocal, those variable are read-only (an attempt to write to such a variable will simply create a new local variable in the innermost scope, leaving the identically named outer variable unchanged).

Usually, the local scope references the local names of the (textually) current function. Outside functions, the local scope references the same namespace as the global scope: the module's namespace. Class definitions place yet another namespace in the local scope.

It is important to realize that scopes are determined textually: the global scope of a function defined in a module is that module's namespace, no matter from where or by what alias the function is called. On the other hand, the actual search for names is done dynamically, at run time — however, the language definition is evolving towards static name resolution, at “compile” time, so don’t rely on dynamic name resolution! (In fact, local variables are already determined statically.)

A special quirk of Python is that – if no `global` statement is in effect – assignments to names always go into the innermost scope.
Assignments do not copy data — they just bind names to objects. The same is true for deletions: the statement `del x` removes the binding of `x` from the namespace referenced by the local scope. In fact, all operations that introduce new names use the local scope: in particular, `import` statements and function definitions bind the module or function name in the local scope.

The `global` statement can be used to indicate that particular variables live in the global scope and should be rebound there; the `nonlocal` statement indicates that particular variables live in an enclosing scope and should be rebound there.

9.2.1. Scopes and Namespaces Example

This is an example demonstrating how to reference the different scopes and namespaces, and how `global` and `nonlocal` affect variable binding:

```python
def scope_test():
    def do_local():
        spam = "local spam"
    def do_nonlocal():
        nonlocal spam
        spam = "nonlocal spam"
    def do_global():
        global spam
        spam = "global spam"
        spam = "test spam"
    do_local()
    print("After local assignment:", spam)
    do_nonlocal()
    print("After nonlocal assignment:", spam)
    do_global()
    print("After global assignment:", spam)
```
scope_test()
print("In global scope:", spam)

The output of the example code is:

After local assignment: test spam
After nonlocal assignment: nonlocal spam
After global assignment: nonlocal spam
In global scope: global spam

Note how the *local* assignment (which is default) didn’t change *scope_test*’s binding of *spam*. The *nonlocal* assignment changed *scope_test*’s binding of *spam*, and the *global* assignment changed the module-level binding.

You can also see that there was no previous binding for *spam* before the *global* assignment.
9.3. A First Look at Classes

Classes introduce a little bit of new syntax, three new object types, and some new semantics.

9.3.1. Class Definition Syntax

The simplest form of class definition looks like this:

```python
class ClassName:
    <statement-1>
    ...
    ...
    <statement-N>
```

Class definitions, like function definitions (`def` statements) must be executed before they have any effect. (You could conceivably place a class definition in a branch of an `if` statement, or inside a function.)

In practice, the statements inside a class definition will usually be function definitions, but other statements are allowed, and sometimes useful — we’ll come back to this later. The function definitions inside a class normally have a peculiar form of argument list, dictated by the calling conventions for methods — again, this is explained later.

When a class definition is entered, a new namespace is created, and used as the local scope — thus, all assignments to local variables go into this new namespace. In particular, function definitions bind the name of the new function here.

When a class definition is left normally (via the end), a class object is
created. This is basically a wrapper around the contents of the namespace created by the class definition; we'll learn more about class objects in the next section. The original local scope (the one in effect just before the class definition was entered) is reinstated, and the class object is bound here to the class name given in the class definition header (ClassName in the example).

9.3.2. Class Objects

Class objects support two kinds of operations: attribute references and instantiation.

Attribute references use the standard syntax used for all attribute references in Python: `obj.name`. Valid attribute names are all the names that were in the class’s namespace when the class object was created. So, if the class definition looked like this:

```python
class MyClass:
    """A simple example class""
    i = 12345
    def f(self):
        return 'hello world'
```

then `MyClass.i` and `MyClass.f` are valid attribute references, returning an integer and a function object, respectively. Class attributes can also be assigned to, so you can change the value of `MyClass.i` by assignment. `__doc__` is also a valid attribute, returning the docstring belonging to the class: "A simple example class".

Class instantiation uses function notation. Just pretend that the class object is a parameterless function that returns a new instance of the
class. For example (assuming the above class):

```python
def __init__(self):
    self.data = []
```

creates a new *instance* of the class and assigns this object to the local variable `x`.

The instantiation operation (“calling” a class object) creates an empty object. Many classes like to create objects with instances customized to a specific initial state. Therefore a class may define a special method named `__init__()`, like this:

```python
def __init__(self):
    self.data = []
```

When a class defines an `__init__()` method, class instantiation automatically invokes `__init__()` for the newly-created class instance. So in this example, a new, initialized instance can be obtained by:

```python
x = MyClass()
```

Of course, the `__init__()` method may have arguments for greater flexibility. In that case, arguments given to the class instantiation operator are passed on to `__init__()`. For example,

```python
>>> class Complex:
...     def __init__(self, realpart, imagpart):
...         self.r = realpart
...         self.i = imagpart
...
>>> x = Complex(3.0, -4.5)
>>> x.r, x.i
(3.0, -4.5)
```
9.3.3. Instance Objects

Now what can we do with instance objects? The only operations understood by instance objects are attribute references. There are two kinds of valid attribute names, data attributes and methods.

Data attributes correspond to “instance variables” in Smalltalk, and to “data members” in C++. Data attributes need not be declared; like local variables, they spring into existence when they are first assigned to. For example, if \( x \) is the instance of MyClass created above, the following piece of code will print the value \( 16 \), without leaving a trace:

```python
x.counter = 1
while x.counter < 10:
    x.counter = x.counter * 2
print(x.counter)
del x.counter
```

The other kind of instance attribute reference is a method. A method is a function that “belongs to” an object. (In Python, the term method is not unique to class instances: other object types can have methods as well. For example, list objects have methods called append, insert, remove, sort, and so on. However, in the following discussion, we’ll use the term method exclusively to mean methods of class instance objects, unless explicitly stated otherwise.)

Valid method names of an instance object depend on its class. By definition, all attributes of a class that are function objects define corresponding methods of its instances. So in our example, \( x.f \) is a valid method reference, since MyClass.f is a function, but \( x.i \) is not, since MyClass.i is not. But \( x.f \) is not the same thing as
MyClass.f — it is a method object, not a function object.

9.3.4. Method Objects

Usually, a method is called right after it is bound:

```python
x.f()
```

In the MyClass example, this will return the string 'hello world'. However, it is not necessary to call a method right away: x.f is a method object, and can be stored away and called at a later time. For example:

```python
xf = x.f
while True:
    print(xf())
```

will continue to print hello world until the end of time.

What exactly happens when a method is called? You may have noticed that x.f() was called without an argument above, even though the function definition for f() specified an argument. What happened to the argument? Surely Python raises an exception when a function that requires an argument is called without any — even if the argument isn’t actually used...

Actually, you may have guessed the answer: the special thing about methods is that the object is passed as the first argument of the function. In our example, the call x.f() is exactly equivalent to MyClass.f(x). In general, calling a method with a list of n arguments is equivalent to calling the corresponding function with an argument list that is created by inserting the method’s object before
the first argument.

If you still don’t understand how methods work, a look at the implementation can perhaps clarify matters. When an instance attribute is referenced that isn’t a data attribute, its class is searched. If the name denotes a valid class attribute that is a function object, a method object is created by packing (pointers to) the instance object and the function object just found together in an abstract object: this is the method object. When the method object is called with an argument list, a new argument list is constructed from the instance object and the argument list, and the function object is called with this new argument list.
9.4. Random Remarks

Data attributes override method attributes with the same name; to avoid accidental name conflicts, which may cause hard-to-find bugs in large programs, it is wise to use some kind of convention that minimizes the chance of conflicts. Possible conventions include capitalizing method names, prefixing data attribute names with a small unique string (perhaps just an underscore), or using verbs for methods and nouns for data attributes.

Data attributes may be referenced by methods as well as by ordinary users (“clients”) of an object. In other words, classes are not usable to implement pure abstract data types. In fact, nothing in Python makes it possible to enforce data hiding — it is all based upon convention. (On the other hand, the Python implementation, written in C, can completely hide implementation details and control access to an object if necessary; this can be used by extensions to Python written in C.)

Clients should use data attributes with care — clients may mess up invariants maintained by the methods by stamping on their data attributes. Note that clients may add data attributes of their own to an instance object without affecting the validity of the methods, as long as name conflicts are avoided — again, a naming convention can save a lot of headaches here.

There is no shorthand for referencing data attributes (or other methods!) from within methods. I find that this actually increases the readability of methods: there is no chance of confusing local variables and instance variables when glancing through a method.

Often, the first argument of a method is called self. This is nothing more than a convention: the name self has absolutely no special
meaning to Python. Note, however, that by not following the convention your code may be less readable to other Python programmers, and it is also conceivable that a class browser program might be written that relies upon such a convention.

Any function object that is a class attribute defines a method for instances of that class. It is not necessary that the function definition is textually enclosed in the class definition: assigning a function object to a local variable in the class is also ok. For example:

```python
# Function defined outside the class
def f1(self, x, y):
    return min(x, x+y)

class C:
    f = f1
    def g(self):
        return 'hello world'
    h = g
```

Now f, g and h are all attributes of class C that refer to function objects, and consequently they are all methods of instances of C — h being exactly equivalent to g. Note that this practice usually only serves to confuse the reader of a program.

Methods may call other methods by using method attributes of the self argument:

```python
class Bag:
    def __init__(self):
        self.data = []
    def add(self, x):
        self.data.append(x)
    def addtwice(self, x):
```
Methods may reference global names in the same way as ordinary functions. The global scope associated with a method is the module containing its definition. (A class is never used as a global scope.) While one rarely encounters a good reason for using global data in a method, there are many legitimate uses of the global scope: for one thing, functions and modules imported into the global scope can be used by methods, as well as functions and classes defined in it. Usually, the class containing the method is itself defined in this global scope, and in the next section we'll find some good reasons why a method would want to reference its own class.

Each value is an object, and therefore has a class (also called its type). It is stored as `object.__class__`. 

```python
self.add(x)
self.add(x)
```
9.5. Inheritance

Of course, a language feature would not be worthy of the name “class” without supporting inheritance. The syntax for a derived class definition looks like this:

```python
class DerivedClassName(BaseClassName):
    <statement-1>
    ...
    ...
    <statement-N>
```

The name `BaseClassName` must be defined in a scope containing the derived class definition. In place of a base class name, other arbitrary expressions are also allowed. This can be useful, for example, when the base class is defined in another module:

```python
class DerivedClassName(modname.BaseClassName):
```

Execution of a derived class definition proceeds the same as for a base class. When the class object is constructed, the base class is remembered. This is used for resolving attribute references: if a requested attribute is not found in the class, the search proceeds to look in the base class. This rule is applied recursively if the base class itself is derived from some other class.

There's nothing special about instantiation of derived classes: `DerivedClassName()` creates a new instance of the class. Method references are resolved as follows: the corresponding class attribute is searched, descending down the chain of base classes if necessary, and the method reference is valid if this yields a function object.
Derived classes may override methods of their base classes. Because methods have no special privileges when calling other methods of the same object, a method of a base class that calls another method defined in the same base class may end up calling a method of a derived class that overrides it. (For C++ programmers: all methods in Python are effectively virtual.)

An overriding method in a derived class may in fact want to extend rather than simply replace the base class method of the same name. There is a simple way to call the base class method directly: just call BaseClassName.methodname(self, arguments). This is occasionally useful to clients as well. (Note that this only works if the base class is accessible as BaseClassName in the global scope.)

Python has two built-in functions that work with inheritance:

- Use `isinstance()` to check an instance's type: `isinstance(obj, int)` will be True only if `obj.__class__` is `int` or some class derived from `int`.
- Use `issubclass()` to check class inheritance: `issubclass(bool, int)` is True since `bool` is a subclass of `int`. However, `issubclass(float, int)` is False since `float` is not a subclass of `int`.

### 9.5.1. Multiple Inheritance

Python supports a form of multiple inheritance as well. A class definition with multiple base classes looks like this:

```python
class DerivedClassName(Base1, Base2, Base3):
    <statement-1>
    ...
```
For most purposes, in the simplest cases, you can think of the search for attributes inherited from a parent class as depth-first, left-to-right, not searching twice in the same class where there is an overlap in the hierarchy. Thus, if an attribute is not found in DerivedClassName, it is searched for in Base1, then (recursively) in the base classes of Base1, and if it was not found there, it was searched for in Base2, and so on.

In fact, it is slightly more complex than that; the method resolution order changes dynamically to support cooperative calls to `super()`. This approach is known in some other multiple-inheritance languages as call-next-method and is more powerful than the super call found in single-inheritance languages.

Dynamic ordering is necessary because all cases of multiple inheritance exhibit one or more diamond relationships (where at least one of the parent classes can be accessed through multiple paths from the bottommost class). For example, all classes inherit from `object`, so any case of multiple inheritance provides more than one path to reach `object`. To keep the base classes from being accessed more than once, the dynamic algorithm linearizes the search order in a way that preserves the left-to-right ordering specified in each class, that calls each parent only once, and that is monotonic (meaning that a class can be subclassed without affecting the precedence order of its parents). Taken together, these properties make it possible to design reliable and extensible classes with multiple inheritance. For more detail, see http://www.python.org/download/releases/2.3/mro/.
9.6. Private Variables

“Private” instance variables that cannot be accessed except from inside an object don’t exist in Python. However, there is a convention that is followed by most Python code: a name prefixed with an underscore (e.g. _spam) should be treated as a non-public part of the API (whether it is a function, a method or a data member). It should be considered an implementation detail and subject to change without notice.

Since there is a valid use-case for class-private members (namely to avoid name clashes of names with names defined by subclasses), there is limited support for such a mechanism, called name mangling. Any identifier of the form __spam (at least two leading underscores, at most one trailing underscore) is textually replaced with __classname__spam, where classname is the current class name with leading underscore(s) stripped. This mangling is done without regard to the syntactic position of the identifier, as long as it occurs within the definition of a class.

Name mangling is helpful for letting subclasses override methods without breaking intraclass method calls. For example:

```python
class Mapping:
    def __init__(self, iterable):
        self.items_list = []
        self.__update(iterable)

    def update(self, iterable):
        for item in iterable:
            self.items_list.append(item)

    __update = update  # private copy of original update method
```
class MappingSubclass(Mapping):

    def update(self, keys, values):
        # provides new signature for update()
        # but does not break __init__()
        for item in zip(keys, values):
            self.items_list.append(item)

Note that the mangling rules are designed mostly to avoid accidents; it still is possible to access or modify a variable that is considered private. This can even be useful in special circumstances, such as in the debugger.

Notice that code passed to exec() or eval() does not consider the classname of the invoking class to be the current class; this is similar to the effect of the global statement, the effect of which is likewise restricted to code that is byte-compiled together. The same restriction applies to getattr(), setattr() and delattr(), as well as when referencing __dict__ directly.
9.7. Odds and Ends

Sometimes it is useful to have a data type similar to the Pascal “record” or C “struct”, bundling together a few named data items. An empty class definition will do nicely:

```python
class Employee:
    pass

john = Employee()  # Create an empty employee record

# Fill the fields of the record
john.name = 'John Doe'
john.dept = 'computer lab'
john.salary = 1000
```

A piece of Python code that expects a particular abstract data type can often be passed a class that emulates the methods of that data type instead. For instance, if you have a function that formats some data from a file object, you can define a class with methods read() and readline() that get the data from a string buffer instead, and pass it as an argument.

Instance method objects have attributes, too: `m.__self__` is the instance object with the method `m()`, and `m.__func__` is the function object corresponding to the method.
9.8. Exceptions Are Classes Too

User-defined exceptions are identified by classes as well. Using this mechanism it is possible to create extensible hierarchies of exceptions.

There are two new valid (semantic) forms for the `raise` statement:

```
raise Class
raise Instance
```

In the first form, `Class` must be an instance of `type` or of a class derived from it. The first form is a shorthand for:

```
raise Class()
```

A class in an `except` clause is compatible with an exception if it is the same class or a base class thereof (but not the other way around — an except clause listing a derived class is not compatible with a base class). For example, the following code will print B, C, D in that order:

```
class B(Exception):
    pass
class C(B):
    pass
class D(C):
    pass
for cls in [B, C, D]:
    try:
        raise cls()
    except D:
        print("D")
```
```python
except C:
    print("C")
except B:
    print("B")
```

Note that if the except clauses were reversed (with `except B` first), it would have printed `B`, `B`, `B` — the first matching except clause is triggered.

When an error message is printed for an unhandled exception, the exception's class name is printed, then a colon and a space, and finally the instance converted to a string using the built-in function `str()`.
By now you have probably noticed that most container objects can be looped over using a `for` statement:

```python
for element in [1, 2, 3]:
    print(element)
for element in (1, 2, 3):
    print(element)
for key in {'one':1, 'two':2}:
    print(key)
for char in "123":
    print(char)
for line in open("myfile.txt"):
    print(line)
```

This style of access is clear, concise, and convenient. The use of iterators pervades and unifies Python. Behind the scenes, the `for` statement calls `iter()` on the container object. The function returns an iterator object that defines the method `__next__()` which accesses elements in the container one at a time. When there are no more elements, `__next__()` raises a `StopIteration` exception which tells the `for` loop to terminate. You can call the `__next__()` method using the `next()` built-in function; this example shows how it all works:

```python
>>> s = 'abc'
>>> it = iter(s)
>>> it
<iterator object at 0x00A1DB50>
>>> next(it)
'a'
>>> next(it)
```
Having seen the mechanics behind the iterator protocol, it is easy to add iterator behavior to your classes. Define an `__iter__()` method which returns an object with a `__next__()` method. If the class defines `__next__()`, then `__iter__()` can just return `self`:

```python
class Reverse:
    '''Iterator for looping over a sequence backwards.'''
    def __init__(self, data):
        self.data = data
        self.index = len(data)
    def __iter__(self):
        return self
    def __next__(self):
        if self.index == 0:
            raise StopIteration
        self.index = self.index - 1
        return self.data[self.index]
```

```python
>>> rev = Reverse('spam')
>>> iter(rev)
<__main__.Reverse object at 0x00A1DB50>
>>> for char in rev:
...     print(char)
...
m
```
9.10. Generators

Generators are a simple and powerful tool for creating iterators. They are written like regular functions but use the `yield` statement whenever they want to return data. Each time `next()` is called on it, the generator resumes where it left-off (it remembers all the data values and which statement was last executed). An example shows that generators can be trivially easy to create:

```python
def reverse(data):
    for index in range(len(data)-1, -1, -1):
        yield data[index]
```

```bash
>>> for char in reverse('golf'):
    ...    print(char)
    ...
flolg
```

Anything that can be done with generators can also be done with class based iterators as described in the previous section. What makes generators so compact is that the `__iter__()` and `__next__()` methods are created automatically.

Another key feature is that the local variables and execution state are automatically saved between calls. This made the function easier to write and much more clear than an approach using instance variables like `self.index` and `self.data`.

In addition to automatic method creation and saving program state, when generators terminate, they automatically raise
StopIteration. In combination, these features make it easy to create iterators with no more effort than writing a regular function.
9.11. Generator Expressions

Some simple generators can be coded succinctly as expressions using a syntax similar to list comprehensions but with parentheses instead of brackets. These expressions are designed for situations where the generator is used right away by an enclosing function. Generator expressions are more compact but less versatile than full generator definitions and tend to be more memory friendly than equivalent list comprehensions.

Examples:

```python
>>> sum(i*i for i in range(10))  # sum of squares
285

>>> xvec = [10, 20, 30]
>>> yvec = [7, 5, 3]
>>> sum(x*y for x,y in zip(xvec, yvec))  # dot product
260

>>> from math import pi, sin
>>> sine_table = {x: sin(x*pi/180) for x in range(0, 181)}

>>> unique_words = set(word for line in page for word

>>> valedictorian = max((student.gpa, student.name)

>>> data = 'golf'
>>> list(data[i] for i in range(len(data)-1, -1, -1))
['f', 'l', 'o', 'g']
```

Footnotes
Except for one thing. Module objects have a secret read-only attribute called `__dict__` which returns the dictionary used to implement the module's namespace; the name `__dict__` is an attribute but not a global name. Obviously, using this violates the abstraction of namespace implementation, and should be restricted to things like post-mortem debuggers.
10. Brief Tour of the Standard Library
10.1. Operating System Interface

The `os` module provides dozens of functions for interacting with the operating system:

```python
>>> import os
>>> os.getcwd()  # Return the current working directory
'C:Python33'
>>> os.chdir('/server/accesslogs')  # Change current working directory
>>> os.system('mkdir today')  # Run the command mkdir in the system shell
```

Be sure to use the `import os` style instead of `from os import *`. This will keep `os.open()` from shadowing the built-in `open()` function which operates much differently.

The built-in `dir()` and `help()` functions are useful as interactive aids for working with large modules like `os`:

```python
>>> import os
>>> dir(os)
<returns a list of all module functions>
>>> help(os)
<returns an extensive manual page created from the module's docstrings>
```

For daily file and directory management tasks, the `shutil` module provides a higher level interface that is easier to use:

```python
>>> import shutil
>>> shutil.copyfile('data.db', 'archive.db')
>>> shutil.move('/build/executables', 'installdir')
```
10.2. File Wildcards

The `glob` module provides a function for making file lists from directory wildcard searches:

```python
>>> import glob
>>> glob.glob('*.py')
['primes.py', 'random.py', 'quote.py']
```
10.3. Command Line Arguments

Common utility scripts often need to process command line arguments. These arguments are stored in the `sys` module's `argv` attribute as a list. For instance the following output results from running `python demo.py one two three` at the command line:

```python
>>> import sys
>>> print(sys.argv)
['demo.py', 'one', 'two', 'three']
```

The `getopt` module processes `sys.argv` using the conventions of the Unix `getopt()` function. More powerful and flexible command line processing is provided by the `argparse` module.
10.4. Error Output Redirection and Program Termination

The `sys` module also has attributes for `stdin`, `stdout`, and `stderr`. The latter is useful for emitting warnings and error messages to make them visible even when `stdout` has been redirected:

```python
>>> sys.stderr.write('Warning, log file not found starting a new one
Warning, log file not found starting a new one
```

The most direct way to terminate a script is to use `sys.exit()`. 
10.5. String Pattern Matching

The `re` module provides regular expression tools for advanced string processing. For complex matching and manipulation, regular expressions offer succinct, optimized solutions:

```python
>>> import re
>>> re.findall(r'\bf[a-z]*', 'which foot or hand fell fastest')
['foot', 'fell', 'fastest']
>>> re.sub(r'\b[a-z]+ \1', r'\1', 'cat in the the hat')
'cat in the hat'
```

When only simple capabilities are needed, string methods are preferred because they are easier to read and debug:

```python
>>> 'tea for too'.replace('too', 'two')
'tea for two'
```
10.6. Mathematics

The `math` module gives access to the underlying C library functions for floating point math:

```python
>>> import math
>>> math.cos(math.pi / 4)
0.70710678118654757
>>> math.log(1024, 2)
10.0
```

The `random` module provides tools for making random selections:

```python
>>> import random
>>> random.choice(['apple', 'pear', 'banana'])
'apple'
>>> random.sample(range(100), 10)  # sampling without replacement
[30, 83, 16, 4, 8, 81, 41, 50, 18, 33]
>>> random.random()  # random float
0.17970987693706186
>>> random.randrange(6)  # random integer chosen from range(6)
4
```

The SciPy project <http://scipy.org> has many other modules for numerical computations.
10.7. Internet Access

There are a number of modules for accessing the internet and processing internet protocols. Two of the simplest are \texttt{urllib.request} for retrieving data from URLs and \texttt{smtplib} for sending mail:

```python
>>> from urllib.request import urlopen
>>> for line in urlopen('http://tycho.usno.navy.mil/
...     line = line.decode('utf-8')  # Decoding the
...     if 'EST' in line or 'EDT' in line:  # look for
...     print(line)

<BR>Nov. 25, 09:43:32 PM EST
```

```python
>>> import smtplib
>>> server = smtplib.SMTP('localhost')
>>> server.sendmail('soothsayer@example.org', 'jcaesar@julius.com',
...     """To: jcaesar@example.org
...     From: soothsayer@example.org
...     """
...     """Beware the Ides of March.
...     """
>>> server.quit()
```

(Note that the second example needs a mailserver running on localhost.)
10.8. Dates and Times

The `datetime` module supplies classes for manipulating dates and times in both simple and complex ways. While date and time arithmetic is supported, the focus of the implementation is on efficient member extraction for output formatting and manipulation. The module also supports objects that are timezone aware.

```python
>>> # dates are easily constructed and formatted
>>> from datetime import date
>>> now = date.today()
>>> now
datetime.date(2003, 12, 2)
>>> now.strftime("%m-%d-%y. %d %b %Y is a %A on the '12-02-03. 02 Dec 2003 is a Tuesday on the 02 day of

>>> # dates support calendar arithmetic
>>> birthday = date(1964, 7, 31)
>>> age = now - birthday
>>> age.days
14368
```
10.9. Data Compression

Common data archiving and compression formats are directly supported by modules including: zlib, gzip, bzip2, lzma, zipfile and tarfile.

```python
>>> import zlib
>>> s = b'witch which has which witches wrist watch'
>>> len(s)
41
>>> t = zlib.compress(s)
>>> len(t)
37
>>> zlib.decompress(t)
b'witch which has which witches wrist watch'
>>> zlib.crc32(s)
226805979
```
10.10. Performance Measurement

Some Python users develop a deep interest in knowing the relative performance of different approaches to the same problem. Python provides a measurement tool that answers those questions immediately.

For example, it may be tempting to use the tuple packing and unpacking feature instead of the traditional approach to swapping arguments. The `timeit` module quickly demonstrates a modest performance advantage:

```python
>>> from timeit import Timer
>>> Timer('t=a; a=b; b=t', 'a=1; b=2').timeit()
0.5753828626024577
>>> Timer('a,b = b,a', 'a=1; b=2').timeit()
0.54962537085770791
```

In contrast to `timeit`'s fine level of granularity, the `profile` and `pstats` modules provide tools for identifying time critical sections in larger blocks of code.
10.11. Quality Control

One approach for developing high quality software is to write tests for each function as it is developed and to run those tests frequently during the development process.

The `doctest` module provides a tool for scanning a module and validating tests embedded in a program’s docstrings. Test construction is as simple as cutting-and-pasting a typical call along with its results into the docstring. This improves the documentation by providing the user with an example and it allows the doctest module to make sure the code remains true to the documentation:

```python
def average(values):
    """Computes the arithmetic mean of a list of numbers."

    >>> print(average([20, 30, 70]))
    40.0
    """
    return sum(values) / len(values)

import doctest
doctest.testmod()  # automatically validate the embedded tests
```

The `unittest` module is not as effortless as the `doctest` module, but it allows a more comprehensive set of tests to be maintained in a separate file:

```python
import unittest
class TestStatisticalFunctions(unittest.TestCase):
    def test_average(self):
```
self.assertEqual(average([20, 30, 70]), 40.0)
self.assertEqual(round(average([1, 5, 7])), 4)

with self.assertRaises(ZeroDivisionError):
    average([])

with self.assertRaises(TypeError):
    average(20, 30, 70)

unittest.main() # Calling from the command line invokes all tests
10.12. Batteries Included

Python has a “batteries included” philosophy. This is best seen through the sophisticated and robust capabilities of its larger packages. For example:

- The `xmlrpc.client` and `xmlrpc.server` modules make implementing remote procedure calls into an almost trivial task. Despite the modules names, no direct knowledge or handling of XML is needed.
- The `email` package is a library for managing email messages, including MIME and other RFC 2822-based message documents. Unlike `smtplib` and `poplib` which actually send and receive messages, the email package has a complete toolset for building or decoding complex message structures (including attachments) and for implementing internet encoding and header protocols.
- The `xml.dom` and `xml.sax` packages provide robust support for parsing this popular data interchange format. Likewise, the `csv` module supports direct reads and writes in a common database format. Together, these modules and packages greatly simplify data interchange between Python applications and other tools.
- Internationalization is supported by a number of modules including `gettext`, `locale`, and the `codecs` package.
11. Brief Tour of the Standard Library – Part II

This second tour covers more advanced modules that support professional programming needs. These modules rarely occur in small scripts.
11.1. Output Formatting

The *reprlib* module provides a version of *repr()* customized for abbreviated displays of large or deeply nested containers:

```python
>>> import reprlib
>>> reprlib.repr(set('supercalifragilisticexpialidocious'))
'Set(['a', 'c', 'd', 'e', 'f', 'g', ...])'
```

The *pprint* module offers more sophisticated control over printing both built-in and user defined objects in a way that is readable by the interpreter. When the result is longer than one line, the “pretty printer” adds line breaks and indentation to more clearly reveal data structure:

```python
>>> import pprint
>>> t = [[['black', 'cyan'], 'white', ['green', 'red', ... 'yellow']], 'blue']
... >>> pprint.pprint(t, width=30)
[['black', 'cyan'],
 'white',
 ['green', 'red'],
 [['magenta', 'yellow'],
  'blue']]
```

The *textwrap* module formats paragraphs of text to fit a given screen width:

```python
>>> import textwrap
>>> doc = """The wrap() method is just like fill() except that it returns a list of strings instead of one big string with ... the wrapped lines.""
```
The `textwrap` module provides the `wrap()` function, which is similar to `fill()` except that it returns a list of strings instead of one big string with newlines to separate the wrapped lines.

The `locale` module accesses a database of culture specific data formats. The grouping attribute of `locale`'s format function provides a direct way of formatting numbers with group separators:

```python
>>> import locale
>>> locale.setlocale(locale.LC_ALL, 'English_United States.1252')
'English_United States.1252'
>>> conv = locale.localeconv()  # get a mapping
>>> x = 1234567.8
>>> locale.format("%d", x, grouping=True)
'1,234,567'
>>> locale.format_string("%s.%*f", (conv['currency_symbol'], conv['frac_digits'], x), grouping=True)
'$1,234,567.80'
```
11.2. Templating

The string module includes a versatile Template class with a simplified syntax suitable for editing by end-users. This allows users to customize their applications without having to alter the application.

The format uses placeholder names formed by $ with valid Python identifiers (alphanumeric characters and underscores). Surrounding the placeholder with braces allows it to be followed by more alphanumeric letters with no intervening spaces. Writing $$ creates a single escaped $:

```python
>>> from string import Template
>>> t = Template('${village}folk send $$10 to $cause.
'Nottinghamfolk send $10 to the ditch fund.'
```

The substitute() method raises a KeyError when a placeholder is not supplied in a dictionary or a keyword argument. For mail-merge style applications, user supplied data may be incomplete and the safe_substitute() method may be more appropriate — it will leave placeholders unchanged if data is missing:

```python
>>> t = Template('Return the $item to $owner.')
>>> d = dict(item='unladen swallow')
>>> t.substitute(d)
Traceback (most recent call last):
... KeyError: 'owner'
>>> t.safe_substitute(d)
'Return the unladen swallow to $owner.'
```
Template subclasses can specify a custom delimiter. For example, a batch renaming utility for a photo browser may elect to use percent signs for placeholders such as the current date, image sequence number, or file format:

```python
>>> import time, os.path
>>> photofiles = ['img_1074.jpg', 'img_1076.jpg', 'img_1077.jpg']
>>> class BatchRename(Template):
...     delimiter = '%'
>>> fmt = input('Enter rename style (%d-date %n-seqnum %f-format):')
Enter rename style (%d-date %n-seqnum %f-format): Ashley_%n%f

>>> t = BatchRename(fmt)
>>> date = time.strftime('%d%b%y')
>>> for i, filename in enumerate(photofiles):
...     base, ext = os.path.splitext(filename)
...     newname = t.substitute(d=date, n=i, f=ext)
...     print('{0} --+> {1}'.format(filename, newname))

img_1074.jpg --+> Ashley_0.jpg
img_1076.jpg --+> Ashley_1.jpg
img_1077.jpg --+> Ashley_2.jpg
```

Another application for templating is separating program logic from the details of multiple output formats. This makes it possible to substitute custom templates for XML files, plain text reports, and HTML web reports.
11.3. Working with Binary Data Record Layouts

The `struct` module provides `pack()` and `unpack()` functions for working with variable length binary record formats. The following example shows how to loop through header information in a ZIP file without using the `zipfile` module. Pack codes "H" and "I" represent two and four byte unsigned numbers respectively. The "<" indicates that they are standard size and in little-endian byte order:

```python
import struct

with open('myfile.zip', 'rb') as f:
    data = f.read()

start = 0
for i in range(3):  # show the first 3 file headers
    start += 14
    fields = struct.unpack('<IIIHH', data[start:start+14])
   crc32, comp_size, uncomp_size, filenamesize, extra_size = fields
    start += 16
    filename = data[start:start+filenamesize]
    start += filenamesize
    extra = data[start:start+extra_size]
    print(filename, hex(crc32), comp_size, uncomp_size)
    start += extra_size + comp_size  # skip to the next header
```

11.4. Multi-threading

Threading is a technique for decoupling tasks which are not sequentially dependent. Threads can be used to improve the responsiveness of applications that accept user input while other tasks run in the background. A related use case is running I/O in parallel with computations in another thread.

The following code shows how the high level `threading` module can run tasks in background while the main program continues to run:

```python
import threading, zipfile

class AsyncZip(threading.Thread):
    def __init__(self, infile, outfile):
        threading.Thread.__init__(self)
        self.infile = infile
        self.outfile = outfile
    def run(self):
        f = zipfile.ZipFile(self.outfile, 'w', zipfile.ZIP_DEFLATED)
        f.write(self.infile)
        f.close()
        print('Finished background zip of:', self.infile)

background = AsyncZip('mydata.txt', 'myarchive.zip')
background.start()
print('The main program continues to run in foreground')
background.join()  # Wait for the background task
print('Main program waited until background was done')
```

The principal challenge of multi-threaded applications is coordinating threads that share data or other resources. To that end, the threading
module provides a number of synchronization primitives including locks, events, condition variables, and semaphores.

While those tools are powerful, minor design errors can result in problems that are difficult to reproduce. So, the preferred approach to task coordination is to concentrate all access to a resource in a single thread and then use the queue module to feed that thread with requests from other threads. Applications using Queue objects for inter-thread communication and coordination are easier to design, more readable, and more reliable.
11.5. Logging

The **logging** module offers a full featured and flexible logging system. At its simplest, log messages are sent to a file or to `sys.stderr`:

```python
import logging
logging.debug('Debugging information')
logging.info('Informational message')
logging.warning('Warning: config file %s not found',
logging.error('Error occurred')
logging.critical('Critical error -- shutting down')
```

This produces the following output:

```
WARNING:root:Warning: config file server.conf not found
ERROR:root:Error occurred
CRITICAL:root:Critical error -- shutting down
```

By default, informational and debugging messages are suppressed and the output is sent to standard error. Other output options include routing messages through email, datagrams, sockets, or to an HTTP Server. New filters can select different routing based on message priority: DEBUG, INFO, WARNING, ERROR, and CRITICAL.

The logging system can be configured directly from Python or can be loaded from a user editable configuration file for customized logging without altering the application.
11.6. Weak References

Python does automatic memory management (reference counting for most objects and garbage collection to eliminate cycles). The memory is freed shortly after the last reference to it has been eliminated.

This approach works fine for most applications but occasionally there is a need to track objects only as long as they are being used by something else. Unfortunately, just tracking them creates a reference that makes them permanent. The weakref module provides tools for tracking objects without creating a reference. When the object is no longer needed, it is automatically removed from a weakref table and a callback is triggered for weakref objects. Typical applications include caching objects that are expensive to create:

```python
g>>> import weakref, gc
g>>> class A:
g    ...    def __init__(self, value):
g        ...        self.value = value
    ...    def __repr__(self):
g    ...        return str(self.value)
    ...

g>>> a = A(10)  # create a reference

g>>> d = weakref.WeakValueDictionary()

g>>> d['primary'] = a  # does not create a reference

g>>> d['primary']  # fetch the object if it is still alive
10

g>>> del a  # remove the one reference

g>>> gc.collect()  # run garbage collector
0

g>>> d['primary']  # entry was automatically removed
Traceback (most recent call last):
  File "<stdin>", line 1, in <module>
    d['primary']  # entry was automatically removed
```

File "C:/python33/lib/weakref.py", line 46, in __getitem__
o = self.data[key]()

KeyError: 'primary'
11.7. Tools for Working with Lists

Many data structure needs can be met with the built-in list type. However, sometimes there is a need for alternative implementations with different performance trade-offs.

The `array` module provides an `array()` object that is like a list that stores only homogeneous data and stores it more compactly. The following example shows an array of numbers stored as two byte unsigned binary numbers (typecode "H") rather than the usual 16 bytes per entry for regular lists of Python int objects:

```python
>>> from array import array
>>> a = array('H', [4000, 10, 700, 22222])
>>> sum(a)
26932
>>> a[1:3]
array('H', [10, 700])
```

The `collections` module provides a `deque()` object that is like a list with faster appends and pops from the left side but slower lookups in the middle. These objects are well suited for implementing queues and breadth first tree searches:

```python
>>> from collections import deque
>>> d = deque(["task1", "task2", "task3"])
>>> d.append("task4")
>>> print("Handling", d.popleft())
Handling task1

unsearched = deque([starting_node])
def breadth_first_search(unsearched):
    node = unsearched.popleft()
```
for m in gen_moves(node):
    if is_goal(m):
        return m
unsearched.append(m)

In addition to alternative list implementations, the library also offers other tools such as the `biseck` module with functions for manipulating sorted lists:

```python
>>> import bisect
>>> scores = [(100, 'perl'), (200, 'tcl'), (400, 'lua')]
>>> bisect.insort(scores, (300, 'ruby'))
>>> scores
[(100, 'perl'), (200, 'tcl'), (300, 'ruby'), (400, 'lua')]
```

The `heapq` module provides functions for implementing heaps based on regular lists. The lowest valued entry is always kept at position zero. This is useful for applications which repeatedly access the smallest element but do not want to run a full list sort:

```python
>>> from heapq import heapify, heappop, heappush
>>> data = [1, 3, 5, 7, 9, 2, 4, 6, 8, 0]
>>> heapify(data) # rearrange the list into heap order
>>> heappush(data, -5) # add a new entry
>>> [heappop(data) for i in range(3)] # fetch the three smallest entries
[-5, 0, 1]
```
11.8. Decimal Floating Point Arithmetic

The `decimal` module offers a `Decimal` datatype for decimal floating point arithmetic. Compared to the built-in `float` implementation of binary floating point, the class is especially helpful for

- financial applications and other uses which require exact decimal representation,
- control over precision,
- control over rounding to meet legal or regulatory requirements,
- tracking of significant decimal places, or
- applications where the user expects the results to match calculations done by hand.

For example, calculating a 5% tax on a 70 cent phone charge gives different results in decimal floating point and binary floating point. The difference becomes significant if the results are rounded to the nearest cent:

```python
>>> from decimal import *
>>> round(Decimal('0.70') * Decimal('1.05'), 2)
Decimal('0.74')
>>> round(.70 * 1.05, 2)
0.73
```

The `Decimal` result keeps a trailing zero, automatically inferring four place significance from multiplicands with two place significance. Decimal reproduces mathematics as done by hand and avoids issues that can arise when binary floating point cannot exactly represent decimal quantities.

Exact representation enables the `Decimal` class to perform modulo calculations and equality tests that are unsuitable for binary floating
The `decimal` module provides arithmetic with as much precision as needed:
12. What Now?

Reading this tutorial has probably reinforced your interest in using Python — you should be eager to apply Python to solving your real-world problems. Where should you go to learn more?

This tutorial is part of Python’s documentation set. Some other documents in the set are:

- **The Python Standard Library**:

  You should browse through this manual, which gives complete (though terse) reference material about types, functions, and the modules in the standard library. The standard Python distribution includes a lot of additional code. There are modules to read Unix mailboxes, retrieve documents via HTTP, generate random numbers, parse command-line options, write CGI programs, compress data, and many other tasks. Skimming through the Library Reference will give you an idea of what’s available.

- **Installing Python Modules** explains how to install external modules written by other Python users.

- **The Python Language Reference**: A detailed explanation of Python’s syntax and semantics. It’s heavy reading, but is useful as a complete guide to the language itself.

More Python resources:

- **http://www.python.org**: The major Python Web site. It contains code, documentation, and pointers to Python-related pages around the Web. This Web site is mirrored in various places around the world, such as Europe, Japan, and Australia; a mirror
may be faster than the main site, depending on your geographical location.

- **http://docs.python.org**: Fast access to Python’s documentation.
- **http://pypi.python.org**: The Python Package Index, previously also nicknamed the Cheese Shop, is an index of user-created Python modules that are available for download. Once you begin releasing code, you can register it here so that others can find it.
- **http://aspn.activestate.com/ASPN/Python/Cookbook/**: The Python Cookbook is a sizable collection of code examples, larger modules, and useful scripts. Particularly notable contributions are collected in a book also titled Python Cookbook (O’Reilly & Associates, ISBN 0-596-00797-3.)
- **http://scipy.org**: The Scientific Python project includes modules for fast array computations and manipulations plus a host of packages for such things as linear algebra, Fourier transforms, non-linear solvers, random number distributions, statistical analysis and the like.

For Python-related questions and problem reports, you can post to the newsgroup *comp.lang.python*, or send them to the mailing list at python-list@python.org. The newsgroup and mailing list are gatewayed, so messages posted to one will automatically be forwarded to the other. There are around 120 postings a day (with peaks up to several hundred), asking (and answering) questions, suggesting new features, and announcing new modules. Before posting, be sure to check the list of *Frequently Asked Questions* (also called the FAQ). Mailing list archives are available at http://mail.python.org/pipermail/. The FAQ answers many of the questions that come up again and again, and may already contain the solution for your problem.
13. Interactive Input Editing and History Substitution

Some versions of the Python interpreter support editing of the current input line and history substitution, similar to facilities found in the Korn shell and the GNU Bash shell. This is implemented using the GNU Readline library, which supports Emacs-style and vi-style editing. This library has its own documentation which I won’t duplicate here; however, the basics are easily explained. The interactive editing and history described here are optionally available in the Unix and Cygwin versions of the interpreter.

This chapter does not document the editing facilities of Mark Hammond’s PythonWin package or the Tk-based environment, IDLE, distributed with Python. The command line history recall which operates within DOS boxes on NT and some other DOS and Windows flavors is yet another beast.
13.1. Line Editing

If supported, input line editing is active whenever the interpreter prints a primary or secondary prompt. The current line can be edited using the conventional Emacs control characters. The most important of these are: C-A (Control-A) moves the cursor to the beginning of the line, C-E to the end, C-B moves it one position to the left, C-F to the right. Backspace erases the character to the left of the cursor, C-D the character to its right. C-K kills (erasers) the rest of the line to the right of the cursor, C-Y yanks back the last killed string. C-underscore undoes the last change you made; it can be repeated for cumulative effect.
13.2. History Substitution

History substitution works as follows. All non-empty input lines issued are saved in a history buffer, and when a new prompt is given you are positioned on a new line at the bottom of this buffer. C-P moves one line up (back) in the history buffer, C-N moves one down. Any line in the history buffer can be edited; an asterisk appears in front of the prompt to mark a line as modified. Pressing the Return key passes the current line to the interpreter. C-R starts an incremental reverse search; C-S starts a forward search.
13.3. Key Bindings

The key bindings and some other parameters of the Readline library can be customized by placing commands in an initialization file called ~/.inputrc. Key bindings have the form

```
key-name: function-name
```

or

```
"string": function-name
```

and options can be set with

```
set option-name value
```

For example:

```
# I prefer vi-style editing:
set editing-mode vi

# Edit using a single line:
set horizontal-scroll-mode On

# Rebind some keys:
Meta-h: backward-kill-word
"\C-u": universal-argument
"\C-x\C-r": re-read-init-file
```

Note that the default binding for Tab in Python is to insert a Tab character instead of Readline's default filename completion function. If you insist, you can override this by putting
Tab: complete

in your ~/.inputrc. (Of course, this makes it harder to type indented continuation lines if you're accustomed to using Tab for that purpose.)

Automatic completion of variable and module names is optionally available. To enable it in the interpreter’s interactive mode, add the following to your startup file: [1]

```python
import rlcompleter, readline
readline.parse_and_bind('tab: complete')
```

This binds the Tab key to the completion function, so hitting the Tab key twice suggests completions; it looks at Python statement names, the current local variables, and the available module names. For dotted expressions such as `string.a`, it will evaluate the expression up to the final `.` and then suggest completions from the attributes of the resulting object. Note that this may execute application-defined code if an object with a `__getattr__()` method is part of the expression.

A more capable startup file might look like this example. Note that this deletes the names it creates once they are no longer needed; this is done since the startup file is executed in the same namespace as the interactive commands, and removing the names avoids creating side effects in the interactive environment. You may find it convenient to keep some of the imported modules, such as `os`, which turn out to be needed in most sessions with the interpreter.

```python
# Add auto-completion and a stored history file of commands to your Python interactive interpreter. Requires Python 2.0+, read
# bound to the Esc key by default (you can change it to your
```
# Store the file in ~/.pystartup, and set an environment variable to it: "export PYTHONSTARTUP=~/.pystartup" in bash.

import atexit
import os
import readline
import rlcompleter

historyPath = os.path.expanduser("~/.pyhistory")

def save_history(historyPath=historyPath):
    import readline
    readline.write_history_file(historyPath)

if os.path.exists(historyPath):
    readline.read_history_file(historyPath)

atexit.register(save_history)

delete os, atexit, readline, rlcompleter, save_history,
13.4. Alternatives to the Interactive Interpreter

This facility is an enormous step forward compared to earlier versions of the interpreter; however, some wishes are left: It would be nice if the proper indentation were suggested on continuation lines (the parser knows if an indent token is required next). The completion mechanism might use the interpreter's symbol table. A command to check (or even suggest) matching parentheses, quotes, etc., would also be useful.

One alternative enhanced interactive interpreter that has been around for quite some time is IPython, which features tab completion, object exploration and advanced history management. It can also be thoroughly customized and embedded into other applications. Another similar enhanced interactive environment is bpython.

Footnotes

[1] Python will execute the contents of a file identified by the PYTHONSTARTUP environment variable when you start an interactive interpreter. To customize Python even for non-interactive mode, see The Customization Modules.
14. Floating Point Arithmetic: Issues and Limitations

Floating-point numbers are represented in computer hardware as base 2 (binary) fractions. For example, the decimal fraction

\[ \boxed{0.125} \]

has value \(1/10 + 2/100 + 5/1000\), and in the same way the binary fraction

\[ \boxed{0.001} \]

has value \(0/2 + 0/4 + 1/8\). These two fractions have identical values, the only real difference being that the first is written in base 10 fractional notation, and the second in base 2.

Unfortunately, most decimal fractions cannot be represented exactly as binary fractions. A consequence is that, in general, the decimal floating-point numbers you enter are only approximated by the binary floating-point numbers actually stored in the machine.

The problem is easier to understand at first in base 10. Consider the fraction \(1/3\). You can approximate that as a base 10 fraction:

\[ \boxed{0.3} \]

or, better,

\[ \boxed{0.33} \]
or, better,

0.333

and so on. No matter how many digits you’re willing to write down, the result will never be exactly 1/3, but will be an increasingly better approximation of 1/3.

In the same way, no matter how many base 2 digits you’re willing to use, the decimal value 0.1 cannot be represented exactly as a base 2 fraction. In base 2, 1/10 is the infinitely repeating fraction

0.0001100110011001100110011001100110011001100110011...

Stop at any finite number of bits, and you get an approximation. On most machines today, floats are approximated using a binary fraction with the numerator using the first 53 bits starting with the most significant bit and with the denominator as a power of two. In the case of 1/10, the binary fraction is \( \frac{3602879701896397}{2^{55}} \) which is close to but not exactly equal to the true value of 1/10.

Many users are not aware of the approximation because of the way values are displayed. Python only prints a decimal approximation to the true decimal value of the binary approximation stored by the machine. On most machines, if Python were to print the true decimal value of the binary approximation stored for 0.1, it would have to display

```
>>> 0.1
0.100000000000000005551115123125782702118158340454101
```

That is more digits than most people find useful, so Python keeps the
number of digits manageable by displaying a rounded value instead

```
>>> 1 / 10
0.1
```

Just remember, even though the printed result looks like the exact value of 1/10, the actual stored value is the nearest representable binary fraction.

Interestingly, there are many different decimal numbers that share the same nearest approximate binary fraction. For example, the numbers 0.1 and 0.10000000000000001 and 0.10000000000000000555111512312578270211815834045410 are all approximated by 3602879701896397 / 2 ** 55. Since all of these decimal values share the same approximation, any one of them could be displayed while still preserving the invariant `eval(repr(x)) == x`.

Historically, the Python prompt and built-in `repr()` function would choose the one with 17 significant digits, 0.1000000000000001. Starting with Python 3.1, Python (on most systems) is now able to choose the shortest of these and simply display 0.1.

Note that this is in the very nature of binary floating-point: this is not a bug in Python, and it is not a bug in your code either. You'll see the same kind of thing in all languages that support your hardware's floating-point arithmetic (although some languages may not display the difference by default, or in all output modes).

For more pleasant output, you may wish to use string formatting to produce a limited number of significant digits:

```
>>> format(math.pi, '.12g')  # give 12 significant digits
```
It's important to realize that this is, in a real sense, an illusion: you're simply rounding the display of the true machine value.

One illusion may beget another. For example, since 0.1 is not exactly 1/10, summing three values of 0.1 may not yield exactly 0.3, either:

```python
>>> .1 + .1 + .1 == .3
False
```

Also, since the 0.1 cannot get any closer to the exact value of 1/10 and 0.3 cannot get any closer to the exact value of 3/10, then pre-rounding with `round()` function cannot help:

```python
>>> round(.1, 1) + round(.1, 1) + round(.1, 1) == round(.3, 1)
False
```

Though the numbers cannot be made closer to their intended exact values, the `round()` function can be useful for post-rounding so that results with inexact values become comparable to one another:

```python
>>> round(.1 + .1 + .1, 10) == round(.3, 10)
True
```

Binary floating-point arithmetic holds many surprises like this. The problem with “0.1” is explained in precise detail below, in the
“Representation Error” section. See *The Perils of Floating Point* for a more complete account of other common surprises.

As that says near the end, “there are no easy answers.” Still, don’t be unduly wary of floating-point! The errors in Python float operations are inherited from the floating-point hardware, and on most machines are on the order of no more than 1 part in $2^{53}$ per operation. That’s more than adequate for most tasks, but you do need to keep in mind that it’s not decimal arithmetic and that every float operation can suffer a new rounding error.

While pathological cases do exist, for most casual use of floating-point arithmetic you’ll see the result you expect in the end if you simply round the display of your final results to the number of decimal digits you expect. `str()` usually suffices, and for finer control see the `str.format()` method’s format specifiers in *Format String Syntax*.

For use cases which require exact decimal representation, try using the `decimal` module which implements decimal arithmetic suitable for accounting applications and high-precision applications.

Another form of exact arithmetic is supported by the `fractions` module which implements arithmetic based on rational numbers (so the numbers like $1/3$ can be represented exactly).

If you are a heavy user of floating point operations you should take a look at the Numerical Python package and many other packages for mathematical and statistical operations supplied by the SciPy project. See <http://scipy.org>.

Python provides tools that may help on those rare occasions when you really *do* want to know the exact value of a float. The `float.as_integer_ratio()` method expresses the value of a
float as a fraction:

```python
g>>> x = 3.14159
g>>> x.as_integer_ratio()
(3537115888337719, 1125899906842624)
```

Since the ratio is exact, it can be used to losslessly recreate the original value:

```python
g>>> x == 3537115888337719 / 1125899906842624
True
```

The `float.hex()` method expresses a float in hexadecimal (base 16), again giving the exact value stored by your computer:

```python
g>>> x.hex()
'0x1.921f9f01b866ep+1'
```

This precise hexadecimal representation can be used to reconstruct the float value exactly:

```python
g>>> x == float.fromhex('0x1.921f9f01b866ep+1')
True
```

Since the representation is exact, it is useful for reliably porting values across different versions of Python (platform independence) and exchanging data with other languages that support the same format (such as Java and C99).

Another helpful tool is the `math.fsum()` function which helps mitigate loss-of-precision during summation. It tracks “lost digits” as values are added onto a running total. That can make a difference in overall accuracy so that the errors do not accumulate to the point where they affect the final total:
```python
>>> sum([0.1] * 10) == 1.0
False
>>> math.fsum([0.1] * 10) == 1.0
True
```
14.1. Representation Error

This section explains the “0.1” example in detail, and shows how you can perform an exact analysis of cases like this yourself. Basic familiarity with binary floating-point representation is assumed.

*Representation error* refers to the fact that some (most, actually) decimal fractions cannot be represented exactly as binary (base 2) fractions. This is the chief reason why Python (or Perl, C, C++, Java, Fortran, and many others) often won’t display the exact decimal number you expect.

Why is that? 1/10 is not exactly representable as a binary fraction. Almost all machines today (November 2000) use IEEE-754 floating point arithmetic, and almost all platforms map Python floats to IEEE-754 “double precision”. 754 doubles contain 53 bits of precision, so on input the computer strives to convert 0.1 to the closest fraction it can of the form \( J/2^{**}N \) where \( J \) is an integer containing exactly 53 bits. Rewriting

\[
1 / 10 \approx J / (2^{**}N)
\]

as

\[
J \approx 2^{**}N / 10
\]

and recalling that \( J \) has exactly 53 bits (is \( \geq 2^{52} \) but \( < 2^{53} \)), the best value for \( N \) is 56:

```python
>>> 2**52 <= 2**56 // 10 < 2**53
True
```
That is, 56 is the only value for $N$ that leaves $J$ with exactly 53 bits. The best possible value for $J$ is then that quotient rounded:

```python
>>> q, r = divmod(2**56, 10)
>>> r
6
```

Since the remainder is more than half of 10, the best approximation is obtained by rounding up:

```python
>>> q+1
7205759403792794
```

Therefore the best possible approximation to $1/10$ in 754 double precision is:

```python
7205759403792794 / 2 ** 56
```

Dividing both the numerator and denominator by two reduces the fraction to:

```python
3602879701896397 / 2 ** 55
```

Note that since we rounded up, this is actually a little bit larger than $1/10$; if we had not rounded up, the quotient would have been a little bit smaller than $1/10$. But in no case can it be exactly $1/10$!

So the computer never “sees” $1/10$: what it sees is the exact fraction given above, the best 754 double approximation it can get:

```python
>>> 0.1 * 2 ** 55
3602879701896397.0
```

If we multiply that fraction by $10^{55}$, we can see the value out to 55
decimal digits:

```
>>> 3602879701896397 * 10 ** 55 // 2 ** 55
1000000000000000055511151231257827021181583404541015625
```

meaning that the exact number stored in the computer is equal to the decimal value 0.1000000000000000055511151231257827021181583404541015625. Instead of displaying the full decimal value, many languages (including older versions of Python), round the result to 17 significant digits:

```
>>> format(0.1, '.17f')
'0.10000000000000001'
```

The `fractions` and `decimal` modules make these calculations easy:

```
>>> from decimal import Decimal
>>> from fractions import Fraction

>>> Fraction.from_float(0.1)
Fraction(3602879701896397, 36028797018963968)

>>> (0.1).as_integer_ratio()
(3602879701896397, 36028797018963968)

>>> Decimal.from_float(0.1)
Decimal('0.1000000000000000055511151231257827021181583404541015625')

>>> format(Decimal.from_float(0.1), '.17f')
'0.10000000000000001'
```
1. Command line and environment

The CPython interpreter scans the command line and the environment for various settings.

**CPython implementation detail:** Other implementations’ command line schemes may differ. See *Alternate Implementations* for further resources.
1.1. Command line

When invoking Python, you may specify any of these options:

```
python [-bBdEhiOqsSuvVwx?] [-c command | -m module-name | script | -]
```

The most common use case is, of course, a simple invocation of a script:

```
python myscript.py
```

1.1.1. Interface options

The interpreter interface resembles that of the UNIX shell, but provides some additional methods of invocation:

- When called with standard input connected to a tty device, it prompts for commands and executes them until an EOF (an end-of-file character, you can produce that with `Ctrl-D` on UNIX or `Ctrl-Z, Enter` on Windows) is read.
- When called with a file name argument or with a file as standard input, it reads and executes a script from that file.
- When called with a directory name argument, it reads and executes an appropriately named script from that directory.
- When called with `-c command`, it executes the Python statement(s) given as `command`. Here `command` may contain multiple statements separated by newlines. Leading whitespace is significant in Python statements!
- When called with `-m module-name`, the given module is located on the Python module path and executed as a script.

In non-interactive mode, the entire input is parsed before it is
executed.

An interface option terminates the list of options consumed by the interpreter, all consecutive arguments will end up in `sys.argv` – note that the first element, subscript zero (`sys.argv[0]`), is a string reflecting the program’s source.

```
-c <command>
```

Execute the Python code in `command`. `command` can be one or more statements separated by newlines, with significant leading whitespace as in normal module code.

If this option is given, the first element of `sys.argv` will be "-c" and the current directory will be added to the start of `sys.path` (allowing modules in that directory to be imported as top level modules).

```
-m <module-name>
```

Search `sys.path` for the named module and execute its contents as the `__main__` module.

Since the argument is a `module` name, you must not give a file extension (.py). The `module-name` should be a valid Python module name, but the implementation may not always enforce this (e.g. it may allow you to use a name that includes a hyphen).

Package names are also permitted. When a package name is supplied instead of a normal module, the interpreter will execute `<pkg>.__main__` as the main module. This behaviour is deliberately similar to the handling of directories and zipfiles that are passed to the interpreter as the script argument.

**Note:** This option cannot be used with built-in modules and
extension modules written in C, since they do not have Python module files. However, it can still be used for precompiled modules, even if the original source file is not available.

If this option is given, the first element of `sys.argv` will be the full path to the module file (while the module file is being located, the first element will be set to "-m"). As with the `-c` option, the current directory will be added to the start of `sys.path`.

Many standard library modules contain code that is invoked on their execution as a script. An example is the `timeit` module:

```bash
python -mtimeit -s 'setup here' 'benchmarked code here'
python -mtimeit -h # for details
```

See also: `runpy.run_module()` Equivalent functionality directly available to Python code

**PEP 338** – Executing modules as scripts

*Changed in version 3.1:* Supply the package name to run a `__main__` submodule.

- Read commands from standard input (`sys.stdin`). If standard input is a terminal, `-i` is implied.

  If this option is given, the first element of `sys.argv` will be "-"
  and the current directory will be added to the start of `sys.path`.

<**script**>

Execute the Python code contained in `script`, which must be a filesystem path (absolute or relative) referring to either a Python
file, a directory containing a `__main__.py` file, or a zipfile containing a `__main__.py` file.

If this option is given, the first element of `sys.argv` will be the script name as given on the command line.

If the script name refers directly to a Python file, the directory containing that file is added to the start of `sys.path`, and the file is executed as the `__main__` module.

If the script name refers to a directory or zipfile, the script name is added to the start of `sys.path` and the `__main__.py` file in that location is executed as the `__main__` module.

If no interface option is given, `-i` is implied, `sys.argv[0]` is an empty string ("") and the current directory will be added to the start of `sys.path`.

See also: *Invoking the Interpreter*

### 1.1.2. Generic options

- `?`
- `h`
- `--help`
  
  Print a short description of all command line options.

- `V`
- `--version`
  
  Print the Python version number and exit. Example output could be:
1.1.3. Miscellaneous options

-b
Issue a warning when comparing str and bytes. Issue an error when the option is given twice (-bb).

-B
If given, Python won’t try to write .pyc or .pyo files on the import of source modules. See also PYTHONDONTWRITEBYTECODE.

-d
Turn on parser debugging output (for wizards only, depending on compilation options). See also PYTHONDEBUG.

-E
Ignore all PYTHON* environment variables, e.g. PYTHONPATH and PYTHONHOME, that might be set.

-i
When a script is passed as first argument or the -c option is used, enter interactive mode after executing the script or the command, even when sys.stdin does not appear to be a terminal. The PYTHONSTARTUP file is not read.

This can be useful to inspect global variables or a stack trace when a script raises an exception. See also PYTHONINSPECT.

-O
Turn on basic optimizations. This changes the filename extension for compiled (bytecode) files from .pyc to .pyo. See also
-OO
Discard docstrings in addition to the -O optimizations.

-q
Don't display the copyright and version messages even in interactive mode.

*New in version 3.2.*

-R
Kept for compatibility. On Python 3.3 and greater, hash randomization is turned on by default.

On previous versions of Python, this option turns on hash randomization, so that the \_\_hash\_\_( ) values of str, bytes and datetime are “salted” with an unpredictable random value. Although they remain constant within an individual Python process, they are not predictable between repeated invocations of Python.

Hash randomization is intended to provide protection against a denial-of-service caused by carefully-chosen inputs that exploit the worst case performance of a dict construction, O(n^2) complexity. See [http://www.ocert.org/advisories/ocert-2011-003.html](http://www.ocert.org/advisories/ocert-2011-003.html) for details.

*PYTHONHASHSEED* allows you to set a fixed value for the hash seed secret.

*New in version 3.2.3.*

-s
Don't add the user site-packages directory to sys.path.
See also: PEP 370 – Per user site-packages directory

-S
Disable the import of the module site and the site-dependent manipulations of sys.path that it entails. Also disable these manipulations if site is explicitly imported later (call site.main() if you want them to be triggered).

-u
Force the binary layer of the stdout and stderr streams (which is available as their buffer attribute) to be unbuffered. The text I/O layer will still be line-buffered if writing to the console, or block-buffered if redirected to a non-interactive file.

See also PYTHONUNBUFFERED.

-v
Print a message each time a module is initialized, showing the place (filename or built-in module) from which it is loaded. When given twice (-vv), print a message for each file that is checked for when searching for a module. Also provides information on module cleanup at exit. See also PYTHONVERBOSE.

-W arg
Warning control. Python's warning machinery by default prints warning messages to sys.stderr. A typical warning message has the following form:

```
file:line: category: message
```

By default, each warning is printed once for each source line where it occurs. This option controls how often warnings are printed.
Multiple `-W` options may be given; when a warning matches more than one option, the action for the last matching option is performed. Invalid `-W` options are ignored (though, a warning message is printed about invalid options when the first warning is issued).

Warnings can also be controlled from within a Python program using the `warnings` module.

The simplest form of argument is one of the following action strings (or a unique abbreviation):

`ignore`  
Ignore all warnings.

`default`  
Explicitly request the default behavior (printing each warning once per source line).

`all`  
Print a warning each time it occurs (this may generate many messages if a warning is triggered repeatedly for the same source line, such as inside a loop).

`module`  
Print each warning only the first time it occurs in each module.

`once`  
Print each warning only the first time it occurs in the program.

`error`  
Raise an exception instead of printing a warning message.

The full form of argument is:

`action:message:category:module:line`
Here, *action* is as explained above but only applies to messages that match the remaining fields. Empty fields match all values; trailing empty fields may be omitted. The *message* field matches the start of the warning message printed; this match is case-insensitive. The *category* field matches the warning category. This must be a class name; the match tests whether the actual warning category of the message is a subclass of the specified warning category. The full class name must be given. The *module* field matches the (fully-qualified) module name; this match is case-sensitive. The *line* field matches the line number, where zero matches all line numbers and is thus equivalent to an omitted line number.

**See also:**  
*warnings* – the warnings module

**PEP 230** – Warning framework

**PYTHONWARNINGS**

**-X**

Skip the first line of the source, allowing use of non-Unix forms of `#!cmd`. This is intended for a DOS specific hack only.

**Note:** The line numbers in error messages will be off by one.

**-X**

Reserved for various implementation-specific options. CPython currently defines just one, you can use `-X faulthandler` to enable `faulthandler`. It also allows to pass arbitrary values and retrieve them through the `sys._xoptions` dictionary.

*Changed in version 3.2:* It is now allowed to pass `-X` with CPython.
New in version 3.3: The -X faulthandler option.

1.1.4. Options you shouldn’t use

-J

Reserved for use by Jython.
1.2. Environment variables

These environment variables influence Python's behavior, they are processed before the command-line switches other than -E. It is customary that command-line switches override environmental variables where there is a conflict.

**PYTHONHOME**

Change the location of the standard Python libraries. By default, the libraries are searched in `prefix/lib/pythonversion` and `exec_prefix/lib/pythonversion`, where `prefix` and `exec_prefix` are installation-dependent directories, both defaulting to `/usr/local`.

When **PYTHONHOME** is set to a single directory, its value replaces both `prefix` and `exec_prefix`. To specify different values for these, set **PYTHONHOME** to `prefix:exec_prefix`.

**PYTHONPATH**

Augment the default search path for module files. The format is the same as the shell's `PATH`: one or more directory pathnames separated by `os.pathsep` (e.g. colons on Unix or semicolons on Windows). Non-existent directories are silently ignored.

In addition to normal directories, individual **PYTHONPATH** entries may refer to zipfiles containing pure Python modules (in either source or compiled form). Extension modules cannot be imported from zipfiles.

The default search path is installation dependent, but generally begins with `prefix/lib/pythonversion` (see **PYTHONHOME**).
above). It is always appended to PYTHONPATH.

An additional directory will be inserted in the search path in front of PYTHONPATH as described above under Interface options. The search path can be manipulated from within a Python program as the variable sys.path.

**PYTHONSTARTUP**

If this is the name of a readable file, the Python commands in that file are executed before the first prompt is displayed in interactive mode. The file is executed in the same namespace where interactive commands are executed so that objects defined or imported in it can be used without qualification in the interactive session. You can also change the prompts sys.ps1 and sys.ps2 in this file.

**PYTHONY2K**

Set this to a non-empty string to cause the time module to require dates specified as strings to include 4-digit years, otherwise 2-digit years are converted based on rules described in the time module documentation.

**PYTHONOPTIMIZE**

If this is set to a non-empty string it is equivalent to specifying the -O option. If set to an integer, it is equivalent to specifying -O multiple times.

**PYTHONDEBUG**

If this is set to a non-empty string it is equivalent to specifying the -d option. If set to an integer, it is equivalent to specifying -d multiple times.

**PYTHONINSPECT**
If this is set to a non-empty string it is equivalent to specifying the \textit{-i} option.

This variable can also be modified by Python code using \texttt{os.environ} to force inspect mode on program termination.

\textbf{PYTHONUNBUFFERED}

If this is set to a non-empty string it is equivalent to specifying the \texttt{-u} option.

\textbf{PYTHONVERBOSE}

If this is set to a non-empty string it is equivalent to specifying the \texttt{-v} option. If set to an integer, it is equivalent to specifying \texttt{-v} multiple times.

\textbf{PYTHONCASEOK}

If this is set, Python ignores case in \texttt{import} statements. This only works on Windows and OS X.

\textbf{PYTHONDONTWRITEBYTECODE}

If this is set, Python won't try to write \texttt{.pyc} or \texttt{.pyo} files on the import of source modules. This is equivalent to specifying the \texttt{-B} option.

\textbf{PYTHONHASHSEED}

If this variable is not set or set to \texttt{random}, a random value is used to seed the hashes of \texttt{str}, \texttt{bytes} and \texttt{datetime} objects.

If \texttt{PYTHONHASHSEED} is set to an integer value, it is used as a fixed seed for generating the hash() of the types covered by the hash randomization.

Its purpose is to allow repeatable hashing, such as for selftests for
the interpreter itself, or to allow a cluster of python processes to share hash values.

The integer must be a decimal number in the range [0,4294967295]. Specifying the value 0 will disable hash randomization.

*New in version 3.2.3.*

**PYTHONIOENCODING**

If this is set before running the interpreter, it overrides the encoding used for stdin/stdout/stderr, in the syntax `encodingname:$errorhandler`. The :errorhandler part is optional and has the same meaning as in `str.encode()`.

For stderr, the :errorhandler part is ignored; the handler will always be '*backslashreplace*'.

**PYTHONNOUSERSITE**

If this is set, Python won’t add the user site-packages directory to `sys.path`.

See also: PEP 370 – Per user site-packages directory

**PYTHONUSERBASE**

Defines the user base directory, which is used to compute the path of the user site-packages directory and *Distutils installation paths* for `python setup.py install --user`.

See also: PEP 370 – Per user site-packages directory

**PYTHONEXECUTABLE**
If this environment variable is set, `sys.argv[0]` will be set to its value instead of the value got through the C runtime. Only works on Mac OS X.

**PYTHONWARNINGS**

This is equivalent to the `-W` option. If set to a comma separated string, it is equivalent to specifying `-W` multiple times.

**PYTHONFAULTHANDLER**

If this environment variable is set, `faulthandler.enable()` is called at startup: install a handler for SIGSEGV, SIGFPE, SIGABRT, SIGBUS and SIGILL signals to dump the Python traceback. This is equivalent to `-X faulthandler` option.

*New in version 3.3.*

**1.2.1. Debug-mode variables**

Setting these variables only has an effect in a debug build of Python, that is, if Python was configured with the `--with-pydebug` build option.

**PYTHONTHREADDEBUG**

If set, Python will print threading debug info.

**PYTHONDUMMPREFS**

If set, Python will dump objects and reference counts still alive after shutting down the interpreter.

**PYTHONMALLOCSTATS**

If set, Python will print memory allocation statistics every time a new object arena is created, and on shutdown.
2. Using Python on Unix platforms
2.1. Getting and installing the latest version of Python

2.1.1. On Linux

Python comes preinstalled on most Linux distributions, and is available as a package on all others. However there are certain features you might want to use that are not available on your distro’s package. You can easily compile the latest version of Python from source.

In the event that Python doesn’t come preinstalled and isn’t in the repositories as well, you can easily make packages for your own distro. Have a look at the following links:

See also:

   for Debian users

http://en.opensuse.org/Portal:Packaging
   for OpenSuse users

   for Fedora users

   for Slackware users

2.1.2. On FreeBSD and OpenBSD

- FreeBSD users, to add the package use:
pkg_add -r python

- OpenBSD users use:

```
```

For example i386 users get the 2.5.1 version of Python using:

```
pkg_add ftp://ftp.openbsd.org/pub/OpenBSD/4.2/packages/i386/python-2.5.1p2.tgz
```

2.1.3. On OpenSolaris

To install the newest Python versions on OpenSolaris, install blastwave and type `pkg_get -i python` at the prompt.
2.2. Building Python

If you want to compile CPython yourself, first thing you should do is get the source. You can download either the latest release’s source or just grab a fresh clone. (If you want to contribute patches, you will need a clone.)

The build process consists in the usual

```
./configure
make
make install
```

invocations. Configuration options and caveats for specific Unix platforms are extensively documented in the README file in the root of the Python source tree.

**Warning:** `make install` can overwrite or masquerade the `python3` binary. `make altinstall` is therefore recommended instead of `make install` since it only installs `exec_prefix/bin/pythonversion`. 
2.3. Python-related paths and files

These are subject to difference depending on local installation conventions; prefix (${prefix}) and exec_prefix (${exec_prefix}) are installation-dependent and should be interpreted as for GNU software; they may be the same.

For example, on most Linux systems, the default for both is `/usr`.

<table>
<thead>
<tr>
<th>File/directory</th>
<th>Meaning</th>
</tr>
</thead>
<tbody>
<tr>
<td><code>exec_prefix/bin/python3</code></td>
<td>Recommended location of the interpreter.</td>
</tr>
<tr>
<td><code>prefix/lib/pythonversion</code>,</td>
<td>Recommended locations of the directories containing the standard modules.</td>
</tr>
<tr>
<td><code>exec_prefix/lib/pythonversion</code></td>
<td></td>
</tr>
<tr>
<td><code>prefix/include/pythonversion</code>,</td>
<td>Recommended locations of the directories containing the include files needed for developing Python extensions and embedding the interpreter.</td>
</tr>
<tr>
<td><code>exec_prefix/include/pythonversion</code></td>
<td></td>
</tr>
</tbody>
</table>
2.4. Miscellaneous

To easily use Python scripts on Unix, you need to make them executable, e.g. with

```
$ chmod +x script
```

and put an appropriate Shebang line at the top of the script. A good choice is usually

```
#!/usr/bin/env python3
```

which searches for the Python interpreter in the whole PATH. However, some Unices may not have the `env` command, so you may need to hardcode `/usr/bin/python3` as the interpreter path.

To use shell commands in your Python scripts, look at the `subprocess` module.
2.5. Editors

Vim and Emacs are excellent editors which support Python very well. For more information on how to code in Python in these editors, look at:

- http://sourceforge.net/projects/python-mode

Geany is an excellent IDE with support for a lot of languages. For more information, read: http://www.geany.org/

Komodo edit is another extremely good IDE. It also has support for a lot of languages. For more information, read: http://www.activestate.com/store/productdetail.aspx?prdGuid=20f4ed15-6684-4118-a78b-d37ff4058c5f
3. Using Python on Windows

This document aims to give an overview of Windows-specific behaviour you should know about when using Python on Microsoft Windows.
3.1. Installing Python

Unlike most Unix systems and services, Windows does not require Python natively and thus does not pre-install a version of Python. However, the CPython team has compiled Windows installers (MSI packages) with every release for many years.

With ongoing development of Python, some platforms that used to be supported earlier are no longer supported (due to the lack of users or developers). Check PEP 11 for details on all unsupported platforms.

- Up to 2.5, Python was still compatible with Windows 95, 98 and ME (but already raised a deprecation warning on installation). For Python 2.6 (and all following releases), this support was dropped and new releases are just expected to work on the Windows NT family.
- Windows CE is still supported.
- The Cygwin installer offers to install the Python interpreter as well; it is located under “Interpreters.” (cf. Cygwin package source, Maintainer releases)

See Python for Windows (and DOS) for detailed information about platforms with precompiled installers.

See also:

Python on XP
“7 Minutes to “Hello World!”” by Richard Dooling, 2006

Installing on Windows

For Windows users
3.2. Alternative bundles

Besides the standard CPython distribution, there are modified packages including additional functionality. The following is a list of popular versions and their key features:

**ActivePython**
- Installer with multi-platform compatibility, documentation, PyWin32

**Enthought Python Distribution**
- Popular modules (such as PyWin32) with their respective documentation, tool suite for building extensible Python applications

Notice that these packages are likely to install *older* versions of Python.
3.3. Configuring Python

In order to run Python flawlessly, you might have to change certain environment settings in Windows.

3.3.1. Excursus: Setting environment variables

Windows has a built-in dialog for changing environment variables (following guide applies to XP classical view): Right-click the icon for your machine (usually located on your Desktop and called “My Computer”) and choose Properties there. Then, open the Advanced tab and click the Environment Variables button.

In short, your path is:

My Computer ▶ Properties ▶ Advanced ▶ Environment Variables

In this dialog, you can add or modify User and System variables. To change System variables, you need non-restricted access to your machine (i.e. Administrator rights).

Another way of adding variables to your environment is using the set command:

```
set PYTHONPATH=%PYTHONPATH%;C:\My_python_lib
```

To make this setting permanent, you could add the corresponding command line to your `autoexec.bat`. `msconfig` is a graphical interface to this file.

Viewing environment variables can also be done more straightforward: The command prompt will expand strings wrapped into
percent signs automatically:

```bash
echo %PATH%
```

Consult `set /?` for details on this behaviour.

  Setting Environment variables, Louis J. Farrugia

### 3.3.2. Finding the Python executable

*Changed in version 3.3.*

Besides using the automatically created start menu entry for the Python interpreter, you might want to start Python in the command prompt. As of Python 3.3, the installer has an option to set that up for you.

At the “Customize Python 3.3” screen, an option called “Add python.exe to search path” can be enabled to have the installer place your installation into the %PATH%. This allows you to type `python` to run the interpreter. Thus, you can also execute your scripts with command line options, see *Command line* documentation.

If you don’t enable this option at install time, you can always re-run the installer to choose it.
The alternative is manually modifying the %PATH% using the directions in *Excursus: Setting environment variables*. You need to set your %PATH% environment variable to include the directory of your Python distribution, delimited by a semicolon from other entries. An example variable could look like this (assuming the first two entries are Windows’ default):

```
C:\WINDOWS\system32;C:\WINDOWS;C:\Python33
```

### 3.3.3. Finding modules

Python usually stores its library (and thereby your site-packages folder) in the installation directory. So, if you had installed Python to `C:\Python\`, the default library would reside in `C:\Python\Lib\` and third-party modules should be stored in `C:\Python\Lib\site-packages\`.

This is how `sys.path` is populated on Windows:

- An empty entry is added at the start, which corresponds to the current directory.
- If the environment variable `PYTHONPATH` exists, as described in *Environment variables*, its entries are added next. Note that on Windows, paths in this variable must be separated by semicolons, to distinguish them from the colon used in drive identifiers (`C:\` etc.).
- Additional “application paths” can be added in the registry as subkeys of `\SOFTWARE\Python\PythonCore\version\PythonPath` under both the `HKEY_CURRENT_USER` and `HKEY_LOCAL_MACHINE` hives. Subkeys which have semicolon-delimited path strings as their default value will cause each path
to be added to \texttt{sys.path}. (Note that all known installers only use HKLM, so HKCU is typically empty.)

- If the environment variable \texttt{PYTHONHOME} is set, it is assumed as “Python Home”. Otherwise, the path of the main Python executable is used to locate a “landmark file” (\texttt{Lib\os.py}) to deduce the “Python Home”. If a Python home is found, the relevant sub-directories added to \texttt{sys.path} (\texttt{Lib}, \texttt{plat-win}, etc) are based on that folder. Otherwise, the core Python path is constructed from the PythonPath stored in the registry.

- If the Python Home cannot be located, no \texttt{PYTHONPATH} is specified in the environment, and no registry entries can be found, a default path with relative entries is used (e.g. \texttt{.\Lib;}\texttt{.\plat-win}, etc).

The end result of all this is:

- When running \texttt{python.exe}, or any other .exe in the main Python directory (either an installed version, or directly from the PCbuild directory), the core path is deduced, and the core paths in the registry are ignored. Other “application paths” in the registry are always read.

- When Python is hosted in another .exe (different directory, embedded via COM, etc), the “Python Home” will not be deduced, so the core path from the registry is used. Other “application paths” in the registry are always read.

- If Python can't find its home and there is no registry (eg, frozen .exe, some very strange installation setup) you get a path with some default, but relative, paths.

### 3.3.4. Executing scripts

As of Python 3.3, Python includes a launcher which facilitates running Python scripts. See \textit{Python Launcher for Windows} for more
3.3.5. Executing scripts without the Python launcher

Without the Python launcher installed, Python scripts (files with the extension `.py`) will be executed by `python.exe` by default. This executable opens a terminal, which stays open even if the program uses a GUI. If you do not want this to happen, use the extension `.pyw` which will cause the script to be executed by `pythonw.exe` by default (both executables are located in the top-level of your Python installation directory). This suppresses the terminal window on startup.

You can also make all `.py` scripts execute with `pythonw.exe`, setting this through the usual facilities, for example (might require administrative rights):

1. Launch a command prompt.
2. Associate the correct file group with `.py` scripts:

   ```
   assoc .py=Python.File
   ```

3. Redirect all Python files to the new executable:

   ```
   ftype Python.File=C:\Path\to\pythonw.exe "%1" %*
   ```
3.4. Python Launcher for Windows

New in version 3.3.

The Python launcher for Windows is a utility which aids in the location and execution of different Python versions. It allows scripts (or the command-line) to indicate a preference for a specific Python version, and will locate and execute that version.

3.4.1. Getting started

3.4.1.1. From the command-line

You should ensure the launcher is on your PATH - depending on how it was installed it may already be there, but check just in case it is not.

From a command-prompt, execute the following command:

```
py
```

You should find that the latest version of Python 2.x you have installed is started - it can be exited as normal, and any additional command-line arguments specified will be sent directly to Python.

If you have multiple versions of Python 2.x installed (e.g., 2.6 and 2.7) you will have noticed that Python 2.7 was started - to launch Python 2.6, try the command:

```
py -2.6
```

If you have a Python 3.x installed, try the command:

```
py -3
```
You should find the latest version of Python 3.x starts.

3.4.1.2. From a script

Let's create a test Python script - create a file called hello.py with the following contents

```python
#!/python
import sys
sys.stdout.write("hello from Python %s\n" % (sys.version,))
```

From the directory in which hello.py lives, execute the command:

```python
py hello.py
```

You should notice the version number of your latest Python 2.x installation is printed. Now try changing the first line to be:

```python
#!/python3
```

Re-executing the command should now print the latest Python 3.x information. As with the above command-line examples, you can specify a more explicit version qualifier. Assuming you have Python 2.6 installed, try changing the first line to `#!/ python2.6` and you should find the 2.6 version information printed.

3.4.1.3. From file associations

The launcher should have been associated with Python files (i.e. .py, .pyw, .pyc, .pyo files) when it was installed. This means that when you double-click on one of these files from Windows explorer the launcher will be used, and therefore you can use the same facilities
described above to have the script specify the version which should be used.

The key benefit of this is that a single launcher can support multiple Python versions at the same time depending on the contents of the first line.

### 3.4.2. Shebang Lines

If the first line of a script file starts with `#!`, it is known as a “shebang” line. Linux and other Unix like operating systems have native support for such lines and are commonly used on such systems to indicate how a script should be executed. This launcher allows the same facilities to be using with Python scripts on Windows and the examples above demonstrate their use.

To allow shebang lines in Python scripts to be portable between Unix and Windows, this launcher supports a number of ‘virtual’ commands to specify which interpreter to use. The supported virtual commands are:

- `/usr/bin/env python`
- `/usr/bin/python`
- `/usr/local/bin/python`
- `python`

For example, if the first line of your script starts with

```
#!/usr/bin/python
```

The default Python will be located and used. As many Python scripts written to work on Unix will already have this line, you should find these scripts can be used by the launcher without modification. If you
are writing a new script on Windows which you hope will be useful on Unix, you should use one of the shebang lines starting with `/usr`.

### 3.4.3. Arguments in shebang lines

The shebang lines can also specify additional options to be passed to the Python interpreter. For example, if you have a shebang line:

```bash
#!/usr/bin/python -v
```

Then Python will be started with the `-v` option.

### 3.4.4. Customization

#### 3.4.4.1. Customization via INI files

Two `.ini` files will be searched by the launcher - `py.ini` in the current user’s “application data” directory (i.e. the directory returned by calling the Windows function `SHGetFolderPath` with `CSIDL_LOCAL_APPDATA`) and `py.ini` in the same directory as the launcher. The same `.ini` files are used for both the ‘console’ version of the launcher (i.e. `py.exe`) and for the ‘windows’ version (i.e. `pyw.exe`)

Customization specified in the “application directory” will have precedence over the one next to the executable, so a user, who may not have write access to the `.ini` file next to the launcher, can override commands in that global `.ini` file.

#### 3.4.4.2. Customizing default Python versions

In some cases, a version qualifier can be included in a command to
dictate which version of Python will be used by the command. A version qualifier starts with a major version number and can optionally be followed by a period (’.’) and a minor version specifier. If the minor qualifier is specified, it may optionally be followed by “-32” to indicate the 32-bit implementation of that version be used.

For example, a shebang line of `#!python` has no version qualifier, while `#!python3` has a version qualifier which specifies only a major version.

If no version qualifiers are found in a command, the environment variable `PY_PYTHON` can be set to specify the default version qualifier - the default value is “2”. Note this value could specify just a major version (e.g. “2”) or a major.minor qualifier (e.g. “2.6”), or even major.minor-32.

If no minor version qualifiers are found, the environment variable `PY_PYTHON{major}` (where `{major}` is the current major version qualifier as determined above) can be set to specify the full version. If no such option is found, the launcher will enumerate the installed Python versions and use the latest minor release found for the major version, which is likely, although not guaranteed, to be the most recently installed version in that family.

On 64-bit Windows with both 32-bit and 64-bit implementations of the same (major.minor) Python version installed, the 64-bit version will always be preferred. This will be true for both 32-bit and 64-bit implementations of the launcher - a 32-bit launcher will prefer to execute a 64-bit Python installation of the specified version if available. This is so the behavior of the launcher can be predicted knowing only what versions are installed on the PC and without regard to the order in which they were installed (i.e., without knowing whether a 32 or 64-bit version of Python and corresponding launcher was installed last).
As noted above, an optional “-32” suffix can be used on a version specifier to change this behaviour.

Examples:

- If no relevant options are set, the commands `python` and `python2` will use the latest Python 2.x version installed and the command `python3` will use the latest Python 3.x installed.
- The commands `python3.1` and `python2.7` will not consult any options at all as the versions are fully specified.
- If `PY_PYTHON=3`, the commands `python` and `python3` will both use the latest installed Python 3 version.
- If `PY_PYTHON=3.1-32`, the command `python` will use the 32-bit implementation of 3.1 whereas the command `python3` will use the latest installed Python (PY_PYTHON was not considered at all as a major version was specified.)
- If `PY_PYTHON=3` and `PY_PYTHON3=3.1`, the commands `python` and `python3` will both use specifically 3.1

In addition to environment variables, the same settings can be configured in the .INI file used by the launcher. The section in the INI file is called `[defaults]` and the key name will be the same as the environment variables without the leading `PY_` prefix (and note that the key names in the INI file are case insensitive.) The contents of an environment variable will override things specified in the INI file.

For example:

- Setting `PY_PYTHON=3.1` is equivalent to the INI file containing:

  ```
  [defaults]
  python=3.1
  ```

- Setting `PY_PYTHON=3` and `PY_PYTHON3=3.1` is equivalent to
the INI file containing:

```ini
[defaults]
python=3
python3=3.1
```

3.4.5. Diagnostics

If an environment variable `PYLAUNCH_DEBUG` is set (to any value), the launcher will print diagnostic information to stderr (i.e. to the console). While this information manages to be simultaneously verbose and terse, it should allow you to see what versions of Python were located, why a particular version was chosen and the exact command-line used to execute the target Python.
3.5. Additional modules

Even though Python aims to be portable among all platforms, there are features that are unique to Windows. A couple of modules, both in the standard library and external, and snippets exist to use these features.

The Windows-specific standard modules are documented in *MS Windows Specific Services*.

3.5.1. PyWin32

The PyWin32 module by Mark Hammond is a collection of modules for advanced Windows-specific support. This includes utilities for:

- Component Object Model (COM)
- Win32 API calls
- Registry
- Event log
- Microsoft Foundation Classes (MFC) user interfaces

PythonWin is a sample MFC application shipped with PyWin32. It is an embeddable IDE with a built-in debugger.

**See also:**

Win32 How Do I...?
by Tim Golden

Python and COM
by David and Paul Boddie

3.5.2. Py2exe
**Py2exe** is a **distutils** extension (see *Extending Distutils*) which wraps Python scripts into executable Windows programs (*.exe files). When you have done this, you can distribute your application without requiring your users to install Python.

### 3.5.3. WConio

Since Python’s advanced terminal handling layer, **curses**, is restricted to Unix-like systems, there is a library exclusive to Windows as well: Windows Console I/O for Python.

**WConio** is a wrapper for Turbo-C’s `CONIO.H`, used to create text user interfaces.
3.6. Compiling Python on Windows

If you want to compile CPython yourself, first thing you should do is get the source. You can download either the latest release’s source or just grab a fresh checkout.

For Microsoft Visual C++, which is the compiler with which official Python releases are built, the source tree contains solutions/project files. View the readme.txt in their respective directories:

<table>
<thead>
<tr>
<th>Directory</th>
<th>MSVC version</th>
<th>Visual Studio version</th>
</tr>
</thead>
<tbody>
<tr>
<td>PC/VC6/</td>
<td>6.0</td>
<td>97</td>
</tr>
<tr>
<td>PC/VS7.1/</td>
<td>7.1</td>
<td>2003</td>
</tr>
<tr>
<td>PC/VS8.0/</td>
<td>8.0</td>
<td>2005</td>
</tr>
<tr>
<td>PCbuild/</td>
<td>9.0</td>
<td>2008</td>
</tr>
</tbody>
</table>

Note that not all of these build directories are fully supported. Read the release notes to see which compiler version the official releases for your version are built with.

Check PC/readme.txt for general information on the build process.

For extension modules, consult Building C and C++ Extensions on Windows.

The proposal for the launcher to be included in the Python distribution.
4. Using Python on a Macintosh

Author: Bob Savage <bobsavage@mac.com>

Python on a Macintosh running Mac OS X is in principle very similar to Python on any other Unix platform, but there are a number of additional features such as the IDE and the Package Manager that are worth pointing out.
4.1. Getting and Installing MacPython

Mac OS X 10.8 comes with Python 2.7 pre-installed by Apple. If you wish, you are invited to install the most recent version of Python 3 from the Python website (http://www.python.org). A current “universal binary” build of Python, which runs natively on the Mac’s new Intel and legacy PPC CPU’s, is available there.

What you get after installing is a number of things:

- A MacPython 3.3 folder in your Applications folder. In here you find IDLE, the development environment that is a standard part of official Python distributions; PythonLauncher, which handles double-clicking Python scripts from the Finder; and the “Build Applet” tool, which allows you to package Python scripts as standalone applications on your system.
- A framework /Library/Frameworks/Python.framework, which includes the Python executable and libraries. The installer adds this location to your shell path. To uninstall MacPython, you can simply remove these three things. A symlink to the Python executable is placed in /usr/local/bin/.

The Apple-provided build of Python is installed in /System/Library/Frameworks/Python.framework and /usr/bin/python, respectively. You should never modify or delete these, as they are Apple-controlled and are used by Apple- or third-party software. Remember that if you choose to install a newer Python version from python.org, you will have two different but functional Python installations on your computer, so it will be important that your paths and usages are consistent with what you want to do.

IDLE includes a help menu that allows you to access Python
documentation. If you are completely new to Python you should start reading the tutorial introduction in that document.

If you are familiar with Python on other Unix platforms you should read the section on running Python scripts from the Unix shell.

4.1.1. How to run a Python script

Your best way to get started with Python on Mac OS X is through the IDLE integrated development environment, see section *The IDE* and use the Help menu when the IDE is running.

If you want to run Python scripts from the Terminal window command line or from the Finder you first need an editor to create your script. Mac OS X comes with a number of standard Unix command line editors, *vim* and *emacs* among them. If you want a more Mac-like editor, *BBEdit* or *TextWrangler* from Bare Bones Software (see [http://www.barebones.com/products/bbedit/index.shtml](http://www.barebones.com/products/bbedit/index.shtml)) are good choices, as is *TextMate* (see [http://macromates.com/](http://macromates.com/)). Other editors include *Gvim* ([http://macvim.org](http://macvim.org)) and *Aquamacs* ([http://aquamacs.org/](http://aquamacs.org/)).

To run your script from the Terminal window you must make sure that /usr/local/bin is in your shell search path.

To run your script from the Finder you have two options:

- Drag it to *PythonLauncher*
- Select *PythonLauncher* as the default application to open your script (or any .py script) through the finder Info window and double-click it. *PythonLauncher* has various preferences to control how your script is launched. Option-dragging allows you to change these for one invocation, or use its Preferences menu to
change things globally.

4.1.2. Running scripts with a GUI

With older versions of Python, there is one Mac OS X quirk that you need to be aware of: programs that talk to the Aqua window manager (in other words, anything that has a GUI) need to be run in a special way. Use pythonw instead of python to start such scripts.

With Python 3.3, you can use either python or pythonw.

4.1.3. Configuration

Python on OS X honors all standard Unix environment variables such as PYTHONPATH, but setting these variables for programs started from the Finder is non-standard as the Finder does not read your .profile or .cshrc at startup. You need to create a file ~/.MacOSX/environment.plist. See Apple's Technical Document QA1067 for details.

For more information on installation Python packages in MacPython, see section Installing Additional Python Packages.
4.2. The IDE

MacPython ships with the standard IDLE development environment. A good introduction to using IDLE can be found at http://hkn.eecs.berkeley.edu/~dyoo/python/idle_intro/index.html.
4.3. Installing Additional Python Packages

There are several methods to install additional Python packages:

- Packages can be installed via the standard Python distutils mode (`python setup.py install`).
- Many packages can also be installed via the `setup tools` extension or `pip` wrapper, see [http://www.pip-installer.org/](http://www.pip-installer.org/).
4.4. GUI Programming on the Mac

There are several options for building GUI applications on the Mac with Python.

PyObjC is a Python binding to Apple’s Objective-C/Cocoa framework, which is the foundation of most modern Mac development. Information on PyObjC is available from http://pyobjc.sourceforge.net.

The standard Python GUI toolkit is tkinter, based on the cross-platform Tk toolkit (http://www.tcl.tk). An Aqua-native version of Tk is bundled with OS X by Apple, and the latest version can be downloaded and installed from http://www.activestate.com; it can also be built from source.

wxPython is another popular cross-platform GUI toolkit that runs natively on Mac OS X. Packages and documentation are available from http://www.wxpython.org.

PyQt is another popular cross-platform GUI toolkit that runs natively on Mac OS X. More information can be found at http://www.riverbankcomputing.co.uk/software/pyqt/intro.
4.5. Distributing Python Applications on the Mac

The “Build Applet” tool that is placed in the MacPython 3.3 folder is fine for packaging small Python scripts on your own machine to run as a standard Mac application. This tool, however, is not robust enough to distribute Python applications to other users.

The standard tool for deploying standalone Python applications on the Mac is **py2app**. More information on installing and using py2app can be found at [http://undefined.org/python/#py2app](http://undefined.org/python/#py2app).
4.6. Other Resources

The MacPython mailing list is an excellent support resource for Python users and developers on the Mac:

http://www.python.org/community/sigs/current/pythonmac-sig/

Another useful resource is the MacPython wiki:

http://wiki.python.org/moin/MacPython
5. Additional Tools and Scripts
5.1. pyvenv - Creating virtual environments

Creation of virtual environments is done by executing the pyvenv script:

```
pyvenv /path/to/new/virtual/environment
```

Running this command creates the target directory (creating any parent directories that don’t exist already) and places a pyvenv.cfg file in it with a home key pointing to the Python installation the command was run from. It also creates a bin (or Scripts on Windows) subdirectory containing a copy of the python binary (or binaries, in the case of Windows). It also creates an (initially empty) lib/pythonX.Y/site-packages subdirectory (on Windows, this is Lib\site-packages).

On Windows, you may have to invoke the pyvenv script as follows, if you don’t have the relevant PATH and PATHEXT settings:

```
c:\Temp>c:\Python33\python c:\Python33\Tools\Scripts\pyvenv.py myenv
```

or equivalently:

```
c:\Temp>c:\Python33\python -m venv myenv
```

The command, if run with -h, will show the available options:

```
```
Creates virtual Python environments in one or more target directories.

Positional arguments:
- **ENV_DIR**
  - A directory to create the environment in.

Optional arguments:
- **-h, --help**
  - Show this help message and exit.
- **--system-site-packages**
  - Give access to the global site-packages dir to the virtual environment.
- **--symlinks**
  - Try to use symlinks rather than copies, when symlinks are not the default for the platform.
- **--clear**
  - Delete the environment directory. If not specified and the directory already exists, an error will be raised.
- **--upgrade**
  - Upgrade the environment directory to use this version of Python, assuming Python has been upgraded in-place.

If the target directory already exists an error will be raised, unless the **--clear** or **--upgrade** option was provided.

The created `pyvenv.cfg` file also includes the `include-system-site-packages` key, set to true if `venv` is run with the **--system-site-packages** option, false otherwise.

Multiple paths can be given to `pyvenv`, in which case an identical virtualenv will be created, according to the given options, at each provided path.

Once a venv has been created, it can be “activated” using a script in the venv’s binary directory. The invocation of the script is platform-specific: on a Posix platform, you would typically do:

```
$ source <venv>/bin/activate
```
whereas on Windows, you might do:

```
C:\> <venv>/Scripts/activate
```

if you are using the `cmd.exe` shell, or perhaps:

```
PS C:\> <venv>/Scripts/Activate.ps1
```

if you use PowerShell.

You don’t specifically need to activate an environment; activation just prepends the venv's binary directory to your path, so that “python” invokes the venv's Python interpreter and you can run installed scripts without having to use their full path. However, all scripts installed in a venv should be runnable without activating it, and run with the venv’s Python automatically.

You can deactivate a venv by typing “deactivate” in your shell. The exact mechanism is platform-specific: for example, the Bash activation script defines a “deactivate” function, whereas on Windows there are separate scripts called `deactivate.bat` and `Deactivate.ps1` which are installed when the venv is created.
1. Introduction

This reference manual describes the Python programming language. It is not intended as a tutorial.

While I am trying to be as precise as possible, I chose to use English rather than formal specifications for everything except syntax and lexical analysis. This should make the document more understandable to the average reader, but will leave room for ambiguities. Consequently, if you were coming from Mars and tried to re-implement Python from this document alone, you might have to guess things and in fact you would probably end up implementing quite a different language. On the other hand, if you are using Python and wonder what the precise rules about a particular area of the language are, you should definitely be able to find them here. If you would like to see a more formal definition of the language, maybe you could volunteer your time — or invent a cloning machine :-).

It is dangerous to add too many implementation details to a language reference document — the implementation may change, and other implementations of the same language may work differently. On the other hand, CPython is the one Python implementation in widespread use (although alternate implementations continue to gain support), and its particular quirks are sometimes worth being mentioned, especially where the implementation imposes additional limitations. Therefore, you’ll find short “implementation notes” sprinkled throughout the text.

Every Python implementation comes with a number of built-in and standard modules. These are documented in The Python Standard Library. A few built-in modules are mentioned when they interact in a significant way with the language definition.
1.1. Alternate Implementations

Though there is one Python implementation which is by far the most popular, there are some alternate implementations which are of particular interest to different audiences.

Known implementations include:

CPython
This is the original and most-maintained implementation of Python, written in C. New language features generally appear here first.

Jython
Python implemented in Java. This implementation can be used as a scripting language for Java applications, or can be used to create applications using the Java class libraries. It is also often used to create tests for Java libraries. More information can be found at the Jython website.

Python for .NET
This implementation actually uses the CPython implementation, but is a managed .NET application and makes .NET libraries available. It was created by Brian Lloyd. For more information, see the Python for .NET home page.

IronPython
An alternate Python for .NET. Unlike Python.NET, this is a complete Python implementation that generates IL, and compiles Python code directly to .NET assemblies. It was created by Jim Hugunin, the original creator of Jython. For more information, see the IronPython website.

PyPy
An implementation of Python written completely in Python. It supports several advanced features not found in other implementations like stackless support and a Just in Time compiler.
One of the goals of the project is to encourage experimentation with the language itself by making it easier to modify the interpreter (since it is written in Python). Additional information is available on the PyPy project’s home page.

Each of these implementations varies in some way from the language as documented in this manual, or introduces specific information beyond what’s covered in the standard Python documentation. Please refer to the implementation-specific documentation to determine what else you need to know about the specific implementation you’re using.
1.2. Notation

The descriptions of lexical analysis and syntax use a modified BNF grammar notation. This uses the following style of definition:

```
name ::= lc_letter (lc_letter | "_")*
lc_letter ::= "a"..."z"
```

The first line says that a name is an lc_letter followed by a sequence of zero or more lc_letters and underscores. An lc_letter in turn is any of the single characters 'a' through 'z'. (This rule is actually adhered to for the names defined in lexical and grammar rules in this document.)

Each rule begins with a name (which is the name defined by the rule) and ::= . A vertical bar (|) is used to separate alternatives; it is the least binding operator in this notation. A star (*) means zero or more repetitions of the preceding item; likewise, a plus (+) means one or more repetitions, and a phrase enclosed in square brackets ([ ] ) means zero or one occurrences (in other words, the enclosed phrase is optional). The * and + operators bind as tightly as possible; parentheses are used for grouping. Literal strings are enclosed in quotes. White space is only meaningful to separate tokens. Rules are normally contained on a single line; rules with many alternatives may be formatted alternatively with each line after the first beginning with a vertical bar.

In lexical definitions (as the example above), two more conventions are used: Two literal characters separated by three dots mean a choice of any single character in the given (inclusive) range of ASCII characters. A phrase between angular brackets (<...>) gives an
informal description of the symbol defined; e.g., this could be used to describe the notion of ‘control character’ if needed.

Even though the notation used is almost the same, there is a big difference between the meaning of lexical and syntactic definitions: a lexical definition operates on the individual characters of the input source, while a syntax definition operates on the stream of tokens generated by the lexical analysis. All uses of BNF in the next chapter (“Lexical Analysis”) are lexical definitions; uses in subsequent chapters are syntactic definitions.
2. Lexical analysis

A Python program is read by a parser. Input to the parser is a stream of tokens, generated by the lexical analyzer. This chapter describes how the lexical analyzer breaks a file into tokens.

Python reads program text as Unicode code points; the encoding of a source file can be given by an encoding declaration and defaults to UTF-8, see PEP 3120 for details. If the source file cannot be decoded, a SyntaxError is raised.
2.1. Line structure

A Python program is divided into a number of *logical lines*.

2.1.1. Logical lines

The end of a logical line is represented by the token NEWLINE. Statements cannot cross logical line boundaries except where NEWLINE is allowed by the syntax (e.g., between statements in compound statements). A logical line is constructed from one or more *physical lines* by following the explicit or implicit *line joining* rules.

2.1.2. Physical lines

A physical line is a sequence of characters terminated by an end-of-line sequence. In source files, any of the standard platform line termination sequences can be used - the Unix form using ASCII LF (linefeed), the Windows form using the ASCII sequence CR LF (return followed by linefeed), or the old Macintosh form using the ASCII CR (return) character. All of these forms can be used equally, regardless of platform.

When embedding Python, source code strings should be passed to Python APIs using the standard C conventions for newline characters (the `\n` character, representing ASCII LF, is the line terminator).

2.1.3. Comments

A comment starts with a hash character (#) that is not part of a string literal, and ends at the end of the physical line. A comment signifies
the end of the logical line unless the implicit line joining rules are invoked. Comments are ignored by the syntax; they are not tokens.

2.1.4. Encoding declarations

If a comment in the first or second line of the Python script matches the regular expression `coding[=:]\s*([-\w.]+)`, this comment is processed as an encoding declaration; the first group of this expression names the encoding of the source code file. The recommended forms of this expression are

```
# -*- coding: <encoding-name> -*-
```

which is recognized also by GNU Emacs, and

```
# vim:fileencoding=<encoding-name>
```

which is recognized by Bram Moolenaar's VIM.

If no encoding declaration is found, the default encoding is UTF-8. In addition, if the first bytes of the file are the UTF-8 byte-order mark (`b'\xef\xbb\xbf'`), the declared file encoding is UTF-8 (this is supported, among others, by Microsoft’s `notepad`).

If an encoding is declared, the encoding name must be recognized by Python. The encoding is used for all lexical analysis, including string literals, comments and identifiers. The encoding declaration must appear on a line of its own.

2.1.5. Explicit line joining

Two or more physical lines may be joined into logical lines using
backslash characters (\), as follows: when a physical line ends in a backslash that is not part of a string literal or comment, it is joined with the following forming a single logical line, deleting the backslash and the following end-of-line character. For example:

```java
if 1900 < year < 2100 and 1 <= month <= 12 \\
    and 1 <= day <= 31 and 0 <= hour < 24 \\
    and 0 <= minute < 60 and 0 <= second < 60:  # Looks like a valid date
    return 1
```

A line ending in a backslash cannot carry a comment. A backslash does not continue a comment. A backslash does not continue a token except for string literals (i.e., tokens other than string literals cannot be split across physical lines using a backslash). A backslash is illegal elsewhere on a line outside a string literal.

### 2.1.6. Implicit line joining

Expressions in parentheses, square brackets or curly braces can be split over more than one physical line without using backslashes. For example:

```python
month_names = ['Januari', 'Februari', 'Maart', 'April', 'Mei', 'Juni', 'Juli', 'Augustus', 'September', 'Oktober', 'November', 'December']
```

Implicitly continued lines can carry comments. The indentation of the continuation lines is not important. Blank continuation lines are allowed. There is no NEWLINE token between implicit continuation lines. Implicitly continued lines can also occur within triple-quoted strings (see below); in that case they cannot carry comments.
2.1.7. Blank lines

A logical line that contains only spaces, tabs, formfeeds and possibly a comment, is ignored (i.e., no NEWLINE token is generated). During interactive input of statements, handling of a blank line may differ depending on the implementation of the read-eval-print loop. In the standard interactive interpreter, an entirely blank logical line (i.e. one containing not even whitespace or a comment) terminates a multi-line statement.

2.1.8. Indentation

Leading whitespace (spaces and tabs) at the beginning of a logical line is used to compute the indentation level of the line, which in turn is used to determine the grouping of statements.

Tabs are replaced (from left to right) by one to eight spaces such that the total number of characters up to and including the replacement is a multiple of eight (this is intended to be the same rule as used by Unix). The total number of spaces preceding the first non-blank character then determines the line's indentation. Indentation cannot be split over multiple physical lines using backslashes; the whitespace up to the first backslash determines the indentation.

Indentation is rejected as inconsistent if a source file mixes tabs and spaces in a way that makes the meaning dependent on the worth of a tab in spaces; a TabError is raised in that case.

Cross-platform compatibility note: because of the nature of text editors on non-UNIX platforms, it is unwise to use a mixture of spaces and tabs for the indentation in a single source file. It should also be noted that different platforms may explicitly limit the maximum
indentation level.

A formfeed character may be present at the start of the line; it will be ignored for the indentation calculations above. Formfeed characters occurring elsewhere in the leading whitespace have an undefined effect (for instance, they may reset the space count to zero).

The indentation levels of consecutive lines are used to generate INDENT and DEDENT tokens, using a stack, as follows.

Before the first line of the file is read, a single zero is pushed on the stack; this will never be popped off again. The numbers pushed on the stack will always be strictly increasing from bottom to top. At the beginning of each logical line, the line's indentation level is compared to the top of the stack. If it is equal, nothing happens. If it is larger, it is pushed on the stack, and one INDENT token is generated. If it is smaller, it must be one of the numbers occurring on the stack; all numbers on the stack that are larger are popped off, and for each number popped off a DEDENT token is generated. At the end of the file, a DEDENT token is generated for each number remaining on the stack that is larger than zero.

Here is an example of a correctly (though confusingly) indented piece of Python code:

```python
def perm(l):
    # Compute the list of all permutations of l
    if len(l) <= 1:
        return [l]
    r = []
    for i in range(len(l)):
        s = l[:i] + l[i+1:]
        p = perm(s)
        for x in p:
```
The following example shows various indentation errors:

```python
def perm(l):
    # error: first line indented
    for i in range(len(l)):
        # error: not indented
        s = l[:i] + l[i+1:]
        p = perm(l[:i] + l[i+1:])
        # error: unexpected indent
        for x in p:
            r.append(l[i:i+1] + x)
    return r
    # error: inconsistent dedent
```

(Actually, the first three errors are detected by the parser; only the last error is found by the lexical analyzer — the indentation of `return r` does not match a level popped off the stack.)

### 2.1.9. Whitespace between tokens

Except at the beginning of a logical line or in string literals, the whitespace characters space, tab and formfeed can be used interchangeably to separate tokens. Whitespace is needed between two tokens only if their concatenation could otherwise be interpreted as a different token (e.g., `ab` is one token, but `a b` is two tokens).
2.2. Other tokens

Besides NEWLINE, INDENT and DEDENT, the following categories of tokens exist: identifiers, keywords, literals, operators, and delimiters. Whitespace characters (other than line terminators, discussed earlier) are not tokens, but serve to delimit tokens. Where ambiguity exists, a token comprises the longest possible string that forms a legal token, when read from left to right.
2.3. Identifiers and keywords

Identifiers (also referred to as names) are described by the following lexical definitions.

The syntax of identifiers in Python is based on the Unicode standard annex UAX-31, with elaboration and changes as defined below; see also PEP 3131 for further details.

Within the ASCII range (U+0001..U+007F), the valid characters for identifiers are the same as in Python 2.x: the uppercase and lowercase letters A through Z, the underscore _ and, except for the first character, the digits 0 through 9.

Python 3.0 introduces additional characters from outside the ASCII range (see PEP 3131). For these characters, the classification uses the version of the Unicode Character Database as included in the unicodedata module.

Identifiers are unlimited in length. Case is significant.

```
identifier ::= xid_start xid_continue*

id_start ::= <all characters in general categories Lu, Ll, Lt, Lm, Lo, Nl, the underscore, and characters with the Other_ID_Start property>

id_continue ::= <all characters in id_start, plus characters in the Mn, Mc, Nd, Pc and others with the Other_ID_Continue property>

xid_start ::= <all characters in id_start whose NFKC normalization is in "id_start xid_continue*">

xid_continue ::= <all characters in id_continue whose NFKC normalization is in "id_continue*">
```

The Unicode category codes mentioned above stand for:

- *Lu* - uppercase letters
- *Ll* - lowercase letters
- *Lt* - titlecase letters
- *Lm* - modifier letters
All identifiers are converted into the normal form NFKC while parsing; comparison of identifiers is based on NFKC.

A non-normative HTML file listing all valid identifier characters for Unicode 4.1 can be found at http://www.dcl.hpi.uni-potsdam.de/home/loewis/table-3131.html.

2.3.1. Keywords

The following identifiers are used as reserved words, or *keywords* of the language, and cannot be used as ordinary identifiers. They must be spelled exactly as written here:

<table>
<thead>
<tr>
<th>False</th>
<th>class</th>
<th>finally</th>
<th>is</th>
<th>return</th>
</tr>
</thead>
<tbody>
<tr>
<td>None</td>
<td>continue</td>
<td>for</td>
<td>is</td>
<td>return</td>
</tr>
<tr>
<td>True</td>
<td>def</td>
<td>from</td>
<td>lambda</td>
<td>try</td>
</tr>
<tr>
<td>and</td>
<td>del</td>
<td>global</td>
<td>nonlocal</td>
<td>while</td>
</tr>
<tr>
<td>as</td>
<td>elif</td>
<td>if</td>
<td>not</td>
<td>with</td>
</tr>
<tr>
<td>assert</td>
<td>else</td>
<td>import</td>
<td>or</td>
<td>yield</td>
</tr>
<tr>
<td>break</td>
<td>except</td>
<td>in</td>
<td>pass</td>
<td></td>
</tr>
<tr>
<td></td>
<td></td>
<td></td>
<td>raise</td>
<td></td>
</tr>
</tbody>
</table>

2.3.2. Reserved classes of identifiers
Certain classes of identifiers (besides keywords) have special meanings. These classes are identified by the patterns of leading and trailing underscore characters:

__*__

Not imported by `from module import *`. The special identifier `_` is used in the interactive interpreter to store the result of the last evaluation; it is stored in the `builtins` module. When not in interactive mode, `_` has no special meaning and is not defined. See section *The import statement*.

**Note:** The name `_` is often used in conjunction with internationalization; refer to the documentation for the `gettext` module for more information on this convention.

__**__

System-defined names. These names are defined by the interpreter and its implementation (including the standard library). Current system names are discussed in the *Special method names* section and elsewhere. More will likely be defined in future versions of Python. Any use of `__**__` names, in any context, that does not follow explicitly documented use, is subject to breakage without warning.

__*__

Class-private names. Names in this category, when used within the context of a class definition, are re-written to use a mangled form to help avoid name clashes between “private” attributes of base and derived classes. See section *Identifiers (Names)*.
2.4. Literals

Literals are notations for constant values of some built-in types.

2.4.1. String and Bytes literals

String literals are described by the following lexical definitions:

```
stringliteral ::= [stringprefix](shortstring | longstring)
stringprefix ::= "r" | "u" | "R" | "U"
shortstring ::= "'" shortstringitem* "'" | "'
longstring ::= "'''" longstringitem* "'''" | "'''
shortstringitem ::= shortstringchar | stringescapeseq
longstringitem ::= longstringchar | stringescapeseq
shortstringchar ::= <any source character except "" or newline or the quote>
longstringchar ::= <any ASCII character except">
stringescapeseq ::= "\" <any source character>
```

```
bytesliteral ::= bytesprefix(shortbytes | longbytes)
bytesprefix ::= "b" | "B" | "br" | "Br" | "bR" | "Br" | "rb" | "rB" | "Rb" | "RB"
shortbytes ::= "'" shortbytesitem* "'" | "'
longbytes ::= "'''" longbytesitem* "'''" | "'''
shortbytesitem ::= shortbyteschar | bytesescapeseq
longbytesitem ::= longbyteschar | bytesescapeseq
shortbyteschar ::= <any ASCII character except "" or newline or the quote>
longbyteschar ::= <any ASCII character except">
bytesescapeseq ::= "\" <any ASCII character>
```

One syntactic restriction not indicated by these productions is that whitespace is not allowed between the stringprefix or bytesprefix and the rest of the literal. The source character set is defined by the encoding declaration; it is UTF-8 if no encoding
declaration is given in the source file; see section *Encoding declarations*.

In plain English: Both types of literals can be enclosed in matching single quotes (') or double quotes ("'). They can also be enclosed in matching groups of three single or double quotes (these are generally referred to as *triple-quoted strings*). The backslash (\) character is used to escape characters that otherwise have a special meaning, such as newline, backslash itself, or the quote character.

Bytes literals are always prefixed with 'b' or 'B'; they produce an instance of the `bytes` type instead of the `str` type. They may only contain ASCII characters; bytes with a numeric value of 128 or greater must be expressed with escapes.

As of Python 3.3 it is possible again to prefix unicode strings with a `u` prefix to simplify maintenance of dual 2.x and 3.x codebases.

Both string and bytes literals may optionally be prefixed with a letter 'r' or 'R'; such strings are called *raw strings* and treat backslashes as literal characters. As a result, in string literals, '\U' and '\u' escapes in raw strings are not treated specially. Given that Python 2.x's raw unicode literals behave differently than Python 3.x's the 'ur' syntax is not supported.

*New in version 3.3:* The 'rb' prefix of raw bytes literals has been added as a synonym of 'br'.

*New in version 3.3:* Support for the unicode legacy literal (u'value') was reintroduced to simplify the maintenance of dual Python 2.x and 3.x codebases. See PEP 414 for more information.
In triple-quoted strings, unescaped newlines and quotes are allowed (and are retained), except that three unescaped quotes in a row terminate the string. (A “quote” is the character used to open the string, i.e. either `'|` or `"`.)

Unless an `'r` or `R` prefix is present, escape sequences in strings are interpreted according to rules similar to those used by Standard C. The recognized escape sequences are:

<table>
<thead>
<tr>
<th>Escape Sequence</th>
<th>Meaning</th>
<th>Notes</th>
</tr>
</thead>
<tbody>
<tr>
<td><code>\n</code></td>
<td>Backslash and newline ignored</td>
<td></td>
</tr>
<tr>
<td><code>\</code></td>
<td>Backslash (<code>\</code>)</td>
<td></td>
</tr>
<tr>
<td><code>\'</code></td>
<td>Single quote (<code>'</code>)</td>
<td></td>
</tr>
<tr>
<td><code>\&quot;</code></td>
<td>Double quote (&quot;&quot;&quot;)</td>
<td></td>
</tr>
<tr>
<td><code>\a</code></td>
<td>ASCII Bell (BEL)</td>
<td></td>
</tr>
<tr>
<td><code>\b</code></td>
<td>ASCII Backspace (BS)</td>
<td></td>
</tr>
<tr>
<td><code>\f</code></td>
<td>ASCII Formfeed (FF)</td>
<td></td>
</tr>
<tr>
<td><code>\n</code></td>
<td>ASCII Linefeed (LF)</td>
<td></td>
</tr>
<tr>
<td><code>\r</code></td>
<td>ASCII Carriage Return (CR)</td>
<td></td>
</tr>
<tr>
<td><code>\t</code></td>
<td>ASCII Horizontal Tab (TAB)</td>
<td></td>
</tr>
<tr>
<td><code>\v</code></td>
<td>ASCII Vertical Tab (VT)</td>
<td></td>
</tr>
<tr>
<td><code>\ooo</code></td>
<td>Character with octal value <code>ooo</code></td>
<td>(1,3)</td>
</tr>
<tr>
<td><code>\xhh</code></td>
<td>Character with hex value <code>hh</code></td>
<td>(2,3)</td>
</tr>
</tbody>
</table>

Escape sequences only recognized in string literals are:

<table>
<thead>
<tr>
<th>Escape Sequence</th>
<th>Meaning</th>
<th>Notes</th>
</tr>
</thead>
</table>

\N{name} Character named name in the Unicode database (4)
\uxxxx Character with 16-bit hex value xxxx (5)
\Uxxxxxxxx Character with 32-bit hex value xxxxxxx (6)

Notes:

1. As in Standard C, up to three octal digits are accepted.

2. Unlike in Standard C, exactly two hex digits are required.

3. In a bytes literal, hexadecimal and octal escapes denote the byte with the given value. In a string literal, these escapes denote a Unicode character with the given value.

4. Changed in version 3.3: Support for name aliases [1] has been added.

5. Individual code units which form parts of a surrogate pair can be encoded using this escape sequence. Exactly four hex digits are required.

6. Any Unicode character can be encoded this way. Exactly eight hex digits are required.

Unlike Standard C, all unrecognized escape sequences are left in the string unchanged, i.e., the backslash is left in the string. (This behavior is useful when debugging: if an escape sequence is mistyped, the resulting output is more easily recognized as broken.) It is also important to note that the escape sequences only recognized in string literals fall into the category of unrecognized escapes for bytes literals.

Even in a raw string, string quotes can be escaped with a backslash,
but the backslash remains in the string; for example, `r"\""` is a valid string literal consisting of two characters: a backslash and a double quote; `r"\"` is not a valid string literal (even a raw string cannot end in an odd number of backslashes). Specifically, a raw string cannot end in a single backslash (since the backslash would escape the following quote character). Note also that a single backslash followed by a newline is interpreted as those two characters as part of the string, not as a line continuation.

### 2.4.2. String literal concatenation

Multiple adjacent string or bytes literals (delimited by whitespace), possibly using different quoting conventions, are allowed, and their meaning is the same as their concatenation. Thus, "hello" 'world' is equivalent to "helloworld". This feature can be used to reduce the number of backslashes needed, to split long strings conveniently across long lines, or even to add comments to parts of strings, for example:

```python
re.compile("[A-Za-z_]"         # letter or underscore
           "[A-Za-z0-9_]"*"  # letter, digit or underscore

Note that this feature is defined at the syntactical level, but implemented at compile time. The ‘+’ operator must be used to concatenate string expressions at run time. Also note that literal concatenation can use different quoting styles for each component (even mixing raw strings and triple quoted strings).

### 2.4.3. Numeric literals
There are three types of numeric literals: integers, floating point numbers, and imaginary numbers. There are no complex literals (complex numbers can be formed by adding a real number and an imaginary number).

Note that numeric literals do not include a sign; a phrase like \(-1\) is actually an expression composed of the unary operator ‘\(-\)’ and the literal \(1\).

2.4.4. Integer literals

Integer literals are described by the following lexical definitions:

<table>
<thead>
<tr>
<th>Token</th>
<th>Syntax</th>
</tr>
</thead>
<tbody>
<tr>
<td>integer</td>
<td>integer ::= decimalinteger</td>
</tr>
<tr>
<td>decimalinteger</td>
<td>decimalinteger ::= nonzerodigit digit*</td>
</tr>
<tr>
<td>nonzerodigit</td>
<td>nonzerodigit ::= &quot;1&quot;...&quot;9&quot;</td>
</tr>
<tr>
<td>digit</td>
<td>digit ::= &quot;0&quot;...&quot;9&quot;</td>
</tr>
<tr>
<td>octinteger</td>
<td>octinteger ::= &quot;0&quot; (&quot;0&quot;</td>
</tr>
<tr>
<td>hexinteger</td>
<td>hexinteger ::= &quot;0&quot; (&quot;x&quot;</td>
</tr>
<tr>
<td>bininteger</td>
<td>bininteger ::= &quot;0&quot; (&quot;b&quot;</td>
</tr>
<tr>
<td>octdigit</td>
<td>octdigit ::= &quot;0&quot;...&quot;7&quot;</td>
</tr>
<tr>
<td>hexdigit</td>
<td>hexdigit ::= digit</td>
</tr>
<tr>
<td>bindigit</td>
<td>bindigit ::= &quot;0&quot;</td>
</tr>
</tbody>
</table>

There is no limit for the length of integer literals apart from what can be stored in available memory.

Note that leading zeros in a non-zero decimal number are not allowed. This is for disambiguation with C-style octal literals, which Python used before version 3.0.

Some examples of integer literals:
2.4.5. Floating point literals

Floating point literals are described by the following lexical definitions:

\[
\begin{align*}
floatnumber & ::= \text{pointfloat } | \text{exponentfloat} \\
\text{pointfloat} & ::= [\text{intpart}] \text{fraction } | \text{intpart }\cdot\\
\text{exponentfloat} & ::= (\text{intpart } | \text{pointfloat}) \text{exponent} \\
\text{intpart} & ::= \text{digit}^+ \\
\text{fraction} & ::= \cdot\text{digit}^+ \\
\text{exponent} & ::= (\text{"e" } | \text{"E"}) [\text{"+" } | \text{"-"}] \text{digit}^+
\end{align*}
\]

Note that the integer and exponent parts are always interpreted using radix 10. For example, \texttt{077e010} is legal, and denotes the same number as \texttt{77e10}. The allowed range of floating point literals is implementation-dependent. Some examples of floating point literals:

\[
\begin{align*}
3.14 & \quad 10. & \quad .001 & \quad 1e100 & \quad 3.14e-10 & \quad 0e0
\end{align*}
\]

Note that numeric literals do not include a sign; a phrase like \texttt{-1} is actually an expression composed of the unary operator \texttt{-} and the literal \texttt{1}.

2.4.6. Imaginary literals

Imaginary literals are described by the following lexical definitions:

\[
\text{imagnumber} ::= (\text{floatnumber } | \text{intpart}) (\text{"j" } | \text{"J"})
\]
An imaginary literal yields a complex number with a real part of 0.0. Complex numbers are represented as a pair of floating point numbers and have the same restrictions on their range. To create a complex number with a nonzero real part, add a floating point number to it, e.g., (3+4j). Some examples of imaginary literals:

<p>| | | | | | |</p>
<table>
<thead>
<tr>
<th></th>
<th></th>
<th></th>
<th></th>
<th></th>
<th></th>
</tr>
</thead>
<tbody>
<tr>
<td>3.14j</td>
<td>10.j</td>
<td>10j</td>
<td>.001j</td>
<td>1e100j</td>
<td>3.14e-10j</td>
</tr>
</tbody>
</table>
2.5. Operators

The following tokens are operators:

<table>
<thead>
<tr>
<th>+</th>
<th>-</th>
<th>*</th>
<th>**</th>
<th>/</th>
<th>//</th>
<th>%</th>
</tr>
</thead>
<tbody>
<tr>
<td>&lt;&lt;</td>
<td>&gt;&gt;</td>
<td>&amp;</td>
<td></td>
<td>^</td>
<td>~</td>
<td></td>
</tr>
<tr>
<td>&lt;</td>
<td>&gt;</td>
<td>&lt;=</td>
<td>&gt;=</td>
<td>==</td>
<td>!=</td>
<td></td>
</tr>
</tbody>
</table>
2.6. Delimiters

The following tokens serve as delimiters in the grammar:

<p>| | | | | |</p>
<table>
<thead>
<tr>
<th></th>
<th></th>
<th></th>
<th></th>
<th></th>
</tr>
</thead>
<tbody>
<tr>
<td>(</td>
<td>)</td>
<td>[</td>
<td>]</td>
<td>{</td>
</tr>
<tr>
<td>,</td>
<td>:</td>
<td>.</td>
<td>;</td>
<td>@</td>
</tr>
<tr>
<td>+=</td>
<td>-=</td>
<td>*=</td>
<td>/=</td>
<td>/=</td>
</tr>
<tr>
<td>&amp;=</td>
<td></td>
<td>=</td>
<td>^=</td>
<td>&gt;&gt;=</td>
</tr>
</tbody>
</table>

The period can also occur in floating-point and imaginary literals. A sequence of three periods has a special meaning as an ellipsis literal. The second half of the list, the augmented assignment operators, serve lexically as delimiters, but also perform an operation.

The following printing ASCII characters have special meaning as part of other tokens or are otherwise significant to the lexical analyzer:

| ' | " | # | \ |

The following printing ASCII characters are not used in Python. Their occurrence outside string literals and comments is an unconditional error:

| $ | ? | ` | \ |

3. Data model
3.1. Objects, values and types

*Objects* are Python’s abstraction for data. All data in a Python program is represented by objects or by relations between objects. (In a sense, and in conformance to Von Neumann’s model of a “stored program computer,” code is also represented by objects.)

Every object has an identity, a type and a value. An object’s *identity* never changes once it has been created; you may think of it as the object’s address in memory. The ‘is’ operator compares the identity of two objects; the *id()* function returns an integer representing its identity.

**CPython implementation detail:** For CPython, *id(x)* is the memory address where *x* is stored.

An object’s type determines the operations that the object supports (e.g., “does it have a length?”) and also defines the possible values for objects of that type. The *type()* function returns an object’s type (which is an object itself). Like its identity, an object’s *type* is also unchangeable. [1]

The *value* of some objects can change. Objects whose value can change are said to be *mutable*; objects whose value is unchangeable once they are created are called *immutable*. (The value of an immutable container object that contains a reference to a mutable object can change when the latter’s value is changed; however the container is still considered immutable, because the collection of objects it contains cannot be changed. So, immutability is not strictly the same as having an unchangeable value, it is more subtle.) An object’s mutability is determined by its type; for instance, numbers,
strings and tuples are immutable, while dictionaries and lists are mutable.

Objects are never explicitly destroyed; however, when they become unreachable they may be garbage-collected. An implementation is allowed to postpone garbage collection or omit it altogether — it is a matter of implementation quality how garbage collection is implemented, as long as no objects are collected that are still reachable.

**CPython implementation detail:** CPython currently uses a reference-counting scheme with (optional) delayed detection of cyclically linked garbage, which collects most objects as soon as they become unreachable, but is not guaranteed to collect garbage containing circular references. See the documentation of the `gc` module for information on controlling the collection of cyclic garbage. Other implementations act differently and CPython may change. Do not depend on immediate finalization of objects when they become unreachable (ex: always close files).

Note that the use of the implementation's tracing or debugging facilities may keep objects alive that would normally be collectable. Also note that catching an exception with a `try...except` statement may keep objects alive.

Some objects contain references to “external” resources such as open files or windows. It is understood that these resources are freed when the object is garbage-collected, but since garbage collection is not guaranteed to happen, such objects also provide an explicit way to release the external resource, usually a `close()` method. Programs are strongly recommended to explicitly close such objects. The `try...finally` statement and the `with` statement provide
convenient ways to do this.

Some objects contain references to other objects; these are called containers. Examples of containers are tuples, lists and dictionaries. The references are part of a container’s value. In most cases, when we talk about the value of a container, we imply the values, not the identities of the contained objects; however, when we talk about the mutability of a container, only the identities of the immediately contained objects are implied. So, if an immutable container (like a tuple) contains a reference to a mutable object, its value changes if that mutable object is changed.

Types affect almost all aspects of object behavior. Even the importance of object identity is affected in some sense: for immutable types, operations that compute new values may actually return a reference to any existing object with the same type and value, while for mutable objects this is not allowed. E.g., after a = 1; b = 1, a and b may or may not refer to the same object with the value one, depending on the implementation, but after c = []; d = [], c and d are guaranteed to refer to two different, unique, newly created empty lists. (Note that c = d = [] assigns the same object to both c and d.)
3.2. The standard type hierarchy

Below is a list of the types that are built into Python. Extension modules (written in C, Java, or other languages, depending on the implementation) can define additional types. Future versions of Python may add types to the type hierarchy (e.g., rational numbers, efficiently stored arrays of integers, etc.), although such additions will often be provided via the standard library instead.

Some of the type descriptions below contain a paragraph listing ‘special attributes.’ These are attributes that provide access to the implementation and are not intended for general use. Their definition may change in the future.

None

This type has a single value. There is a single object with this value. This object is accessed through the built-in name None. It is used to signify the absence of a value in many situations, e.g., it is returned from functions that don’t explicitly return anything. Its truth value is false.

NotImplemented

This type has a single value. There is a single object with this value. This object is accessed through the built-in name NotImplemented. Numeric methods and rich comparison methods may return this value if they do not implement the operation for the operands provided. (The interpreter will then try the reflected operation, or some other fallback, depending on the operator.) Its truth value is true.

Ellipsis

This type has a single value. There is a single object with this
value. This object is accessed through the literal \ldots{} or the built-in name \texttt{Ellipsis}. Its truth value is true.

\texttt{numbers.Number}

These are created by numeric literals and returned as results by arithmetic operators and arithmetic built-in functions. Numeric objects are immutable; once created their value never changes. Python numbers are of course strongly related to mathematical numbers, but subject to the limitations of numerical representation in computers.

Python distinguishes between integers, floating point numbers, and complex numbers:

\texttt{numbers.Integral}

These represent elements from the mathematical set of integers (positive and negative).

There are two types of integers:

Integers (\texttt{int})

These represent numbers in an unlimited range, subject to available (virtual) memory only. For the purpose of shift and mask operations, a binary representation is assumed, and negative numbers are represented in a variant of 2’s complement which gives the illusion of an infinite string of sign bits extending to the left.

Booleans (\texttt{bool})

These represent the truth values False and True. The two objects representing the values False and True are the only Boolean objects. The Boolean type is a subtype of the integer type, and Boolean values behave like the values 0
and 1, respectively, in almost all contexts, the exception being that when converted to a string, the strings "False" or "True" are returned, respectively.

The rules for integer representation are intended to give the most meaningful interpretation of shift and mask operations involving negative integers.

**numbers.Real (float)**

These represent machine-level double precision floating point numbers. You are at the mercy of the underlying machine architecture (and C or Java implementation) for the accepted range and handling of overflow. Python does not support single-precision floating point numbers; the savings in processor and memory usage that are usually the reason for using these is dwarfed by the overhead of using objects in Python, so there is no reason to complicate the language with two kinds of floating point numbers.

**numbers.Complex (complex)**

These represent complex numbers as a pair of machine-level double precision floating point numbers. The same caveats apply as for floating point numbers. The real and imaginary parts of a complex number \( z \) can be retrieved through the read-only attributes \( z\text{.real} \) and \( z\text{.imag} \).

**Sequences**

These represent finite ordered sets indexed by non-negative numbers. The built-in function \( \text{len()} \) returns the number of items of a sequence. When the length of a sequence is \( n \), the index set contains the numbers 0, 1, ..., \( n-1 \). Item \( i \) of sequence \( a \) is selected by \( a[i] \).
Sequences also support slicing: $a[i:j]$ selects all items with index $k$ such that $i \leq k < j$. When used as an expression, a slice is a sequence of the same type. This implies that the index set is renumbered so that it starts at 0.

Some sequences also support “extended slicing” with a third “step” parameter: $a[i:j:k]$ selects all items of $a$ with index $x$ where $x = i + n*k$, $n \geq 0$ and $i \leq x < j$.

Sequences are distinguished according to their mutability:

Immutable sequences

An object of an immutable sequence type cannot change once it is created. (If the object contains references to other objects, these other objects may be mutable and may be changed; however, the collection of objects directly referenced by an immutable object cannot change.)

The following types are immutable sequences:

Strings

A string is a sequence of values that represent Unicode codepoints. All the codepoints in range U+0000 - U+10FFFF can be represented in a string. Python doesn’t have a chr type, and every character in the string is represented as a string object with length 1. The built-in function `ord()` converts a character to its codepoint (as an integer); `chr()` converts an integer in range 0 - 10FFFF to the corresponding character. `str.encode()` can be used to convert a `str` to `bytes` using the given encoding, and `bytes.decode()` can be used to achieve the opposite.
Tuples

The items of a tuple are arbitrary Python objects. Tuples of two or more items are formed by comma-separated lists of expressions. A tuple of one item (a ‘singleton’) can be formed by affixing a comma to an expression (an expression by itself does not create a tuple, since parentheses must be usable for grouping of expressions). An empty tuple can be formed by an empty pair of parentheses.

Bytes

A bytes object is an immutable array. The items are 8-bit bytes, represented by integers in the range $0 \leq x < 256$. Bytes literals (like `b'abc'`) and the built-in function `bytes()` can be used to construct bytes objects. Also, bytes objects can be decoded to strings via the `decode()` method.

Mutable sequences

Mutable sequences can be changed after they are created. The subscription and slicing notations can be used as the target of assignment and `del` (delete) statements.

There are currently two intrinsic mutable sequence types:

Lists

The items of a list are arbitrary Python objects. Lists are formed by placing a comma-separated list of expressions in square brackets. (Note that there are no special cases needed to form lists of length 0 or 1.)

Byte Arrays

A bytearray object is a mutable array. They are created by the built-in `bytearray()` constructor. Aside from being
mutable (and hence unhashable), byte arrays otherwise provide the same interface and functionality as immutable bytes objects.

The extension module array provides an additional example of a mutable sequence type, as does the collections module.

Set types
These represent unordered, finite sets of unique, immutable objects. As such, they cannot be indexed by any subscript. However, they can be iterated over, and the built-in function `len()` returns the number of items in a set. Common uses for sets are fast membership testing, removing duplicates from a sequence, and computing mathematical operations such as intersection, union, difference, and symmetric difference.

For set elements, the same immutability rules apply as for dictionary keys. Note that numeric types obey the normal rules for numeric comparison: if two numbers compare equal (e.g., 1 and 1.0), only one of them can be contained in a set.

There are currently two intrinsic set types:

Sets
These represent a mutable set. They are created by the built-in `set()` constructor and can be modified afterwards by several methods, such as `add()`.

Frozen sets
These represent an immutable set. They are created by the built-in `frozenset()` constructor. As a frozenset is immutable and **hashable**, it can be used again as an element of another
set, or as a dictionary key.

Mappings
These represent finite sets of objects indexed by arbitrary index sets. The subscript notation \(a[k]\) selects the item indexed by \(k\) from the mapping \(a\); this can be used in expressions and as the target of assignments or \texttt{del} statements. The built-in function \texttt{len()} returns the number of items in a mapping.

There is currently a single intrinsic mapping type:

Dictionaries
These represent finite sets of objects indexed by nearly arbitrary values. The only types of values not acceptable as keys are values containing lists or dictionaries or other mutable types that are compared by value rather than by object identity, the reason being that the efficient implementation of dictionaries requires a key's hash value to remain constant. Numeric types used for keys obey the normal rules for numeric comparison: if two numbers compare equal (e.g., \(1\) and \(1.0\)) then they can be used interchangeably to index the same dictionary entry.

Dictionaries are mutable; they can be created by the \{...\} notation (see section \textit{Dictionary displays}).

The extension modules \texttt{dbm.ndbm} and \texttt{dbm.gnu} provide additional examples of mapping types, as does the \texttt{collections} module.

Callable types
These are the types to which the function call operation (see section \textit{Calls}) can be applied:
User-defined functions

A user-defined function object is created by a function definition (see section *Function definitions*). It should be called with an argument list containing the same number of items as the function’s formal parameter list.

Special attributes:

<table>
<thead>
<tr>
<th>Attribute</th>
<th>Meaning</th>
<th>Writable</th>
</tr>
</thead>
<tbody>
<tr>
<td><strong>doc</strong></td>
<td>The function’s documentation string, or None if unavailable</td>
<td></td>
</tr>
<tr>
<td><strong>name</strong></td>
<td>The function's name</td>
<td></td>
</tr>
<tr>
<td><strong>qualname</strong></td>
<td>The function’s <em>qualified name</em></td>
<td></td>
</tr>
<tr>
<td></td>
<td><em>New in version 3.3.</em></td>
<td></td>
</tr>
<tr>
<td><strong>module</strong></td>
<td>The name of the module the function was defined in, or None if unavailable.</td>
<td></td>
</tr>
<tr>
<td><strong>defaults</strong></td>
<td>A tuple containing default argument values for those arguments that have defaults, or None if no arguments have a default value</td>
<td></td>
</tr>
<tr>
<td><strong>code</strong></td>
<td>The code object representing the compiled function body.</td>
<td></td>
</tr>
<tr>
<td><strong>globals</strong></td>
<td>A reference to the dictionary that holds the function’s global variables — the global namespace</td>
<td></td>
</tr>
<tr>
<td>Attribute</td>
<td>Description</td>
<td>Readability</td>
</tr>
<tr>
<td>--------------</td>
<td>------------------------------------------------------------------------------</td>
<td>-------------</td>
</tr>
<tr>
<td><strong>dict</strong></td>
<td>The namespace supporting arbitrary function attributes.</td>
<td>Writable</td>
</tr>
<tr>
<td><strong>closure</strong></td>
<td>None or a tuple of cells that contain bindings for the function's free variables.</td>
<td>Read-only</td>
</tr>
<tr>
<td><strong>annotations</strong></td>
<td>A dict containing annotations of parameters. The keys of the dict are the parameter names, or 'return' for the return annotation, if provided.</td>
<td>Writable</td>
</tr>
<tr>
<td><strong>kwdefaults</strong></td>
<td>A dict containing defaults for keyword-only parameters.</td>
<td>Writable</td>
</tr>
</tbody>
</table>

Most of the attributes labelled “Writable” check the type of the assigned value.

Function objects also support getting and setting arbitrary attributes, which can be used, for example, to attach metadata to functions. Regular attribute dot-notation is used to get and set such attributes. *Note that the current implementation only supports function attributes on user-defined functions. Function attributes on built-in functions may be supported in the future.*

Additional information about a function’s definition can be retrieved from its code object; see the description of internal types below.
Instance methods

An instance method object combines a class, a class instance and any callable object (normally a user-defined function).

Special read-only attributes: __self__ is the class instance object, __func__ is the function object; __doc__ is the method's documentation (same as __func__.__doc__); __name__ is the method name (same as __func__.__name__); __module__ is the name of the module the method was defined in, or None if unavailable.

Methods also support accessing (but not setting) the arbitrary function attributes on the underlying function object.

User-defined method objects may be created when getting an attribute of a class (perhaps via an instance of that class), if that attribute is a user-defined function object or a class method object.

When an instance method object is created by retrieving a user-defined function object from a class via one of its instances, its __self__ attribute is the instance, and the method object is said to be bound. The new method's __func__ attribute is the original function object.

When a user-defined method object is created by retrieving another method object from a class or instance, the behaviour is the same as for a function object, except that the __func__ attribute of the new instance is not the original method object but its __func__ attribute.

When an instance method object is created by retrieving a class method object from a class or instance, its __self__ attribute
is the class itself, and its `__func__` attribute is the function object underlying the class method.

When an instance method object is called, the underlying function (`__func__`) is called, inserting the class instance (`__self__`) in front of the argument list. For instance, when `C` is a class which contains a definition for a function `f()`, and `x` is an instance of `C`, calling `x.f(1)` is equivalent to calling `C.f(x, 1)`.

When an instance method object is derived from a class method object, the “class instance” stored in `__self__` will actually be the class itself, so that calling either `x.f(1)` or `C.f(1)` is equivalent to calling `f(C, 1)` where `f` is the underlying function.

Note that the transformation from function object to instance method object happens each time the attribute is retrieved from the instance. In some cases, a fruitful optimization is to assign the attribute to a local variable and call that local variable. Also notice that this transformation only happens for user-defined functions; other callable objects (and all non-callable objects) are retrieved without transformation. It is also important to note that user-defined functions which are attributes of a class instance are not converted to bound methods; this only happens when the function is an attribute of the class.

Generator functions

A function or method which uses the `yield` statement (see section *The yield statement*) is called a *generator function*. Such a function, when called, always returns an iterator object which can be used to execute the body of the function: calling
the iterator's `iterator.__next__()` method will cause the function to execute until it provides a value using the `yield` statement. When the function executes a `return` statement or falls off the end, a `StopIteration` exception is raised and the iterator will have reached the end of the set of values to be returned.

Built-in functions
A built-in function object is a wrapper around a C function. Examples of built-in functions are `len()` and `math.sin()` (`math` is a standard built-in module). The number and type of the arguments are determined by the C function. Special read-only attributes: `__doc__` is the function’s documentation string, or None if unavailable; `__name__` is the function's name; `__self__` is set to None (but see the next item); `__module__` is the name of the module the function was defined in or None if unavailable.

Built-in methods
This is really a different disguise of a built-in function, this time containing an object passed to the C function as an implicit extra argument. An example of a built-in method is `alist.append()`, assuming `alist` is a list object. In this case, the special read-only attribute `__self__` is set to the object denoted by `alist`.

Classes
Classes are callable. These objects normally act as factories for new instances of themselves, but variations are possible for class types that override `__new__()`. The arguments of the call are passed to `__new__()` and, in the typical case, to `__init__()` to initialize the new instance.
Class Instances

Instances of arbitrary classes can be made callable by defining a `__call__()` method in their class.

Modules

Modules are a basic organizational unit of Python code, and are created by the `import system` as invoked either by the `import` statement (see `import`), or by calling functions such as `importlib.import_module()` and built-in `__import__()`. A module object has a namespace implemented by a dictionary object (this is the dictionary referenced by the `__globals__` attribute of functions defined in the module). Attribute references are translated to lookups in this dictionary, e.g., `m.x` is equivalent to `m.__dict__['x']`. A module object does not contain the code object used to initialize the module (since it isn’t needed once the initialization is done).

Attribute assignment updates the module’s namespace dictionary, e.g., `m.x = 1` is equivalent to `m.__dict__['x'] = 1`.

Special read-only attribute: `__dict__` is the module’s namespace as a dictionary object.

**CPython implementation detail:** Because of the way CPython clears module dictionaries, the module dictionary will be cleared when the module falls out of scope even if the dictionary still has live references. To avoid this, copy the dictionary or keep the module around while using its dictionary directly.

Predefined (writable) attributes: `__name__` is the module’s name; `__doc__` is the module’s documentation string, or `None` if unavailable; `__file__` is the pathname of the file from which the
module was loaded, if it was loaded from a file. The __file__ attribute may be missing for certain types of modules, such as C modules that are statically linked into the interpreter; for extension modules loaded dynamically from a shared library, it is the pathname of the shared library file.

Custom classes

Custom class types are typically created by class definitions (see section Class definitions). A class has a namespace implemented by a dictionary object. Class attribute references are translated to lookups in this dictionary, e.g., C.x is translated to C.__dict__['x'] (although there are a number of hooks which allow for other means of locating attributes). When the attribute name is not found there, the attribute search continues in the base classes. This search of the base classes uses the C3 method resolution order which behaves correctly even in the presence of 'diamond' inheritance structures where there are multiple inheritance paths leading back to a common ancestor. Additional details on the C3 MRO used by Python can be found in the documentation accompanying the 2.3 release at http://www.python.org/download/releases/2.3/mro/.

When a class attribute reference (for class C, say) would yield a class method object, it is transformed into an instance method object whose __self__ attributes is C. When it would yield a static method object, it is transformed into the object wrapped by the static method object. See section Implementing Descriptors for another way in which attributes retrieved from a class may differ from those actually contained in its __dict__.

Class attribute assignments update the class's dictionary, never the dictionary of a base class.
A class object can be called (see above) to yield a class instance (see below).

Special attributes: __name__ is the class name; __module__ is the module name in which the class was defined; __dict__ is the dictionary containing the class's namespace; __bases__ is a tuple (possibly empty or a singleton) containing the base classes, in the order of their occurrence in the base class list; __doc__ is the class's documentation string, or None if undefined.

Class instances

A class instance is created by calling a class object (see above). A class instance has a namespace implemented as a dictionary which is the first place in which attribute references are searched. When an attribute is not found there, and the instance's class has an attribute by that name, the search continues with the class attributes. If a class attribute is found that is a user-defined function object, it is transformed into an instance method object whose __self__ attribute is the instance. Static method and class method objects are also transformed; see above under “Classes”. See section Implementing Descriptors for another way in which attributes of a class retrieved via its instances may differ from the objects actually stored in the class's __dict__. If no class attribute is found, and the object's class has a __getattr__() method, that is called to satisfy the lookup.

Attribute assignments and deletions update the instance's dictionary, never a class's dictionary. If the class has a __setattr__() or __delattr__() method, this is called instead of updating the instance dictionary directly.

Class instances can pretend to be numbers, sequences, or
mappings if they have methods with certain special names. See section *Special method names*.

Special attributes: `_dict_` is the attribute dictionary; `_class_` is the instance’s class.

I/O objects (also known as file objects)  
A **file object** represents an open file. Various shortcuts are available to create file objects: the `open()` built-in function, and also `os.popen()`, `os.fdopen()`, and the `makefile()` method of socket objects (and perhaps by other functions or methods provided by extension modules).

The objects `sys.stdin`, `sys.stdout` and `sys.stderr` are initialized to file objects corresponding to the interpreter’s standard input, output and error streams; they are all open in text mode and therefore follow the interface defined by the `io.TextIOBase` abstract class.

Internal types  
A few types used internally by the interpreter are exposed to the user. Their definitions may change with future versions of the interpreter, but they are mentioned here for completeness.

Code objects  
Code objects represent *byte-compiled* executable Python code, or *bytecode*. The difference between a code object and a function object is that the function object contains an explicit reference to the function’s globals (the module in which it was defined), while a code object contains no context; also the default argument values are stored in the function object, not in the code object (because they represent values calculated at run-time). Unlike function objects, code objects are immutable.
and contain no references (directly or indirectly) to mutable objects.

Special read-only attributes: co_name gives the function name; co_argcount is the number of positional arguments (including arguments with default values); co_nlocals is the number of local variables used by the function (including arguments); co_varnames is a tuple containing the names of the local variables (starting with the argument names); co_cellvars is a tuple containing the names of local variables that are referenced by nested functions; co_freevars is a tuple containing the names of free variables; co_code is a string representing the sequence of bytecode instructions; co_consts is a tuple containing the literals used by the bytecode; co_names is a tuple containing the names used by the bytecode; co_filename is the filename from which the code was compiled; co_firstlineno is the first line number of the function; co_lnotab is a string encoding the mapping from bytecode offsets to line numbers (for details see the source code of the interpreter); co_stacksize is the required stack size (including local variables); co_flags is an integer encoding a number of flags for the interpreter.

The following flag bits are defined for co_flags: bit 0x04 is set if the function uses the *arguments syntax to accept an arbitrary number of positional arguments; bit 0x08 is set if the function uses the **keywords syntax to accept arbitrary keyword arguments; bit 0x20 is set if the function is a generator.

Future feature declarations (from __future__ import
division) also use bits in co_flags to indicate whether a code object was compiled with a particular feature enabled: bit \(0x2000\) is set if the function was compiled with future division enabled; bits \(0x10\) and \(0x1000\) were used in earlier versions of Python.

Other bits in co_flags are reserved for internal use.

If a code object represents a function, the first item in co_consts is the documentation string of the function, or None if undefined.

Frame objects
Frame objects represent execution frames. They may occur in traceback objects (see below).

Special read-only attributes: f_back is to the previous stack frame (towards the caller), or None if this is the bottom stack frame; f_code is the code object being executed in this frame; f_locals is the dictionary used to look up local variables; f_globals is used for global variables; f_builtins is used for built-in (intrinsic) names; f_lasti gives the precise instruction (this is an index into the bytecode string of the code object).

Special writable attributes: f_trace, if not None, is a function called at the start of each source code line (this is used by the debugger); f_lineno is the current line number of the frame — writing to this from within a trace function jumps to the given line (only for the bottom-most frame). A debugger can implement a Jump command (aka Set Next Statement) by writing to f_lineno.
Traceback objects

Traceback objects represent a stack trace of an exception. A traceback object is created when an exception occurs. When the search for an exception handler unwinds the execution stack, at each unwound level a traceback object is inserted in front of the current traceback. When an exception handler is entered, the stack trace is made available to the program. (See section \textit{The try statement}.) It is accessible as the third item of the tuple returned by \texttt{sys.exc_info()}. When the program contains no suitable handler, the stack trace is written (nicely formatted) to the standard error stream; if the interpreter is interactive, it is also made available to the user as \texttt{sys.last_traceback}.

Special read-only attributes: \texttt{tb\_next} is the next level in the stack trace (towards the frame where the exception occurred), or \texttt{None} if there is no next level; \texttt{tb\_frame} points to the execution frame of the current level; \texttt{tb\_ lineno} gives the line number where the exception occurred; \texttt{tb\_lasti} indicates the precise instruction. The line number and last instruction in the traceback may differ from the line number of its frame object if the exception occurred in a \texttt{try} statement with no matching except clause or with a finally clause.

Slice objects

Slice objects are used to represent slices for \texttt{\_getitem\_()} methods. They are also created by the built-in \texttt{slice()} function.

Special read-only attributes: \texttt{start} is the lower bound; \texttt{stop} is the upper bound; \texttt{step} is the step value; each is \texttt{None} if omitted. These attributes can have any type.
Slice objects support one method:

```
slice.\texttt{indices}(self, length)
```

This method takes a single integer argument \textit{length} and computes information about the slice that the slice object would describe if applied to a sequence of \textit{length} items. It returns a tuple of three integers; respectively these are the \textit{start} and \textit{stop} indices and the \textit{step} or stride length of the slice. Missing or out-of-bounds indices are handled in a manner consistent with regular slices.

Static method objects

Static method objects provide a way of defeating the transformation of function objects to method objects described above. A static method object is a wrapper around any other object, usually a user-defined method object. When a static method object is retrieved from a class or a class instance, the object actually returned is the wrapped object, which is not subject to any further transformation. Static method objects are not themselves callable, although the objects they wrap usually are. Static method objects are created by the built-in \texttt{staticmethod()} constructor.

Class method objects

A class method object, like a static method object, is a wrapper around another object that alters the way in which that object is retrieved from classes and class instances. The behaviour of class method objects upon such retrieval is described above, under “User-defined methods”. Class method objects are created by the built-in \texttt{classmethod()} constructor.
3.3. Special method names

A class can implement certain operations that are invoked by special syntax (such as arithmetic operations or subscripting and slicing) by defining methods with special names. This is Python's approach to operator overloading, allowing classes to define their own behavior with respect to language operators. For instance, if a class defines a method named `__getitem__`, and \( x \) is an instance of this class, then \( x[i] \) is roughly equivalent to `type(x).__getitem__(x, i)`.

Except where mentioned, attempts to execute an operation raise an exception when no appropriate method is defined (typically `AttributeError` or `TypeError`).

When implementing a class that emulates any built-in type, it is important that the emulation only be implemented to the degree that it makes sense for the object being modelled. For example, some sequences may work well with retrieval of individual elements, but extracting a slice may not make sense. (One example of this is the `NodeList` interface in the W3C's Document Object Model.)

3.3.1. Basic customization

```python
object.__new__(cls[, ...])
```

Called to create a new instance of class `cls`. `__new__()` is a static method (special-cased so you need not declare it as such) that takes the class of which an instance was requested as its first argument. The remaining arguments are those passed to the object constructor expression (the call to the class). The return value of `__new__()` should be the new object instance (usually an instance of `cls`).
Typical implementations create a new instance of the class by invoking the superclass's `).__new__()` method using
super(currentclass, cls).__new__(cls[, ...]) with appropriate arguments and then modifying the newly-created instance as necessary before returning it.

If `).__new__()` returns an instance of `cls`, then the new instance's `).__init__()` method will be invoked like `).__init__(self[, ...])`, where `self` is the new instance and the remaining arguments are the same as were passed to `).__new__()`.

If `).__new__()` does not return an instance of `cls`, then the new instance's `).__init__()` method will not be invoked.

`).__new__()` is intended mainly to allow subclasses of immutable types (like int, str, or tuple) to customize instance creation. It is also commonly overridden in custom metaclasses in order to customize class creation.

```
object.).__init__(self[, ...])
```

Called when the instance is created. The arguments are those passed to the class constructor expression. If a base class has an `).__init__()` method, the derived class's `).__init__()` method, if any, must explicitly call it to ensure proper initialization of the base class part of the instance; for example: `BaseClass.).__init__(self, [args...])`. As a special constraint on constructors, no value may be returned; doing so will cause a `TypeError` to be raised at runtime.

```
object.).__del__(self)
```

Called when the instance is about to be destroyed. This is also called a destructor. If a base class has a `).__del__()` method, the
derived class’s \texttt{\_\_del\_\_()} method, if any, must explicitly call it to ensure proper deletion of the base class part of the instance. Note that it is possible (though not recommended!) for the \texttt{\_\_del\_\_()} method to postpone destruction of the instance by creating a new reference to it. It may then be called at a later time when this new reference is deleted. It is not guaranteed that \texttt{\_\_del\_\_()} methods are called for objects that still exist when the interpreter exits.

\textbf{Note:} \texttt{del} \texttt{x} doesn’t directly call \texttt{x.\_\_del\_\_()} — the former decrements the reference count for \texttt{x} by one, and the latter is only called when \texttt{x}‘s reference count reaches zero. Some common situations that may prevent the reference count of an object from going to zero include: circular references between objects (e.g., a doubly-linked list or a tree data structure with parent and child pointers); a reference to the object on the stack frame of a function that caught an exception (the traceback stored in \texttt{sys.exc_info()[2]} keeps the stack frame alive); or a reference to the object on the stack frame that raised an unhandled exception in interactive mode (the traceback stored in \texttt{sys.last_traceback} keeps the stack frame alive). The first situation can only be remedied by explicitly breaking the cycles; the latter two situations can be resolved by storing \texttt{None} in \texttt{sys.last_traceback}. Circular references which are garbage are detected when the option cycle detector is enabled (it’s on by default), but can only be cleaned up if there are no Python- level \texttt{\_\_del\_\_()} methods involved. Refer to the documentation for the \texttt{gc} module for more information about how \texttt{\_\_del\_\_()} methods are handled by the cycle detector, particularly the description of the garbage value.

\textbf{Warning:} Due to the precarious circumstances under which
__del__() methods are invoked, exceptions that occur during their execution are ignored, and a warning is printed to sys.stderr instead. Also, when __del__() is invoked in response to a module being deleted (e.g., when execution of the program is done), other globals referenced by the __del__() method may already have been deleted or in the process of being torn down (e.g. the import machinery shutting down). For this reason, __del__() methods should do the absolute minimum needed to maintain external invariants. Starting with version 1.5, Python guarantees that globals whose name begins with a single underscore are deleted from their module before other globals are deleted; if no other references to such globals exist, this may help in assuring that imported modules are still available at the time when the __del__() method is called.

object.__repr__(self)
Called by the repr() built-in function to compute the “official” string representation of an object. If at all possible, this should look like a valid Python expression that could be used to recreate an object with the same value (given an appropriate environment). If this is not possible, a string of the form <...some useful description...> should be returned. The return value must be a string object. If a class defines __repr__() but not __str__(), then __repr__() is also used when an “informal” string representation of instances of that class is required.

This is typically used for debugging, so it is important that the representation is information-rich and unambiguous.

object.__str__(self)
Called by str(object) and the built-in functions format() and
print() to compute the “informal” or nicely printable string representation of an object. The return value must be a string object.

This method differs from object.__repr__() in that there is no expectation that __str__() return a valid Python expression: a more convenient or concise representation can be used.

The default implementation defined by the built-in type object calls object.__repr__().

object.__bytes__(self)
Called by bytes() to compute a byte-string representation of an object. This should return a bytes object.

object.__format__(self, format_spec)
Called by the format() built-in function (and by extension, the str.format() method of class str) to produce a “formatted” string representation of an object. The format_spec argument is a string that contains a description of the formatting options desired. The interpretation of the format_spec argument is up to the type implementing __format__(), however most classes will either delegate formatting to one of the built-in types, or use a similar formatting option syntax.

The return value must be a string object.

object.__lt__(self, other)
object.__le__(self, other)
object.__eq__(self, other)
object.__ne__(self, other)
object.__gt__(self, other)
object.__ge__(self, other)

These are the so-called “rich comparison” methods. The correspondence between operator symbols and method names is as follows: \(x < y\) calls \(x.__lt__(y)\), \(x <= y\) calls \(x.__le__(y)\), \(x == y\) calls \(x.__eq__(y)\), \(x != y\) calls \(x.__ne__(y)\), \(x > y\) calls \(x.__gt__(y)\), and \(x >= y\) calls \(x.__ge__(y)\).

A rich comparison method may return the singleton \texttt{NotImplemented} if it does not implement the operation for a given pair of arguments. By convention, \texttt{False} and \texttt{True} are returned for a successful comparison. However, these methods can return any value, so if the comparison operator is used in a Boolean context (e.g., in the condition of an if statement), Python will call \texttt{bool()} on the value to determine if the result is true or false.

There are no implied relationships among the comparison operators. The truth of \(x == y\) does not imply that \(x != y\) is false. Accordingly, when defining \texttt{__eq__()}, one should also define \texttt{__ne__() so that the operators will behave as expected. See the paragraph on \texttt{__hash__()} for some important notes on creating \texttt{hashable} objects which support custom comparison operations and are usable as dictionary keys.

There are no swapped-argument versions of these methods (to be used when the left argument does not support the operation but the right argument does); rather, \texttt{__lt__() and __gt__()} are each other's reflection, \texttt{__le__() and __ge__()} are each other's
reflection, and __eq__() and __ne__() are their own reflection.

Arguments to rich comparison methods are never coerced.

To automatically generate ordering operations from a single root operation, see functools.total_ordering().

object.__hash__(self)

Called by built-in function hash() and for operations on members of hashed collections including set, frozenset, and dict. __hash__() should return an integer. The only required property is that objects which compare equal have the same hash value; it is advised to somehow mix together (e.g. using exclusive or) the hash values for the components of the object that also play a part in comparison of objects.

Note: hash() truncates the value returned from an object's custom __hash__() method to the size of a Py_ssize_t. This is typically 8 bytes on 64-bit builds and 4 bytes on 32-bit builds. If an object's __hash__() must interoperate on builds of different bit sizes, be sure to check the width on all supported builds. An easy way to do this is with python -c "import sys; print(sys.hash_info.width)"

If a class does not define an __eq__() method it should not define a __hash__() operation either; if it defines __eq__() but not __hash__(), its instances will not be usable as items in hashable collections. If a class defines mutable objects and implements an __eq__() method, it should not implement __hash__(), since the implementation of hashable collections requires that a key's hash value is immutable (if the object's hash value changes, it will be in the wrong hash bucket).
User-defined classes have `__eq__()` and `__hash__()` methods by default; with them, all objects compare unequal (except with themselves) and `x.__hash__()` returns an appropriate value such that `x == y` implies both that `x is y` and `hash(x) == hash(y)`.

A class that overrides `__eq__()` and does not define `__hash__()` will have its `__hash__()` implicitly set to None. When the `__hash__()` method of a class is None, instances of the class will raise an appropriate `TypeError` when a program attempts to retrieve their hash value, and will also be correctly identified as unhashable when checking `isinstance(obj, collections.Hashable)`.

If a class that overrides `__eq__()` needs to retain the implementation of `__hash__()` from a parent class, the interpreter must be told this explicitly by setting `__hash__ = <ParentClass>.__hash__`.

If a class that does not override `__eq__()` wishes to suppress hash support, it should include `__hash__ = None` in the class definition. A class which defines its own `__hash__()` that explicitly raises a `TypeError` would be incorrectly identified as hashable by an `isinstance(obj, collections.Hashable)` call.

**Note:** By default, the `__hash__()` values of `str`, `bytes` and `datetime` objects are “salted” with an unpredictable random value. Although they remain constant within an individual Python process, they are not predictable between repeated invocations of Python.
This is intended to provide protection against a denial-of-service caused by carefully-chosen inputs that exploit the worst case performance of a dict insertion, O(n^2) complexity. See http://www.ocert.org/advisories/ocert-2011-003.html for details.

Changing hash values affects the iteration order of dicts, sets and other mappings. Python has never made guarantees about this ordering (and it typically varies between 32-bit and 64-bit builds).

See also PYTHONHASHSEED.

*Changed in version 3.3:* Hash randomization is enabled by default.

```python
object.__bool__(self)
```

Called to implement truth value testing and the built-in operation `bool();` should return `False` or `True`. When this method is not defined, `__len__()` is called, if it is defined, and the object is considered true if its result is nonzero. If a class defines neither `__len__()` nor `__bool__`, all its instances are considered true.

### 3.3.2. Customizing attribute access

The following methods can be defined to customize the meaning of attribute access (use of, assignment to, or deletion of `x.name`) for class instances.

```python
object.__getattr__(self, name)
```

Called when an attribute lookup has not found the attribute in the usual places (i.e. it is not an instance attribute nor is it found in the class tree for `self`). `name` is the attribute name. This method should return the (computed) attribute value or raise an `AttributeError` exception.
Note that if the attribute is found through the normal mechanism, `__getattr__()` is not called. (This is an intentional asymmetry between `__getattr__()` and `__setattr__()`. This is done both for efficiency reasons and because otherwise `__getattr__()` would have no way to access other attributes of the instance. Note that at least for instance variables, you can fake total control by not inserting any values in the instance attribute dictionary (but instead inserting them in another object). See the `__getattribute__()` method below for a way to actually get total control over attribute access.

```python
object.__getattribute__(self, name)
```

Called unconditionally to implement attribute accesses for instances of the class. If the class also defines `__getattr__()`, the latter will not be called unless `__getattribute__()` either calls it explicitly or raises an `AttributeError`. This method should return the (computed) attribute value or raise an `AttributeError` exception. In order to avoid infinite recursion in this method, its implementation should always call the base class method with the same name to access any attributes it needs, for example, `object.__getattribute__(self, name)`.

**Note:** This method may still be bypassed when looking up special methods as the result of implicit invocation via language syntax or built-in functions. See [Special method lookup](#).

```python
object.__setattr__(self, name, value)
```

Called when an attribute assignment is attempted. This is called instead of the normal mechanism (i.e. store the value in the instance dictionary). `name` is the attribute name, `value` is the value to be assigned to it.
If \texttt{\_setattr\_}() wants to assign to an instance attribute, it should call the base class method with the same name, for example, \texttt{object.\_setattr\_(self, name, value)}.

\texttt{object.\_delattr\_(self, name)}  
Like \texttt{\_setattr\_}() but for attribute deletion instead of assignment. This should only be implemented if \texttt{del obj.name} is meaningful for the object.

\texttt{object.\_dir\_(self)}  
Called when \texttt{dir()} is called on the object. A sequence must be returned. \texttt{dir()} converts the returned sequence to a list and sorts it.

3.3.2.1. Implementing Descriptors  
The following methods only apply when an instance of the class containing the method (a so-called \textit{descriptor} class) appears in an \textit{owner} class (the descriptor must be in either the owner’s class dictionary or in the class dictionary for one of its parents). In the examples below, “the attribute” refers to the attribute whose name is the key of the property in the owner class’ \texttt{\_dict\_}.

\texttt{object.\_get\_(self, instance, owner)}  
Called to get the attribute of the owner class (class attribute access) or of an instance of that class (instance attribute access). \textit{owner} is always the owner class, while \textit{instance} is the instance that the attribute was accessed through, or None when the attribute is accessed through the \textit{owner}. This method should return the (computed) attribute value or raise an \texttt{AttributeError} exception.
3.3.2.2. Invoking Descriptors

In general, a descriptor is an object attribute with “binding behavior”, one whose attribute access has been overridden by methods in the descriptor protocol: `__get__`, `__set__`, and `__delete__`. If any of those methods are defined for an object, it is said to be a descriptor.

The default behavior for attribute access is to get, set, or delete the attribute from an object's dictionary. For instance, `a.x` has a lookup chain starting with `a.__dict__["x"]`, then `type(a).__dict__["x"]`, and continuing through the base classes of `type(a)` excluding metaclasses.

However, if the looked-up value is an object defining one of the descriptor methods, then Python may override the default behavior and invoke the descriptor method instead. Where this occurs in the precedence chain depends on which descriptor methods were defined and how they were called.

The starting point for descriptor invocation is a binding, `a.x`. How the arguments are assembled depends on `a`:

Direct Call

The simplest and least common call is when user code directly
invokes a descriptor method: `x.__get__(a)`.

**Instance Binding**

If binding to an object instance, `a.x` is transformed into the call:
```
type(a).__dict__['x'].__get__(a, type(a)).
```

**Class Binding**

If binding to a class, `A.x` is transformed into the call:
```
A.__dict__['x'].__get__(None, A).
```

**Super Binding**

If `a` is an instance of `super`, then the binding `super(B, obj).m()` searches `obj.__class__.__mro__` for the base class `A` immediately preceding `B` and then invokes the descriptor with the call:
```
A.__dict__['m'].__get__(obj, obj.__class__).
```

For instance bindings, the precedence of descriptor invocation depends on the which descriptor methods are defined. A descriptor can define any combination of `__get__()`, `__set__()`, and `__delete__()`. If it does not define `__get__()`, then accessing the attribute will return the descriptor object itself unless there is a value in the object's instance dictionary. If the descriptor defines `__set__()` and/or `__delete__()`, it is a data descriptor; if it defines neither, it is a non-data descriptor. Normally, data descriptors define both `__get__()` and `__set__()`, while non-data descriptors have just the `__get__()` method. Data descriptors with `__set__()` and `__get__()` defined always override a redefinition in an instance dictionary. In contrast, non-data descriptors can be overridden by instances.

Python methods (including `staticmethod()` and `classmethod()`) are implemented as non-data descriptors. Accordingly, instances can redefine and override methods. This allows individual instances to
acquire behaviors that differ from other instances of the same class.

The `property()` function is implemented as a data descriptor. Accordingly, instances cannot override the behavior of a property.

3.3.2.3. __slots__

By default, instances of classes have a dictionary for attribute storage. This wastes space for objects having very few instance variables. The space consumption can become acute when creating large numbers of instances.

The default can be overridden by defining `__slots__` in a class definition. The `__slots__` declaration takes a sequence of instance variables and reserves just enough space in each instance to hold a value for each variable. Space is saved because `__dict__` is not created for each instance.

This class variable can be assigned a string, iterable, or sequence of strings with variable names used by instances. If defined in a class, `__slots__` reserves space for the declared variables and prevents the automatic creation of `__dict__` and `__weakref__` for each instance.

3.3.2.3.1. Notes on using `__slots__`

- When inheriting from a class without `__slots__`, the `__dict__` attribute of that class will always be accessible, so a `__slots__` definition in the subclass is meaningless.
- Without a `__dict__` variable, instances cannot be assigned new variables not listed in the `__slots__` definition. Attempts to assign to an unlisted variable name raises `AttributeError`. If
dynamic assignment of new variables is desired, then add '.__dict__' to the sequence of strings in the __slots__ declaration.

- Without a __weakref__ variable for each instance, classes defining __slots__ do not support weak references to its instances. If weak reference support is needed, then add '__weakref__' to the sequence of strings in the __slots__ declaration.

- __slots__ are implemented at the class level by creating descriptors (Implementing Descriptors) for each variable name. As a result, class attributes cannot be used to set default values for instance variables defined by __slots__; otherwise, the class attribute would overwrite the descriptor assignment.

- The action of a __slots__ declaration is limited to the class where it is defined. As a result, subclasses will have a __dict__ unless they also define __slots__ (which must only contain names of any additional slots).

- If a class defines a slot also defined in a base class, the instance variable defined by the base class slot is inaccessible (except by retrieving its descriptor directly from the base class). This renders the meaning of the program undefined. In the future, a check may be added to prevent this.

- Nonempty __slots__ does not work for classes derived from “variable-length” built-in types such as int, str and tuple.

- Any non-string iterable may be assigned to __slots__. Mappings may also be used; however, in the future, special meaning may be assigned to the values corresponding to each key.

- __class__ assignment works only if both classes have the same __slots__.

3.3.3. Customizing class creation

By default, classes are constructed using type(). The class body is
executed in a new namespace and the class name is bound locally to the result of `type(name, bases, namespace)`. The class creation process can be customised by passing the `metaclass` keyword argument in the class definition line, or by inheriting from an existing class that included such an argument. In the following example, both `MyClass` and `MySubclass` are instances of `Meta`:

```python
class Meta(type):
    pass

class MyClass(metaclass=Meta):
    pass

class MySubclass(MyClass):
    pass
```

Any other keyword arguments that are specified in the class definition are passed through to all metaclass operations described below.

When a class definition is executed, the following steps occur:

- the appropriate metaclass is determined
- the class namespace is prepared
- the class body is executed
- the class object is created

3.3.3.1. Determining the appropriate metaclass

The appropriate metaclass for a class definition is determined as follows:

- if no bases and no explicit metaclass are given, then `type()` is
- if an explicit metaclass is given and it is not an instance of `type()`, then it is used directly as the metaclass
- if an instance of `type()` is given as the explicit metaclass, or bases are defined, then the most derived metaclass is used

The most derived metaclass is selected from the explicitly specified metaclass (if any) and the metaclasses (i.e. `type(cls)`) of all specified base classes. The most derived metaclass is one which is a subtype of all of these candidate metaclasses. If none of the candidate metaclasses meets that criterion, then the class definition will fail with `TypeError`.

### 3.3.3.2. Preparing the class namespace

Once the appropriate metaclass has been identified, then the class namespace is prepared. If the metaclass has a `__prepare__` attribute, it is called as `namespace = metaclass.__prepare__(name, bases, **kwds)` (where the additional keyword arguments, if any, come from the class definition).

If the metaclass has no `__prepare__` attribute, then the class namespace is initialised as an empty `dict()` instance.

**See also:**

**PEP 3115 - Metaclasses in Python 3000**

Introduced the `__prepare__` namespace hook

### 3.3.3.3. Executing the class body

The class body is executed (approximately) as `exec(body,
globals(), namespace). The key difference from a normal call to exec() is that lexical scoping allows the class body (including any methods) to reference names from the current and outer scopes when the class definition occurs inside a function.

However, even when the class definition occurs inside the function, methods defined inside the class still cannot see names defined at the class scope. Class variables must be accessed through the first parameter of instance or class methods, and cannot be accessed at all from static methods.

3.3.3.4. Creating the class object

Once the class namespace has been populated by executing the class body, the class object is created by calling metaclass(name, bases, namespace, **kwds) (the additional keywords passed here are the same as those passed to __prepare__).

This class object is the one that will be referenced by the zero-argument form of super(). __class__ is an implicit closure reference created by the compiler if any methods in a class body refer to either __class__ or super. This allows the zero argument form of super() to correctly identify the class being defined based on lexical scoping, while the class or instance that was used to make the current call is identified based on the first argument passed to the method.

After the class object is created, it is passed to the class decorators included in the class definition (if any) and the resulting object is bound in the local namespace as the defined class.

See also:

PEP 3135 - New super
3.3.3.5. Metaclass example

The potential uses for metaclasses are boundless. Some ideas that have been explored include logging, interface checking, automatic delegation, automatic property creation, proxies, frameworks, and automatic resource locking/synchronization.

Here is an example of a metaclass that uses an `collections.OrderedDict` to remember the order that class members were defined:

```python
class OrderedClass(type):

    @classmethod
    def __prepare__(metacls, name, bases, **kwds):
        return collections.OrderedDict()

    def __new__(cls, name, bases, namespace, **kwds):
        result = type.__new__(cls, name, bases, dict(result).members = tuple(namespace)
        return result

class A(metaclass=OrderedClass):
    def one(self): pass
    def two(self): pass
    def three(self): pass
    def four(self): pass

>>> A.members
('__module__', 'one', 'two', 'three', 'four')

When the class definition for A gets executed, the process begins with
calling the metaclass's __prepare__() method which returns an empty collections.OrderedDict. That mapping records the methods and attributes of A as they are defined within the body of the class statement. Once those definitions are executed, the ordered dictionary is fully populated and the metaclass's __new__() method gets invoked. That method builds the new type and it saves the ordered dictionary keys in an attribute called members.

3.3.4. Customizing instance and subclass checks

The following methods are used to override the default behavior of the isinstance() and issubclass() built-in functions.

In particular, the metaclass abc.ABCMeta implements these methods in order to allow the addition of Abstract Base Classes (ABCs) as “virtual base classes” to any class or type (including built-in types), including other ABCs.

class.__instancecheck__(self, instance)

Return true if instance should be considered a (direct or indirect) instance of class. If defined, called to implement isinstance(instance, class).

class.__subclasscheck__(self, subclass)

Return true if subclass should be considered a (direct or indirect) subclass of class. If defined, called to implement issubclass(subclass, class).

Note that these methods are looked up on the type (metaclass) of a class. They cannot be defined as class methods in the actual class. This is consistent with the lookup of special methods that are called on instances, only in this case the instance is itself a class.
See also:

**PEP 3119 - Introducing Abstract Base Classes**

Includes the specification for customizing `isinstance()` and `issubclass()` behavior through `__instancecheck__()` and `__subclasscheck__()`, with motivation for this functionality in the context of adding Abstract Base Classes (see the `abc` module) to the language.

3.3.5. Emulating callable objects

```python
object.__call__(self[, args...])
```

Called when the instance is “called” as a function; if this method is defined, `x(arg1, arg2, ...)` is a shorthand for `x.__call__(arg1, arg2, ...)`.  

3.3.6. Emulating container types

The following methods can be defined to implement container objects. Containers usually are sequences (such as lists or tuples) or mappings (like dictionaries), but can represent other containers as well. The first set of methods is used either to emulate a sequence or to emulate a mapping; the difference is that for a sequence, the allowable keys should be the integers `k` for which `0 <= k < N` where `N` is the length of the sequence, or slice objects, which define a range of items. It is also recommended that mappings provide the methods `keys()`, `values()`, `items()`, `get()`, `clear()`, `setdefault()`, `pop()`, `popitem()`, `copy()`, and `update()` behaving similar to those for Python’s standard dictionary objects. The `collections` module provides a `MutableMapping` abstract base class to help
create those methods from a base set of \_getitem\_(\_), \_setitem\_(\_), \_delitem\_(\_), and \_keys\_(\_). Mutable sequences should provide methods append\_(\_), count\_(\_), index\_(\_), extend\_(\_), insert\_(\_), pop\_(\_), remove\_(\_), reverse\_(\_) and sort\_(\_), like Python standard list objects. Finally, sequence types should implement addition (meaning concatenation) and multiplication (meaning repetition) by defining the methods \_add\_(\_), \_radd\_(\_), \_iadd\_(\_), \_mul\_(\_), \_rmul\_(\_) and \_imul\_(\_) described below; they should not define other numerical operators. It is recommended that both mappings and sequences implement the \_contains\_(\_) method to allow efficient use of the \_in\_ operator; for mappings, \_in\_ should search the mapping’s keys; for sequences, it should search through the values. It is further recommended that both mappings and sequences implement the \_iter\_(\_) method to allow efficient iteration through the container; for mappings, \_iter\_(\_) should be the same as \_keys\_(\_); for sequences, it should iterate through the values.

**object.\_len\_(\_)**

Called to implement the built-in function \_len\_(\_). Should return the length of the object, an integer \(\geq 0\). Also, an object that doesn’t define a \_bool\_(\_) method and whose \_len\_(\_) method returns zero is considered to be false in a Boolean context.

**Note:** Slicing is done exclusively with the following three methods. A call like

```
a[1:2] = b
```

is translated to
and so forth. Missing slice items are always filled in with None.

object.__getitem__(self, key)

Called to implement evaluation of self[key]. For sequence types, the accepted keys should be integers and slice objects. Note that the special interpretation of negative indexes (if the class wishes to emulate a sequence type) is up to the __getitem__() method. If key is of an inappropriate type, TypeError may be raised; if of a value outside the set of indexes for the sequence (after any special interpretation of negative values), IndexError should be raised. For mapping types, if key is missing (not in the container), KeyError should be raised.

Note: for loops expect that an IndexError will be raised for illegal indexes to allow proper detection of the end of the sequence.

object.__setitem__(self, key, value)

Called to implement assignment to self[key]. Same note as for __getitem__(). This should only be implemented for mappings if the objects support changes to the values for keys, or if new keys can be added, or for sequences if elements can be replaced. The same exceptions should be raised for improper key values as for the __getitem__() method.

object.__delitem__(self, key)

Called to implement deletion of self[key]. Same note as for __getitem__(). This should only be implemented for mappings
if the objects support removal of keys, or for sequences if elements can be removed from the sequence. The same exceptions should be raised for improper key values as for the \texttt{\_\_getitem\_\_()} method.

\textbf{object.\texttt{\_\_iter\_\_}(self)}

This method is called when an iterator is required for a container. This method should return a new iterator object that can iterate over all the objects in the container. For mappings, it should iterate over the keys of the container, and should also be made available as the method \texttt{keys()}.

Iterator objects also need to implement this method; they are required to return themselves. For more information on iterator objects, see \textit{Iterator Types}.

\textbf{object.\texttt{\_\_reversed\_\_}(self)}

Called (if present) by the \texttt{reversed()} built-in to implement reverse iteration. It should return a new iterator object that iterates over all the objects in the container in reverse order.

If the \texttt{\_\_reversed\_\_()} method is not provided, the \texttt{reversed()} built-in will fall back to using the sequence protocol (\texttt{\_\_len\_\_()} and \texttt{\_\_getitem\_\_()}). Objects that support the sequence protocol should only provide \texttt{\_\_reversed\_\_()} if they can provide an implementation that is more efficient than the one provided by \texttt{reversed()}.

The membership test operators (\texttt{in} and \texttt{not in}) are normally implemented as an iteration through a sequence. However, container objects can supply the following special method with a more efficient implementation, which also does not require the object be a sequence.
object.__contains__(self, item)
Called to implement membership test operators. Should return true if item is in self, false otherwise. For mapping objects, this should consider the keys of the mapping rather than the values or the key-item pairs.

For objects that don’t define __contains__(), the membership test first tries iteration via __iter__(), then the old sequence iteration protocol via __getitem__(), see this section in the language reference.

3.3.7. Emulating numeric types

The following methods can be defined to emulate numeric objects. Methods corresponding to operations that are not supported by the particular kind of number implemented (e.g., bitwise operations for non-integral numbers) should be left undefined.

object.__add__(self, other)
object.__sub__(self, other)
object.__mul__(self, other)
object.__truediv__(self, other)
object.__floordiv__(self, other)
object.__mod__(self, other)
object.__divmod__(self, other)
object.__pow__(self, other[, modulo])
object.__lshift__(self, other)
object.__rshift__(self, other)
object.__and__(self, other)
object.__xor__(self, other)
object.__or__(self, other)
These methods are called to implement the binary arithmetic operations (\(+\), \(-\), \(*\), \(/\), \(\div\), divmod(), pow(), ***, <<, >>, &\), ^, |). For instance, to evaluate the expression \(x + y\), where \(x\) is an instance of a class that has an \_\_add\_\_( ) method, \(x.\_\_add\_\_(y)\) is called. The \_\_divmod\_\_( ) method should be the equivalent to using \_\_floordiv\_\_() and \_\_mod\_\_( ); it should not be related to \_\_truediv\_\_( ). Note that \_\_pow\_\_( ) should be defined to accept an optional third argument if the ternary version of the built-in pow() function is to be supported.

If one of those methods does not support the operation with the supplied arguments, it should return NotImplemented.

object.\_\_radd\_\_(self, other)
object.\_\_rsub\_\_(self, other)
object.\_\_rmul\_\_(self, other)
object.\_\_rtruediv\_\_(self, other)
object.\_\_rfloordiv\_\_(self, other)
object.\_\_rmod\_\_(self, other)
object.\_\_rdivmod\_\_(self, other)
object.\_\_rpow\_\_(self, other)
object.\_\_rlshift\_\_(self, other)
object.\_\_rrshift\_\_(self, other)
object.\_\_rand\_\_(self, other)
object.\_\_rxor\_\_(self, other)
object.\_\_ror\_\_(self, other)

These methods are called to implement the binary arithmetic operations (\(+\), \(-\), \(*\), \(/\), \(\div\), divmod(), pow(), ***, <<, >>, &\), ^, |) with reflected (swapped) operands. These functions are only called if the left operand does not support the corresponding operation and the operands are of different types. \[2\] For instance,
to evaluate the expression \( x - y \), where \( y \) is an instance of a class that has an \_rsub\_() method, \( y._\text{rsub}_(x) \) is called if \( x._\text{sub}_(y) \) returns NotImplemented.

Note that ternary pow() will not try calling \_rpow\_() (the coercion rules would become too complicated).

**Note:** If the right operand's type is a subclass of the left operand's type and that subclass provides the reflected method for the operation, this method will be called before the left operand's non-reflected method. This behavior allows subclasses to override their ancestors' operations.

```
object._iadd__(self, other)
object._isub__(self, other)
object._imul__(self, other)
object._ipow__(self, other[, modulo])
object._ilshift__(self, other)
object._irshift__(self, other)
object._iand__(self, other)
object._ixor__(self, other)
object._ior__(self, other)
```

These methods are called to implement the augmented arithmetic assignments (\( +=, -=, *=, /=, //=, **=, <<=, >>=, &=, ^=, |= \)). These methods should attempt to do the operation in-place (modifying self) and return the result (which could be, but does not have to be, self). If a specific method is not defined, the augmented assignment falls back to the normal methods. For instance, to
execute the statement $x += y$, where $x$ is an instance of a class that has an `__iadd__()` method, $x.__iadd__(y)$ is called. If $x$ is an instance of a class that does not define a `__iadd__()` method, $x.__add__(y)$ and $y.__radd__(x)$ are considered, as with the evaluation of $x + y$.

```
object.__neg__(self)
object.__pos__(self)
object.__abs__(self)
object.__invert__(self)
```

Called to implement the unary arithmetic operations (-, +, abs() and ~).

```
object.__complex__(self)
object.__int__(self)
object.__float__(self)
object.__round__(self[n])
```

Called to implement the built-in functions complex(), int(), float() and round(). Should return a value of the appropriate type.

```
object.__index__(self)
```

Called to implement operator.index(). Also called whenever Python needs an integer object (such as in slicing, or in the built-in bin(), hex() and oct() functions). Must return an integer.

### 3.3.8. With Statement Context Managers

A context manager is an object that defines the runtime context to be established when executing a `with` statement. The context manager handles the entry into, and the exit from, the desired runtime context
for the execution of the block of code. Context managers are normally invoked using the \texttt{with} statement (described in section \textit{The with statement}), but can also be used by directly invoking their methods.

Typical uses of context managers include saving and restoring various kinds of global state, locking and unlocking resources, closing opened files, etc.

For more information on context managers, see \textit{Context Manager Types}.

\begin{verbatim}
object.__enter__(self)
    Enter the runtime context related to this object. The \texttt{with} statement will bind this method’s return value to the target(s) specified in the \texttt{as} clause of the statement, if any.

object.__exit__(self, exc_type, exc_value, traceback)
    Exit the runtime context related to this object. The parameters describe the exception that caused the context to be exited. If the context was exited without an exception, all three arguments will be \texttt{None}.

    If an exception is supplied, and the method wishes to suppress the exception (i.e., prevent it from being propagated), it should return a true value. Otherwise, the exception will be processed normally upon exit from this method.

    Note that \texttt{__exit__()} methods should not reraise the passed-in exception; this is the caller’s responsibility.
\end{verbatim}

\textit{PEP 0343 - The “with” statement}
3.3.9. Special method lookup

For custom classes, implicit invocations of special methods are only guaranteed to work correctly if defined on an object’s type, not in the object’s instance dictionary. That behaviour is the reason why the following code raises an exception:

```python
>>> class C:
...     pass
...     pass
>>> c = C()
>>> c.__len__ = lambda: 5
>>> len(c)
Traceback (most recent call last):
  File "<stdin>", line 1, in <module>
TypeError: object of type 'C' has no len()
```

The rationale behind this behaviour lies with a number of special methods such as `__hash__()` and `__repr__()` that are implemented by all objects, including type objects. If the implicit lookup of these methods used the conventional lookup process, they would fail when invoked on the type object itself:

```python
>>> 1.__hash__() == hash(1)
True
>>> int.__hash__() == hash(int)
Traceback (most recent call last):
  File "<stdin>", line 1, in <module>
TypeError: descriptor '__hash__' of 'int' object needs an argument
```
Incorrectly attempting to invoke an unbound method of a class in this way is sometimes referred to as ‘metaclass confusion’, and is avoided by bypassing the instance when looking up special methods:

```python
>>> type(1).__hash__(1) == hash(1)
True
>>> type(int).__hash__(int) == hash(int)
True
```

In addition to bypassing any instance attributes in the interest of correctness, implicit special method lookup generally also bypasses the `__getattribute__()` method even of the object’s metaclass:

```python
>>> class Meta(type):
...     def __getattribute__(*args):
...         print("Metaclass getattribute invoked")
...         return type.__getattribute__(*args)
...
>>> class C(object, metaclass=Meta):
...     def __len__(self):
...         return 10
...     def __getattribute__(*args):
...         print("Class getattribute invoked")
...         return object.__getattribute__(*args)
...
>>> c = C()
>>> c.__len__()  # Explicit lookup via caller
Class getattribute invoked
10
>>> type(c).__len__(c)  # Explicit lookup via type
Metaclass getattribute invoked
10
>>> len(c)  # Implicit lookup
10
```
Bypassing the `__getattribute__()` machinery in this fashion provides significant scope for speed optimisations within the interpreter, at the cost of some flexibility in the handling of special methods (the special method `must` be set on the class object itself in order to be consistently invoked by the interpreter).

**Footnotes**

[1] It is possible in some cases to change an object's type, under certain controlled conditions. It generally isn't a good idea though, since it can lead to some very strange behaviour if it is handled incorrectly.

[2] For operands of the same type, it is assumed that if the non-reflected method (such as `__add__()`) fails the operation is not supported, which is why the reflected method is not called.
4. Execution model
4.1. Naming and binding

*Names* refer to objects. Names are introduced by name binding operations. Each occurrence of a name in the program text refers to the *binding* of that name established in the innermost function block containing the use.

A *block* is a piece of Python program text that is executed as a unit. The following are blocks: a module, a function body, and a class definition. Each command typed interactively is a block. A script file (a file given as standard input to the interpreter or specified on the interpreter command line the first argument) is a code block. A script command (a command specified on the interpreter command line with the ‘-c’ option) is a code block. The string argument passed to the built-in functions `eval()` and `exec()` is a code block.

A code block is executed in an *execution frame*. A frame contains some administrative information (used for debugging) and determines where and how execution continues after the code block’s execution has completed.

A *scope* defines the visibility of a name within a block. If a local variable is defined in a block, its scope includes that block. If the definition occurs in a function block, the scope extends to any blocks contained within the defining one, unless a contained block introduces a different binding for the name. The scope of names defined in a class block is limited to the class block; it does not extend to the code blocks of methods – this includes comprehensions and generator expressions since they are implemented using a function scope. This means that the following will fail:

```python
class A:
```
When a name is used in a code block, it is resolved using the nearest enclosing scope. The set of all such scopes visible to a code block is called the block’s *environment*.

If a name is bound in a block, it is a local variable of that block, unless declared as *nonlocal*. If a name is bound at the module level, it is a global variable. (The variables of the module code block are local and global.) If a variable is used in a code block but not defined there, it is a *free variable*.

When a name is not found at all, a *NameError* exception is raised. If the name refers to a local variable that has not been bound, a *UnboundLocalError* exception is raised. *UnboundLocalError* is a subclass of *NameError*.

The following constructs bind names: formal parameters to functions, *import* statements, class and function definitions (these bind the class or function name in the defining block), and targets that are identifiers if occurring in an assignment, *for* loop header, or after *as* in a *with* statement or *except* clause. The *import* statement of the form `from ... import *` binds all names defined in the imported module, except those beginning with an underscore. This form may only be used at the module level.

A target occurring in a *del* statement is also considered bound for this purpose (though the actual semantics are to unbind the name).

Each assignment or import statement occurs within a block defined by a class or function definition or at the module level (the top-level code block).
If a name binding operation occurs anywhere within a code block, all uses of the name within the block are treated as references to the current block. This can lead to errors when a name is used within a block before it is bound. This rule is subtle. Python lacks declarations and allows name binding operations to occur anywhere within a code block. The local variables of a code block can be determined by scanning the entire text of the block for name binding operations.

If the `global` statement occurs within a block, all uses of the name specified in the statement refer to the binding of that name in the top-level namespace. Names are resolved in the top-level namespace by searching the `global` namespace, i.e. the namespace of the module containing the code block, and the `builtins` namespace, the namespace of the module `builtins`. The `global` statement must precede all uses of the name.

The `builtins` namespace associated with the execution of a code block is actually found by looking up the name `__builtins__` in its global namespace; this should be a dictionary or a module (in the latter case the module’s dictionary is used). By default, when in the `__main__` module, `__builtins__` is the built-in module `builtins`; when in any other module, `__builtins__` is an alias for the dictionary of the `builtins` module itself. `__builtins__` can be set to a user-created dictionary to create a weak form of restricted execution.

**CPython implementation detail:** Users should not touch `__builtins__`; it is strictly an implementation detail. Users wanting to override values in the `builtins` namespace should import the `builtins` module and modify its attributes appropriately.

The namespace for a module is automatically created the first time a
module is imported. The main module for a script is always called __main__.

The global statement has the same scope as a name binding operation in the same block. If the nearest enclosing scope for a free variable contains a global statement, the free variable is treated as a global.

A class definition is an executable statement that may use and define names. These references follow the normal rules for name resolution. The namespace of the class definition becomes the attribute dictionary of the class. Names defined at the class scope are not visible in methods.

4.1.1. Interaction with dynamic features

There are several cases where Python statements are illegal when used in conjunction with nested scopes that contain free variables.

If a variable is referenced in an enclosing scope, it is illegal to delete the name. An error will be reported at compile time.

If the wild card form of import — import * — is used in a function and the function contains or is a nested block with free variables, the compiler will raise a SyntaxError.

The eval() and exec() functions do not have access to the full environment for resolving names. Names may be resolved in the local and global namespaces of the caller. Free variables are not resolved in the nearest enclosing namespace, but in the global namespace. [1] The exec() and eval() functions have optional arguments to override the global and local namespace. If only one namespace is
specified, it is used for both.
4.2. Exceptions

Exceptions are a means of breaking out of the normal flow of control of a code block in order to handle errors or other exceptional conditions. An exception is raised at the point where the error is detected; it may be handled by the surrounding code block or by any code block that directly or indirectly invoked the code block where the error occurred.

The Python interpreter raises an exception when it detects a run-time error (such as division by zero). A Python program can also explicitly raise an exception with the `raise` statement. Exception handlers are specified with the `try ... except` statement. The `finally` clause of such a statement can be used to specify cleanup code which does not handle the exception, but is executed whether an exception occurred or not in the preceding code.

Python uses the “termination” model of error handling: an exception handler can find out what happened and continue execution at an outer level, but it cannot repair the cause of the error and retry the failing operation (except by re-entering the offending piece of code from the top).

When an exception is not handled at all, the interpreter terminates execution of the program, or returns to its interactive main loop. In either case, it prints a stack backtrace, except when the exception is `SystemExit`.

Exceptions are identified by class instances. The `except` clause is selected depending on the class of the instance: it must reference the class of the instance or a base class thereof. The instance can be received by the handler and can carry additional information about the exceptional condition.
Note: Exception messages are not part of the Python API. Their contents may change from one version of Python to the next without warning and should not be relied on by code which will run under multiple versions of the interpreter.

See also the description of the \texttt{try} statement in section \textit{The try statement} and \texttt{raise} statement in section \textit{The raise statement}.

Footnotes

\footnote{This limitation occurs because the code that is executed by these operations is not available at the time the module is compiled.}
5. The import system

Python code in one *module* gains access to the code in another module by the process of *importing* it. The *import* statement is the most common way of invoking the import machinery, but it is not the only way. Functions such as `importlib.import_module()` and built-in `__import__()` can also be used to invoke the import machinery.

The *import* statement combines two operations; it searches for the named module, then it binds the results of that search to a name in the local scope. The search operation of the *import* statement is defined as a call to the `__import__()` function, with the appropriate arguments. The return value of `__import__()` is used to perform the name binding operation of the *import* statement. See the *import* statement for the exact details of that name binding operation.

A direct call to `__import__()` performs only the module search and, if found, the module creation operation. While certain side-effects may occur, such as the importing of parent packages, and the updating of various caches (including `sys.modules`), only the *import* statement performs a name binding operation.

When calling `__import__()` as part of an import statement, the import system first checks the module global namespace for a function by that name. If it is not found, then the standard builtin `__import__()` is called. Other mechanisms for invoking the import system (such as `importlib.import_module()`) do not perform this check and will always use the standard import system.

When a module is first imported, Python searches for the module and
if found, it creates a module object [1], initializing it. If the named module cannot be found, an `ImportError` is raised. Python implements various strategies to search for the named module when the import machinery is invoked. These strategies can be modified and extended by using various hooks described in the sections below.

*Changed in version 3.3:* The import system has been updated to fully implement the second phase of [PEP 302](https://www.python.org/dev/peps/pep-0302/). There is no longer any implicit import machinery - the full import system is exposed through `sys.meta_path`. In addition, native namespace package support has been implemented (see [PEP 420](https://www.python.org/dev/peps/pep-0420/)).
5.1. `importlib`

The `importlib` module provides a rich API for interacting with the import system. For example `importlib.import_module()` provides a recommended, simpler API than built-in `__import__()` for invoking the import machinery. Refer to the `importlib` library documentation for additional detail.
5.2. Packages

Python has only one type of module object, and all modules are of this type, regardless of whether the module is implemented in Python, C, or something else. To help organize modules and provide a naming hierarchy, Python has a concept of packages.

You can think of packages as the directories on a file system and modules as files within directories, but don’t take this analogy too literally since packages and modules need not originate from the file system. For the purposes of this documentation, we’ll use this convenient analogy of directories and files. Like file system directories, packages are organized hierarchically, and packages may themselves contain subpackages, as well as regular modules.

It’s important to keep in mind that all packages are modules, but not all modules are packages. Or put another way, packages are just a special kind of module. Specifically, any module that contains a `__path__` attribute is considered a package.

All modules have a name. Subpackage names are separated from their parent package name by dots, akin to Python’s standard attribute access syntax. Thus you might have a module called `sys` and a package called `email`, which in turn has a subpackage called `email.mime` and a module within that subpackage called `email.mime.text`.

5.2.1. Regular packages

Python defines two types of packages, regular packages and namespace packages. Regular packages are traditional packages as
they existed in Python 3.2 and earlier. A regular package is typically implemented as a directory containing an `__init__.py` file. When a regular package is imported, this `__init__.py` file is implicitly executed, and the objects it defines are bound to names in the package's namespace. The `__init__.py` file can contain the same Python code that any other module can contain, and Python will add some additional attributes to the module when it is imported.

For example, the following file system layout defines a top level `parent` package with three subpackages:

```
parent/
  __init__.py
one/
  __init__.py
two/
  __init__.py
three/
  __init__.py
```

Importing `parent.one` will implicitly execute `parent/__init__.py` and `parent/one/__init__.py`. Subsequent imports of `parent.two` or `parent.three` will execute `parent/two/__init__.py` and `parent/three/__init__.py` respectively.

### 5.2.2. Namespace packages

A namespace package is a composite of various portions, where each portion contributes a subpackage to the parent package. Portions may reside in different locations on the file system. Portions may also be found in zip files, on the network, or anywhere else that Python...
searches during import. Namespace packages may or may not correspond directly to objects on the file system; they may be virtual modules that have no concrete representation.

Namespace packages do not use an ordinary list for their `__path__` attribute. They instead use a custom iterable type which will automatically perform a new search for package portions on the next import attempt within that package if the path of their parent package (or `sys.path` for a top level package) changes.

With namespace packages, there is no `parent/__init__.py` file. In fact, there may be multiple `parent` directories found during import search, where each one is provided by a different portion. Thus `parent/one` may not be physically located next to `parent/two`. In this case, Python will create a namespace package for the top-level parent package whenever it or one of its subpackages is imported.

See also PEP 420 for the namespace package specification.
5.3. Searching

To begin the search, Python needs the fully qualified name of the module (or package, but for the purposes of this discussion, the difference is immaterial) being imported. This name may come from various arguments to the import statement, or from the parameters to the importlib.import_module() or __import__() functions.

This name will be used in various phases of the import search, and it may be the dotted path to a submodule, e.g. foo.bar.baz. In this case, Python first tries to import foo, then foo.bar, and finally foo.bar.baz. If any of the intermediate imports fail, an ImportError is raised.

5.3.1. The module cache

The first place checked during import search is sys.modules. This mapping serves as a cache of all modules that have been previously imported, including the intermediate paths. So if foo.bar.baz was previously imported, sys.modules will contain entries for foo, foo.bar, and foo.bar.baz. Each key will have as its value the corresponding module object.

During import, the module name is looked up in sys.modules and if present, the associated value is the module satisfying the import, and the process completes. However, if the value is None, then an ImportError is raised. If the module name is missing, Python will continue searching for the module.

sys.modules is writable. Deleting a key may not destroy the
associated module (as other modules may hold references to it), but it will invalidate the cache entry for the named module, causing Python to search anew for the named module upon its next import. The key can also be assigned to None, forcing the next import of the module to result in an \texttt{ImportError}.

Beware though, as if you keep a reference to the module object, invalidate its cache entry in \texttt{sys.modules}, and then re-import the named module, the two module objects will \textit{not} be the same. By contrast, \texttt{imp.reload()} will reuse the \textit{same} module object, and simply reinitialise the module contents by rerunning the module's code.

\textbf{5.3.2. Finders and loaders}

If the named module is not found in \texttt{sys.modules}, then Python's import protocol is invoked to find and load the module. This protocol consists of two conceptual objects, \textit{finders} and \textit{loaders}. A finder's job is to determine whether it can find the named module using whatever strategy it knows about. Objects that implement both of these interfaces are referred to as \textit{importers} - they return themselves when they find that they can load the requested module.

Python includes a number of default finders and importers. The first one knows how to locate built-in modules, and the second knows how to locate frozen modules. A third default finder searches an \textit{import path} for modules. The \textit{import path} is a list of locations that may name file system paths or zip files. It can also be extended to search for any locatable resource, such as those identified by URLs.

The import machinery is extensible, so new finders can be added to extend the range and scope of module searching.
Finders do not actually load modules. If they can find the named module, they return a *loader*, which the import machinery then invokes to load the module and create the corresponding module object.

The following sections describe the protocol for finders and loaders in more detail, including how you can create and register new ones to extend the import machinery.

### 5.3.3. Import hooks

The import machinery is designed to be extensible; the primary mechanism for this are the *import hooks*. There are two types of import hooks: *meta hooks* and *import path hooks*.

Meta hooks are called at the start of import processing, before any other import processing has occurred, other than `sys.modules` cache look up. This allows meta hooks to override `sys.path` processing, frozen modules, or even built-in modules. Meta hooks are registered by adding new finder objects to `sys.meta_path`, as described below.

Import path hooks are called as part of `sys.path` (or `package.__path__`) processing, at the point where their associated path item is encountered. Import path hooks are registered by adding new callables to `sys.path_hooks` as described below.

### 5.3.4. The meta path

When the named module is not found in `sys.modules`, Python next searches `sys.meta_path`, which contains a list of meta path finder objects. These finders are queried in order to see if they know how to handle the named module. Meta path finders must implement a
method called `find_module()` which takes two arguments, a name and an import path. The meta path finder can use any strategy it wants to determine whether it can handle the named module or not.

If the meta path finder knows how to handle the named module, it returns a loader object. If it cannot handle the named module, it returns None. If `sys.meta_path` processing reaches the end of its list without returning a loader, then an `ImportError` is raised. Any other exceptions raised are simply propagated up, aborting the import process.

The `find_module()` method of meta path finders is called with two arguments. The first is the fully qualified name of the module being imported, for example `foo.bar.baz`. The second argument is the path entries to use for the module search. For top-level modules, the second argument is None, but for submodules or subpackages, the second argument is the value of the parent package's `__path__` attribute. If the appropriate `__path__` attribute cannot be accessed, an `ImportError` is raised.

The meta path may be traversed multiple times for a single import request. For example, assuming none of the modules involved has already been cached, importing `foo.bar.baz` will first perform a top level import, calling `mpf.find_module("foo", None)` on each meta path finder (mpf). After `foo` has been imported, `foo.bar` will be imported by traversing the meta path a second time, calling `mpf.find_module("foo.bar", foo.__path__)`. Once `foo.bar` has been imported, the final traversal will call `mpf.find_module("foo.bar.baz", foo.bar.__path__)`.

Some meta path finders only support top level imports. These importers will always return None when anything other than None is
passed as the second argument.

Python's default `sys.meta_path` has three meta path finders, one that knows how to import built-in modules, one that knows how to import frozen modules, and one that knows how to import modules from an *import path* (i.e. the *path based finder*).
5.4. Loaders

If and when a module loader is found its `load_module()` method is called, with a single argument, the fully qualified name of the module being imported. This method has several responsibilities, and should return the module object it has loaded [2]. If it cannot load the module, it should raise an `ImportError`, although any other exception raised during `load_module()` will be propagated.

In many cases, the finder and loader can be the same object; in such cases the `finder.find_module()` would just return `self`.

Loaders must satisfy the following requirements:

- If there is an existing module object with the given name in `sys.modules`, the loader must use that existing module. (Otherwise, `imp.reload()` will not work correctly.) If the named module does not exist in `sys.modules`, the loader must create a new module object and add it to `sys.modules`.

Note that the module must exist in `sys.modules` before the loader executes the module code. This is crucial because the module code may (directly or indirectly) import itself; adding it to `sys.modules` beforehand prevents unbounded recursion in the worst case and multiple loading in the best.

If loading fails, the loader must remove any modules it has inserted into `sys.modules`, but it must remove only the failing module, and only if the loader itself has loaded it explicitly. Any module already in the `sys.modules` cache,
and any module that was successfully loaded as a side-effect, must remain in the cache.

- The loader may set the `__file__` attribute of the module. If set, this attribute’s value must be a string. The loader may opt to leave `__file__` unset if it has no semantic meaning (e.g. a module loaded from a database). If `__file__` is set, it may also be appropriate to set the `__cached__` attribute which is the path to any compiled version of the code (e.g. byte-compiled file). The file does not need to exist to set this attribute; the path can simply point to whether the compiled file would exist (see PEP 3147).

- The loader may set the `__name__` attribute of the module. While not required, setting this attribute is highly recommended so that the `repr()` of the module is more informative.

- If the module is a package (either regular or namespace), the loader must set the module object’s `__path__` attribute. The value must be iterable, but may be empty if `__path__` has no further significance to the loader. If `__path__` is not empty, it must produce strings when iterated over. More details on the semantics of `__path__` are given below.

- The `__loader__` attribute must be set to the loader object that loaded the module. This is mostly for introspection and reloading, but can be used for additional loader-specific functionality, for example getting data associated with a loader.

- The module’s `__package__` attribute should be set. Its
value must be a string, but it can be the same value as its
__name__. If the attribute is set to None or is missing, the
import system will fill it in with a more appropriate value.
When the module is a package, its __package__ value
should be set to its __name__. When the module is not a
package, __package__ should be set to the empty string for
top-level modules, or for submodules, to the parent
package’s name. See PEP 366 for further details.

This attribute is used instead of __name__ to calculate
explicit relative imports for main modules, as defined in PEP
366.

- If the module is a Python module (as opposed to a built-in
module or a dynamically loaded extension), the loader should
execute the module’s code in the module’s global name
space (module.__dict__).

5.4.1. Module reprs

By default, all modules have a usable repr, however depending on the
attributes set above, and hooks in the loader, you can more explicitly
control the repr of module objects.

Loaders may implement a module_repr() method which takes a
single argument, the module object. When repr(module) is called
for a module with a loader supporting this protocol, whatever is
returned from module.__loader__.module_repr(module) is
returned as the module’s repr without further processing. This return
value must be a string.

If the module has no __loader__ attribute, or the loader has no
module_repr() method, then the module object implementation itself will craft a default repr using whatever information is available. It will try to use the `module.__name__`, `module.__file__`, and `module.__loader__` as input into the repr, with defaults for whatever information is missing.

Here are the exact rules used:

- If the module has a `__loader__` and that loader has a `module_repr()` method, call it with a single argument, which is the module object. The value returned is used as the module's repr.
- If an exception occurs in `module_repr()`, the exception is caught and discarded, and the calculation of the module's repr continues as if `module_repr()` did not exist.
- If the module has a `__file__` attribute, this is used as part of the module's repr.
- If the module has no `__file__` but does have a `__loader__`, then the loader’s repr is used as part of the module's repr.
- Otherwise, just use the module’s `__name__` in the repr.

This example, from PEP 420 shows how a loader can craft its own module repr:

```python
class NamespaceLoader:
    @classmethod
    def module_repr(cls, module):
        return "<module '{0}' (namespace)>".format(module)
```

5.4.2. module.__path__
By definition, if a module has an __path__ attribute, it is a package, regardless of its value.

A package's __path__ attribute is used during imports of its subpackages. Within the import machinery, it functions much the same as sys.path, i.e. providing a list of locations to search for modules during import. However, __path__ is typically much more constrained than sys.path.

__path__ must be an iterable of strings, but it may be empty. The same rules used for sys.path also apply to a package's __path__, and sys.path_hooks (described below) are consulted when traversing a package's __path__.

A package's __init__.py file may set or alter the package's __path__ attribute, and this was typically the way namespace packages were implemented prior to PEP 420. With the adoption of PEP 420, namespace packages no longer need to supply __init__.py files containing only __path__ manipulation code; the namespace loader automatically sets __path__ correctly for the namespace package.
5.5. The Path Based Finder

As mentioned previously, Python comes with several default meta path finders. One of these, called the *path based finder*, searches an *import path*, which contains a list of *path entries*. Each path entry names a location to search for modules.

The path based finder itself doesn't know how to import anything. Instead, it traverses the individual path entries, associating each of them with a path entry finder that knows how to handle that particular kind of path.

The default set of path entry finders implement all the semantics for finding modules on the file system, handling special file types such as Python source code (*.py files), Python byte code (*.pyc and *.pyo files) and shared libraries (e.g. *.so files). When supported by the *zipimport* module in the standard library, the default path entry finders also handle loading all of these file types (other than shared libraries) from zipfiles.

Path entries need not be limited to file system locations. They can refer to URLs, database queries, or any other location that can be specified as a string.

The path based finder provides additional hooks and protocols so that you can extend and customize the types of searchable path entries. For example, if you wanted to support path entries as network URLs, you could write a hook that implements HTTP semantics to find modules on the web. This hook (a callable) would return a *path entry finder* supporting the protocol described below, which was then used to get a loader for the module from the web.
A word of warning: this section and the previous both use the term *finder*, distinguishing between them by using the terms *meta path finder* and *path entry finder*. These two types of finders are very similar, support similar protocols, and function in similar ways during the import process, but it's important to keep in mind that they are subtly different. In particular, meta path finders operate at the beginning of the import process, as keyed off the `sys.meta_path` traversal.

By contrast, path entry finders are in a sense an implementation detail of the path based finder, and in fact, if the path based finder were to be removed from `sys.meta_path`, none of the path entry finder semantics would be invoked.

### 5.5.1. Path entry finders

The *path based finder* is responsible for finding and loading Python modules and packages whose location is specified with a string *path entry*. Most path entries name locations in the file system, but they need not be limited to this.

As a meta path finder, the *path based finder* implements the `find_module()` protocol previously described, however it exposes additional hooks that can be used to customize how modules are found and loaded from the *import path*.

Three variables are used by the *path based finder*, `sys.path`, `sys.path_hooks` and `sys.path_importer_cache`. The `__path__` attributes on package objects are also used. These provide additional ways that the import machinery can be customized.

`sys.path` contains a list of strings providing search locations for
modules and packages. It is initialized from the PYTHONPATH environment variable and various other installation- and implementation-specific defaults. Entries in sys.path can name directories on the file system, zip files, and potentially other “locations” (see the site module) that should be searched for modules, such as URLs, or database queries. Only strings and bytes should be present on sys.path; all other data types are ignored. The encoding of bytes entries is determined by the individual path entry finders.

The path based finder is a meta path finder, so the import machinery begins the import path search by calling the path based finder’s find_module() method as described previously. When the path argument to find_module() is given, it will be a list of string paths to traverse - typically a package’s __path__ attribute for an import within that package. If the path argument is None, this indicates a top level import and sys.path is used.

The path based finder iterates over every entry in the search path, and for each of these, looks for an appropriate path entry finder for the path entry. Because this can be an expensive operation (e.g. there may be stat() call overheads for this search), the path based finder maintains a cache mapping path entries to path entry finders. This cache is maintained in sys.path_importer_cache (despite the name, this cache actually stores finder objects rather than being limited to importer objects). In this way, the expensive search for a particular path entry location’s path entry finder need only be done once. User code is free to remove cache entries from sys.path_importer_cache forcing the path based finder to perform the path entry search again [3].

If the path entry is not present in the cache, the path based finder iterates over every callable in sys.path_hooks. Each of the path
**entry hooks** in this list is called with a single argument, the path entry to be searched. This callable may either return a **path entry finder** that can handle the path entry, or it may raise **ImportError**. An **ImportError** is used by the path based finder to signal that the hook cannot find a **path entry finder** for that **path entry**. The exception is ignored and import path iteration continues. The hook should expect either a string or bytes object; the encoding of bytes objects is up to the hook (e.g. it may be a file system encoding, UTF-8, or something else), and if the hook cannot decode the argument, it should raise **ImportError**.

If **sys.path_hooks** iteration ends with no **path entry finder** being returned, then the path based finder's **find_module()** method will store None in **sys.path_importer_cache** (to indicate that there is no finder for this path entry) and return None, indicating that this **meta path finder** could not find the module.

If a **path entry finder** is returned by one of the **path entry hook** callables on **sys.path_hooks**, then the following protocol is used to ask the finder for a module loader, which is then used to load the module.

### 5.5.2. Path entry finder protocol

In order to support imports of modules and initialized packages and also to contribute portions to namespace packages, path entry finders must implement the **find_loader()** method.

**find_loader()** takes one argument, the fully qualified name of the module being imported. **find_loader()** returns a 2-tuple where the first item is the loader and the second item is a namespace **portion**. When the first item (i.e. the loader) is None, this means that while the
path entry finder does not have a loader for the named module, it knows that the path entry contributes to a namespace portion for the named module. This will almost always be the case where Python is asked to import a namespace package that has no physical presence on the file system. When a path entry finder returns None for the loader, the second item of the 2-tuple return value must be a sequence, although it can be empty.

If `find_loader()` returns a non-None loader value, the portion is ignored and the loader is returned from the path based finder, terminating the search through the path entries.

For backwards compatibility with other implementations of the import protocol, many path entry finders also support the same, traditional `find_module()` method that meta path finders support. However path entry finder `find_module()` methods are never called with a path argument (they are expected to record the appropriate path information from the initial call to the path hook).

The `find_module()` method on path entry finders is deprecated, as it does not allow the path entry finder to contribute portions to namespace packages. Instead path entry finders should implement the `find_loader()` method as described above. If it exists on the path entry finder, the import system will always call `find_loader()` in preference to `find_module()`.
5.6. Replacing the standard import system

The most reliable mechanism for replacing the entire import system is to delete the default contents of `sys.meta_path`, replacing them entirely with a custom meta path hook.

If it is acceptable to only alter the behaviour of import statements without affecting other APIs that access the import system, then replacing the builtin `__import__()` function may be sufficient. This technique may also be employed at the module level to only alter the behaviour of import statements within that module.

To selectively prevent import of some modules from a hook early on the meta path (rather than disabling the standard import system entirely), it is sufficient to raise `ImportError` directly from `find_module()` instead of returning None. The latter indicates that the meta path search should continue, while raising an exception terminates it immediately.
5.7. Open issues

XXX It would be really nice to have a diagram.

XXX * (import_machinery.rst) how about a section devoted just to the attributes of modules and packages, perhaps expanding upon or supplanting the related entries in the data model reference page?

XXX runpy, pkgutil, et al in the library manual should all get “See Also” links at the top pointing to the new import system section.
5.8. References

The import machinery has evolved considerably since Python’s early days. The original specification for packages is still available to read, although some details have changed since the writing of that document.

The original specification for `sys.meta_path` was PEP 302, with subsequent extension in PEP 420.

PEP 420 introduced namespace packages for Python 3.3. PEP 420 also introduced the `find_loader()` protocol as an alternative to `find_module()`.

PEP 366 describes the addition of the `__package__` attribute for explicit relative imports in main modules.

PEP 328 introduced absolute and explicit relative imports and initially proposed `__name__` for semantics PEP 366 would eventually specify for `__package__`.

PEP 338 defines executing modules as scripts.

Footnotes

The importlib implementation avoids using the return value directly. Instead, it gets the module object by looking the module name up in `sys.modules`. The indirect effect of this is that an imported module may replace itself in `sys.modules`. This is implementation-specific behavior that is not guaranteed to work in other Python implementations.
In legacy code, it is possible to find instances of `imp.NullImporter` in the `sys.path_importer_cache`. It is recommended that code be changed to use `None` instead. See *Porting Python code* for more details.
6. Expressions

This chapter explains the meaning of the elements of expressions in Python.

**Syntax Notes:** In this and the following chapters, extended BNF notation will be used to describe syntax, not lexical analysis. When (one alternative of) a syntax rule has the form

```
name ::= othername
```

and no semantics are given, the semantics of this form of `name` are the same as for `othername`. 
6.1. Arithmetic conversions

When a description of an arithmetic operator below uses the phrase “the numeric arguments are converted to a common type,” this means that the operator implementation for built-in types works that way:

- If either argument is a complex number, the other is converted to complex;
- otherwise, if either argument is a floating point number, the other is converted to floating point;
- otherwise, both must be integers and no conversion is necessary.

Some additional rules apply for certain operators (e.g., a string left argument to the ‘%’ operator). Extensions must define their own conversion behavior.
6.2. Atoms

Atoms are the most basic elements of expressions. The simplest atoms are identifiers or literals. Forms enclosed in parentheses, brackets or braces are also categorized syntactically as atoms. The syntax for atoms is:

\[
\begin{align*}
\text{atom} & ::= \text{identifier} | \text{literal} | \text{enclosure} \\
\text{enclosure} & ::= \text{parenth_form} | \text{list_display} | \text{dict_display} | \text{generator_expression} | \text{yield_atom}
\end{align*}
\]

6.2.1. Identifiers (Names)

An identifier occurring as an atom is a name. See section *Identifiers and keywords* for lexical definition and section *Naming and binding* for documentation of naming and binding.

When the name is bound to an object, evaluation of the atom yields that object. When a name is not bound, an attempt to evaluate it raises a `NameError` exception.

**Private name mangling:** When an identifier that textually occurs in a class definition begins with two or more underscore characters and does not end in two or more underscores, it is considered a *private name* of that class. Private names are transformed to a longer form before code is generated for them. The transformation inserts the class name, with leading underscores removed and a single underscore inserted, in front of the name. For example, the identifier `__spam` occurring in a class named `Ham` will be transformed to `_Ham__spam`. This transformation is independent of the syntactical context in which the identifier is used. If the transformed name is
extremely long (longer than 255 characters), implementation defined truncation may happen. If the class name consists only of underscores, no transformation is done.

6.2.2. Literals

Python supports string and bytes literals and various numeric literals:

```
literal ::= stringliteral | bytesliteral | integer | floatnumber | imagnumber
```

Evaluation of a literal yields an object of the given type (string, bytes, integer, floating point number, complex number) with the given value. The value may be approximated in the case of floating point and imaginary (complex) literals. See section Literals for details.

All literals correspond to immutable data types, and hence the object's identity is less important than its value. Multiple evaluations of literals with the same value (either the same occurrence in the program text or a different occurrence) may obtain the same object or a different object with the same value.

6.2.3. Parenthesized forms

A parenthesized form is an optional expression list enclosed in parentheses:

```
parenth_form ::= "(" [expression_list] ")"
```

A parenthesized expression list yields whatever that expression list yields: if the list contains at least one comma, it yields a tuple; otherwise, it yields the single expression that makes up the expression
list.

An empty pair of parentheses yields an empty tuple object. Since tuples are immutable, the rules for literals apply (i.e., two occurrences of the empty tuple may or may not yield the same object).

Note that tuples are not formed by the parentheses, but rather by use of the comma operator. The exception is the empty tuple, for which parentheses are required — allowing unparenthesized “nothing” in expressions would cause ambiguities and allow common typos to pass uncaught.

6.2.4. Displays for lists, sets and dictionaries

For constructing a list, a set or a dictionary Python provides special syntax called “displays”, each of them in two flavors:

- either the container contents are listed explicitly, or
- they are computed via a set of looping and filtering instructions, called a comprehension.

Common syntax elements for comprehensions are:

```
comprehension ::= expression comp_for
comp_for ::= "for" target_list "in" or_test [comp_iter]
comp_iter ::= comp_for | comp_if
comp_if ::= "if" expression_nocond [comp_iter]
```

The comprehension consists of a single expression followed by at least one for clause and zero or more for or if clauses. In this case, the elements of the new container are those that would be produced by considering each of the for or if clauses a block, nesting from left to right, and evaluating the expression to produce an
element each time the innermost block is reached.

Note that the comprehension is executed in a separate scope, so names assigned to in the target list don't “leak” in the enclosing scope.

6.2.5. List displays

A list display is a possibly empty series of expressions enclosed in square brackets:

```
list_display ::= "[" [expression_list | comprehension] "]"
```

A list display yields a new list object, the contents being specified by either a list of expressions or a comprehension. When a comma-separated list of expressions is supplied, its elements are evaluated from left to right and placed into the list object in that order. When a comprehension is supplied, the list is constructed from the elements resulting from the comprehension.

6.2.6. Set displays

A set display is denoted by curly braces and distinguishable from dictionary displays by the lack of colons separating keys and values:

```
set_display ::= "{" (expression_list | comprehension) "]"
```

A set display yields a new mutable set object, the contents being specified by either a sequence of expressions or a comprehension. When a comma-separated list of expressions is supplied, its elements are evaluated from left to right and added to the set object. When a comprehension is supplied, the set is constructed from the elements
resulting from the comprehension.

An empty set cannot be constructed with \{\}; this literal constructs an empty dictionary.

6.2.7. Dictionary displays

A dictionary display is a possibly empty series of key/datum pairs enclosed in curly braces:

```
\begin{verbatim}
dict_display ::= "{" [key_datum_list | dict_comprehension]
key_datum_list ::= key_datum ("," key_datum)*
key_datum ::= expression "":"" expression
dict_comprehension ::= expression "":"" expression comp_for
\end{verbatim}
```

A dictionary display yields a new dictionary object.

If a comma-separated sequence of key/datum pairs is given, they are evaluated from left to right to define the entries of the dictionary: each key object is used as a key into the dictionary to store the corresponding datum. This means that you can specify the same key multiple times in the key/datum list, and the final dictionary’s value for that key will be the last one given.

A dict comprehension, in contrast to list and set comprehensions, needs two expressions separated with a colon followed by the usual “for” and “if” clauses. When the comprehension is run, the resulting key and value elements are inserted in the new dictionary in the order they are produced.

Restrictions on the types of the key values are listed earlier in section \textit{The standard type hierarchy}. (To summarize, the key type should be \textit{hashable}, which excludes all mutable objects.) Clashes between
duplicate keys are not detected; the last datum (textually rightmost in the display) stored for a given key value prevails.

6.2.8. Generator expressions

A generator expression is a compact generator notation in parentheses:

\[
generator_expression ::= (" expression comp_for ")
\]

A generator expression yields a new generator object. Its syntax is the same as for comprehensions, except that it is enclosed in parentheses instead of brackets or curly braces.

Variables used in the generator expression are evaluated lazily when the `__next__()` method is called for generator object (in the same fashion as normal generators). However, the leftmost `for` clause is immediately evaluated, so that an error produced by it can be seen before any other possible error in the code that handles the generator expression. Subsequent `for` clauses cannot be evaluated immediately since they may depend on the previous `for` loop. For example: `(x*y for x in range(10) for y in bar(x))`.

The parentheses can be omitted on calls with only one argument. See section *Calls* for the detail.

6.2.9. Yield expressions

\[
yield_atom ::= "(" yield_expression ")"
yield_expression ::= "yield" [expression_list | "for"
\]
The `yield` expression is only used when defining a generator function, and can only be used in the body of a function definition. Using a `yield` expression in a function definition is sufficient to cause that definition to create a generator function instead of a normal function.

When a generator function is called, it returns an iterator known as a generator. That generator then controls the execution of a generator function. The execution starts when one of the generator’s methods is called. At that time, the execution proceeds to the first `yield` expression, where it is suspended again, returning the value of `expression_list` to generator’s caller. By suspended we mean that all local state is retained, including the current bindings of local variables, the instruction pointer, and the internal evaluation stack. When the execution is resumed by calling one of the generator’s methods, the function can proceed exactly as if the `yield` expression was just another external call. The value of the `yield` expression after resuming depends on the method which resumed the execution. If `__next__()` is used (typically via either a `for` or the `next()` builtin) then the result is `None`, otherwise, if `send()` is used, then the result will be the value passed in to that method.

All of this makes generator functions quite similar to coroutines; they yield multiple times, they have more than one entry point and their execution can be suspended. The only difference is that a generator function cannot control where should the execution continue after it yields; the control is always transferred to the generator’s caller.

`yield` expressions are allowed in the `try` clause of a `try ... finally` construct. If the generator is not resumed before it is finalized (by reaching a zero reference count or by being garbage collected), the generator-iterator’s `close()` method will be called,
allowing any pending `finally` clauses to execute.

When `yield from <expr>` is used, it treats the supplied expression as a subiterator. All values produced by that subiterator are passed directly to the caller of the current generator’s methods. Any values passed in with `send()` and any exceptions passed in with `throw()` are passed to the underlying iterator if it has the appropriate methods. If this is not the case, then `send()` will raise `AttributeError` or `TypeError`, while `throw()` will just raise the passed in exception immediately.

When the underlying iterator is complete, the value attribute of the raised `StopIteration` instance becomes the value of the yield expression. It can be either set explicitly when raising `StopIteration`, or automatically when the sub-iterator is a generator (by returning a value from the sub-generator).

`Changed in version 3.3: Added yield from <expr> to delegate control flow to a subiterator`

The parentheses can be omitted when the `yield` expression is the sole expression on the right hand side of an assignment statement.

6.2.9.1. Generator-iterator methods

This subsection describes the methods of a generator iterator. They can be used to control the execution of a generator function.

Note that calling any of the generator methods below when the generator is already executing raises a `ValueError` exception.

`class generator`
generator.__next__()

Starts the execution of a generator function or resumes it at the last executed `yield` expression. When a generator function is resumed with a `__next__()` method, the current `yield` expression always evaluates to `None`. The execution then continues to the next `yield` expression, where the generator is suspended again, and the value of the `expression_list` is returned to `next()`'s caller. If the generator exits without yielding another value, a `StopIteration` exception is raised.

This method is normally called implicitly, e.g. by a `for` loop, or by the built-in `next()` function.

generator.send(value)

Resumes the execution and “sends” a value into the generator function. The `value` argument becomes the result of the current `yield` expression. The `send()` method returns the next value yielded by the generator, or raises `StopIteration` if the generator exits without yielding another value. When `send()` is called to start the generator, it must be called with `None` as the argument, because there is no `yield` expression that could receive the value.

generator.throw(type[, value[, traceback]])

Raises an exception of type `type` at the point where generator was paused, and returns the next value yielded by the generator function. If the generator exits without yielding another value, a `StopIteration` exception is raised. If the generator function does not catch the passed-in exception, or raises a different exception, then that exception propagates to the caller.
generator. close()

Raises a GeneratorExit at the point where the generator function was paused. If the generator function then raises StopIteration (by exiting normally, or due to already being closed) or GeneratorExit (by not catching the exception), close returns to its caller. If the generator yields a value, a RuntimeError is raised. If the generator raises any other exception, it is propagated to the caller. close() does nothing if the generator has already exited due to an exception or normal exit.

6.2.9.2. Examples

Here is a simple example that demonstrates the behavior of generators and generator functions:

```python
>>> def echo(value=None):
...     print("Execution starts when 'next()' is called.")
...     try:
...         while True:
...             try:
...                 value = (yield value)
...             except Exception as e:
...                 value = e
...     finally:
...         print("Don't forget to clean up when 'close()' is called.")
...     return value

>>> generator = echo(1)
>>> print(next(generator))
Execution starts when 'next()' is called for the first time.
1
>>> print(next(generator))
```
None

```python
>>> print(generator.send(2))
2
>>> generator.throw(TypeError, "spam")
TypeError('spam',)
>>> generator.close()
```

Don't forget to clean up when 'close()' is called.

For examples using `yield from`, see **PEP 380: Syntax for Delegating to a Subgenerator** in “What’s New in Python.”

**See also:**

**PEP 0255 - Simple Generators**

The proposal for adding generators and the `yield` statement to Python.

**PEP 0342 - Coroutines via Enhanced Generators**

The proposal to enhance the API and syntax of generators, making them usable as simple coroutines.

**PEP 0380 - Syntax for Delegating to a Subgenerator**

The proposal to introduce the `yield_from` syntax, making delegation to sub-generators easy.
6.3. Primaries

Primaries represent the most tightly bound operations of the language. Their syntax is:

```
primary ::= atom | attributeref | subscription | slicing
```

6.3.1. Attribute references

An attribute reference is a primary followed by a period and a name:

```
attributeref ::= primary "." identifier
```

The primary must evaluate to an object of a type that supports attribute references, which most objects do. This object is then asked to produce the attribute whose name is the identifier (which can be customized by overriding the `__getattr__()` method). If this attribute is not available, the exception `AttributeError` is raised. Otherwise, the type and value of the object produced is determined by the object. Multiple evaluations of the same attribute reference may yield different objects.

6.3.2. Subscriptions

A subscription selects an item of a sequence (string, tuple or list) or mapping (dictionary) object:

```
subscription ::= primary "]" expression_list "[/
```

The primary must evaluate to an object that supports subscription, e.g.
a list or dictionary. User-defined objects can support subscription by defining a `__getitem__()` method.

For built-in objects, there are two types of objects that support subscription:

If the primary is a mapping, the expression list must evaluate to an object whose value is one of the keys of the mapping, and the subscription selects the value in the mapping that corresponds to that key. (The expression list is a tuple except if it has exactly one item.)

If the primary is a sequence, the expression `(list)` must evaluate to an integer or a slice (as discussed in the following section).

The formal syntax makes no special provision for negative indices in sequences; however, built-in sequences all provide a `__getitem__()` method that interprets negative indices by adding the length of the sequence to the index (so that `x[-1]` selects the last item of `x`). The resulting value must be a nonnegative integer less than the number of items in the sequence, and the subscription selects the item whose index is that value (counting from zero). Since the support for negative indices and slicing occurs in the object’s `__getitem__()` method, subclasses overriding this method will need to explicitly add that support.

A string’s items are characters. A character is not a separate data type but a string of exactly one character.

6.3.3. Slicings

A slicing selects a range of items in a sequence object (e.g., a string, tuple or list). Slicings may be used as expressions or as targets in
assignment or `del` statements. The syntax for a slicing:

```
slicing ::= primary "[" slice_list "]"
slice_list ::= slice_item ("," slice_item)* [","]
slice_item ::= expression | proper_slice
proper_slice ::= [lower_bound] ":" [upper_bound] [ stride
lower_bound ::= expression
upper_bound ::= expression
stride ::= expression
```

There is ambiguity in the formal syntax here: anything that looks like an expression list also looks like a slice list, so any subscription can be interpreted as a slicing. Rather than further complicating the syntax, this is disambiguated by defining that in this case the interpretation as a subscription takes priority over the interpretation as a slicing (this is the case if the slice list contains no proper slice).

The semantics for a slicing are as follows. The primary must evaluate to a mapping object, and it is indexed (using the same `__getitem__()` method as normal subscription) with a key that is constructed from the slice list, as follows. If the slice list contains at least one comma, the key is a tuple containing the conversion of the slice items; otherwise, the conversion of the lone slice item is the key. The conversion of a slice item that is an expression is that expression. The conversion of a proper slice is a slice object (see section *The standard type hierarchy*) whose start, stop and step attributes are the values of the expressions given as lower bound, upper bound and stride, respectively, substituting `None` for missing expressions.

6.3.4. Calls

A call calls a callable object (e.g., a `function`) with a possibly empty
series of **arguments**: 

```
call ::= primary "(" [argument_list] "" ["," "] ["" "" "" expression [",""] ["" "" expression [",""] 
| keyword_arguments [",""] ["" keyword_arguments [",""] ["" "] expression [",""] keyword_arguments |
| "" expression [",""] keyword_arguments |

argument_list ::= positional_arguments [",""] ["" "" "" expression [",""] ["" "" expression [",""] 
| keyword_arguments [",""] ["" keyword_arguments [",""] ["" "] expression [",""] keyword_arguments |
| "" expression [",""] keyword_arguments |

positional_arguments ::= expression [",""] expression |

keyword_arguments ::= keyword_item [",""] keyword_item |

keyword_item ::= identifier "=" expression |
```

A trailing comma may be present after the positional and keyword arguments but does not affect the semantics.

The primary must evaluate to a callable object (user-defined functions, built-in functions, methods of built-in objects, class objects, methods of class instances, and all objects having a `__call__()` method are callable). All argument expressions are evaluated before the call is attempted. Please refer to section *Function definitions* for the syntax of formal parameter lists.

If keyword arguments are present, they are first converted to positional arguments, as follows. First, a list of unfilled slots is created for the formal parameters. If there are N positional arguments, they are placed in the first N slots. Next, for each keyword argument, the identifier is used to determine the corresponding slot (if the identifier is the same as the first formal parameter name, the first slot is used, and so on). If the slot is already filled, a `TypeError` exception is raised. Otherwise, the value of the argument is placed in the slot, filling it (even if the expression is None, it fills the slot). When all arguments
have been processed, the slots that are still unfilled are filled with the corresponding default value from the function definition. (Default values are calculated, once, when the function is defined; thus, a mutable object such as a list or dictionary used as default value will be shared by all calls that don’t specify an argument value for the corresponding slot; this should usually be avoided.) If there are any unfilled slots for which no default value is specified, a TypeError exception is raised. Otherwise, the list of filled slots is used as the argument list for the call.

**CPython implementation detail:** An implementation may provide built-in functions whose positional parameters do not have names, even if they are ‘named’ for the purpose of documentation, and which therefore cannot be supplied by keyword. In CPython, this is the case for functions implemented in C that use `PyArg_ParseTuple()` to parse their arguments.

If there are more positional arguments than there are formal parameter slots, a TypeError exception is raised, unless a formal parameter using the syntax `*identifier` is present; in this case, that formal parameter receives a tuple containing the excess positional arguments (or an empty tuple if there were no excess positional arguments).

If any keyword argument does not correspond to a formal parameter name, a TypeError exception is raised, unless a formal parameter using the syntax `**identifier` is present; in this case, that formal parameter receives a dictionary containing the excess keyword arguments (using the keywords as keys and the argument values as corresponding values), or a (new) empty dictionary if there were no excess keyword arguments.

If the syntax `*expression` appears in the function call, expression
must evaluate to an iterable. Elements from this iterable are treated as if they were additional positional arguments; if there are positional arguments \(x1, \ldots, xN\), and \texttt{expression} evaluates to a sequence \(y1, \ldots, yM\), this is equivalent to a call with \(M+N\) positional arguments \(x1, \ldots, xN, y1, \ldots, yM\).

A consequence of this is that although the \texttt{*expression} syntax may appear \texttt{after} some keyword arguments, it is processed \texttt{before} the keyword arguments (and the \texttt{**expression} argument, if any – see below). So:

```python
>>> def f(a, b):
...     print(a, b)
...
>>> f(b=1, *(2,))
2 1
>>> f(a=1, *(2,))
Traceback (most recent call last):
  File "<stdin>" , line 1, in ?
TypeError: f() got multiple values for keyword argument 'a'
>>> f(1, *(2,))
1 2
```

It is unusual for both keyword arguments and the \texttt{*expression} syntax to be used in the same call, so in practice this confusion does not arise.

If the syntax \texttt{**expression} appears in the function call, \texttt{expression} must evaluate to a mapping, the contents of which are treated as additional keyword arguments. In the case of a keyword appearing in both \texttt{expression} and as an explicit keyword argument, a \texttt{TypeError} exception is raised.
Formal parameters using the syntax `*identifier` or `**identifier` cannot be used as positional argument slots or as keyword argument names.

A call always returns some value, possibly None, unless it raises an exception. How this value is computed depends on the type of the callable object.

If it is—

a user-defined function:
The code block for the function is executed, passing it the argument list. The first thing the code block will do is bind the formal parameters to the arguments; this is described in section `Function definitions`. When the code block executes a `return` statement, this specifies the return value of the function call.

a built-in function or method:
The result is up to the interpreter; see `Built-in Functions` for the descriptions of built-in functions and methods.

a class object:
A new instance of that class is returned.

a class instance method:
The corresponding user-defined function is called, with an argument list that is one longer than the argument list of the call: the instance becomes the first argument.

a class instance:
The class must define a `__call__()` method; the effect is then the same as if that method was called.
6.4. The power operator

The power operator binds more tightly than unary operators on its left; it binds less tightly than unary operators on its right. The syntax is:

```
power ::= primary ["**" u_expr]
```

Thus, in an unparenthesized sequence of power and unary operators, the operators are evaluated from right to left (this does not constrain the evaluation order for the operands): -1**2 results in -1.

The power operator has the same semantics as the built-in pow() function, when called with two arguments: it yields its left argument raised to the power of its right argument. The numeric arguments are first converted to a common type, and the result is of that type.

For int operands, the result has the same type as the operands unless the second argument is negative; in that case, all arguments are converted to float and a float result is delivered. For example, 10**2 returns 100, but 10**-2 returns 0.01.

Raising 0.0 to a negative power results in a ZeroDivisionError. Raising a negative number to a fractional power results in a complex number. (In earlier versions it raised a ValueError.)
6.5. Unary arithmetic and bitwise operations

All unary arithmetic and bitwise operations have the same priority:

```
u_expr ::= power | "-" u_expr | "+" u_expr | "~" u_expr
```

The unary `-` (minus) operator yields the negation of its numeric argument.

The unary `+` (plus) operator yields its numeric argument unchanged.

The unary `~` (invert) operator yields the bitwise inversion of its integer argument. The bitwise inversion of `x` is defined as `- (x + 1)`. It only applies to integral numbers.

In all three cases, if the argument does not have the proper type, a `TypeError` exception is raised.
6.6. Binary arithmetic operations

The binary arithmetic operations have the conventional priority levels. Note that some of these operations also apply to certain non-numeric types. Apart from the power operator, there are only two levels, one for multiplicative operators and one for additive operators:

\[
\begin{align*}
m_{\text{expr}} & ::= u_{\text{expr}} \mid m_{\text{expr}} \ast u_{\text{expr}} \mid m_{\text{expr}} \div u_{\text{expr}} \\
a_{\text{expr}} & ::= m_{\text{expr}} \mid a_{\text{expr}} + m_{\text{expr}} \mid a_{\text{expr}} - m_{\text{expr}}
\end{align*}
\]

The \(\ast\) (multiplication) operator yields the product of its arguments. The arguments must either both be numbers, or one argument must be an integer and the other must be a sequence. In the former case, the numbers are converted to a common type and then multiplied together. In the latter case, sequence repetition is performed; a negative repetition factor yields an empty sequence.

The \(\div\) (division) and \(\div\div\) (floor division) operators yield the quotient of their arguments. The numeric arguments are first converted to a common type. Division of integers yields a float, while floor division of integers results in an integer; the result is that of mathematical division with the ‘floor’ function applied to the result. Division by zero raises the \texttt{ZeroDivisionError} exception.

The \(\%\) (modulo) operator yields the remainder from the division of the first argument by the second. The numeric arguments are first converted to a common type. A zero right argument raises the \texttt{ZeroDivisionError} exception. The arguments may be floating point numbers, e.g., \(3.14\%0.7\) equals \(0.34\) (since \(3.14\) equals \(4\ast0.7 + 0.34\).) The modulo operator always yields a result with the
same sign as its second operand (or zero); the absolute value of the result is strictly smaller than the absolute value of the second operand [1].

The floor division and modulo operators are connected by the following identity: \( x == (x//y)*y + (x\%y) \). Floor division and modulo are also connected with the built-in function \( \text{divmod()} \): \( \text{divmod}(x, y) == (x//y, x\%y) \).[2]

In addition to performing the modulo operation on numbers, the \% operator is also overloaded by string objects to perform old-style string formatting (also known as interpolation). The syntax for string formatting is described in the Python Library Reference, section printf-style String Formatting.

The floor division operator, the modulo operator, and the \( \text{divmod()} \) function are not defined for complex numbers. Instead, convert to a floating point number using the abs() function if appropriate.

The + (addition) operator yields the sum of its arguments. The arguments must either both be numbers or both sequences of the same type. In the former case, the numbers are converted to a common type and then added together. In the latter case, the sequences are concatenated.

The - (subtraction) operator yields the difference of its arguments. The numeric arguments are first converted to a common type.
6.7. Shifting operations

The shifting operations have lower priority than the arithmetic operations:

```
shift_expr ::= a_expr | shift_expr ( "<<" | ">>" )
```

These operators accept integers as arguments. They shift the first argument to the left or right by the number of bits given by the second argument.

A right shift by \( n \) bits is defined as floor division by \( \text{pow}(2,n) \). A left shift by \( n \) bits is defined as multiplication with \( \text{pow}(2,n) \).

**Note:** In the current implementation, the right-hand operand is required to be at most `sys.maxsize`. If the right-hand operand is larger than `sys.maxsize` an `OverflowError` exception is raised.
6.8. Binary bitwise operations

Each of the three bitwise operations has a different priority level:

- `and_expr ::= shift_expr | and_expr "&" shift_expr`
- `xor_expr ::= and_expr | xor_expr "^" and_expr`
- `or_expr ::= xor_expr | or_expr "|" xor_expr`

The `&` operator yields the bitwise AND of its arguments, which must be integers.

The `^` operator yields the bitwise XOR (exclusive OR) of its arguments, which must be integers.

The `|` operator yields the bitwise (inclusive) OR of its arguments, which must be integers.
6.9. Comparisons

Unlike C, all comparison operations in Python have the same priority, which is lower than that of any arithmetic, shifting or bitwise operation. Also unlike C, expressions like \( a < b < c \) have the interpretation that is conventional in mathematics:

```
comparison ::= or_expr ( comp_operator or_expr
comp_operator ::= "<" | ">" | ">=", | ";=", | "is" | ["not"] | ["not"] "in"
```

Comparisons yield boolean values: True or False.

Comparisons can be chained arbitrarily, e.g., \( x < y <= z \) is equivalent to \( x < y \) and \( y <= z \), except that \( y \) is evaluated only once (but in both cases \( z \) is not evaluated at all when \( x < y \) is found to be false).

Formally, if \( a, b, c, \ldots, y, z \) are expressions and \( op1, op2, \ldots, opN \) are comparison operators, then \( a \ op1 \ b \ op2 \ c \ \ldots \ y \ opN \ z \) is equivalent to \( a \ op1 \ b \) and \( b \ op2 \ c \) and \( \ldots \ y \ opN \ z \), except that each expression is evaluated at most once.

Note that \( a \ op1 \ b \ op2 \ c \) doesn’t imply any kind of comparison between \( a \) and \( c \), so that, e.g., \( x < y > z \) is perfectly legal (though perhaps not pretty).

The operators \(<, >, ==, >=, <=, !=\) compare the values of two objects. The objects need not have the same type. If both are numbers, they are converted to a common type. Otherwise, the \( == \) and \( != \) operators always consider objects of different types to be
unequal, while the `<`, `>`, `>=` and `<=` operators raise a `TypeError` when comparing objects of different types that do not implement these operators for the given pair of types. You can control comparison behavior of objects of non-built-in types by defining rich comparison methods like `__gt__()`, described in section Basic customization.

Comparison of objects of the same type depends on the type:

- Numbers are compared arithmetically.

- The values `float('NaN')` and `Decimal('NaN')` are special. They are identical to themselves, `x is x` but are not equal to themselves, `x != x`. Additionally, comparing any value to a not-a-number value will return `False`. For example, both `3 < float('NaN')` and `float('NaN') < 3` will return `False`.

- Bytes objects are compared lexicographically using the numeric values of their elements.

- Strings are compared lexicographically using the numeric equivalents (the result of the built-in function `ord()`) of their characters. String and bytes object can’t be compared!

- Tuples and lists are compared lexicographically using comparison of corresponding elements. This means that to compare equal, each element must compare equal and the two sequences must be of the same type and have the same length.

  If not equal, the sequences are ordered the same as their first differing elements. For example, `[1, 2, x] <= [1, 2, y]` has the same value as `x <= y`. If the corresponding element does not exist, the shorter sequence is ordered first (for example, `[1, 2] < [1, 2, 3]`).
Mappings (dictionaries) compare equal if and only if they have the same (key, value) pairs. Order comparisons ('<', '<=', '>', '>=', '>') raise TypeError.

Sets and frozensets define comparison operators to mean subset and superset tests. Those relations do not define total orderings (the two sets {1, 2} and {2,3} are not equal, nor subsets of one another, nor supersets of one another). Accordingly, sets are not appropriate arguments for functions which depend on total ordering. For example, min(), max(), and sorted() produce undefined results given a list of sets as inputs.

Most other objects of built-in types compare unequal unless they are the same object; the choice whether one object is considered smaller or larger than another one is made arbitrarily but consistently within one execution of a program.

Comparison of objects of the differing types depends on whether either of the types provide explicit support for the comparison. Most numeric types can be compared with one another. When cross-type comparison is not supported, the comparison method returns NotImplemented.

The operators in and not in test for membership. x in s evaluates to true if x is a member of s, and false otherwise. x not in s returns the negation of x in s. All built-in sequences and set types support this as well as dictionary, for which in tests whether a the dictionary has a given key. For container types such as list, tuple, set, frozenset, dict, or collections.deque, the expression x in y is equivalent to any(x is e or x == e for e in y).

For the string and bytes types, x in y is true if and only if x is a
substring of \( y \). An equivalent test is \( y.\text{find}(x) \neq -1 \). Empty strings are always considered to be a substring of any other string, so "" in "abc" will return True.

For user-defined classes which define the \( \text{__contains__}() \) method, \( x \ in \ y \) is true if and only if \( y.\text{__contains__}(x) \) is true.

For user-defined classes which do not define \( \text{__contains__}() \) but do define \( \text{__iter__}() \), \( x \ in \ y \) is true if some value \( z \) with \( x == z \) is produced while iterating over \( y \). If an exception is raised during the iteration, it is as if \( in \) raised that exception.

Lastly, the old-style iteration protocol is tried: if a class defines \( \text{__getitem__}() \), \( x \ in \ y \) is true if and only if there is a non-negative integer index \( i \) such that \( x == y[i] \), and all lower integer indices do not raise \( \text{IndexError} \) exception. (If any other exception is raised, it is as if \( in \) raised that exception).

The operator \( \text{not in} \) is defined to have the inverse true value of \( in \).

The operators \( is \) and \( is \ not \) test for object identity: \( x \ is \ y \) is true if and only if \( x \) and \( y \) are the same object. \( x \ is \ not \ y \) yields the inverse truth value. [4]
6.10. Boolean operations

```
or_test ::= and_test | or_test "or" and_test
and_test ::= not_test | and_test "and" not_test
not_test ::= comparison | "not" not_test
```

In the context of Boolean operations, and also when expressions are used by control flow statements, the following values are interpreted as false: False, None, numeric zero of all types, and empty strings and containers (including strings, tuples, lists, dictionaries, sets and frozensets). All other values are interpreted as true. User-defined objects can customize their truth value by providing a `__bool__()` method.

The operator `not` yields True if its argument is false, False otherwise.

The expression `x and y` first evaluates `x`; if `x` is false, its value is returned; otherwise, `y` is evaluated and the resulting value is returned.

The expression `x or y` first evaluates `x`; if `x` is true, its value is returned; otherwise, `y` is evaluated and the resulting value is returned.

(Note that neither `and` nor `or` restrict the value and type they return to False and True, but rather return the last evaluated argument. This is sometimes useful, e.g., if `s` is a string that should be replaced by a default value if it is empty, the expression `s or 'foo'` yields the desired value. Because `not` has to invent a value anyway, it does not bother to return a value of the same type as its argument, so e.g., `not 'foo'` yields False, not '').
6.11. Conditional expressions

Conditional expressions (sometimes called a “ternary operator”) have the lowest priority of all Python operations.

The expression `x if C else y` first evaluates the condition, `C (not x)`; if `C` is true, `x` is evaluated and its value is returned; otherwise, `y` is evaluated and its value is returned.

See PEP 308 for more details about conditional expressions.
6.12. Lambdas

Lambda expressions (sometimes called lambda forms) have the same syntactic position as expressions. They are a shorthand to create anonymous functions; the expression \texttt{\texttt{lambda \ arguments: \ expression}} yields a function object. The unnamed object behaves like a function object defined with

\begin{verbatim}
def <lambda>(arguments):
    return expression
\end{verbatim}

See section \textit{Function definitions} for the syntax of parameter lists. Note that functions created with lambda expressions cannot contain statements or annotations.
6.13. Expression lists

```
expression_list ::= expression ( "," expression )* [","]
```

An expression list containing at least one comma yields a tuple. The length of the tuple is the number of expressions in the list. The expressions are evaluated from left to right.

The trailing comma is required only to create a single tuple (a.k.a. a singleton); it is optional in all other cases. A single expression without a trailing comma doesn't create a tuple, but rather yields the value of that expression. (To create an empty tuple, use an empty pair of parentheses: ().)

Python evaluates expressions from left to right. Notice that while evaluating an assignment, the right-hand side is evaluated before the left-hand side.

In the following lines, expressions will be evaluated in the arithmetic order of their suffixes:

```python
expr1, expr2, expr3, expr4
(expr1, expr2, expr3, expr4)
{expr1: expr2, expr3: expr4}
expr1 + expr2 * (expr3 - expr4)
expr1(expr2, expr3, *expr4, **expr5)
expr3, expr4 = expr1, expr2
```
# 6.15. Operator precedence

The following table summarizes the operator precedences in Python, from lowest precedence (least binding) to highest precedence (most binding). Operators in the same box have the same precedence. Unless the syntax is explicitly given, operators are binary. Operators in the same box group left to right (except for comparisons, including tests, which all have the same precedence and chain from left to right — see section *Comparisons* — and exponentiation, which groups from right to left).

Footnotes

While \( \text{abs}(x\%y) < \text{abs}(y) \) is true mathematically, for floats it may not be true numerically due to roundoff. For example, and assuming a platform on which a Python float is an IEEE 754 double-precision number, in order that \(-1e-100 \ % \ 1e100\) have the same sign as \(1e100\), the computed result is \(-1e-100 + 1e100\), which is numerically exactly equal to \(1e100\). The function `math.fmod()` returns a result whose sign matches the sign of the first argument instead, and so returns \(-1e-100\) in this case. Which approach is more appropriate depends on the application.

If \(x\) is very close to an exact integer multiple of \(y\), it’s possible for \(x\div\div y\) to be one larger than \((x-x\%y)\div y\) due to rounding.

In such cases, Python returns the latter result, in order to preserve that \(\text{divmod}(x,y)[0] \times y + x \% y\) be very close to \(x\).

While comparisons between strings make sense at the byte level, they may be counter-intuitive to users. For example, the strings "\u00C7" and "\u0327\u0043" compare differently, even though they both represent the same unicode character (LATIN CAPITAL LETTER C WITH CEDILLA). To compare strings in a human recognizable way, compare using `unicodedata.normalize()`.
Due to automatic garbage-collection, free lists, and the
dynamic nature of descriptors, you may notice seemingly
unusual behaviour in certain uses of the `is` operator, like those
involving comparisons between instance methods, or
constants. Check their documentation for more info.

The `%` operator is also used for string formatting; the same
precedence applies.

The power operator `**` binds less tightly than an arithmetic or
bitwise unary operator on its right, that is, `2**-1` is `0.5`.
7. Simple statements

Simple statements are comprised within a single logical line. Several simple statements may occur on a single line separated by semicolons. The syntax for simple statements is:

```
simple_stmt ::= expression_stmt
| assert_stmt
| assignment_stmt
| augmented_assignment_stmt
| pass_stmt
| del_stmt
| return_stmt
| yield_stmt
| raise_stmt
| break_stmt
| continue_stmt
| import_stmt
| global_stmt
| nonlocal_stmt
```
7.1. Expression statements

Expression statements are used (mostly interactively) to compute and write a value, or (usually) to call a procedure (a function that returns no meaningful result; in Python, procedures return the value None). Other uses of expression statements are allowed and occasionally useful. The syntax for an expression statement is:

```
expression_stmt ::= expression_list
```

An expression statement evaluates the expression list (which may be a single expression).

In interactive mode, if the value is not None, it is converted to a string using the built-in `repr()` function and the resulting string is written to standard output on a line by itself (except if the result is None, so that procedure calls do not cause any output.)
7.2. Assignment statements

Assignment statements are used to (re)bind names to values and to modify attributes or items of mutable objects:

\[
\text{assignment_stmt} ::= (\text{target_list} \ "\ = \")+ (\text{expression_list})
\]

\[
\text{target_list} ::= \text{target} (",\ \text{target})* [",",]
\]

\[
\text{target} ::= \text{identifier} \ | \ "(\ \text{target_list} \ )" \ | \ "[\ \text{target_list} \ ]" \ | \ \text{attributeref} \ | \ \text{subscription} \ | \ \text{slicing} \ | \ "*\ \text{target}
\]

(See section *Primaries* for the syntax definitions for the last three symbols.)

An assignment statement evaluates the expression list (remember that this can be a single expression or a comma-separated list, the latter yielding a tuple) and assigns the single resulting object to each of the target lists, from left to right.

Assignment is defined recursively depending on the form of the target (list). When a target is part of a mutable object (an attribute reference, subscription or slicing), the mutable object must ultimately perform the assignment and decide about its validity, and may raise an exception if the assignment is unacceptable. The rules observed by various types and the exceptions raised are given with the definition of the object types (see section *The standard type hierarchy*).

Assignment of an object to a target list, optionally enclosed in parentheses or square brackets, is recursively defined as follows.
• If the target list is a single target: The object is assigned to that target.
• If the target list is a comma-separated list of targets: The object must be an iterable with the same number of items as there are targets in the target list, and the items are assigned, from left to right, to the corresponding targets.
  ○ If the target list contains one target prefixed with an asterisk, called a “starred” target: The object must be a sequence with at least as many items as there are targets in the target list, minus one. The first items of the sequence are assigned, from left to right, to the targets before the starred target. The final items of the sequence are assigned to the targets after the starred target. A list of the remaining items in the sequence is then assigned to the starred target (the list can be empty).
  ○ Else: The object must be a sequence with the same number of items as there are targets in the target list, and the items are assigned, from left to right, to the corresponding targets.

Assignment of an object to a single target is recursively defined as follows.

• If the target is an identifier (name):
  ○ If the name does not occur in a `global` or `nonlocal` statement in the current code block: the name is bound to the object in the current local namespace.
  ○ Otherwise: the name is bound to the object in the global namespace or the outer namespace determined by `nonlocal`, respectively.

The name is rebound if it was already bound. This may cause the reference count for the object previously bound to the name to reach zero, causing the object to be deallocated and its destructor
(if it has one) to be called.

- If the target is a target list enclosed in parentheses or in square brackets: The object must be an iterable with the same number of items as there are targets in the target list, and its items are assigned, from left to right, to the corresponding targets.

- If the target is an attribute reference: The primary expression in the reference is evaluated. It should yield an object with assignable attributes; if this is not the case, `TypeError` is raised. That object is then asked to assign the assigned object to the given attribute; if it cannot perform the assignment, it raises an exception (usually but not necessarily `AttributeError`).

Note: If the object is a class instance and the attribute reference occurs on both sides of the assignment operator, the RHS expression, `a.x` can access either an instance attribute or (if no instance attribute exists) a class attribute. The LHS target `a.x` is always set as an instance attribute, creating it if necessary. Thus, the two occurrences of `a.x` do not necessarily refer to the same attribute: if the RHS expression refers to a class attribute, the LHS creates a new instance attribute as the target of the assignment:

```python
class Cls:  
    x = 3       # class variable
inst = Cls()  
inst.x = inst.x + 1  # writes inst.x as 4 leaving Cls.x as 3
```

This description does not necessarily apply to descriptor attributes, such as properties created with `property()`.

- If the target is a subscription: The primary expression in the reference is evaluated. It should yield either a mutable sequence
object (such as a list) or a mapping object (such as a dictionary). Next, the subscript expression is evaluated.

If the primary is a mutable sequence object (such as a list), the subscript must yield an integer. If it is negative, the sequence's length is added to it. The resulting value must be a nonnegative integer less than the sequence's length, and the sequence is asked to assign the assigned object to its item with that index. If the index is out of range, IndexError is raised (assignment to a subscripted sequence cannot add new items to a list).

If the primary is a mapping object (such as a dictionary), the subscript must have a type compatible with the mapping's key type, and the mapping is then asked to create a key/datum pair which maps the subscript to the assigned object. This can either replace an existing key/value pair with the same key value, or insert a new key/value pair (if no key with the same value existed).

For user-defined objects, the __setitem__() method is called with appropriate arguments.

- If the target is a slicing: The primary expression in the reference is evaluated. It should yield a mutable sequence object (such as a list). The assigned object should be a sequence object of the same type. Next, the lower and upper bound expressions are evaluated, insofar they are present; defaults are zero and the sequence's length. The bounds should evaluate to integers. If either bound is negative, the sequence's length is added to it. The resulting bounds are clipped to lie between zero and the sequence's length, inclusive. Finally, the sequence object is asked to replace the slice with the items of the assigned sequence. The length of the slice may be different from the length of the assigned
sequence, thus changing the length of the target sequence, if the object allows it.

**CPython implementation detail:** In the current implementation, the syntax for targets is taken to be the same as for expressions, and invalid syntax is rejected during the code generation phase, causing less detailed error messages.

**WARNING:** Although the definition of assignment implies that overlaps between the left-hand side and the right-hand side are ‘safe’ (for example `a, b = b, a` swaps two variables), overlaps within the collection of assigned-to variables are not safe! For instance, the following program prints `[0, 2]`:

```python
x = [0, 1]
i = 0
i, x[i] = 1, 2
print(x)
```

**See also:**

**PEP 3132 - Extended Iterable Unpacking**
The specification for the `*target` feature.

### 7.2.1. Augmented assignment statements

Augmented assignment is the combination, in a single statement, of a binary operation and an assignment statement:

```plaintext
augmented_assignment_stmt ::= augtarget augop (exp)
augtarget ::= identifier | attribut
augop ::= "+=" | "-=" | "/=" | "/=" | "/=" | "/=" | "+=" | "-=" | "*=" | "*=" |
```
(See section *Primaries* for the syntax definitions for the last three symbols.)

An augmented assignment evaluates the target (which, unlike normal assignment statements, cannot be an unpacking) and the expression list, performs the binary operation specific to the type of assignment on the two operands, and assigns the result to the original target. The target is only evaluated once.

An augmented assignment expression like `x += 1` can be rewritten as `x = x + 1` to achieve a similar, but not exactly equal effect. In the augmented version, `x` is only evaluated once. Also, when possible, the actual operation is performed *in-place*, meaning that rather than creating a new object and assigning that to the target, the old object is modified instead.

With the exception of assigning to tuples and multiple targets in a single statement, the assignment done by augmented assignment statements is handled the same way as normal assignments. Similarly, with the exception of the possible *in-place* behavior, the binary operation performed by augmented assignment is the same as the normal binary operations.

For targets which are attribute references, the same *caveat about class and instance attributes* applies as for regular assignments.
7.3. The `assert` statement

Assert statements are a convenient way to insert debugging assertions into a program:

```
assert_stmt ::= "assert" expression ["," expression]
```

The simple form, `assert expression`, is equivalent to

```
if __debug__:
    if not expression: raise AssertionError
```

The extended form, `assert expression1, expression2`, is equivalent to

```
if __debug__:
    if not expression1: raise AssertionError(expression2)
```

These equivalences assume that `__debug__` and `AssertionError` refer to the built-in variables with those names. In the current implementation, the built-in variable `__debug__` is True under normal circumstances, False when optimization is requested (command line option -O). The current code generator emits no code for an assert statement when optimization is requested at compile time. Note that it is unnecessary to include the source code for the expression that failed in the error message; it will be displayed as part of the stack trace.

Assignments to `__debug__` are illegal. The value for the built-in variable is determined when the interpreter starts.
7.4. The **pass** statement

```python
pass_stmt ::= "pass"
```

**pass** is a null operation — when it is executed, nothing happens. It is useful as a placeholder when a statement is required syntactically, but no code needs to be executed, for example:

```python
def f(arg): pass  # a function that does nothing

class C: pass     # a class with no methods (yet)
```
7.5. The `del` statement

```
    del_stmt ::= "del" target_list
```

Deletion is recursively defined very similar to the way assignment is defined. Rather than spelling it out in full details, here are some hints.

Deletion of a target list recursively deletes each target, from left to right.

Deletion of a name removes the binding of that name from the local or global namespace, depending on whether the name occurs in a `global` statement in the same code block. If the name is unbound, a `NameError` exception will be raised.

Deletion of attribute references, subscriptions and slicings is passed to the primary object involved; deletion of a slicing is in general equivalent to assignment of an empty slice of the right type (but even this is determined by the sliced object).

*Changed in version 3.2:* Previously it was illegal to delete a name from the local namespace if it occurs as a free variable in a nested block.
7.6. The `return` statement

```plaintext
return_stmt ::= "return" [expression_list]
```

`return` may only occur syntactically nested in a function definition, not within a nested class definition.

If an expression list is present, it is evaluated, else None is substituted.

`return` leaves the current function call with the expression list (or None) as return value.

When `return` passes control out of a `try` statement with a `finally` clause, that `finally` clause is executed before really leaving the function.

In a generator function, the `return` statement indicates that the generator is done and will cause `StopIteration` to be raised. The returned value (if any) is used as an argument to construct `StopIteration` and becomes the `StopIteration.value` attribute.
7.7. The `yield` statement

```
yield_stmt ::= yield_expression
```

The `yield` statement is only used when defining a generator function, and is only used in the body of the generator function. Using a `yield` statement in a function definition is sufficient to cause that definition to create a generator function instead of a normal function.

When a generator function is called, it returns an iterator known as a generator iterator, or more commonly, a generator. The body of the generator function is executed by calling the `next()` function on the generator repeatedly until it raises an exception.

When a `yield` statement is executed, the state of the generator is frozen and the value of `expression_list` is returned to `next()`'s caller. By “frozen” we mean that all local state is retained, including the current bindings of local variables, the instruction pointer, and the internal evaluation stack: enough information is saved so that the next time `next()` is invoked, the function can proceed exactly as if the `yield` statement were just another external call.

The `yield` statement is allowed in the `try` clause of a `try` ... `finally` construct. If the generator is not resumed before it is finalized (by reaching a zero reference count or by being garbage collected), the generator-iterator’s `close()` method will be called, allowing any pending `finally` clauses to execute.

When `yield from <expr>` is used, it treats the supplied expression as a subiterator, producing values from it until the underlying iterator is exhausted.
Changed in version 3.3: Added `yield from <expr>` to delegate control flow to a subiterator

For full details of `yield` semantics, refer to the *Yield expressions* section.

**PEP 0342 - Coroutines via Enhanced Generators**
The proposal to enhance the API and syntax of generators, making them usable as simple coroutines.

**PEP 0380 - Syntax for Delegating to a Subgenerator**
The proposal to introduce the `yield_from` syntax, making delegation to sub-generators easy.
7.8. The `raise` statement

```
raiseStmt ::= "raise" [expression ["from" expression]]
```

If no expressions are present, `raise` re-raises the last exception that was active in the current scope. If no exception is active in the current scope, a `RuntimeError` exception is raised indicating that this is an error.

Otherwise, `raise` evaluates the first expression as the exception object. It must be either a subclass or an instance of `BaseException`. If it is a class, the exception instance will be obtained when needed by instantiating the class with no arguments.

The `type` of the exception is the exception instance’s class, the `value` is the instance itself.

A traceback object is normally created automatically when an exception is raised and attached to it as the `__traceback__` attribute, which is writable. You can create an exception and set your own traceback in one step using the `with_traceback()` exception method (which returns the same exception instance, with its traceback set to its argument), like so:

```
raise Exception("foo occurred").with_traceback(tracebackobj)
```

The `from` clause is used for exception chaining: if given, the second `expression` must be another exception class or instance, which will then be attached to the raised exception as the `__cause__` attribute (which is writable). If the raised exception is not handled, both
exceptions will be printed:

```python
>>> try:
...     print(1 / 0)
... except Exception as exc:
...     raise RuntimeError("Something bad happened")
```

Traceback (most recent call last):
  File "<stdin>", line 2, in <module>
ZeroDivisionError: int division or modulo by zero

The above exception was the direct cause of the following exception:

Traceback (most recent call last):
  File "<stdin>", line 4, in <module>
RuntimeError: Something bad happened

A similar mechanism works implicitly if an exception is raised inside an exception handler: the previous exception is then attached as the new exception's `__context__` attribute:

```python
>>> try:
...     print(1 / 0)
... except:
...     raise RuntimeError("Something bad happened")
```

Traceback (most recent call last):
  File "<stdin>", line 2, in <module>
ZeroDivisionError: int division or modulo by zero

During handling of the above exception, another exception occurred:

Traceback (most recent call last):
  File "<stdin>", line 4, in <module>
RuntimeError: Something bad happened
Additional information on exceptions can be found in section *Exceptions*, and information about handling exceptions is in section *The try statement*. 
7.9. The **break** statement

**break_stmt** ::= "break"

**break** may only occur syntactically nested in a **for** or **while** loop, but not nested in a function or class definition within that loop.

It terminates the nearest enclosing loop, skipping the optional **else** clause if the loop has one.

If a **for** loop is terminated by **break**, the loop control target keeps its current value.

When **break** passes control out of a **try** statement with a **finally** clause, that **finally** clause is executed before really leaving the loop.
7.10. The `continue` statement

```
continue_stmt ::= "continue"
```

`continue` may only occur syntactically nested in a `for` or `while` loop, but not nested in a function or class definition or `finally` clause within that loop. It continues with the next cycle of the nearest enclosing loop.

When `continue` passes control out of a `try` statement with a `finally` clause, that `finally` clause is executed before really starting the next loop cycle.
7.11. The `import` statement

The basic import statement (no `from` clause) is executed in two steps:

1. find a module, loading and initializing it if necessary
2. define a name or names in the local namespace for the scope where the `import` statement occurs.

When the statement contains multiple clauses (separated by commas) the two steps are carried out separately for each clause, just as though the clauses had been separated out into individual import statements.

The details of the first step, finding and loading modules is described in greater detail in the section on the `import system`, which also describes the various types of packages and modules that can be imported, as well as all the hooks that can be used to customize the import system. Note that failures in this step may indicate either that the module could not be located, or that an error occurred while initializing the module, which includes execution of the module's code.

If the requested module is retrieved successfully, it will be made available in the local namespace in one of three ways:
If the module name is followed by `as`, then the name following `as` is bound directly to the imported module.

If no other name is specified, and the module being imported is a top level module, the module’s name is bound in the local namespace as a reference to the imported module.

If the module being imported is not a top level module, then the name of the top level package that contains the module is bound in the local namespace as a reference to the top level package. The imported module must be accessed using its full qualified name rather than directly.

The `from` form uses a slightly more complex process:

1. find the module specified in the `from` clause loading and initializing it if necessary;
2. for each of the identifiers specified in the `import` clauses:
   1. check if the imported module has an attribute by that name
   2. if not, attempt to import a submodule with that name and then check the imported module again for that attribute
   3. if the attribute is not found, `ImportError` is raised.
   4. otherwise, a reference to that value is bound in the local namespace, using the name in the `as` clause if it is present, otherwise using the attribute name.

Examples:

```python
import foo  # foo imported and bound
import foo.bar.baz  # foo.bar.baz imported, foo bound locally
import foo.bar.baz as fbb  # foo.bar.baz imported and bound as fbb
from foo.bar import baz  # foo.bar.baz imported and bound as baz
from foo import attr  # foo imported and foo.attr bound as attr
```

If the list of identifiers is replaced by a star (`'*'`), all public names
defined in the module are bound in the local namespace for the scope where the `import` statement occurs.

The *public names* defined by a module are determined by checking the module’s namespace for a variable named `__all__`; if defined, it must be a sequence of strings which are names defined or imported by that module. The names given in `__all__` are all considered public and are required to exist. If `__all__` is not defined, the set of public names includes all names found in the module's namespace which do not begin with an underscore character (`'_'`). `__all__` should contain the entire public API. It is intended to avoid accidentally exporting items that are not part of the API (such as library modules which were imported and used within the module).

The `from` form with `*` may only occur in a module scope. The wildcard form of import — `import *` — is only allowed at the module level. Attempting to use it in class or function definitions will raise a `SyntaxError`.

When specifying what module to import you do not have to specify the absolute name of the module. When a module or package is contained within another package it is possible to make a relative import within the same top package without having to mention the package name. By using leading dots in the specified module or package after `from` you can specify how high to traverse up the current package hierarchy without specifying exact names. One leading dot means the current package where the module making the import exists. Two dots means up one package level. Three dots is up two levels, etc. So if you execute `from . import mod` from a module in the `pkg` package then you will end up importing `pkg.mod`. If you execute `from ..subpkg2 import mod` from within `pkg.subpkg1` you will import `pkg.subpkg2.mod`. The specification for relative imports is contained
within PEP 328.

importlib.import_module() is provided to support applications that determine which modules need to be loaded dynamically.

7.11.1. Future statements

A future statement is a directive to the compiler that a particular module should be compiled using syntax or semantics that will be available in a specified future release of Python. The future statement is intended to ease migration to future versions of Python that introduce incompatible changes to the language. It allows use of the new features on a per-module basis before the release in which the feature becomes standard.

```
future_statement ::= "from" "__future__" "import" f
                                                                     ("," feature ["as" name]]* |
                                                                      "from" "__future__" "import"
                                                                         ("," feature ["as" name]]* [",

feature                           ::=  identifier
name                              ::=  identifier
```

A future statement must appear near the top of the module. The only lines that can appear before a future statement are:

- the module docstring (if any),
- comments,
- blank lines, and
- other future statements.

The features recognized by Python 3.0 are absolute_import, division, generators, unicode_literals, print_function, nested_scopes and with_statement. They are all redundant
because they are always enabled, and only kept for backwards compatibility.

A future statement is recognized and treated specially at compile time: Changes to the semantics of core constructs are often implemented by generating different code. It may even be the case that a new feature introduces new incompatible syntax (such as a new reserved word), in which case the compiler may need to parse the module differently. Such decisions cannot be pushed off until runtime.

For any given release, the compiler knows which feature names have been defined, and raises a compile-time error if a future statement contains a feature not known to it.

The direct runtime semantics are the same as for any import statement: there is a standard module `__future__`, described later, and it will be imported in the usual way at the time the future statement is executed.

The interesting runtime semantics depend on the specific feature enabled by the future statement.

Note that there is nothing special about the statement:

```python
import __future__ [as name]
```

That is not a future statement; it's an ordinary import statement with no special semantics or syntax restrictions.

Code compiled by calls to the built-in functions `exec()` and `compile()` that occur in a module `M` containing a future statement will, by default, use the new syntax or semantics associated with the future statement. This can be controlled by optional arguments to
compile() — see the documentation of that function for details.

A future statement typed at an interactive interpreter prompt will take effect for the rest of the interpreter session. If an interpreter is started with the `-i` option, is passed a script name to execute, and the script includes a future statement, it will be in effect in the interactive session started after the script is executed.

**PEP 236 - Back to the __future__**

The original proposal for the __future__ mechanism.
7.12. The **global** statement

```plaintext
global_stmt ::= "global" identifier ("," identifier)*
```

The **global** statement is a declaration which holds for the entire current code block. It means that the listed identifiers are to be interpreted as globals. It would be impossible to assign to a global variable without **global**, although free variables may refer to globals without being declared global.

Names listed in a **global** statement must not be used in the same code block textually preceding that **global** statement.

Names listed in a **global** statement must not be defined as formal parameters or in a **for** loop control target, **class** definition, function definition, or **import** statement.

**CPython implementation detail:** The current implementation does not enforce the latter two restrictions, but programs should not abuse this freedom, as future implementations may enforce them or silently change the meaning of the program.

**Programmer's note:** the **global** is a directive to the parser. It applies only to code parsed at the same time as the **global** statement. In particular, a **global** statement contained in a string or code object supplied to the built-in **exec()** function does not affect the code block containing the function call, and code contained in such a string is unaffected by **global** statements in the code containing the function call. The same applies to the **eval()** and **compile()** functions.
7.13. The `nonlocal` statement

```
nonlocal_stmt ::= "nonlocal" identifier ("," identifier)*
```

The `nonlocal` statement causes the listed identifiers to refer to previously bound variables in the nearest enclosing scope. This is important because the default behavior for binding is to search the local namespace first. The statement allows encapsulated code to rebind variables outside of the local scope besides the global (module) scope.

Names listed in a `nonlocal` statement, unlike to those listed in a `global` statement, must refer to pre-existing bindings in an enclosing scope (the scope in which a new binding should be created cannot be determined unambiguously).

Names listed in a `nonlocal` statement must not collide with pre-existing bindings in the local scope.

**See also:**

**PEP 3104 - Access to Names in Outer Scopes**

The specification for the `nonlocal` statement.
8. Compound statements

Compound statements contain (groups of) other statements; they affect or control the execution of those other statements in some way. In general, compound statements span multiple lines, although in simple incarnations a whole compound statement may be contained in one line.

The `if`, `while` and `for` statements implement traditional control flow constructs. `try` specifies exception handlers and/or cleanup code for a group of statements, while the `with` statement allows the execution of initialization and finalization code around a block of code. Function and class definitions are also syntactically compound statements.

Compound statements consist of one or more ‘clauses.’ A clause consists of a header and a ‘suite.’ The clause headers of a particular compound statement are all at the same indentation level. Each clause header begins with a uniquely identifying keyword and ends with a colon. A suite is a group of statements controlled by a clause. A suite can be one or more semicolon-separated simple statements on the same line as the header, following the header’s colon, or it can be one or more indented statements on subsequent lines. Only the latter form of suite can contain nested compound statements; the following is illegal, mostly because it wouldn’t be clear to which `if` clause a following `else` clause would belong:

```
if test1: if test2: print(x)
```

Also note that the semicolon binds tighter than the colon in this context, so that in the following example, either all or none of the `print()` calls are executed:
if x < y < z: print(x); print(y); print(z)

Summarizing:

```
compound_stmt ::= if_stmt |
                    while_stmt |
                    for_stmt |
                    try_stmt |
                    with_stmt |
                    funcdef |
                    classdef
suite ::= stmt_list NEWLINE | NEWLINE INDENT
statement ::= stmt_list NEWLINE | compound_stmt
stmt_list ::= stmt_list (;) stmt_list |
```

Note that statements always end in a NEWLINE possibly followed by a DEDENT. Also note that optional continuation clauses always begin with a keyword that cannot start a statement, thus there are no ambiguities (the ‘dangling else‘ problem is solved in Python by requiring nested if statements to be indented).

The formatting of the grammar rules in the following sections places each clause on a separate line for clarity.
8.1. The if statement

The if statement is used for conditional execution:

```
if_stmt ::= "if" expression ":" suite
( "elif" expression ":" suite )*
["else" ":" suite]
```

It selects exactly one of the suites by evaluating the expressions one by one until one is found to be true (see section Boolean operations for the definition of true and false); then that suite is executed (and no other part of the if statement is executed or evaluated). If all expressions are false, the suite of the else clause, if present, is executed.
8.2. The **while** statement

The **while** statement is used for repeated execution as long as an expression is true:

```
while_stmt ::= "while" expression ":" suite
              ["else" ":" suite]
```

This repeatedly tests the expression and, if it is true, executes the first suite; if the expression is false (which may be the first time it is tested) the suite of the **else** clause, if present, is executed and the loop terminates.

A **break** statement executed in the first suite terminates the loop without executing the **else** clause's suite. A **continue** statement executed in the first suite skips the rest of the suite and goes back to testing the expression.
8.3. The **for** statement

The **for** statement is used to iterate over the elements of a sequence (such as a string, tuple or list) or other iterable object:

```
for_stmt ::= "for" target_list "in" expression_list
            ["else" "::" suite]
```

The expression list is evaluated once; it should yield an iterable object. An iterator is created for the result of the `expression_list`. The suite is then executed once for each item provided by the iterator, in the order of ascending indices. Each item in turn is assigned to the target list using the standard rules for assignments (see *Assignment statements*), and then the suite is executed. When the items are exhausted (which is immediately when the sequence is empty or an iterator raises a `StopIteration` exception), the suite in the `else` clause, if present, is executed, and the loop terminates.

A **break** statement executed in the first suite terminates the loop without executing the `else` clause’s suite. A **continue** statement executed in the first suite skips the rest of the suite and continues with the next item, or with the `else` clause if there was no next item.

The suite may assign to the variable(s) in the target list; this does not affect the next item assigned to it.

Names in the target list are not deleted when the loop is finished, but if the sequence is empty, it will not have been assigned to at all by the loop. Hint: the built-in function `range()` returns an iterator of integers suitable to emulate the effect of Pascal’s `for i := a to b do;` e.g., `list(range(3))` returns the list `[0, 1, 2]`. 
Note: There is a subtlety when the sequence is being modified by the loop (this can only occur for mutable sequences, i.e. lists). An internal counter is used to keep track of which item is used next, and this is incremented on each iteration. When this counter has reached the length of the sequence the loop terminates. This means that if the suite deletes the current (or a previous) item from the sequence, the next item will be skipped (since it gets the index of the current item which has already been treated). Likewise, if the suite inserts an item in the sequence before the current item, the current item will be treated again the next time through the loop. This can lead to nasty bugs that can be avoided by making a temporary copy using a slice of the whole sequence, e.g.,

```python
for x in a[:]:
    if x < 0: a.remove(x)
```
8.4. The **try** statement

The **try** statement specifies exception handlers and/or cleanup code for a group of statements:

```
try_stmt ::= try1_stmt | try2_stmt
try1_stmt ::= "try" ":" suite
             ("except" [expression ["as" target]]
              ["else" ":" suite]
              ["finally" ":" suite]
try2_stmt ::= "try" ":" suite
              "finally" ":" suite
```

The **except** clause(s) specify one or more exception handlers. When no exception occurs in the **try** clause, no exception handler is executed. When an exception occurs in the **try** suite, a search for an exception handler is started. This search inspects the except clauses in turn until one is found that matches the exception. An expression-less except clause, if present, must be last; it matches any exception. For an except clause with an expression, that expression is evaluated, and the clause matches the exception if the resulting object is “compatible” with the exception. An object is compatible with an exception if it is the class or a base class of the exception object or a tuple containing an item compatible with the exception.

If no except clause matches the exception, the search for an exception handler continues in the surrounding code and on the invocation stack. [1]

If the evaluation of an expression in the header of an except clause raises an exception, the original search for a handler is canceled and a search starts for the new exception in the surrounding code and on the
call stack (it is treated as if the entire try statement raised the exception).

When a matching except clause is found, the exception is assigned to the target specified after the as keyword in that except clause, if present, and the except clause's suite is executed. All except clauses must have an executable block. When the end of this block is reached, execution continues normally after the entire try statement. (This means that if two nested handlers exist for the same exception, and the exception occurs in the try clause of the inner handler, the outer handler will not handle the exception.)

When an exception has been assigned using as target, it is cleared at the end of the except clause. This is as if

```python
except E as N:
    foo
```

was translated to

```python
except E as N:
    try:
        foo
    finally:
        del N
```

This means the exception must be assigned to a different name to be able to refer to it after the except clause. Exceptions are cleared because with the traceback attached to them, they form a reference cycle with the stack frame, keeping all locals in that frame alive until the next garbage collection occurs.

Before an except clause’s suite is executed, details about the exception are stored in the sys module and can be access via
sys.exc_info(). sys.exc_info() returns a 3-tuple consisting of the exception class, the exception instance and a traceback object (see section *The standard type hierarchy*) identifying the point in the program where the exception occurred. sys.exc_info() values are restored to their previous values (before the call) when returning from a function that handled an exception.

The optional else clause is executed if and when control flows off the end of the try clause. [2] Exceptions in the else clause are not handled by the preceding except clauses.

If finally is present, it specifies a ‘cleanup’ handler. The try clause is executed, including any except and else clauses. If an exception occurs in any of the clauses and is not handled, the exception is temporarily saved. The finally clause is executed. If there is a saved exception it is re-raised at the end of the finally clause. If the finally clause raises another exception, the saved exception is set as the context of the new exception. If the finally clause executes a return or break statement, the saved exception is discarded:

```
def f():
    try:
        1/0
    finally:
        return 42

>>> f()
42
```

The exception information is not available to the program during execution of the finally clause.

When a return, break or continue statement is executed in the
try suite of a try...finally statement, the finally clause is also executed 'on the way out.' A continue statement is illegal in the finally clause. (The reason is a problem with the current implementation — this restriction may be lifted in the future).

Additional information on exceptions can be found in section Exceptions, and information on using the raise statement to generate exceptions may be found in section The raise statement.
8.5. The `with` statement

The `with` statement is used to wrap the execution of a block with methods defined by a context manager (see section *With Statement Context Managers*). This allows common `try...except...finally` usage patterns to be encapsulated for convenient reuse.

```plaintext
with_stmt ::= "with" with_item ("," with_item)* "":"
with_item ::= expression ["as" target]
```

The execution of the `with` statement with one “item” proceeds as follows:

1. The context expression (the expression given in the `with_item`) is evaluated to obtain a context manager.

2. The context manager’s `__exit__()` is loaded for later use.

3. The context manager’s `__enter__()` method is invoked.

4. If a target was included in the `with` statement, the return value from `__enter__()` is assigned to it.

   **Note:** The `with` statement guarantees that if the `__enter__()` method returns without an error, then `__exit__()` will always be called. Thus, if an error occurs during the assignment to the target list, it will be treated the same as an error occurring within the suite would be. See step 6 below.

5. The suite is executed.
6. The context manager's \texttt{\_\_exit\_\_()} method is invoked. If an exception caused the suite to be exited, its type, value, and traceback are passed as arguments to \texttt{\_\_exit\_\_()}. Otherwise, three \texttt{None} arguments are supplied.

   If the suite was exited due to an exception, and the return value from the \texttt{\_\_exit\_\_()} method was false, the exception is rerased. If the return value was true, the exception is suppressed, and execution continues with the statement following the \texttt{with} statement.

   If the suite was exited for any reason other than an exception, the return value from \texttt{\_\_exit\_\_()} is ignored, and execution proceeds at the normal location for the kind of exit that was taken.

With more than one item, the context managers are processed as if multiple \texttt{with} statements were nested:

\begin{verbatim}
with A() as a, B() as b:
suite
\end{verbatim}

is equivalent to

\begin{verbatim}
with A() as a:
    with B() as b:
        suite
\end{verbatim}

\textit{Changed in version 3.1:} Support for multiple context expressions.

\textbf{See also:}

\textbf{PEP 0343 - The “with” statement}

The specification, background, and examples for the Python
with statement.
8.6. Function definitions

A function definition defines a user-defined function object (see section *The standard type hierarchy*):

```
funcdef ::= [decorators] "def" funcname "(" [parameter_list] ")"
decorators ::= decorator+
decorator ::= "@" dotted_name ["(" [parameter_list] ")]"
dotted_name ::= identifier ("." identifier)*
parameter_list ::= (defparameter ",")*
| "**" [parameter] ("," defparameter | "**" parameter | defparameter ["," ] )
| parameter [":" expression]
defparameter ::= parameter ["=" expression]
funcname ::= identifier
```

A function definition is an executable statement. Its execution binds the function name in the current local namespace to a function object (a wrapper around the executable code for the function). This function object contains a reference to the current global namespace as the global namespace to be used when the function is called.

The function definition does not execute the function body; this gets executed only when the function is called. [3]

A function definition may be wrapped by one or more *decorator* expressions. Decorator expressions are evaluated when the function is defined, in the scope that contains the function definition. The result must be a callable, which is invoked with the function object as the only argument. The returned value is bound to the function name instead of the function object. Multiple decorators are applied in nested fashion. For example, the following code
is equivalent to

```python
def func():
    pass
```

When one or more *parameters* have the form `parameter = expression`, the function is said to have “default parameter values.” For a parameter with a default value, the corresponding *argument* may be omitted from a call, in which case the parameter's default value is substituted. If a parameter has a default value, all following parameters up until the `*` must also have a default value — this is a syntactic restriction that is not expressed by the grammar.

**Default parameter values are evaluated when the function definition is executed.** This means that the expression is evaluated once, when the function is defined, and that the same “pre-computed” value is used for each call. This is especially important to understand when a default parameter is a mutable object, such as a list or a dictionary: if the function modifies the object (e.g. by appending an item to a list), the default value is in effect modified. This is generally not what was intended. A way around this is to use `None` as the default, and explicitly test for it in the body of the function, e.g.:

```python
def whats_on_the_telly(penguin=None):
    if penguin is None:
        penguin = []
        penguin.append("property of the zoo")
    return penguin
```
Function call semantics are described in more detail in section *Calls*. A function call always assigns values to all parameters mentioned in the parameter list, either from position arguments, from keyword arguments, or from default values. If the form “*identifier” is present, it is initialized to a tuple receiving any excess positional parameters, defaulting to the empty tuple. If the form “**identifier” is present, it is initialized to a new dictionary receiving any excess keyword arguments, defaulting to a new empty dictionary. Parameters after “*” or “*identifier” are keyword-only parameters and may only be passed used keyword arguments.

Parameters may have annotations of the form “: expression” following the parameter name. Any parameter may have an annotation even those of the form *identifier or **identifier. Functions may have “return” annotation of the form “-> expression” after the parameter list. These annotations can be any valid Python expression and are evaluated when the function definition is executed. Annotations may be evaluated in a different order than they appear in the source code. The presence of annotations does not change the semantics of a function. The annotation values are available as values of a dictionary keyed by the parameters’ names in the __annotations__ attribute of the function object.

It is also possible to create anonymous functions (functions not bound to a name), for immediate use in expressions. This uses lambda expressions, described in section *Lambdas*. Note that the lambda expression is merely a shorthand for a simplified function definition; a function defined in a “def” statement can be passed around or assigned to another name just like a function defined by a lambda expression. The “def” form is actually more powerful since it allows the execution of multiple statements and annotations.
**Programmer’s note:** Functions are first-class objects. A “`def`” statement executed inside a function definition defines a local function that can be returned or passed around. Free variables used in the nested function can access the local variables of the function containing the def. See section *Naming and binding* for details.

**See also:**

**PEP 3107 - Function Annotations**

The original specification for function annotations.
8.7. Class definitions

A class definition defines a class object (see section *The standard type hierarchy*):

```
classdef ::= [decorators] "class" classname [inheritance]
inheritance ::= "(" [parameter_list] ")"
classname ::= identifier
```

A class definition is an executable statement. The inheritance list usually gives a list of base classes (see *Customizing class creation* for more advanced uses), so each item in the list should evaluate to a class object which allows subclassing. Classes without an inheritance list inherit, by default, from the base class `object`; hence,

```
class Foo:
    pass
```

is equivalent to

```
class Foo(object):
    pass
```

The class's suite is then executed in a new execution frame (see *Naming and binding*), using a newly created local namespace and the original global namespace. (Usually, the suite contains mostly function definitions.) When the class's suite finishes execution, its execution frame is discarded but its local namespace is saved. [4] A class object is then created using the inheritance list for the base classes and the saved local namespace for the attribute dictionary. The class name is bound to this class object in the original local namespace.
Class creation can be customized heavily using *metaclasses*.

Classes can also be decorated: just like when decorating functions,

```python
@f1(arg)
@f2
class Foo: pass
```

is equivalent to

```python
class Foo: pass
Foo = f1(arg)(f2(Foo))
```

The evaluation rules for the decorator expressions are the same as for function decorators. The result must be a class object, which is then bound to the class name.

**Programmer's note:** Variables defined in the class definition are class attributes; they are shared by instances. Instance attributes can be set in a method with `self.name = value`. Both class and instance attributes are accessible through the notation “`self.name`”, and an instance attribute hides a class attribute with the same name when accessed in this way. Class attributes can be used as defaults for instance attributes, but using mutable values there can lead to unexpected results. *Descriptors* can be used to create instance variables with different implementation details.

PEP 3115 - Metaclasses in Python 3  
PEP 3129 - Class Decorators

**Footnotes**

The exception is propagated to the invocation stack unless
there is a **finally** clause which happens to raise another exception. That new exception causes the old one to be lost.

Currently, control “flows off the end” except in the case of an exception or the execution of a **return**, **continue**, or **break** statement.

A string literal appearing as the first statement in the function body is transformed into the function’s `__doc__` attribute and therefore the function’s **docstring**.

A string literal appearing as the first statement in the class body is transformed into the namespace’s `__doc__` item and therefore the class's **docstring**.
9. Top-level components

The Python interpreter can get its input from a number of sources: from a script passed to it as standard input or as program argument, typed in interactively, from a module source file, etc. This chapter gives the syntax used in these cases.
9.1. Complete Python programs

While a language specification need not prescribe how the language interpreter is invoked, it is useful to have a notion of a complete Python program. A complete Python program is executed in a minimally initialized environment: all built-in and standard modules are available, but none have been initialized, except for \texttt{sys} (various system services), \texttt{builtins} (built-in functions, exceptions and \texttt{None}) and \texttt{\_\_main\_\_}. The latter is used to provide the local and global namespace for execution of the complete program.

The syntax for a complete Python program is that for file input, described in the next section.

The interpreter may also be invoked in interactive mode; in this case, it does not read and execute a complete program but reads and executes one statement (possibly compound) at a time. The initial environment is identical to that of a complete program; each statement is executed in the namespace of \texttt{\_\_main\_\_}.

Under Unix, a complete program can be passed to the interpreter in three forms: with the \texttt{-c string} command line option, as a file passed as the first command line argument, or as standard input. If the file or standard input is a tty device, the interpreter enters interactive mode; otherwise, it executes the file as a complete program.
9.2. File input

All input read from non-interactive files has the same form:

\[
\text{file_input ::= (NEWLINE | statement)}^*\]

This syntax is used in the following situations:

- when parsing a complete Python program (from a file or from a string);
- when parsing a module;
- when parsing a string passed to the `exec()` function;
9.3. Interactive input

Input in interactive mode is parsed using the following grammar:

```
interactive_input ::= [stmt_list] NEWLINE | compound
```

Note that a (top-level) compound statement must be followed by a blank line in interactive mode; this is needed to help the parser detect the end of the input.
9.4. Expression input

There are two forms of expression input. Both ignore leading whitespace. The string argument to `eval()` must have the following form:

```
expr = expression_list \n
Note: to read ‘raw’ input line without interpretation, you can use the `readline()` method of file objects, including `sys.stdin`.
```
10. Full Grammar specification

This is the full Python grammar, as it is read by the parser generator and used to parse Python source files:

```python
# Grammar for Python

# Note: Changing the grammar specified in this file
#  require corresponding changes in the parser
#  (../Modules/parsermodule.c). If you can't
#  that module yourself, please co-ordinate the
#  with someone who can; ask around on python-dev
#  Drake <fdrake@acm.org> will probably be list

# NOTE WELL: You should also follow all the steps list
# "How to Change Python's Grammar"

# Start symbols for the grammar:
#   single_input is a single interactive statement
#   file_input is a module or sequence of commands
#   eval_input is the input for the eval() function
# NB: compound_stmt in single_input is followed by an

Last updated on Nov 11, 2013. Found a bug?
1. Introduction

The “Python library” contains several different kinds of components.

It contains data types that would normally be considered part of the “core” of a language, such as numbers and lists. For these types, the Python language core defines the form of literals and places some constraints on their semantics, but does not fully define the semantics. (On the other hand, the language core does define syntactic properties like the spelling and priorities of operators.)

The library also contains built-in functions and exceptions — objects that can be used by all Python code without the need of an `import` statement. Some of these are defined by the core language, but many are not essential for the core semantics and are only described here.

The bulk of the library, however, consists of a collection of modules. There are many ways to dissect this collection. Some modules are written in C and built in to the Python interpreter; others are written in Python and imported in source form. Some modules provide interfaces that are highly specific to Python, like printing a stack trace; some provide interfaces that are specific to particular operating systems, such as access to specific hardware; others provide interfaces that are specific to a particular application domain, like the World Wide Web. Some modules are available in all versions and ports of Python; others are only available when the underlying system supports or requires them; yet others are available only when a particular configuration option was chosen at the time when Python was compiled and installed.

This manual is organized “from the inside out:” it first describes the
built-in data types, then the built-in functions and exceptions, and finally the modules, grouped in chapters of related modules. The ordering of the chapters as well as the ordering of the modules within each chapter is roughly from most relevant to least important.

This means that if you start reading this manual from the start, and skip to the next chapter when you get bored, you will get a reasonable overview of the available modules and application areas that are supported by the Python library. Of course, you don’t have to read it like a novel — you can also browse the table of contents (in front of the manual), or look for a specific function, module or term in the index (in the back). And finally, if you enjoy learning about random subjects, you choose a random page number (see module random) and read a section or two. Regardless of the order in which you read the sections of this manual, it helps to start with chapter Built-in Functions, as the remainder of the manual assumes familiarity with this material.

Let the show begin!
2. Built-in Functions

The Python interpreter has a number of functions and types built into it that are always available. They are listed here in alphabetical order.

<p>| | | | |</p>
<table>
<thead>

</tr>
</tbody>
</table>

**abs(x)**

Return the absolute value of a number. The argument may be an integer or a floating point number. If the argument is a complex number, its magnitude is returned.
**all(iterable)**

Return True if all elements of the *iterable* are true (or if the iterable is empty). Equivalent to:

```python
def all(iterable):
    for element in iterable:
        if not element:
            return False
    return True
```

**any(iterable)**

Return True if any element of the *iterable* is true. If the iterable is empty, return False. Equivalent to:

```python
def any(iterable):
    for element in iterable:
        if element:
            return True
    return False
```

**ascii(object)**

As `repr()`, return a string containing a printable representation of an object, but escape the non-ASCII characters in the string returned by `repr()` using \\x, \\u or \\U escapes. This generates a string similar to that returned by `repr()` in Python 2.

**bin(x)**

Convert an integer number to a binary string. The result is a valid Python expression. If `x` is not a Python `int` object, it has to define an `__index__()` method that returns an integer.

**bool([x])**

Convert a value to a Boolean, using the standard *truth testing*
procedure. If \(x\) is false or omitted, this returns \texttt{False}; otherwise it returns \texttt{True}. \texttt{bool} is also a class, which is a subclass of \texttt{int} (see \textit{Numeric Types — int, float, complex}). Class \texttt{bool} cannot be subclassed further. Its only instances are \texttt{False} and \texttt{True} (see \textit{Boolean Values}).

\texttt{bytearray([source[, encoding[, errors]]])}

Return a new array of bytes. The \texttt{bytearray} type is a mutable sequence of integers in the range \(0 \leq x < 256\). It has most of the usual methods of mutable sequences, described in \textit{Mutable Sequence Types}, as well as most methods that the \texttt{bytes} type has, see \textit{Bytes and Bytearray Operations}.

The optional \texttt{source} parameter can be used to initialize the array in a few different ways:

- If it is a \texttt{string}, you must also give the \texttt{encoding} (and optionally, \texttt{errors}) parameters; \texttt{bytearray()} then converts the string to bytes using \texttt{str.encode()}
- If it is an \texttt{integer}, the array will have that size and will be initialized with null bytes.
- If it is an object conforming to the \texttt{buffer} interface, a read-only buffer of the object will be used to initialize the bytes array.
- If it is an \texttt{iterable}, it must be an iterable of integers in the range \(0 \leq x < 256\), which are used as the initial contents of the array.

Without an argument, an array of size 0 is created.

See also \textit{Binary Sequence Types — bytes, bytearray, memoryview} and \textit{Bytearray Objects}.

\texttt{bytes([source[, encoding[, errors]]])}
Return a new “bytes” object, which is an immutable sequence of integers in the range \(0 \leq x < 256\). bytes is an immutable version of bytearray – it has the same non-mutating methods and the same indexing and slicing behavior.

Accordingly, constructor arguments are interpreted as for bytearray().

Bytes objects can also be created with literals, see String and Bytes literals.

See also Binary Sequence Types — bytes, bytearray, memoryview, Bytes, and Bytes and Bytearray Operations.

callable(object)

Return True if the object argument appears callable, False if not. If this returns true, it is still possible that a call fails, but if it is false, calling object will never succeed. Note that classes are callable (calling a class returns a new instance); instances are callable if their class has a __call__() method.

New in version 3.2: This function was first removed in Python 3.0 and then brought back in Python 3.2.

chr(i)

Return the string representing a character whose Unicode codepoint is the integer \(i\). For example, chr(97) returns the string 'a'. This is the inverse of ord(). The valid range for the argument is from 0 through 1,114,111 (0x10FFFF in base 16). ValueError will be raised if \(i\) is outside that range.

classmethod(function)

Return a class method for function.
A class method receives the class as implicit first argument, just like an instance method receives the instance. To declare a class method, use this idiom:

```python
class C:
    @classmethod
    def f(cls, arg1, arg2, ...):
        ...
```

The `@classmethod` form is a function decorator – see the description of function definitions in *Function definitions* for details.

It can be called either on the class (such as `C.f()`) or on an instance (such as `C().f()`). The instance is ignored except for its class. If a class method is called for a derived class, the derived class object is passed as the implied first argument.

Class methods are different than C++ or Java static methods. If you want those, see `staticmethod()` in this section.

For more information on class methods, consult the documentation on the standard type hierarchy in *The standard type hierarchy*.

```python
compile(source, filename, mode, flags=0, dont_inherit=False, optimize=-1)
```

Compile the source into a code or AST object. Code objects can be executed by `exec()` or `eval()`. `source` can either be a string or an AST object. Refer to the `ast` module documentation for information on how to work with AST objects.

The `filename` argument should give the file from which the code was read; pass some recognizable value if it wasn’t read from a file (`'<string>'` is commonly used).
The *mode* argument specifies what kind of code must be compiled; it can be `exec` if *source* consists of a sequence of statements, `eval` if it consists of a single expression, or `single` if it consists of a single interactive statement (in the latter case, expression statements that evaluate to something other than None will be printed).

The optional arguments *flags* and *dont_inherit* control which future statements (see PEP 236) affect the compilation of *source*. If neither is present (or both are zero) the code is compiled with those future statements that are in effect in the code that is calling compile. If the *flags* argument is given and *dont_inherit* is not (or is zero) then the future statements specified by the *flags* argument are used in addition to those that would be used anyway. If *dont_inherit* is a non-zero integer then the *flags* argument is it – the future statements in effect around the call to compile are ignored.

Future statements are specified by bits which can be bitwise ORed together to specify multiple statements. The bitfield required to specify a given feature can be found as the compiler_flag attribute on the _Feature instance in the __future__ module.

The argument *optimize* specifies the optimization level of the compiler; the default value of `-1` selects the optimization level of the interpreter as given by `-O` options. Explicit levels are 0 (no optimization; __debug__ is true), 1 (asserts are removed, __debug__ is false) or 2 (docstrings are removed too).

This function raises `SyntaxError` if the compiled source is invalid, and `TypeError` if the source contains null bytes.

**Note:** When compiling a string with multi-line code in `single`
or 'eval' mode, input must be terminated by at least one newline character. This is to facilitate detection of incomplete and complete statements in the code module.

*Changed in version 3.2:* Allowed use of Windows and Mac newlines. Also input in 'exec' mode does not have to end in a newline anymore. Added the optimize parameter.

### complex([real[, imag]])

Create a complex number with the value real + imag\(j\) or convert a string or number to a complex number. If the first parameter is a string, it will be interpreted as a complex number and the function must be called without a second parameter. The second parameter can never be a string. Each argument may be any numeric type (including complex). If imag is omitted, it defaults to zero and the function serves as a numeric conversion function like int() and float(). If both arguments are omitted, returns 0j.

**Note:** When converting from a string, the string must not contain whitespace around the central + or - operator. For example, complex('1+2j') is fine, but complex('1 + 2j') raises ValueError.

The complex type is described in *Numeric Types — int, float, complex.*

### delattr(object, name)

This is a relative of setattr(). The arguments are an object and a string. The string must be the name of one of the object’s attributes. The function deletes the named attribute, provided the object allows it. For example, delattr(x, 'foobar') is equivalent to del x.foobar.
dict(**kwarg)
dict(mapping, **kwarg)
dict(iterable, **kwarg)

Create a new dictionary. The dict object is the dictionary class. See dict and Mapping Types — dict for documentation about this class.

For other containers see the built-in list, set, and tuple classes, as well as the collections module.

dir([object])
Without arguments, return the list of names in the current local scope. With an argument, attempt to return a list of valid attributes for that object.

If the object has a method named __dir__() , this method will be called and must return the list of attributes. This allows objects that implement a custom __getattr__() or __getattribute__() function to customize the way dir() reports their attributes.

If the object does not provide __dir__() , the function tries its best to gather information from the object's __dict__ attribute, if defined, and from its type object. The resulting list is not necessarily complete, and may be inaccurate when the object has a custom __getattr__() .

The default dir() mechanism behaves differently with different types of objects, as it attempts to produce the most relevant, rather than complete, information:

- If the object is a module object, the list contains the names of the module’s attributes.
- If the object is a type or class object, the list contains the names of its attributes, and recursively of the attributes of its bases.
- Otherwise, the list contains the object's attributes' names, the names of its class's attributes, and recursively of the attributes of its class's base classes.

The resulting list is sorted alphabetically. For example:

```python
>>> import struct
>>> dir()  # show the names in the module namespace
['__builtins__', '__name__', 'struct']
>>> dir(struct)  # show the names in the struct module
['Struct', '__all__', '__builtins__', '__cached__', '__initializing__', '__loader__', '__name__', '_clearcache', 'calcsize', 'error', 'pack', 'pack_into', 'unpack', 'unpack_from']
>>> class Shape:
...   def __dir__(self):
...       return ['area', 'perimeter', 'location']
>>> s = Shape()
>>> dir(s)
['area', 'location', 'perimeter']
```

**Note:** Because `dir()` is supplied primarily as a convenience for use at an interactive prompt, it tries to supply an interesting set of names more than it tries to supply a rigorously or consistently defined set of names, and its detailed behavior may change across releases. For example, metaclass attributes are not in the result list when the argument is a class.

**divmod**\((a, b)\)

Take two (non complex) numbers as arguments and return a pair of numbers consisting of their quotient and remainder when using
integer division. With mixed operand types, the rules for binary arithmetic operators apply. For integers, the result is the same as \((a \div b, a \mod b)\). For floating point numbers the result is \((q, a \mod b)\), where \(q\) is usually \(\text{math.floor}(a / b)\) but may be 1 less than that. In any case \(q \times b + a \mod b\) is very close to \(a\), if \(a \mod b\) is non-zero it has the same sign as \(b\), and \(0 \leq \text{abs}(a \mod b) < \text{abs}(b)\).

**enumerate(iterable, start=0)**

Return an enumerate object. *iterable* must be a sequence, an *iterator*, or some other object which supports iteration. The `__next__()` method of the iterator returned by **enumerate()** returns a tuple containing a count (from *start* which defaults to 0) and the values obtained from iterating over *iterable*.

```python
>>> seasons = ['Spring', 'Summer', 'Fall', 'Winter']
>>> list(enumerate(seasons))
[(0, 'Spring'), (1, 'Summer'), (2, 'Fall'), (3, 'Winter')]
>>> list(enumerate(seasons, start=1))
[(1, 'Spring'), (2, 'Summer'), (3, 'Fall'), (4, 'Winter')]
```

Equivalent to:

```python
def enumerate(sequence, start=0):
    n = start
    for elem in sequence:
        yield n, elem
    n += 1
```

**eval(expression, globals=None, locals=None)**

The arguments are a string and optional globals and locals. If provided, *globals* must be a dictionary. If provided, *locals* can be
any mapping object.

The *expression* argument is parsed and evaluated as a Python expression (technically speaking, a condition list) using the *globals* and *locals* dictionaries as global and local namespace. If the *globals* dictionary is present and lacks ‘__builtins__’, the current globals are copied into *globals* before *expression* is parsed. This means that *expression* normally has full access to the standard *builtins* module and restricted environments are propagated. If the *locals* dictionary is omitted it defaults to the *globals* dictionary. If both dictionaries are omitted, the expression is executed in the environment where *eval()* is called. The return value is the result of the evaluated expression. Syntax errors are reported as exceptions. Example:

```python
>>> x = 1
>>> eval('x+1')
2
```

This function can also be used to execute arbitrary code objects (such as those created by *compile()*). In this case pass a code object instead of a string. If the code object has been compiled with 'exec' as the *mode* argument, *eval()*’s return value will be None.

Hints: dynamic execution of statements is supported by the *exec()* function. The *globals()* and *locals()* functions returns the current global and local dictionary, respectively, which may be useful to pass around for use by *eval()* or *exec()*.

See *ast.literal_eval()* for a function that can safely evaluate strings with expressions containing only literals.
exec(*object*, *globals*, *locals*)

This function supports dynamic execution of Python code. *object* must be either a string or a code object. If it is a string, the string is parsed as a suite of Python statements which is then executed (unless a syntax error occurs). [1] If it is a code object, it is simply executed. In all cases, the code that's executed is expected to be valid as file input (see the section “File input” in the Reference Manual). Be aware that the return and yield statements may not be used outside of function definitions even within the context of code passed to the exec() function. The return value is None.

In all cases, if the optional parts are omitted, the code is executed in the current scope. If only *globals* is provided, it must be a dictionary, which will be used for both the global and the local variables. If *globals* and *locals* are given, they are used for the global and local variables, respectively. If provided, *locals* can be any mapping object. Remember that at module level, globals and locals are the same dictionary. If exec gets two separate objects as *globals* and *locals*, the code will be executed as if it were embedded in a class definition.

If the *globals* dictionary does not contain a value for the key __builtins__, a reference to the dictionary of the built-in module **builtins** is inserted under that key. That way you can control what builtins are available to the executed code by inserting your own __builtins__ dictionary into *globals* before passing it to exec().

**Note:** The built-in functions **globals()** and **locals()** return the current global and local dictionary, respectively, which may be useful to pass around for use as the second and third argument.
to `exec()`.

**Note:** The default `locals` act as described for function `locals()` below: modifications to the default `locals` dictionary should not be attempted. Pass an explicit `locals` dictionary if you need to see effects of the code on `locals` after function `exec()` returns.

**filter**(*function, iterable*)

Construct an iterator from those elements of `iterable` for which `function` returns true. `iterable` may be either a sequence, a container which supports iteration, or an iterator. If `function` is None, the identity function is assumed, that is, all elements of `iterable` that are false are removed.

Note that `filter(function, iterable)` is equivalent to the generator expression `\[(item for item in iterable if function(item))\]` if `function` is not None and `\[(item for item in iterable if item)\]` if `function` is None.

See `itertools.filterfalse()` for the complementary function that returns elements of `iterable` for which `function` returns false.

**float**([*x*])

Convert a string or a number to floating point.

If the argument is a string, it should contain a decimal number, optionally preceded by a sign, and optionally embedded in whitespace. The optional sign may be `'+'` or `'-'`; a `'+'` sign has no effect on the value produced. The argument may also be a string representing a NaN (not-a-number), or a positive or negative
infinity. More precisely, the input must conform to the following grammar after leading and trailing whitespace characters are removed:

```
sign ::= "+" | "-
infinity ::= "Infinity" | "inf"
nan ::= "nan"
numeric_value ::= floatnumber | infinity | nan
numeric_string ::= [sign] numeric_value
```

Here `floatnumber` is the form of a Python floating-point literal, described in *Floating point literals*. Case is not significant, so, for example, “inf”, “Inf”, “INFINITY” and “iNfINity” are all acceptable spellings for positive infinity.

Otherwise, if the argument is an integer or a floating point number, a floating point number with the same value (within Python’s floating point precision) is returned. If the argument is outside the range of a Python float, an `OverflowError` will be raised.

For a general Python object `x`, `float(x)` delegates to `x.__float__()`.

If no argument is given, `0.0` is returned.

Examples:

```
>>> float('+1.23')
1.23
>>> float('-12345\n')
-12345.0
>>> float('1e-003')
0.001
>>> float('+1E6')
1000000.0
```
The float type is described in *Numeric Types — int, float, complex.*

```python
gt>> float('-Infinity')
-inf
```

`format(value[, format_spec])`

Convert a `value` to a “formatted” representation, as controlled by `format_spec`. The interpretation of `format_spec` will depend on the type of the `value` argument, however there is a standard formatting syntax that is used by most built-in types: *Format Specification Mini-Language*.

The default `format_spec` is an empty string which usually gives the same effect as calling `str(value)`.

A call to `format(value, format_spec)` is translated to `type(value).__format__(format_spec)` which bypasses the instance dictionary when searching for the value's `__format__()` method. A `TypeError` exception is raised if the method is not found or if either the `format_spec` or the return value are not strings.

`frozenset([iterable])`

Return a new `frozenset` object, optionally with elements taken from `iterable`. `frozenset` is a built-in class. See `frozenset` and *Set Types — set, frozenset* for documentation about this class.

For other containers see the built-in `set, list, tuple, and dict` classes, as well as the `collections` module.

`getattr(object, name[, default])`

Return the value of the named attribute of `object`. `name` must be a
string. If the string is the name of one of the object's attributes, the result is the value of that attribute. For example, `getattr(x, 'foobar')` is equivalent to `x.foobar`. If the named attribute does not exist, `default` is returned if provided, otherwise `AttributeError` is raised.

**globals()**
Return a dictionary representing the current global symbol table. This is always the dictionary of the current module (inside a function or method, this is the module where it is defined, not the module from which it is called).

**hasattr(object, name)**
The arguments are an object and a string. The result is `True` if the string is the name of one of the object's attributes, `False` if not. (This is implemented by calling `getattr(object, name)` and seeing whether it raises an `AttributeError` or not.)

**hash(object)**
Return the hash value of the object (if it has one). Hash values are integers. They are used to quickly compare dictionary keys during a dictionary lookup. Numeric values that compare equal have the same hash value (even if they are of different types, as is the case for 1 and 1.0).

**Note:** For object's with custom `__hash__()` methods, note that `hash()` truncates the return value based on the bit width of the host machine. See `__hash__()` for details.

**help([object])**
Invoke the built-in help system. (This function is intended for
interactive use.) If no argument is given, the interactive help system starts on the interpreter console. If the argument is a string, then the string is looked up as the name of a module, function, class, method, keyword, or documentation topic, and a help page is printed on the console. If the argument is any other kind of object, a help page on the object is generated.

This function is added to the built-in namespace by the `site` module.

**hex(x)**

Convert an integer number to a hexadecimal string. The result is a valid Python expression. If \( x \) is not a Python `int` object, it has to define an `__index__()` method that returns an integer.

**Note:** To obtain a hexadecimal string representation for a float, use the `float.hex()` method.

**id(object)**

Return the “identity” of an object. This is an integer which is guaranteed to be unique and constant for this object during its lifetime. Two objects with non-overlapping lifetimes may have the same `id()` value.

**CPython implementation detail:** This is the address of the object in memory.

**input([prompt])**

If the `prompt` argument is present, it is written to standard output without a trailing newline. The function then reads a line from input, converts it to a string (stripping a trailing newline), and returns that.
When EOF is read, `EOFError` is raised. Example:

```python
>>> s = input('--> ')
--> Monty Python's Flying Circus
>>> s
"Monty Python's Flying Circus"
```

If the `readline` module was loaded, then `input()` will use it to provide elaborate line editing and history features.

```python
int(x=0)
```

```python
int(x, base=10)
```

Convert a number or string `x` to an integer, or return `0` if no arguments are given. If `x` is a number, return `x.__int__()`. For floating point numbers, this truncates towards zero.

If `x` is not a number or if `base` is given, then `x` must be a string, `bytes`, or `bytearray` instance representing an `integer literal` in radix `base`. Optionally, the literal can be preceded by `+` or `-` (with no space in between) and surrounded by whitespace. A base-n literal consists of the digits 0 to n-1, with a to z (or A to Z) having values 10 to 35. The default `base` is 10. The allowed values are 0 and 2-36. Base-2, -8, and -16 literals can be optionally prefixed with `0b/0B`, `0o/0O`, or `0x/0X`, as with integer literals in code. Base 0 means to interpret exactly as a code literal, so that the actual base is 2, 8, 10, or 16, and so that `int('010', 0)` is not legal, while `int('010')` is, as well as `int('010', 8)`.

The integer type is described in `Numeric Types — int, float, complex`.

```python
isinstance(object, classinfo)
```
Return true if the object argument is an instance of the classinfo argument, or of a (direct, indirect or virtual) subclass thereof. If object is not an object of the given type, the function always returns false. If classinfo is not a class (type object), it may be a tuple of type objects, or may recursively contain other such tuples (other sequence types are not accepted). If classinfo is not a type or tuple of types and such tuples, a TypeError exception is raised.

issubclass(class, classinfo)
Return true if class is a subclass (direct, indirect or virtual) of classinfo. A class is considered a subclass of itself. classinfo may be a tuple of class objects, in which case every entry in classinfo will be checked. In any other case, a TypeError exception is raised.

iter(object[, sentinel])
Return an iterator object. The first argument is interpreted very differently depending on the presence of the second argument. Without a second argument, object must be a collection object which supports the iteration protocol (the __iter__() method), or it must support the sequence protocol (the __getitem__() method with integer arguments starting at 0). If it does not support either of those protocols, TypeError is raised. If the second argument, sentinel, is given, then object must be a callable object. The iterator created in this case will call object with no arguments for each call to its __next__() method; if the value returned is equal to sentinel, StopIteration will be raised, otherwise the value will be returned.

See also Iterator Types.

One useful application of the second form of iter() is to read
lines of a file until a certain line is reached. The following example reads a file until the `readline()` method returns an empty string:

```python
with open('mydata.txt') as fp:
    for line in iter(fp.readline, ''):
        process_line(line)
```

**len()**
Return the length (the number of items) of an object. The argument may be a sequence (string, tuple or list) or a mapping (dictionary).

**list([[iterable]])**
Rather than being a function, `list` is actually a mutable sequence type, as documented in *Lists* and *Sequence Types — list, tuple, range*.

**locals()**
Update and return a dictionary representing the current local symbol table. Free variables are returned by `locals()` when it is called in function blocks, but not in class blocks.

**Note:** The contents of this dictionary should not be modified; changes may not affect the values of local and free variables used by the interpreter.

**map(function, iterable, ...)**
Return an iterator that applies `function` to every item of `iterable`, yielding the results. If additional `iterable` arguments are passed, `function` must take that many arguments and is applied to the items from all iterables in parallel. With multiple iterables, the iterator stops when the shortest iterable is exhausted. For cases where the function inputs are already arranged into argument tuples, see
**itertools.starmap()**

**max(iterable, *[key]*)**

**max(arg1, arg2, *args[, key])**

Return the largest item in an iterable or the largest of two or more arguments.

If one positional argument is provided, *iterable* must be a non-empty iterable (such as a non-empty string, tuple or list). The largest item in the iterable is returned. If two or more positional arguments are provided, the largest of the positional arguments is returned.

The optional keyword-only *key* argument specifies a one-argument ordering function like that used for *list.sort()*.

If multiple items are maximal, the function returns the first one encountered. This is consistent with other sort-stability preserving tools such as *sorted(iterable, key=keyfunc, reverse=True)[0]* and *heapq.nlargest(1, iterable, key=keyfunc)*.

**memoryview(obj)**

Return a “memory view” object created from the given argument. See *Memory Views* for more information.

**min(iterable, *[key]*)**

**min(arg1, arg2, *args[, key])**

Return the smallest item in an iterable or the smallest of two or more arguments.

If one positional argument is provided, *iterable* must be a non-
empty iterable (such as a non-empty string, tuple or list). The smallest item in the iterable is returned. If two or more positional arguments are provided, the smallest of the positional arguments is returned.

The optional keyword-only key argument specifies a one-argument ordering function like that used for list.sort().

If multiple items are minimal, the function returns the first one encountered. This is consistent with other sort-stability preserving tools such as sorted(iterable, key=keyfunc)[0] and heapq.nsmallest(1, iterable, key=keyfunc).

next(iterator[, default])
Retrieve the next item from the iterator by calling its __next__() method. If default is given, it is returned if the iterator is exhausted, otherwise StopIteration is raised.

object()
Return a new featureless object. object is a base for all classes. It has the methods that are common to all instances of Python classes. This function does not accept any arguments.

Note: object does not have a __dict__, so you can't assign arbitrary attributes to an instance of the object class.

oct(x)
Convert an integer number to an octal string. The result is a valid Python expression. If x is not a Python int object, it has to define an __index__() method that returns an integer.

open(file, mode='r', buffering=-1, encoding=None, errors=None,
Open file and return a corresponding file object. If the file cannot be opened, an OSError is raised.

file is either a string or bytes object giving the pathname (absolute or relative to the current working directory) of the file to be opened or an integer file descriptor of the file to be wrapped. (If a file descriptor is given, it is closed when the returned I/O object is closed, unless closefd is set to False.)

mode is an optional string that specifies the mode in which the file is opened. It defaults to 'r' which means open for reading in text mode. Other common values are 'w' for writing (truncating the file if it already exists), 'x' for exclusive creation and 'a' for appending (which on some Unix systems, means that all writes append to the end of the file regardless of the current seek position). In text mode, if encoding is not specified the encoding used is platform dependent: locale.getpreferredencoding(False) is called to get the current locale encoding. (For reading and writing raw bytes use binary mode and leave encoding unspecified.) The available modes are:

<table>
<thead>
<tr>
<th>Character</th>
<th>Meaning</th>
</tr>
</thead>
<tbody>
<tr>
<td>'r'</td>
<td>open for reading (default)</td>
</tr>
<tr>
<td>'w'</td>
<td>open for writing, truncating the file first</td>
</tr>
<tr>
<td>'x'</td>
<td>open for exclusive creation, failing if the file already exists</td>
</tr>
<tr>
<td>'a'</td>
<td>open for writing, appending to the end of the file if it exists</td>
</tr>
<tr>
<td>'b'</td>
<td>binary mode</td>
</tr>
</tbody>
</table>
The default mode is `'r'` (open for reading text, synonym of `'rt'`). For binary read-write access, the mode `'w+b'` opens and truncates the file to 0 bytes. `'r+b'` opens the file without truncation.

As mentioned in the *Overview*, Python distinguishes between binary and text I/O. Files opened in binary mode (including `'b'` in the *mode* argument) return contents as *bytes* objects without any decoding. In text mode (the default, or when `'t'` is included in the *mode* argument), the contents of the file are returned as *str*, the bytes having been first decoded using a platform-dependent encoding or using the specified *encoding* if given.

**Note:** Python doesn't depend on the underlying operating system's notion of text files; all the processing is done by Python itself, and is therefore platform-independent.

*buffering* is an optional integer used to set the buffering policy. Pass 0 to switch buffering off (only allowed in binary mode), 1 to select line buffering (only usable in text mode), and an integer > 1 to indicate the size in bytes of a fixed-size chunk buffer. When no *buffering* argument is given, the default buffering policy works as follows:

- Binary files are buffered in fixed-size chunks; the size of the buffer is chosen using a heuristic trying to determine the underlying device's "block size" and falling back on
io.DEFAULT_BUFFER_SIZE. On many systems, the buffer will typically be 4096 or 8192 bytes long.

- “Interactive” text files (files for which isatty() returns True) use line buffering. Other text files use the policy described above for binary files.

**encoding** is the name of the encoding used to decode or encode the file. This should only be used in text mode. The default encoding is platform dependent (whatever locale.getpreferredencoding() returns), but any encoding supported by Python can be used. See the codecs module for the list of supported encodings.

**errors** is an optional string that specifies how encoding and decoding errors are to be handled–this cannot be used in binary mode. A variety of standard error handlers are available, though any error handling name that has been registered with codecs.register_error() is also valid. The standard names are:

- 'strict' to raise a ValueError exception if there is an encoding error. The default value of None has the same effect.
- 'ignore' ignores errors. Note that ignoring encoding errors can lead to data loss.
- 'replace' causes a replacement marker (such as '?' ) to be inserted where there is malformed data.
- 'surrogateescape' will represent any incorrect bytes as code points in the Unicode Private Use Area ranging from U+DC80 to U+DCFF. These private code points will then be turned back into the same bytes when the surrogateescape error handler is used when writing data. This is useful for processing files in an unknown encoding.
- 'xmlcharrefreplace' is only supported when writing to a
file. Characters not supported by the encoding are replaced with the appropriate XML character reference `&#nnn;`.

- `'backslashreplace'` (also only supported when writing) replaces unsupported characters with Python's backslashed escape sequences.

`newline` controls how universal newlines mode works (it only applies to text mode). It can be None, `'`, `'\n'`, `'\r'`, and `'\r\n'`. It works as follows:

- When reading input from the stream, if `newline` is None, universal newlines mode is enabled. Lines in the input can end in `'\n'`, `'\r'`, or `'\r\n'`, and these are translated into `'\n'` before being returned to the caller. If it is `'` or `'\n'`, universal newlines mode is enabled, but line endings are returned to the caller untranslated. If it has any of the other legal values, input lines are only terminated by the given string, and the line ending is returned to the caller untranslated.

- When writing output to the stream, if `newline` is None, any `'\n'` characters written are translated to the system default line separator, `os.linesep`. If `newline` is `'` or `'\n'`, no translation takes place. If `newline` is any of the other legal values, any `'\n'` characters written are translated to the given string.

If `closefd` is False and a file descriptor rather than a filename was given, the underlying file descriptor will be kept open when the file is closed. If a filename is given `closefd` has no effect and must be True (the default).

A custom opener can be used by passing a callable as `opener`. The underlying file descriptor for the file object is then obtained by calling `opener` with `(file, flags)`. `opener` must return an open file descriptor (passing `os.open` as `opener` results in functionality
similar to passing None).

The following example uses the `dir_fd` parameter of the `os.open()` function to open a file relative to a given directory:

```python
>>> import os
>>> dir_fd = os.open('somedir', os.O_RDONLY)
>>> def opener(path, flags):
...     return os.open(path, flags, dir_fd=dir_fd)
...
>>> with open('spamspam.txt', 'w', opener=opener) as f:
...     print('This will be written to somedir/spamspam.txt')
...
>>> os.close(dir_fd)  # don't leak a file descriptor
```

*Changed in version 3.3:* The `opener` parameter was added. The `'x'` mode was added.

The type of file object returned by the `open()` function depends on the mode. When `open()` is used to open a file in a text mode (`'w'`, `'r'`, `'wt'`, `'rt'`, etc.), it returns a subclass of `io.TextIOBase` (specifically `io.TextIOWrapper`). When used to open a file in a binary mode with buffering, the returned class is a subclass of `io.BufferedIOBase`. The exact class varies: in read binary mode, it returns a `io.BufferedReader`; in write binary and append binary modes, it returns a `io.BufferedWriter`, and in read/write mode, it returns a `io.BufferedRandom`. When buffering is disabled, the raw stream, a subclass of `io.RawIOBase`, `io.FileIO`, is returned.

See also the file handling modules, such as, `fileinput`, `io` (where `open()` is declared), `os`, `os.path`, `tempfile`, and
shutil.

Changed in version 3.3: IOError used to be raised, it is now an alias of OSError. FileExistsError is now raised if the file opened in exclusive creation mode ('x') already exists.

ord(c)

Given a string representing one Unicode character, return an integer representing the Unicode code point of that character. For example, \texttt{ord('a')} returns the integer 97 and \texttt{ord('\\u2020')} returns 8224. This is the inverse of \texttt{chr( )}.

pow(x, y[, z])

Return \( x \) to the power \( y \); if \( z \) is present, return \( x \) to the power \( y \), modulo \( z \) (computed more efficiently than \texttt{pow(x, y) \% z} ). The two-argument form \texttt{pow(x, y)} is equivalent to using the power operator: \( x^{**}y \).

The arguments must have numeric types. With mixed operand types, the coercion rules for binary arithmetic operators apply. For \texttt{int} operands, the result has the same type as the operands (after coercion) unless the second argument is negative; in that case, all arguments are converted to float and a float result is delivered. For example, \texttt{10**2} returns 100, but \texttt{10**-2} returns 0.01. If the second argument is negative, the third argument must be omitted. If \( z \) is present, \( x \) and \( y \) must be of integer types, and \( y \) must be non-negative.

print(*objects, sep=' ', end='
', file=sys.stdout, flush=False)

Print objects to the stream file, separated by sep and followed by end. sep, end and file, if present, must be given as keyword arguments.
All non-keyword arguments are converted to strings like `str()` does and written to the stream, separated by `sep` and followed by `end`. Both `sep` and `end` must be strings; they can also be None, which means to use the default values. If no `objects` are given, `print()` will just write `end`.

The `file` argument must be an object with a `write(string)` method; if it is not present or None, `sys.stdout` will be used. Whether output is buffered is usually determined by `file`, but if the `flush` keyword argument is true, the stream is forcibly flushed.

*Changed in version 3.3:* Added the `flush` keyword argument.

**property**(fget=None, fset=None, fdel=None, doc=None)

Return a property attribute.

`fget` is a function for getting an attribute value, likewise `fset` is a function for setting, and `fdel` a function for del’ing, an attribute. Typical use is to define a managed attribute `x`:

```python
class C:
    def __init__(self):
        self._x = None

    def getx(self):
        return self._x
    def setx(self, value):
        self._x = value
    def delx(self):
        del self._x

x = property(getx, setx, delx, "I'm the 'x' p")
```

If then `c` is an instance of `C`, `c.x` will invoke the getter, `c.x =`
value will invoke the setter and del c.x the deleter.

If given, doc will be the docstring of the property attribute. Otherwise, the property will copy fget’s docstring (if it exists). This makes it possible to create read-only properties easily using property() as a decorator:

```python
class Parrot:
    def __init__(self):
        self._voltage = 100000

@property
def voltage(self):
    """Get the current voltage."""
    return self._voltage

```

turns the voltage() method into a “getter” for a read-only attribute with the same name.

A property object has getter, setter, and deleter methods usable as decorators that create a copy of the property with the corresponding accessor function set to the decorated function. This is best explained with an example:

```python
class C:
    def __init__(self):
        self._x = None

@property
def x(self):
    """I'm the 'x' property.""
    return self._x

@x.setter
def x(self, value):
```

```python
self._x = value

@x.deleter
def x(self):
    del self._x
```

This code is exactly equivalent to the first example. Be sure to give the additional functions the same name as the original property (x in this case.)

The returned property also has the attributes `fget`, `fset`, and `fdel` corresponding to the constructor arguments.

```python
range(stop)
range(start, stop[, step])
```

Rather than being a function, `range` is actually an immutable sequence type, as documented in *Ranges* and *Sequence Types — list, tuple, range*.

```python
repr(object)
```

Return a string containing a printable representation of an object. For many types, this function makes an attempt to return a string that would yield an object with the same value when passed to `eval()`, otherwise the representation is a string enclosed in angle brackets that contains the name of the type of the object together with additional information often including the name and address of the object. A class can control what this function returns for its instances by defining a `__repr__()` method.

```python
reversed(seq)
```

Return a reverse `iterator`. `seq` must be an object which has a `__reversed__()` method or supports the sequence protocol (the
__len__() method and the __getitem__() method with integer arguments starting at 0).

round(number[, ndigits])
Return the floating point value number rounded to ndigits digits after the decimal point. If ndigits is omitted, it defaults to zero. Delegates to number.__round__(ndigits).

For the built-in types supporting round(), values are rounded to the closest multiple of 10 to the power minus ndigits; if two multiples are equally close, rounding is done toward the even choice (so, for example, both round(0.5) and round(-0.5) are 0, and round(1.5) is 2). The return value is an integer if called with one argument, otherwise of the same type as number.

**Note:** The behavior of round() for floats can be surprising: for example, round(2.675, 2) gives 2.67 instead of the expected 2.68. This is not a bug: it’s a result of the fact that most decimal fractions can’t be represented exactly as a float. See *Floating Point Arithmetic: Issues and Limitations* for more information.

set([iterable])
Return a new set object, optionally with elements taken from iterable. set is a built-in class. See set and Set Types — set, frozenset for documentation about this class.

For other containers see the built-in frozenset, list, tuple, and dict classes, as well as the collections module.

setattr(object, name, value)
This is the counterpart of `getattr()`. The arguments are an object, a string and an arbitrary value. The string may name an existing attribute or a new attribute. The function assigns the value to the attribute, provided the object allows it. For example, `setattr(x, 'foobar', 123)` is equivalent to `x.foobar = 123`.

### slice

**slice(stop)**

**slice(start, stop[, step])**

Return a slice object representing the set of indices specified by `range(start, stop, step)`. The `start` and `step` arguments default to None. Slice objects have read-only data attributes `start`, `stop` and `step` which merely return the argument values (or their default). They have no other explicit functionality; however they are used by Numerical Python and other third party extensions. Slice objects are also generated when extended indexing syntax is used. For example: `a[start:stop:step]` or `a[start:stop, i]`. See `itertools.islice()` for an alternate version that returns an iterator.

### sorted

**sorted(iterable[, key][, reverse])**

Return a new sorted list from the items in `iterable`.

Has two optional arguments which must be specified as keyword arguments.

`key` specifies a function of one argument that is used to extract a comparison key from each list element: `key=str.lower`. The default value is None (compare the elements directly).

`reverse` is a boolean value. If set to True, then the list elements are sorted as if each comparison were reversed.
Use `functools.cmp_to_key()` to convert an old-style `cmp` function to a key function.

For sorting examples and a brief sorting tutorial, see Sorting HowTo.

**staticmethod(function)**

Return a static method for `function`.

A static method does not receive an implicit first argument. To declare a static method, use this idiom:

```python
class C:
    @staticmethod
    def f(arg1, arg2, ...):
        ...
```

The `@staticmethod` form is a function decorator – see the description of function definitions in Function definitions for details.

It can be called either on the class (such as `C.f()`) or on an instance (such as `C().f()`). The instance is ignored except for its class.

Static methods in Python are similar to those found in Java or C++. Also see `classmethod()` for a variant that is useful for creating alternate class constructors.

For more information on static methods, consult the documentation on the standard type hierarchy in The standard type hierarchy.

**str(object="")**

`str(object=b", encoding='utf-8', errors='strict')`  
Return a `str` version of `object`. See `str()` for details.
str is the built-in string class. For general information about strings, see Text Sequence Type — str.

sum(iterable[, start])
Sums start and the items of an iterable from left to right and returns the total. start defaults to 0. The iterable's items are normally numbers, and the start value is not allowed to be a string.

For some use cases, there are good alternatives to sum(). The preferred, fast way to concatenate a sequence of strings is by calling ''.join(sequence). To add floating point values with extended precision, see math.fsum(). To concatenate a series of iterables, consider using itertools.chain().

super([type[, object-or-type]])
Return a proxy object that delegates method calls to a parent or sibling class of type. This is useful for accessing inherited methods that have been overridden in a class. The search order is same as that used by getattr() except that the type itself is skipped.

The __mro__ attribute of the type lists the method resolution search order used by both getattr() and super(). The attribute is dynamic and can change whenever the inheritance hierarchy is updated.

If the second argument is omitted, the super object returned is unbound. If the second argument is an object, isinstance(obj, type) must be true. If the second argument is a type, issubclass(type2, type) must be true (this is useful for classmethods).

There are two typical use cases for super. In a class hierarchy with
single inheritance, *super* can be used to refer to parent classes without naming them explicitly, thus making the code more maintainable. This use closely parallels the use of *super* in other programming languages.

The second use case is to support cooperative multiple inheritance in a dynamic execution environment. This use case is unique to Python and is not found in statically compiled languages or languages that only support single inheritance. This makes it possible to implement “diamond diagrams” where multiple base classes implement the same method. Good design dictates that this method have the same calling signature in every case (because the order of calls is determined at runtime, because that order adapts to changes in the class hierarchy, and because that order can include sibling classes that are unknown prior to runtime).

For both use cases, a typical superclass call looks like this:

```
class C(B):
    def method(self, arg):
        super().method(arg)  # This does the same
        # super(C, self).method(arg)
```

Note that *super()* is implemented as part of the binding process for explicit dotted attribute lookups such as *super()*.__getitem__(name). It does so by implementing its own __getattr__() method for searching classes in a predictable order that supports cooperative multiple inheritance. Accordingly, *super()* is undefined for implicit lookups using statements or operators such as *super()*[name].
Also note that, aside from the zero argument form, `super()` is not limited to use inside methods. The two argument form specifies the arguments exactly and makes the appropriate references. The zero argument form only works inside a class definition, as the compiler fills in the necessary details to correctly retrieve the class being defined, as well as accessing the current instance for ordinary methods.

For practical suggestions on how to design cooperative classes using `super()`, see guide to using `super()`.

`tuple([iterable])`

Rather than being a function, `tuple` is actually an immutable sequence type, as documented in *Tuples* and *Sequence Types — list, tuple, range*.

`type(object)`

`type(name, bases, dict)`

With one argument, return the type of an `object`. The return value is a type object and generally the same object as returned by `object.__class__`.

The `isinstance()` built-in function is recommended for testing the type of an object, because it takes subclasses into account.

With three arguments, return a new type object. This is essentially a dynamic form of the `class` statement. The `name` string is the class name and becomes the `__name__` attribute; the `bases` tuple itemizes the base classes and becomes the `__bases__` attribute; and the `dict` dictionary is the namespace containing definitions for class body and becomes the `__dict__` attribute. For example, the following two statements create identical `type` objects:
```python
>>> class X:
...     a = 1
... >>> X = type('X', (object,), dict(a=1))

See also *Type Objects*.

**vars([object])**

Return the **dict** attribute for a module, class, instance, or any other object with a **dict** attribute.

Objects such as modules and instances have an updateable **dict** attribute; however, other objects may have write restrictions on their **dict** attributes (for example, classes use a dictproxy to prevent direct dictionary updates).

Without an argument, `vars()` acts like `locals()`. Note, the locals dictionary is only useful for reads since updates to the locals dictionary are ignored.

**zip(*iterables)**

Make an iterator that aggregates elements from each of the iterables.

Returns an iterator of tuples, where the *i*-th tuple contains the *i*-th element from each of the argument sequences or iterables. The iterator stops when the shortest input iterable is exhausted. With a single iterable argument, it returns an iterator of 1-tuples. With no arguments, it returns an empty iterator. Equivalent to:

```python
def zip(*iterables):
    # zip('ABCD', 'xy') --> Ax By
    sentinel = object()
```
iterators = [iter(it) for it in iterables]

while iterators:
    result = []
    for it in iterators:
        elem = next(it, sentinel)
        if elem is sentinel:
            return
        result.append(elem)
    yield tuple(result)

The left-to-right evaluation order of the iterables is guaranteed. This makes possible an idiom for clustering a data series into n-length groups using zip(*[iter(s)]*n).

zip() should only be used with unequal length inputs when you don’t care about trailing, unmatched values from the longer iterables. If those values are important, use itertools.zip_longest() instead.

zip() in conjunction with the * operator can be used to unzip a list:

```python
>>> x = [1, 2, 3]
>>> y = [4, 5, 6]
>>> zipped = zip(x, y)
>>> list(zipped)
[(1, 4), (2, 5), (3, 6)]
>>> x2, y2 = zip(*zip(x, y))
>>> x == list(x2) and y == list(y2)
True
```

__import__(name, globals=None, locals=None, fromlist=(), level=0)

Note: This is an advanced function that is not needed in
This function is invoked by the `import` statement. It can be replaced (by importing the `builtins` module and assigning to `builtins.__import__`) in order to change semantics of the `import` statement, but doing so is strongly discouraged as it is usually simpler to use import hooks (see PEP 302) to attain the same goals and does not cause issues with code which assumes the default import implementation is in use. Direct use of `__import__()` is also discouraged in favor of `importlib.import_module()`.

The function imports the module `name`, potentially using the given `globals` and `locals` to determine how to interpret the name in a package context. The `fromlist` gives the names of objects or submodules that should be imported from the module given by `name`. The standard implementation does not use its `locals` argument at all, and uses its `globals` only to determine the package context of the `import` statement.

`level` specifies whether to use absolute or relative imports. 0 (the default) means only perform absolute imports. Positive values for `level` indicate the number of parent directories to search relative to the directory of the module calling `__import__()` (see PEP 328 for the details).

When the `name` variable is of the form `package.module`, normally, the top-level package (the name up till the first dot) is returned, not the module named by `name`. However, when a non-empty `fromlist` argument is given, the module named by `name` is returned.
For example, the statement `import spam` results in bytecode resembling the following code:

```python
spam = __import__('spam', globals(), locals(), [])
```

The statement `import spam.ham` results in this call:

```python
spam = __import__('spam.ham', globals(), locals(), []
```

Note how `__import__() `returns the toplevel module here because this is the object that is bound to a name by the `import` statement.

On the other hand, the statement `from spam.ham import eggs, sausage as saus` results in

```python
_temp = __import__('spam.ham', globals(), locals()
eggs = _temp.eggs
saus = _temp.sausage
```

Here, the `spam.ham` module is returned from `__import__()`.
From this object, the names to import are retrieved and assigned to their respective names.

If you simply want to import a module (potentially within a package) by name, use `importlib.import_module()`.

*Changed in version 3.3:* Negative values for `level` are no longer supported (which also changes the default value to 0).

Footnotes
Note that the parser only accepts the Unix-style end of line convention. If you are reading the code from a file, make sure to use newline conversion mode to convert Windows or Mac-style newlines.
3. Built-in Constants

A small number of constants live in the built-in namespace. They are:

**False**
- The false value of the `bool` type. Assignments to `False` are illegal and raise a `SyntaxError`.

**True**
- The true value of the `bool` type. Assignments to `True` are illegal and raise a `SyntaxError`.

**None**
- The sole value of the type `NoneType`. `None` is frequently used to represent the absence of a value, as when default arguments are not passed to a function. Assignments to `None` are illegal and raise a `SyntaxError`.

**NotImplemented**
- Special value which can be returned by the “rich comparison” special methods (`__eq__`, `__lt__`, and friends), to indicate that the comparison is not implemented with respect to the other type.

**Ellipsis**
- The same as `...`. Special value used mostly in conjunction with extended slicing syntax for user-defined container data types.

**__debug__**
- This constant is true if Python was not started with an `-O` option. See also the `assert` statement.
**Note:** The names `None`, `False`, `True` and `__debug__` cannot be reassigned (assignments to them, even as an attribute name, raise `SyntaxError`), so they can be considered “true” constants.
3.1. Constants added by the **site** module

The **site** module (which is imported automatically during startup, except if the `-S` command-line option is given) adds several constants to the built-in namespace. They are useful for the interactive interpreter shell and should not be used in programs.

```python
quit(code=None)
exit(code=None)
```

Objects that when printed, print a message like “Use quit() or Ctrl-D (i.e. EOF) to exit”, and when called, raise **SystemExit** with the specified exit code.

```python
copyright
license
credits
```

Objects that when printed, print a message like “Type license() to see the full license text”, and when called, display the corresponding text in a pager-like fashion (one screen at a time).
4. Built-in Types

The following sections describe the standard types that are built into the interpreter.

The principal built-in types are numerics, sequences, mappings, classes, instances and exceptions.

Some collection classes are mutable. The methods that add, subtract, or rearrange their members in place, and don’t return a specific item, never return the collection instance itself but None.

Some operations are supported by several object types; in particular, practically all objects can be compared, tested for truth value, and converted to a string (with the \texttt{repr()} function or the slightly different \texttt{str()} function). The latter function is implicitly used when an object is written by the \texttt{print()} function.
4.1. Truth Value Testing

Any object can be tested for truth value, for use in an if or while condition or as operand of the Boolean operations below. The following values are considered false:

- None
- False
- zero of any numeric type, for example, 0, 0.0, 0j.
- any empty sequence, for example, '', (),[].
- any empty mapping, for example, {}.
- instances of user-defined classes, if the class defines a __bool__() or __len__() method, when that method returns the integer zero or bool value False. [1]

All other values are considered true — so objects of many types are always true.

Operations and built-in functions that have a Boolean result always return 0 or False for false and 1 or True for true, unless otherwise stated. (Important exception: the Boolean operations or and and always return one of their operands.)
4.2. Boolean Operations — and, or, not

These are the Boolean operations, ordered by ascending priority:

<table>
<thead>
<tr>
<th>Operation</th>
<th>Result</th>
<th>Notes</th>
</tr>
</thead>
<tbody>
<tr>
<td>x or y</td>
<td>if x is false, then y, else x</td>
<td>(1)</td>
</tr>
<tr>
<td>x and y</td>
<td>if x is false, then x, else y</td>
<td>(2)</td>
</tr>
<tr>
<td>not x</td>
<td>if x is false, then True, else False</td>
<td>(3)</td>
</tr>
</tbody>
</table>

Notes:

1. This is a short-circuit operator, so it only evaluates the second argument if the first one is False.
2. This is a short-circuit operator, so it only evaluates the second argument if the first one is True.
3. not has a lower priority than non-Boolean operators, so not a == b is interpreted as not (a == b), and a == not b is a syntax error.
4.3. Comparisons

There are eight comparison operations in Python. They all have the same priority (which is higher than that of the Boolean operations). Comparisons can be chained arbitrarily; for example, \( x < y \leq z \) is equivalent to \( x < y \) and \( y \leq z \), except that \( y \) is evaluated only once (but in both cases \( z \) is not evaluated at all when \( x < y \) is found to be false).

This table summarizes the comparison operations:

<table>
<thead>
<tr>
<th>Operation</th>
<th>Meaning</th>
</tr>
</thead>
<tbody>
<tr>
<td>&lt;</td>
<td>strictly less than</td>
</tr>
<tr>
<td>&lt;=</td>
<td>less than or equal</td>
</tr>
<tr>
<td>&gt;</td>
<td>strictly greater than</td>
</tr>
<tr>
<td>&gt;=</td>
<td>greater than or equal</td>
</tr>
<tr>
<td>==</td>
<td>equal</td>
</tr>
<tr>
<td>!=</td>
<td>not equal</td>
</tr>
<tr>
<td>is</td>
<td>object identity</td>
</tr>
<tr>
<td>is not</td>
<td>negated object identity</td>
</tr>
</tbody>
</table>

Objects of different types, except different numeric types, never compare equal. Furthermore, some types (for example, function objects) support only a degenerate notion of comparison where any two objects of that type are unequal. The \(<, \leq, >, \geq\) operators will raise a \texttt{TypeError} exception when comparing a complex number with another built-in numeric type, when the objects are of different types that cannot be compared, or in other cases where there is no defined ordering.
Non-identical instances of a class normally compare as non-equal unless the class defines the __eq__() method.

Instances of a class cannot be ordered with respect to other instances of the same class, or other types of object, unless the class defines enough of the methods __lt__(), __le__(), __gt__(), and __ge__() (in general, __lt__() and __eq__() are sufficient, if you want the conventional meanings of the comparison operators).

The behavior of the is and is not operators cannot be customized; also they can be applied to any two objects and never raise an exception.

Two more operations with the same syntactic priority, in and not in, are supported only by sequence types (below).
4.4. Numeric Types — int, float, complex

There are three distinct numeric types: integers, floating point numbers, and complex numbers. In addition, Booleans are a subtype of integers. Integers have unlimited precision. Floating point numbers are usually implemented using double in C; information about the precision and internal representation of floating point numbers for the machine on which your program is running is available in `sys.float_info`. Complex numbers have a real and imaginary part, which are each a floating point number. To extract these parts from a complex number z, use `z.real` and `z.imag`. (The standard library includes additional numeric types, fractions that hold rationals, and decimal that hold floating-point numbers with user-definable precision.)

Numbers are created by numeric literals or as the result of built-in functions and operators. Unadorned integer literals (including hex, octal and binary numbers) yield integers. Numeric literals containing a decimal point or an exponent sign yield floating point numbers. Appending 'j' or 'J' to a numeric literal yields an imaginary number (a complex number with a zero real part) which you can add to an integer or float to get a complex number with real and imaginary parts.

Python fully supports mixed arithmetic: when a binary arithmetic operator has operands of different numeric types, the operand with the “narrower” type is widened to that of the other, where integer is narrower than floating point, which is narrower than complex. Comparisons between numbers of mixed type use the same rule. [2] The constructors `int()`, `float()`, and `complex()` can be used to
produce numbers of a specific type.

All numeric types (except complex) support the following operations, sorted by ascending priority (operations in the same box have the same priority; all numeric operations have a higher priority than comparison operations):

<table>
<thead>
<tr>
<th>Operation</th>
<th>Result</th>
<th>Notes</th>
<th>Full documentation</th>
</tr>
</thead>
<tbody>
<tr>
<td>x + y</td>
<td>sum of x and y</td>
<td></td>
<td></td>
</tr>
<tr>
<td>x - y</td>
<td>difference of x and y</td>
<td></td>
<td></td>
</tr>
<tr>
<td>x * y</td>
<td>product of x and y</td>
<td></td>
<td></td>
</tr>
<tr>
<td>x / y</td>
<td>quotient of x and y</td>
<td></td>
<td></td>
</tr>
<tr>
<td>x // y</td>
<td>floored quotient of x and y</td>
<td>(1)</td>
<td></td>
</tr>
<tr>
<td>x % y</td>
<td>remainder of x / y</td>
<td>(2)</td>
<td></td>
</tr>
<tr>
<td>-x</td>
<td>x negated</td>
<td></td>
<td></td>
</tr>
<tr>
<td>+x</td>
<td>x unchanged</td>
<td></td>
<td></td>
</tr>
<tr>
<td>abs(x)</td>
<td>absolute value or magnitude of x</td>
<td></td>
<td>abs()</td>
</tr>
<tr>
<td>int(x)</td>
<td>x converted to integer</td>
<td>(3)(6)</td>
<td>int()</td>
</tr>
<tr>
<td>float(x)</td>
<td>x converted to floating point</td>
<td>(4)(6)</td>
<td>float()</td>
</tr>
<tr>
<td>complex(re, im)</td>
<td>a complex number with real part re, imaginary part im. im defaults to zero.</td>
<td>(6)</td>
<td>complex()</td>
</tr>
<tr>
<td>c.conjugate()</td>
<td>conjugate of the complex number c</td>
<td></td>
<td></td>
</tr>
</tbody>
</table>
The `divmod()` function computes the pair `(x // y, x % y)`.

- `pow(x, y)` represents `x` to the power `y`.
- `x ** y` is another way to represent `x` to the power `y`.

**Notes:**

1. Also referred to as integer division. The resultant value is a whole integer, though the result's type is not necessarily int. The result is always rounded towards minus infinity: `1//2` is `0`, `(-1)//2` is `-1`, `1//(-2)` is `-1`, and `(-1)//(-2)` is `0`.

2. Not for complex numbers. Instead convert to floats using `abs()` if appropriate.

3. Conversion from floating point to integer may round or truncate as in C; see functions `math.floor()` and `math.ceil()` for well-defined conversions.

4. `float` also accepts the strings “nan” and “inf” with an optional prefix “+” or “-” for Not a Number (NaN) and positive or negative infinity.

5. Python defines `pow(0, 0)` and `0 ** 0` to be 1, as is common for programming languages.

6. The numeric literals accepted include the digits 0 to 9 or any Unicode equivalent (code points with the Nd property).

   See [http://www.unicode.org/Public/6.0.0/ucd/extracted/DerivedNumericType.txt](http://www.unicode.org/Public/6.0.0/ucd/extracted/DerivedNumericType.txt) for a complete list of code points with the Nd property.

All `numbers.Real` types (int and float) also include the following
operations:

<table>
<thead>
<tr>
<th>Operation</th>
<th>Result</th>
<th>Notes</th>
</tr>
</thead>
<tbody>
<tr>
<td><code>math.trunc(x)</code></td>
<td>x truncated to Integral</td>
<td></td>
</tr>
<tr>
<td><code>round(x[, n])</code></td>
<td>x rounded to n digits, rounding half to even. If n is omitted, it defaults to 0.</td>
<td></td>
</tr>
<tr>
<td><code>math.floor(x)</code></td>
<td>the greatest integral float &lt;= x</td>
<td></td>
</tr>
<tr>
<td><code>math.ceil(x)</code></td>
<td>the least integral float &gt;= x</td>
<td></td>
</tr>
</tbody>
</table>

For additional numeric operations see the `math` and `cmath` modules.

4.4.1. Bitwise Operations on Integer Types

Bitwise operations only make sense for integers. Negative numbers are treated as their 2’s complement value (this assumes a sufficiently large number of bits that no overflow occurs during the operation).

The priorities of the binary bitwise operations are all lower than the numeric operations and higher than the comparisons; the unary operation ~ has the same priority as the other unary numeric operations (+ and -).

This table lists the bitwise operations sorted in ascending priority (operations in the same box have the same priority):

<table>
<thead>
<tr>
<th>Operation</th>
<th>Result</th>
<th>Notes</th>
</tr>
</thead>
<tbody>
<tr>
<td>`x</td>
<td>y`</td>
<td>bitwise or of x and y</td>
</tr>
<tr>
<td><code>x ^ y</code></td>
<td>bitwise exclusive or of x and y</td>
<td></td>
</tr>
<tr>
<td><code>x &amp; y</code></td>
<td>bitwise and of x and y</td>
<td></td>
</tr>
<tr>
<td><code>x &lt;&lt; n</code></td>
<td>x shifted left by n bits</td>
<td>(1)(2)</td>
</tr>
<tr>
<td>x &gt;&gt; n</td>
<td>x shifted right by n bits</td>
<td>(1)(3)</td>
</tr>
<tr>
<td>--------</td>
<td>-------------------------------------------</td>
<td>-------</td>
</tr>
<tr>
<td>~x</td>
<td>the bits of x inverted</td>
<td></td>
</tr>
</tbody>
</table>

Notes:

1. Negative shift counts are illegal and cause a `ValueError` to be raised.
2. A left shift by $n$ bits is equivalent to multiplication by `pow(2, n)` without overflow check.
3. A right shift by $n$ bits is equivalent to division by `pow(2, n)` without overflow check.

### 4.4.2. Additional Methods on Integer Types

The `int` type implements the `numbers.Integral` abstract base class. In addition, it provides one more method:

```python
int.bit_length()
```

Return the number of bits necessary to represent an integer in binary, excluding the sign and leading zeros:

```python
>>> n = -37
>>> bin(n)
'-0b100101'
>>> n.bit_length()
6
```

More precisely, if $x$ is nonzero, then $x$.bit_length() is the unique positive integer $k$ such that $2**(k-1) \leq \text{abs}(x) < 2**k$. Equivalently, when abs($x$) is small enough to have a correctly rounded logarithm, then $k = 1 + \text{int}(\log(\text{abs}(x), 2))$. If $x$ is zero, then $x$.bit_length() returns 0.
Equivalent to:

```python
def bit_length(self):
    s = bin(self)  # binary representation:
    s = s.lstrip('-0b')  # remove leading zeros and
    return len(s)  # len('100101') --> 6
```

*New in version 3.1.*

```python
int.to_bytes(length, byteorder, *, signed=False)
```

Return an array of bytes representing an integer.

```bash
>>> (1024).to_bytes(2, byteorder='big')
b'\x04\x00'
>>> (1024).to_bytes(10, byteorder='big')
b'\x00\x00\x00\x00\x00\x00\x00\x00\x04\x00'
>>> (-1024).to_bytes(10, byteorder='big', signed=True)
b'\xff\xff\xff\xff\xff\xff\xff\xff\xfc\x00'
>>> x = 1000
>>> x.to_bytes((x.bit_length() // 8) + 1, byteorder='big')
b'\xe8\x03'
```

The integer is represented using *length* bytes. An *OverflowError* is raised if the integer is not representable with the given number of bytes.

The *byteorder* argument determines the byte order used to represent the integer. If *byteorder* is "big", the most significant byte is at the beginning of the byte array. If *byteorder* is "little", the most significant byte is at the end of the byte array. To request the native byte order of the host system, use `sys.byteorder` as the byte order value.
The *signed* argument determines whether two’s complement is used to represent the integer. If *signed* is False and a negative integer is given, an *OverflowError* is raised. The default value for *signed* is False.

*New in version 3.2.*

**classmethod int.from_bytes**(bytes, byteorder, *, signed=False)

Return the integer represented by the given array of bytes.

```python
>>> int.from_bytes(b'\x00\x10', byteorder='big')
16
>>> int.from_bytes(b'\x00\x10', byteorder='little')
4096
>>> int.from_bytes(b'\xfc\x00', byteorder='big', signed=True)
-1024
>>> int.from_bytes(b'\xfc\x00', byteorder='big', signed=True)
64512
>>> int.from_bytes([255, 0, 0], byteorder='big')
16711680
```

The argument *bytes* must either be a *bytes-like object* or an iterable producing bytes.

The *byteorder* argument determines the byte order used to represent the integer. If *byteorder* is "big", the most significant byte is at the beginning of the byte array. If *byteorder* is "little", the most significant byte is at the end of the byte array. To request the native byte order of the host system, use `sys.byteorder` as the byte order value.

The *signed* argument indicates whether two’s complement is used to represent the integer.
New in version 3.2.

4.4.3. Additional Methods on Float

The float type implements the `numbers.Real abstract base class`. Float also has the following additional methods.

float.`as_integer_ratio()`

Return a pair of integers whose ratio is exactly equal to the original float and with a positive denominator. Raises `OverflowError` on infinities and a `ValueError` on NaNs.

float.`is_integer()`

Return True if the float instance is finite with integral value, and False otherwise:

```python
>>> (-2.0).is_integer()
True
>>> (3.2).is_integer()
False
```

Two methods support conversion to and from hexadecimal strings. Since Python’s floats are stored internally as binary numbers, converting a float to or from a `decimal` string usually involves a small rounding error. In contrast, hexadecimal strings allow exact representation and specification of floating-point numbers. This can be useful when debugging, and in numerical work.

float.`hex()`

Return a representation of a floating-point number as a hexadecimal string. For finite floating-point numbers, this representation will always include a leading `0x` and a trailing `p` and
exponent.

class method float.fromhex(s)

Class method to return the float represented by a hexadecimal string s. The string s may have leading and trailing whitespace.

Note that float.hex() is an instance method, while float.fromhex() is a class method.

A hexadecimal string takes the form:

```
[sign] ['0x'] integer ['.' fraction] ['p' exponent]
```

where the optional sign may be either + or -, integer and fraction are strings of hexadecimal digits, and exponent is a decimal integer with an optional leading sign. Case is not significant, and there must be at least one hexadecimal digit in either the integer or the fraction. This syntax is similar to the syntax specified in section 6.4.4.2 of the C99 standard, and also to the syntax used in Java 1.5 onwards. In particular, the output of float.hex() is usable as a hexadecimal floating-point literal in C or Java code, and hexadecimal strings produced by C's %a format character or Java's Double.toHexString are accepted by float.fromhex().

Note that the exponent is written in decimal rather than hexadecimal, and that it gives the power of 2 by which to multiply the coefficient. For example, the hexadecimal string 0x3.a7p10 represents the floating-point number $3 + 10./16 + 7./16^{**2} \times 2.0^{**10}$, or 3740.0:

```
>>> float.fromhex('0x3.a7p10')
3740.0
```
Applying the reverse conversion to 3740.0 gives a different hexadecimal string representing the same number:

```
>>> float.hex(3740.0)
'0x1.d3800000000000p+11'
```

### 4.4.4. Hashing of numeric types

For numbers $x$ and $y$, possibly of different types, it's a requirement that $\text{hash}(x) == \text{hash}(y)$ whenever $x == y$ (see the `__hash__()` method documentation for more details). For ease of implementation and efficiency across a variety of numeric types (including `int`, `float`, `decimal.Decimal` and `fractions.Fraction`) Python's hash for numeric types is based on a single mathematical function that's defined for any rational number, and hence applies to all instances of `int` and `fractions.Fraction`, and all finite instances of `float` and `decimal.Decimal`. Essentially, this function is given by reduction modulo $P$ for a fixed prime $P$. The value of $P$ is made available to Python as the modulus attribute of `sys.hash_info`.

**CPython implementation detail:** Currently, the prime used is $P = 2**31 - 1$ on machines with 32-bit C longs and $P = 2**61 - 1$ on machines with 64-bit C longs.

Here are the rules in detail:

- If $x = \frac{m}{n}$ is a nonnegative rational number and $n$ is not divisible by $P$, define $\text{hash}(x)$ as $m \times \text{invmod}(n, P) \mod P$, where $\text{invmod}(n, P)$ gives the inverse of $n$ modulo $P$.
- If $x = \frac{m}{n}$ is a nonnegative rational number and $n$ is divisible
by $P$ (but $m$ is not) then $n$ has no inverse modulo $P$ and the rule above doesn't apply; in this case define $\text{hash}(x)$ to be the constant value $\text{sys.hash_info.inf}$.

- If $x = m / n$ is a negative rational number define $\text{hash}(x)$ as $-\text{hash}(-x)$. If the resulting hash is $-1$, replace it with $-2$.
- The particular values $\text{sys.hash_info.inf}$, $-\text{sys.hash_info.inf}$ and $\text{sys.hash_info.nan}$ are used as hash values for positive infinity, negative infinity, or nans (respectively). (All hashable nans have the same hash value.)
- For a complex number $z$, the hash values of the real and imaginary parts are combined by computing $\text{hash}(z.real) + \text{sys.hash_info.imag} \times \text{hash}(z.imag)$, reduced modulo $2^{\text{sys.hash_info.width}}$ so that it lies in range($-2^{\text{sys.hash_info.width} - 1}$, $2^{\text{sys.hash_info.width} - 1}$). Again, if the result is $-1$, it's replaced with $-2$.

To clarify the above rules, here's some example Python code, equivalent to the built-in hash, for computing the hash of a rational number, float, or complex:

```python
import sys, math

def hash_fraction(m, n):
    """Compute the hash of a rational number $m / n$. Assumes $m$ and $n$ are integers, with $n$ positive. Equivalent to hash(fractions.Fraction(m, n)).""

    P = sys.hash_info.modulus
    # Remove common factors of $P$. (Unnecessary if $m$ and $n$ are coprime.)
    while m % P == n % P == 0:
        m, n = m // P, n // P
```
if n % P == 0:
    hash_ = sys.hash_info.inf
else:
    # Fermat's Little Theorem: \( \text{pow}(n, P-1, P) \) is
    # \( \text{pow}(n, P-2, P) \) gives the inverse of \( n \) modulo \( P \).
    hash_ = \((\text{abs}(m) \mod P) \times \text{pow}(n, P - 2, P) \mod P\)
if m < 0:
    hash_ = -hash_
if hash_ == -1:
    hash_ = -2
return hash_

def hash_float(x):
    """Compute the hash of a float \( x \)."""

    if math.isnan(x):
        return sys.hash_info.nan
    elif math.isinf(x):
        return sys.hash_info.inf if x > 0 else -sys.
    else:
        return hash_fraction(*x.as_integer_ratio())

def hash_complex(z):
    """Compute the hash of a complex number \( z \)."""

    hash_ = hash_float(z.real) + sys.hash_info.imag
    # do a signed reduction modulo \( 2^{\text{sys.hash_info.width}} \)
    M = 2**(sys.hash_info.width - 1)
    hash_ = (hash_ & (M - 1)) - (hash & M)
if hash_ == -1:
    hash_ = -2
return hash_
4.5. Iterator Types

Python supports a concept of iteration over containers. This is implemented using two distinct methods; these are used to allow user-defined classes to support iteration. Sequences, described below in more detail, always support the iteration methods.

One method needs to be defined for container objects to provide iteration support:

container.__iter__()  
Return an iterator object. The object is required to support the iterator protocol described below. If a container supports different types of iteration, additional methods can be provided to specifically request iterators for those iteration types. (An example of an object supporting multiple forms of iteration would be a tree structure which supports both breadth-first and depth-first traversal.) This method corresponds to the tp_iter slot of the type structure for Python objects in the Python/C API.

The iterator objects themselves are required to support the following two methods, which together form the iterator protocol:

iterator.__iter__()  
Return the iterator object itself. This is required to allow both containers and iterators to be used with the for and in statements. This method corresponds to the tp_iter slot of the type structure for Python objects in the Python/C API.

iterator.__next__()  
Return the next item from the container. If there are no further items, raise the StopIteration exception. This method
corresponds to the `tp_iternext` slot of the type structure for Python objects in the Python/C API.

Python defines several iterator objects to support iteration over general and specific sequence types, dictionaries, and other more specialized forms. The specific types are not important beyond their implementation of the iterator protocol.

Once an iterator's `__next__()` method raises `StopIteration`, it must continue to do so on subsequent calls. Implementations that do not obey this property are deemed broken.

### 4.5.1. Generator Types

Python's **generators** provide a convenient way to implement the iterator protocol. If a container object’s `__iter__()` method is implemented as a generator, it will automatically return an iterator object (technically, a generator object) supplying the `__iter__()` and `__next__()` methods. More information about generators can be found in *the documentation for the yield expression*. 
4.6. Sequence Types — *list*, *tuple*, *range*

There are three basic sequence types: lists, tuples, and range objects. Additional sequence types tailored for processing of *binary data* and *text strings* are described in dedicated sections.

4.6.1. Common Sequence Operations

The operations in the following table are supported by most sequence types, both mutable and immutable. The *collections.abc.Sequence* ABC is provided to make it easier to correctly implement these operations on custom sequence types.

This table lists the sequence operations sorted in ascending priority (operations in the same box have the same priority). In the table, *s* and *t* are sequences of the same type, *n*, *i*, *j* and *k* are integers and *x* is an arbitrary object that meets any type and value restrictions imposed by *s*.

The *in* and *not in* operations have the same priorities as the comparison operations. The *+* (concatenation) and *\*\* (repetition) operations have the same priority as the corresponding numeric operations.

<table>
<thead>
<tr>
<th>Operation</th>
<th>Result</th>

<td>largest item of <code>s</code></td>
<td></td>
</tr>
<tr>
<td><code>s.index(x[, i[, j]])</code></td>
<td>index of the first occurrence of <code>x</code> in <code>s</code> (at or after index <code>i</code> and before index <code>j</code>)</td>
<td>(8)</td>
</tr>
<tr>
<td><code>s.count(x)</code></td>
<td>total number of occurrences of <code>x</code> in <code>s</code></td>
<td></td>
</tr>
</tbody>
</table>

Sequences of the same type also support comparisons. In particular, tuples and lists are compared lexicographically by comparing corresponding elements. This means that to compare equal, every element must compare equal and the two sequences must be of the same type and have the same length. (For full details see *Comparisons* in the language reference.)

Notes:

1. While the `in` and `not in` operations are used only for simple containment testing in the general case, some specialised sequences (such as `str`, `bytes` and `bytearray`) also use them for subsequence testing:

```
>>> "gg" in "eggs"
True
```
2. Values of $n$ less than 0 are treated as 0 (which yields an empty sequence of the same type as $s$). Note also that the copies are shallow; nested structures are not copied. This often haunts new Python programmers; consider:

```python
>>> lists = [[]] * 3
>>> lists
[[], [], []]
>>> lists[0].append(3)
>>> lists
[[3], [3], [3]]
```

What has happened is that `[[ ]]` is a one-element list containing an empty list, so all three elements of `[[ ]] * 3` are (pointers to) this single empty list. Modifying any of the elements of `lists` modifies this single list. You can create a list of different lists this way:

```python
>>> lists = [[] for i in range(3)]
>>> lists[0].append(3)
>>> lists[1].append(5)
>>> lists[2].append(7)
>>> lists
[[3], [5], [7]]
```

3. If $i$ or $j$ is negative, the index is relative to the end of the string: `len(s) + i` or `len(s) + j` is substituted. But note that `-0` is still 0.

4. The slice of $s$ from $i$ to $j$ is defined as the sequence of items with index $k$ such that $i \leq k < j$. If $i$ or $j$ is greater than `len(s)`, use `len(s)`. If $i$ is omitted or `None`, use 0. If $j$ is omitted or `None`, use `len(s)`. If $i$ is greater than or equal to $j$, the slice is empty.
5. The slice of $s$ from $i$ to $j$ with step $k$ is defined as the sequence of items with index $x = i + n*k$ such that $0 \leq n < (j-i)/k$. In other words, the indices are $i, i+k, i+2*k, i+3*k$ and so on, stopping when $j$ is reached (but never including $j$). If $i$ or $j$ is greater than $\text{len}(s)$, use $\text{len}(s)$. If $i$ or $j$ are omitted or None, they become “end” values (which end depends on the sign of $k$). Note, $k$ cannot be zero. If $k$ is None, it is treated like 1.

6. Concatenating immutable sequences always results in a new object. This means that building up a sequence by repeated concatenation will have a quadratic runtime cost in the total sequence length. To get a linear runtime cost, you must switch to one of the alternatives below:

   - if concatenating str objects, you can build a list and use $\text{str.join()}$ at the end or else write to a $\text{io.StringIO}$ instance and retrieve its value when complete
   - if concatenating bytes objects, you can similarly use $\text{bytes.join()}$ or $\text{io.BytesIO}$, or you can do in-place concatenation with a bytearray object. bytearray objects are mutable and have an efficient overallocation mechanism
   - if concatenating tuple objects, extend a list instead
   - for other types, investigate the relevant class documentation

7. Some sequence types (such as range) only support item sequences that follow specific patterns, and hence don’t support sequence concatenation or repetition.

8. $\text{index}$ raises $\text{ValueError}$ when $x$ is not found in $s$. When supported, the additional arguments to the index method allow efficient searching of subsections of the sequence. Passing the extra arguments is roughly equivalent to using
\[s[i:j].index(x)\], only without copying any data and with the returned index being relative to the start of the sequence rather than the start of the slice.

4.6.2. Immutable Sequence Types

The only operation that immutable sequence types generally implement that is not also implemented by mutable sequence types is support for the \texttt{hash()} built-in.

This support allows immutable sequences, such as \texttt{tuple} instances, to be used as \texttt{dict} keys and stored in \texttt{set} and \texttt{frozenset} instances.

Attempting to hash an immutable sequence that contains unhashable values will result in \texttt{TypeError}.

4.6.3. Mutable Sequence Types

The operations in the following table are defined on mutable sequence types. The \texttt{collections.abc.MutableSequence} ABC is provided to make it easier to correctly implement these operations on custom sequence types.

In the table \(s\) is an instance of a mutable sequence type, \(t\) is any iterable object and \(x\) is an arbitrary object that meets any type and value restrictions imposed by \(s\) (for example, \texttt{bytearray} only accepts integers that meet the value restriction \(0 \leq x \leq 255\)).

<table>
<thead>
<tr>
<th>Operation</th>
<th>Result</th>
<th>Notes</th>
</tr>
</thead>
<tbody>
<tr>
<td>(s[i] = x)</td>
<td>item (i) of (s) is replaced by (x)</td>
<td></td>
</tr>
<tr>
<td>Operation</td>
<td>Description</td>
<td></td>
</tr>
<tr>
<td>--------------------------</td>
<td>-----------------------------------------------------------------------------</td>
<td></td>
</tr>
<tr>
<td><code>s[i:j] = t</code></td>
<td>slice of <code>s</code> from <code>i</code> to <code>j</code> is replaced by the contents of the iterable <code>t</code></td>
<td></td>
</tr>
<tr>
<td><code>del s[i:j]</code></td>
<td>same as <code>s[i:j] = []</code></td>
<td></td>
</tr>
<tr>
<td><code>s[i:j:k] = t</code></td>
<td>the elements of <code>s[i:j:k]</code> are replaced by those of <code>t</code></td>
<td></td>
</tr>
<tr>
<td><code>del s[i:j:k]</code></td>
<td>removes the elements of <code>s[i:j:k]</code> from the list</td>
<td></td>
</tr>
<tr>
<td><code>s.append(x)</code></td>
<td>appends <code>x</code> to the end of the sequence (same as <code>s[len(s):len(s)] = [x]</code>)</td>
<td></td>
</tr>
<tr>
<td><code>s.clear()</code></td>
<td>removes all items from <code>s</code> (same as <code>del s[:]</code>)</td>
<td></td>
</tr>
<tr>
<td><code>s.copy()</code></td>
<td>creates a shallow copy of <code>s</code> (same as <code>s[:]</code>)</td>
<td></td>
</tr>
<tr>
<td><code>s.extend(t)</code></td>
<td>extends <code>s</code> with the contents of <code>t</code> (same as <code>s[len(s):len(s)] = t</code>)</td>
<td></td>
</tr>
<tr>
<td><code>s.insert(i, x)</code></td>
<td>inserts <code>x</code> into <code>s</code> at the index given by <code>i</code> (same as <code>s[i:i] = [x]</code>)</td>
<td></td>
</tr>
<tr>
<td><code>s.pop([i])</code></td>
<td>retrieves the item at <code>i</code> and also removes it from <code>s</code></td>
<td></td>
</tr>
<tr>
<td><code>s.remove(x)</code></td>
<td>remove the first item from <code>s</code> where <code>s[i] == x</code></td>
<td></td>
</tr>
<tr>
<td><code>s.reverse()</code></td>
<td>reverses the items of <code>s</code> in place</td>
<td></td>
</tr>
</tbody>
</table>
Notes:

1. \[ t \] must have the same length as the slice it is replacing.

2. The optional argument \[ i \] defaults to \[-1\], so that by default the last item is removed and returned.

3. \texttt{remove} raises \texttt{ValueError} when \( x \) is not found in \( s \).

4. The \texttt{reverse()} method modifies the sequence in place for economy of space when reversing a large sequence. To remind users that it operates by side effect, it does not return the reversed sequence.

5. \texttt{clear()} and \texttt{copy()} are included for consistency with the interfaces of mutable containers that don’t support slicing operations (such as \texttt{dict} and \texttt{set})

\textit{New in version 3.3: clear()} and \texttt{copy()} methods.

4.6.4. Lists

Lists are mutable sequences, typically used to store collections of homogeneous items (where the precise degree of similarity will vary by application).

\texttt{class list([iterable])}

Lists may be constructed in several ways:

- Using a pair of square brackets to denote the empty list: \([\,]\)
- Using square brackets, separating items with commas: \([a], [a, b, c]\)
- Using a list comprehension: `[x for x in iterable]`
- Using the type constructor: `list()` or `list(iterable)`

The constructor builds a list whose items are the same and in the same order as `iterable`'s items. `iterable` may be either a sequence, a container that supports iteration, or an iterator object. If `iterable` is already a list, a copy is made and returned, similar to `iterable[:]`. For example, `list('abc')` returns `['a', 'b', 'c']` and `list((1, 2, 3))` returns `[1, 2, 3]`. If no argument is given, the constructor creates a new empty list, `[]`.

Many other operations also produce lists, including the `sorted()` built-in.

Lists implement all of the `common` and `mutable` sequence operations. Lists also provide the following additional method:

```python
sort(*, key=None, reverse=None)
```

This method sorts the list in place, using only `<` comparisons between items. Exceptions are not suppressed - if any comparison operations fail, the entire sort operation will fail (and the list will likely be left in a partially modified state).

`key` specifies a function of one argument that is used to extract a comparison key from each list element (for example, `key=str.lower`). The key corresponding to each item in the list is calculated once and then used for the entire sorting process. The default value of `None` means that list items are sorted directly without calculating a separate key value.

The `functools.cmp_to_key()` utility is available to convert a 2.x style `cmp` function to a `key` function.
reverse is a boolean value. If set to True, then the list elements are sorted as if each comparison were reversed.

This method modifies the sequence in place for economy of space when sorting a large sequence. To remind users that it operates by side effect, it does not return the sorted sequence (use \texttt{sorted()} to explicitly request a new sorted list instance).

The \texttt{sort()} method is guaranteed to be stable. A sort is stable if it guarantees not to change the relative order of elements that compare equal — this is helpful for sorting in multiple passes (for example, sort by department, then by salary grade).

\textbf{CPython implementation detail:} While a list is being sorted, the effect of attempting to mutate, or even inspect, the list is undefined. The C implementation of Python makes the list appear empty for the duration, and raises \texttt{ValueError} if it can detect that the list has been mutated during a sort.

4.6.5. Tuples

Tuples are immutable sequences, typically used to store collections of heterogeneous data (such as the 2-tuples produced by the \texttt{enumerate()} built-in). Tuples are also used for cases where an immutable sequence of homogeneous data is needed (such as allowing storage in a \texttt{set} or \texttt{dict} instance).

\texttt{class tuple([iterable])}

Tuples may be constructed in a number of ways:

- Using a pair of parentheses to denote the empty tuple: ( )
- Using a trailing comma for a singleton tuple: a, or (a, )
- Separating items with commas: \(a, b, c\) or \((a, b, c)\)
- Using the `tuple()` built-in: `tuple()` or `tuple(iterable)`

The constructor builds a tuple whose items are the same and in the same order as `iterable`'s items. `iterable` may be either a sequence, a container that supports iteration, or an iterator object. If `iterable` is already a tuple, it is returned unchanged. For example, `tuple('abc')` returns \('a', 'b', 'c'\) and `tuple([1, 2, 3])` returns \(1, 2, 3\). If no argument is given, the constructor creates a new empty tuple, \(()\).

Note that it is actually the comma which makes a tuple, not the parentheses. The parentheses are optional, except in the empty tuple case, or when they are needed to avoid syntactic ambiguity. For example, `f(a, b, c)` is a function call with three arguments, while `f((a, b, c))` is a function call with a 3-tuple as the sole argument.

Tuples implement all of the `common` sequence operations.

For heterogeneous collections of data where access by name is clearer than access by index, `collections.namedtuple()` may be a more appropriate choice than a simple tuple object.

### 4.6.6. Ranges

The `range` type represents an immutable sequence of numbers and is commonly used for looping a specific number of times in `for` loops.

```python
class range(stop)
class range(start, stop[, step])
```

The arguments to the range constructor must be integers (either
built-in `int` or any object that implements the `__index__` special method). If the `step` argument is omitted, it defaults to 1. If the `start` argument is omitted, it defaults to 0. If `step` is zero, `ValueError` is raised.

For a positive `step`, the contents of a range `r` are determined by the formula `r[i] = start + step*i` where `i >= 0` and `r[i] < stop`.

For a negative `step`, the contents of the range are still determined by the formula `r[i] = start + step*i`, but the constraints are `i >= 0` and `r[i] > stop`.

A range object will be empty if `r[0]` does not meet the value constraint. Ranges do support negative indices, but these are interpreted as indexing from the end of the sequence determined by the positive indices.

Ranges containing absolute values larger than `sys.maxsize` are permitted but some features (such as `len()`) may raise `OverflowError`.

Range examples:

```python
generate a list from range(10)
>>> list(range(10))
[0, 1, 2, 3, 4, 5, 6, 7, 8, 9]
generate a list from range(11)
>>> list(range(11))
[1, 2, 3, 4, 5, 6, 7, 8, 9, 10]
generate a list from range(0, 30, 5)
>>> list(range(0, 30, 5))
[0, 5, 10, 15, 20, 25]
generate a list from range(0, 10, 3)
>>> list(range(0, 10, 3))
[0, 3, 6, 9]
generate a list from range(0, -10, -1)
>>> list(range(0, -10, -1))
[0, -1, -2, -3, -4, -5, -6, -7, -8, -9]
```
Ranges implement all of the *common* sequence operations except concatenation and repetition (due to the fact that range objects can only represent sequences that follow a strict pattern and repetition and concatenation will usually violate that pattern).

The advantage of the `range` type over a regular `list` or `tuple` is that a `range` object will always take the same (small) amount of memory, no matter the size of the range it represents (as it only stores the `start`, `stop` and `step` values, calculating individual items and subranges as needed).

Range objects implement the `collections.abc.Sequence` ABC, and provide features such as containment tests, element index lookup, slicing and support for negative indices (see *Sequence Types — list, tuple, range*):

```python
>>> r = range(0, 20, 2)
>>> r
range(0, 20, 2)
>>> 11 in r
False
>>> 10 in r
True
>>> r.index(10)
5
>>> r[5]
10
>>> r[:5]
range(0, 10, 2)
>>> r[-1]
18
```
Testing range objects for equality with `==` and `!=` compares them as sequences. That is, two range objects are considered equal if they represent the same sequence of values. (Note that two range objects that compare equal might have different start, stop and step attributes, for example `range(0) == range(2, 1, 3)` or `range(0, 3, 2) == range(0, 4, 2)`.)

*Changed in version 3.2:* Implement the Sequence ABC. Support slicing and negative indices. Test `int` objects for membership in constant time instead of iterating through all items.

*Changed in version 3.3:* Define `==` and `!=` to compare range objects based on the sequence of values they define (instead of comparing based on object identity).

*New in version 3.3:* The start, stop and step attributes.
4.7. Text Sequence Type — `str`

Textual data in Python is handled with `str` objects, or *strings*. Strings are immutable *sequences* of Unicode code points. String literals are written in a variety of ways:

- Single quotes: "allows embedded "double" quotes"
- Double quotes: "allows embedded 'single' quotes".
- Triple quoted: "'''Three single quotes'''", """"Three double quotes""

Triple quoted strings may span multiple lines - all associated whitespace will be included in the string literal.

String literals that are part of a single expression and have only whitespace between them will be implicitly converted to a single string literal. That is, ('spam "eggs") == "spam eggs".

See *String and Bytes literals* for more about the various forms of string literal, including supported escape sequences, and the `r` ("raw") prefix that disables most escape sequence processing.

Strings may also be created from other objects using the `str` constructor.

Since there is no separate “character” type, indexing a string produces strings of length 1. That is, for a non-empty string `s`, `s[0] == s[0:1]`.

There is also no mutable string type, but `str.join()` or `io.StringIO` can be used to efficiently construct strings from multiple fragments.
*Changed in version 3.3:* For backwards compatibility with the Python 2 series, the `u` prefix is once again permitted on string literals. It has no effect on the meaning of string literals and cannot be combined with the `r` prefix.

```python
class str(object="")
class str(object=b'', encoding='utf-8', errors='strict')
```

Return a *string* version of `object`. If `object` is not provided, returns the empty string. Otherwise, the behavior of `str()` depends on whether `encoding` or `errors` is given, as follows.

If neither `encoding` nor `errors` is given, `str(object)` returns `object.__str__()`, which is the “informal” or nicely printable string representation of `object`. For string objects, this is the string itself. If `object` does not have a `__str__()` method, then `str()` falls back to returning `repr(object)`.

If at least one of `encoding` or `errors` is given, `object` should be a *bytes-like object* (e.g. `bytes` or `bytearray`). In this case, if `object` is a `bytes` (or `bytearray`) object, then `str(bytes, encoding, errors)` is equivalent to `bytes.decode(encoding, errors)`. Otherwise, the bytes object underlying the buffer object is obtained before calling `bytes.decode()`. See *Binary Sequence Types — bytes, bytearray, memoryview* and *Buffer Protocol* for information on buffer objects.

Passing a `bytes` object to `str()` without the `encoding` or `errors` arguments falls under the first case of returning the informal string representation (see also the `-b` command-line option to Python). For example:
For more information on the str class and its methods, see Text Sequence Type — str and the String Methods section below. To output formatted strings, see the String Formatting section. In addition, see the Text Processing Services section.

### 4.7.1. String Methods

Strings implement all of the common sequence operations, along with the additional methods described below.

Strings also support two styles of string formatting, one providing a large degree of flexibility and customization (see str.format(), Format String Syntax and String Formatting) and the other based on C printf style formatting that handles a narrower range of types and is slightly harder to use correctly, but is often faster for the cases it can handle (printf-style String Formatting).

The Text Processing Services section of the standard library covers a number of other modules that provide various text related utilities (including regular expression support in the re module).

**str.capitalize()**

Return a copy of the string with its first character capitalized and the rest lowercased.

**str.casefold()**

Return a casefolded copy of the string. Casefolded strings may be used for caseless matching.
Casefolding is similar to lowercasing but more aggressive because it is intended to remove all case distinctions in a string. For example, the German lowercase letter 'ß' is equivalent to "ss". Since it is already lowercase, `lower()` would do nothing to 'ß'; `casefold()` converts it to "ss".

The casefolding algorithm is described in section 3.13 of the Unicode Standard.

*New in version 3.3.*

```python
str.center(width[, fillchar])
```

Return centered in a string of length `width`. Padding is done using the specified `fillchar` (default is a space).

```python
str.count(sub[, start[, end]])
```

Return the number of non-overlapping occurrences of substring `sub` in the range `[start, end]`. Optional arguments `start` and `end` are interpreted as in slice notation.

```python
str.encode(encoding="utf-8", errors="strict")
```

Return an encoded version of the string as a bytes object. Default encoding is 'utf-8'. `errors` may be given to set a different error handling scheme. The default for `errors` is 'strict', meaning that encoding errors raise a `UnicodeError`. Other possible values are 'ignore', 'replace', 'xmlcharrefreplace', 'backslashreplace' and any other name registered via `codecs.register_error()`, see section *Codec Base Classes*. For a list of possible encodings, see section *Standard Encodings*.

*Changed in version 3.1: Support for keyword arguments added.*
str.\texttt{endswith}(\texttt{suffix[, start[, end]]})

Return True if the string ends with the specified \texttt{suffix}, otherwise return False. \texttt{suffix} can also be a tuple of suffixes to look for. With optional \texttt{start}, test beginning at that position. With optional \texttt{end}, stop comparing at that position.

str.\texttt{expandtabs}([\texttt{tabsize}])

Return a copy of the string where all tab characters are replaced by one or more spaces, depending on the current column and the given tab size. Tab positions occur every \texttt{tabsize} characters (default is 8, giving tab positions at columns 0, 8, 16 and so on). To expand the string, the current column is set to zero and the string is examined character by character. If the character is a tab (\texttt{\tab}), one or more space characters are inserted in the result until the current column is equal to the next tab position. (The tab character itself is not copied.) If the character is a newline (\texttt{\n}) or return (\texttt{\r}), it is copied and the current column is reset to zero. Any other character is copied unchanged and the current column is incremented by one regardless of how the character is represented when printed.

\begin{verbatim}
>>> '01\t012\t0123\t01234'.expandtabs()
'01 012 0123 01234'
>>> '01\t012\t0123\t01234'.expandtabs(4)
'01 012 0123 01234'
\end{verbatim}

str.\texttt{find}(\texttt{sub[, start[, end]]})

Return the lowest index in the string where substring \texttt{sub} is found, such that \texttt{sub} is contained in the slice \texttt{s[start:end]}. Optional arguments \texttt{start} and \texttt{end} are interpreted as in slice notation. Return -1 if \texttt{sub} is not found.
Note: The `find()` method should be used only if you need to know the position of `sub`. To check if `sub` is a substring or not, use the `in` operator:

```python
>>> 'Py' in 'Python'
True
```

`str.format(*args, **kwargs)`
Perform a string formatting operation. The string on which this method is called can contain literal text or replacement fields delimited by braces `{}`. Each replacement field contains either the numeric index of a positional argument, or the name of a keyword argument. Returns a copy of the string where each replacement field is replaced with the string value of the corresponding argument.

```python
>>> "The sum of 1 + 2 is {0}".format(1+2)
'The sum of 1 + 2 is 3'
```

See *Format String Syntax* for a description of the various formatting options that can be specified in format strings.

`str.format_map(mapping)`
Similar to `str.format(**mapping)`, except that `mapping` is used directly and not copied to a `dict`. This is useful if for example `mapping` is a dict subclass:

```python
>>> class Default(dict):
...     def __missing__(self, key):
...         return key
...     ...
>>> '{name} was born in {country}'.format_map(Default)
```

'Guido was born in country'

New in version 3.2.

```python
str.index(sub[, start[, end]])
```
Like `find()`, but raise `ValueError` when the substring is not found.

```python
str.isalnum()
```
Return true if all characters in the string are alphanumerics and there is at least one character, false otherwise. A character `c` is alphanumeric if one of the following returns True: `c.isalpha()`, `c.isdecimal()`, `c.isdigit()`, or `c.isnumeric()`.

```python
str.isalpha()
```
Return true if all characters in the string are alphabetic and there is at least one character, false otherwise. Alphabetic characters are those characters defined in the Unicode character database as “Letter”, i.e., those with general category property being one of “Lm”, “Lt”, “Lu”, “Ll”, or “Lo”. Note that this is different from the “Alphabetic” property defined in the Unicode Standard.

```python
str.isdecimal()
```
Return true if all characters in the string are decimal characters and there is at least one character, false otherwise. Decimal characters are those from general category “Nd”. This category includes digit characters, and all characters that can be used to form decimal-radix numbers, e.g. U+0660, ARABIC-INDIC DIGIT ZERO.

```python
str.isdigit()
```
Return true if all characters in the string are digits and there is at least one character, false otherwise. Digits include decimal
characters and digits that need special handling, such as the compatibility superscript digits. Formally, a digit is a character that has the property value `Numeric_Type=Digit` or `Numeric_Type=Decimal`.

**str. isidentifier()**
Return true if the string is a valid identifier according to the language definition, section *Identifiers and keywords*.

Use `keyword.iskeyword()` to test for reserved identifiers such as `def` and `class`.

**str. islower()**
Return true if all cased characters [4] in the string are lowercase and there is at least one cased character, false otherwise.

**str. isnumeric()**
Return true if all characters in the string are numeric characters, and there is at least one character, false otherwise. Numeric characters include digit characters, and all characters that have the Unicode numeric value property, e.g. U+2155, VULGAR FRACTION ONE FIFTH. Formally, numeric characters are those with the property value `Numeric_Type=Digit`, `Numeric_Type=Decimal` or `Numeric_Type=Numeric`.

**str. isprintable()**
Return true if all characters in the string are printable or the string is empty, false otherwise. Nonprintable characters are those characters defined in the Unicode character database as “Other” or “Separator”, excepting the ASCII space (0x20) which is considered printable. (Note that printable characters in this context are those which should not be escaped when `repr()` is invoked on a string.)
It has no bearing on the handling of strings written to `sys.stdout` or `sys.stderr`.

`str.isspace()`  
Return true if there are only whitespace characters in the string and there is at least one character, false otherwise. Whitespace characters are those characters defined in the Unicode character database as “Other” or “Separator” and those with bidirectional property being one of “WS”, “B”, or “S”.

`str.istitle()`  
Return true if the string is a titlecased string and there is at least one character, for example uppercase characters may only follow uncased characters and lowercase characters only cased ones. Return false otherwise.

`str.isupper()`  
Return true if all cased characters in the string are uppercase and there is at least one cased character, false otherwise.

`str.join(iterable)`  
Return a string which is the concatenation of the strings in the `iterable iterable`. A `TypeError` will be raised if there are any non-string values in `iterable`, including `bytes` objects. The separator between elements is the string providing this method.

`str.ljust(width[, fillchar])`  
Return the string left justified in a string of length `width`. Padding is done using the specified `fillchar` (default is a space). The original string is returned if `width` is less than or equal to `len(s)`.

`str.lower()`
Return a copy of the string with all the cased characters [4] converted to lowercase.

The lowercasing algorithm used is described in section 3.13 of the Unicode Standard.

\textbf{str.} \texttt{lstrip([chars])}

Return a copy of the string with leading characters removed. The \texttt{chars} argument is a string specifying the set of characters to be removed. If omitted or None, the \texttt{chars} argument defaults to removing whitespace. The \texttt{chars} argument is not a prefix; rather, all combinations of its values are stripped:

\begin{verbatim}
>>> '   spacious   '.lstrip()
'spacious   '
>>> 'www.example.com'.lstrip('cmowz.')
'exmple.com'
\end{verbatim}

\textbf{static str.} \texttt{maketrans(x[, y[, z]])}

This static method returns a translation table usable for \texttt{str.translate()}.

If there is only one argument, it must be a dictionary mapping Unicode ordinals (integers) or characters (strings of length 1) to Unicode ordinals, strings (of arbitrary lengths) or None. Character keys will then be converted to ordinals.

If there are two arguments, they must be strings of equal length, and in the resulting dictionary, each character in \texttt{x} will be mapped to the character at the same position in \texttt{y}. If there is a third argument, it must be a string, whose characters will be mapped to None in the result.
str. **partition**(sep)

Split the string at the first occurrence of *sep*, and return a 3-tuple containing the part before the separator, the separator itself, and the part after the separator. If the separator is not found, return a 3-tuple containing the string itself, followed by two empty strings.

str. **replace**(old, new[, count])

Return a copy of the string with all occurrences of substring *old* replaced by *new*. If the optional argument *count* is given, only the first *count* occurrences are replaced.

str. **rfind**(sub[, start[, end]])

Return the highest index in the string where substring *sub* is found, such that *sub* is contained within *s[start:end]*. Optional arguments *start* and *end* are interpreted as in slice notation. Return -1 on failure.

str. **rindex**(sub[, start[, end]])

Like rfind() but raises ValueError when the substring *sub* is not found.

str. **rjust**(width[, fillchar])

Return the string right justified in a string of length *width*. Padding is done using the specified *fillchar* (default is a space). The original string is returned if *width* is less than or equal to len(s).

str. **rpartition**(sep)

Split the string at the last occurrence of *sep*, and return a 3-tuple containing the part before the separator, the separator itself, and the part after the separator. If the separator is not found, return a 3-tuple containing two empty strings, followed by the string itself.
str.rsplit(sep=None, maxsplit=-1)
Return a list of the words in the string, using `sep` as the delimiter string. If `maxsplit` is given, at most `maxsplit` splits are done, the rightmost ones. If `sep` is not specified or None, any whitespace string is a separator. Except for splitting from the right, `rsplit()` behaves like `split()` which is described in detail below.

str.rstrip([chars])
Return a copy of the string with trailing characters removed. The `chars` argument is a string specifying the set of characters to be removed. If omitted or None, the `chars` argument defaults to removing whitespace. The `chars` argument is not a suffix; rather, all combinations of its values are stripped:

```python
>>> '    spacious    '.rstrip()
'    spacious'
>>> 'mississippi'.rstrip('ipz')
'mississ'
```

str.split(sep=None, maxsplit=-1)
Return a list of the words in the string, using `sep` as the delimiter string. If `maxsplit` is given, at most `maxsplit` splits are done (thus, the list will have at most `maxsplit+1` elements). If `maxsplit` is not specified or -1, then there is no limit on the number of splits (all possible splits are made).

If `sep` is given, consecutive delimiters are not grouped together and are deemed to delimit empty strings (for example, '1,,2'.split(',,')) returns ['1', '', '2']]. The `sep` argument may consist of multiple characters (for example, '1<>2<>3'.split('<>')) returns ['1', '2', '3']]. Splitting an empty string with a specified separator returns [''].
If `sep` is not specified or is `None`, a different splitting algorithm is applied: runs of consecutive whitespace are regarded as a single separator, and the result will contain no empty strings at the start or end if the string has leading or trailing whitespace. Consequently, splitting an empty string or a string consisting of just whitespace with a `None` separator returns `[]`.

For example, `'1 2 3}'.split() returns `['1', '2', '3']`, and `'1 2 3}'.split(None, 1) returns `['1', '2 3 '].

**str.splitlines([keepends])**

Return a list of the lines in the string, breaking at line boundaries. This method uses the *universal newlines* approach to splitting lines. Line breaks are not included in the resulting list unless `keepends` is given and true.

For example, `'ab c\n\nde fg\rkl\r\n'.splitlines() returns `['ab c', '', 'de fg', 'kl']`, while the same call with `splitlines(True)` returns `['ab c\n', '\n', 'de fg\r', 'kl\r\n']`.

Unlike `split()` when a delimiter string `sep` is given, this method returns an empty list for the empty string, and a terminal line break does not result in an extra line.

**str.startswith(prefix[, start[, end]])**

Return `True` if string starts with the `prefix`, otherwise return `False`. `prefix` can also be a tuple of prefixes to look for. With optional `start`, test string beginning at that position. With optional `end`, stop comparing string at that position.
str. `strip([chars])`

Return a copy of the string with the leading and trailing characters removed. The `chars` argument is a string specifying the set of characters to be removed. If omitted or None, the `chars` argument defaults to removing whitespace. The `chars` argument is not a prefix or suffix; rather, all combinations of its values are stripped:

```python
>>> '   spacious   '.strip()
'spacious'
>>> 'www.example.com'.strip('cmowz.')
'example'
```

str. `swapcase()`

Return a copy of the string with uppercase characters converted to lowercase and vice versa. Note that it is not necessarily true that `s.swapcase().swapcase() == s`.

str. `title()`

Return a titlecased version of the string where words start with an uppercase character and the remaining characters are lowercase.

The algorithm uses a simple language-independent definition of a word as groups of consecutive letters. The definition works in many contexts but it means that apostrophes in contractions and possessives form word boundaries, which may not be the desired result:

```python
>>> "they're bill's friends from the UK".title()
"They'Re Bill'S Friends From The Uk"
```

A workaround for apostrophes can be constructed using regular expressions:

```python
>>> import re
>>> def titlecase(s):
...     return re.sub(r"[A-Za-z]+('[A-Za-z]+)?",
...                   lambda mo: mo.group(0)[0].upper() + mo.group(0)[1:].lower(),
...                   s)
...     titlecase("they're bill's friends.")
"They're Bill's Friends."
```

`str.translate(map)`

Return a copy of the s where all characters have been mapped through the `map` which must be a dictionary of Unicode ordinals (integers) to Unicode ordinals, strings or None. Unmapped characters are left untouched. Characters mapped to None are deleted.

You can use `str.maketrans()` to create a translation map from character-to-character mappings in different formats.

**Note:** An even more flexible approach is to create a custom character mapping codec using the `codecs` module (see `encodings.cp1251` for an example).

`str.upper()`

Return a copy of the string with all the cased characters [4] converted to uppercase. Note that `str.upper().isupper()` might be False if `s` contains uncased characters or if the Unicode category of the resulting character(s) is not “Lu” (Letter, uppercase), but e.g. “Lt” (Letter, titlecase).

The uppercasing algorithm used is described in section 3.13 of the
str.\texttt{zfill}(width)

Return the numeric string left filled with zeros in a string of length \textit{width}. A sign prefix is handled correctly. The original string is returned if \textit{width} is less than or equal to \texttt{len(s)}.

4.7.2. \texttt{printf}-style String Formatting

\begin{quote}
\textbf{Note:} The formatting operations described here exhibit a variety of quirks that lead to a number of common errors (such as failing to display tuples and dictionaries correctly). Using the newer \texttt{str.format()} interface helps avoid these errors, and also provides a generally more powerful, flexible and extensible approach to formatting text.
\end{quote}

String objects have one unique built-in operation: the \texttt{%} operator (modulo). This is also known as the string \textit{formatting} or \textit{interpolation} operator. Given \texttt{format \% values} (where \texttt{format} is a string), \% conversion specifications in \texttt{format} are replaced with zero or more elements of \texttt{values}. The effect is similar to using the \texttt{sprintf()} in the C language.

If \texttt{format} requires a single argument, \texttt{values} may be a single non-tuple object. \cite{footnote:5} Otherwise, \texttt{values} must be a tuple with exactly the number of items specified by the format string, or a single mapping object (for example, a dictionary).

A conversion specifier contains two or more characters and has the following components, which must occur in this order:

1. The \texttt{'\%'} character, which marks the start of the specifier.
2. Mapping key (optional), consisting of a parenthesised sequence of characters (for example, (somename)).
3. Conversion flags (optional), which affect the result of some conversion types.
4. Minimum field width (optional). If specified as an '*' (asterisk), the actual width is read from the next element of the tuple in values, and the object to convert comes after the minimum field width and optional precision.
5. Precision (optional), given as a '.' (dot) followed by the precision. If specified as '*' (an asterisk), the actual precision is read from the next element of the tuple in values, and the value to convert comes after the precision.
7. Conversion type.

When the right argument is a dictionary (or other mapping type), then the formats in the string must include a parenthesised mapping key into that dictionary inserted immediately after the '%' character. The mapping key selects the value to be formatted from the mapping. For example:

```python
>>> print('%(language)s has %(number)03d quote types
...     { 'language': "Python", "number": 2 })
Python has 002 quote types.
```

In this case no * specifiers may occur in a format (since they require a sequential parameter list).

The conversion flag characters are:

<table>
<thead>
<tr>
<th>Flag</th>
<th>Meaning</th>
</tr>
</thead>
<tbody>
<tr>
<td>'#'</td>
<td>The value conversion will use the “alternate form” (where defined below).</td>
</tr>
</tbody>
</table>
The conversion will be zero padded for numeric values.

The converted value is left adjusted (overrides the '0' conversion if both are given).

(a space) A blank should be left before a positive number (or empty string) produced by a signed conversion.

A sign character ( '+' or '-' ) will precede the conversion (overrides a “space” flag).

A length modifier (h, l, or L) may be present, but is ignored as it is not necessary for Python – so e.g. %ld is identical to %d.

The conversion types are:

<table>
<thead>
<tr>
<th>Conversion</th>
<th>Meaning</th>
<th>Notes</th>
</tr>
</thead>
<tbody>
<tr>
<td>'d'</td>
<td>Signed integer decimal.</td>
<td></td>
</tr>
<tr>
<td>'i'</td>
<td>Signed integer decimal.</td>
<td></td>
</tr>
<tr>
<td>'o'</td>
<td>Signed octal value.</td>
<td>(1)</td>
</tr>
<tr>
<td>'u'</td>
<td>Obsolete type – it is identical to 'd'.</td>
<td>(7)</td>
</tr>
<tr>
<td>'x'</td>
<td>Signed hexadecimal (lowercase).</td>
<td>(2)</td>
</tr>
<tr>
<td>'X'</td>
<td>Signed hexadecimal (uppercase).</td>
<td>(2)</td>
</tr>
<tr>
<td>'e'</td>
<td>Floating point exponential format (lowercase).</td>
<td>(3)</td>
</tr>
<tr>
<td>'E'</td>
<td>Floating point exponential format (uppercase).</td>
<td>(3)</td>
</tr>
<tr>
<td>'f'</td>
<td>Floating point decimal format.</td>
<td>(3)</td>
</tr>
<tr>
<td>'F'</td>
<td>Floating point decimal format.</td>
<td>(3)</td>
</tr>
<tr>
<td>'g'</td>
<td>Floating point format. Uses lowercase exponential format if exponent is less than -4 or not less than precision, decimal format</td>
<td>(4)</td>
</tr>
</tbody>
</table>
otherwise.

<table>
<thead>
<tr>
<th>'G'</th>
<th>Floating point format. Uses uppercase exponential format if exponent is less than -4 or not less than precision, decimal format otherwise.</th>
</tr>
</thead>
<tbody>
<tr>
<td>'c'</td>
<td>Single character (accepts integer or single character string).</td>
</tr>
<tr>
<td>'r'</td>
<td>String (converts any Python object using \texttt{repr()}).</td>
</tr>
<tr>
<td>'s'</td>
<td>String (converts any Python object using \texttt{str()}).</td>
</tr>
<tr>
<td>'a'</td>
<td>String (converts any Python object using \texttt{ascii()}).</td>
</tr>
<tr>
<td>'%'</td>
<td>No argument is converted, results in a '&quot;%' character in the result.</td>
</tr>
</tbody>
</table>

Notes:

1. The alternate form causes a leading zero ('0') to be inserted between left-hand padding and the formatting of the number if the leading character of the result is not already a zero.

2. The alternate form causes a leading '0x' or '0X' (depending on whether the 'x' or 'X' format was used) to be inserted between left-hand padding and the formatting of the number if the leading character of the result is not already a zero.

3. The alternate form causes the result to always contain a decimal point, even if no digits follow it.

   The precision determines the number of digits after the decimal point and defaults to 6.
4. The alternate form causes the result to always contain a decimal point, and trailing zeroes are not removed as they would otherwise be.

The precision determines the number of significant digits before and after the decimal point and defaults to 6.

5. If precision is \( N \), the output is truncated to \( N \) characters.

7. See PEP 237.

Since Python strings have an explicit length, \%s conversions do not assume that '\0' is the end of the string.

*Changed in version 3.1:* \%f conversions for numbers whose absolute value is over 1e50 are no longer replaced by \%g conversions.
4.8. Binary Sequence Types — \texttt{bytes, bytarray, memoryview}

The core built-in types for manipulating binary data are \texttt{bytes} and \texttt{bytearray}. They are supported by \texttt{memoryview} which uses the \textit{buffer protocol} to access the memory of other binary objects without needing to make a copy.

The \texttt{array} module supports efficient storage of basic data types like 32-bit integers and IEEE754 double-precision floating values.

4.8.1. Bytes

Bytes objects are immutable sequences of single bytes. Since many major binary protocols are based on the ASCII text encoding, bytes objects offer several methods that are only valid when working with ASCII compatible data and are closely related to string objects in a variety of other ways.

Firstly, the syntax for bytes literals is largely the same as that for string literals, except that a \texttt{b} prefix is added:

- Single quotes: \texttt{b}'still allows embedded "double" quotes'
- Double quotes: \texttt{b"still allows embedded 'single' quotes"}
- Triple quoted: \texttt{b'''3 single quotes''', b'''3 double quotes'''}

Only ASCII characters are permitted in bytes literals (regardless of the declared source code encoding). Any binary values over 127 must be
entered into bytes literals using the appropriate escape sequence.

As with string literals, bytes literals may also use a `r` prefix to disable processing of escape sequences. See *String and Bytes literals* for more about the various forms of bytes literal, including supported escape sequences.

While bytes literals and representations are based on ASCII text, bytes objects actually behave like immutable sequences of integers, with each value in the sequence restricted such that $0 \leq x < 256$ (attempts to violate this restriction will trigger `ValueError`. This is done deliberately to emphasise that while many binary formats include ASCII based elements and can be usefully manipulated with some text-oriented algorithms, this is not generally the case for arbitrary binary data (blindly applying text processing algorithms to binary data formats that are not ASCII compatible will usually lead to data corruption).

In addition to the literal forms, bytes objects can be created in a number of other ways:

- A zero-filled bytes object of a specified length: `bytes(10)`
- From an iterable of integers: `bytes(range(20))`
- Copying existing binary data via the buffer protocol: `bytes(obj)`

Also see the `bytes` built-in.

Since bytes objects are sequences of integers, for a bytes object $b$, $b[0]$ will be an integer, while $b[0:1]$ will be a bytes object of length 1. (This contrasts with text strings, where both indexing and slicing will produce a string of length 1)

The representation of bytes objects uses the literal format (`b'...'`)
since it is often more useful than e.g. \texttt{bytes([46, 46, 46])}. You can always convert a bytes object into a list of integers using \texttt{list(b)}.

\textbf{Note}: For Python 2.x users: In the Python 2.x series, a variety of implicit conversions between 8-bit strings (the closest thing 2.x offers to a built-in binary data type) and Unicode strings were permitted. This was a backwards compatibility workaround to account for the fact that Python originally only supported 8-bit text, and Unicode text was a later addition. In Python 3.x, those implicit conversions are gone - conversions between 8-bit binary data and Unicode text must be explicit, and bytes and string objects will always compare unequal.

4.8.2. Bytearray Objects

\texttt{bytearray} objects are a mutable counterpart to \texttt{bytes} objects. There is no dedicated literal syntax for bytearray objects, instead they are always created by calling the constructor:

- Creating an empty instance: \texttt{bytearray()}
- Creating a zero-filled instance with a given length: \texttt{bytearray(10)}
- From an iterable of integers: \texttt{bytearray(range(20))}
- Copying existing binary data via the buffer protocol: \texttt{bytearray(b'Hi!')}  

As bytearray objects are mutable, they support the \textit{mutable} sequence operations in addition to the common bytes and bytearray operations described in \textit{Bytes and Bytearray Operations}.

Also see the \texttt{bytearray} built-in.
4.8.3. Bytes and Bytearray Operations

Both bytes and bytearray objects support the *common* sequence operations. They interoperate not just with operands of the same type, but with any object that supports the *buffer protocol*. Due to this flexibility, they can be freely mixed in operations without causing errors. However, the return type of the result may depend on the order of operands.

Due to the common use of ASCII text as the basis for binary protocols, bytes and bytearray objects provide almost all methods found on text strings, with the exceptions of:

- `str.encode()` (which converts text strings to bytes objects)
- `str.format()` and `str.format_map()` (which are used to format text for display to users)
- `str.isidentifier()`, `str.isnumeric()`, `str.isdecimal()`, `str.isprintable()` (which are used to check various properties of text strings which are not typically applicable to binary protocols).

All other string methods are supported, although sometimes with slight differences in functionality and semantics (as described below).

**Note:** The methods on bytes and bytearray objects don’t accept strings as their arguments, just as the methods on strings don’t accept bytes as their arguments. For example, you have to write:

```python
a = "abc"
b = a.replace("a", "f")
```

and:
a = b"abc"
b = a.replace(b"a", b"f")

Whenever a bytes or bytearray method needs to interpret the bytes as characters (e.g. the is...() methods, split(), strip()), the ASCII character set is assumed (text strings use Unicode semantics).

**Note:** Using these ASCII based methods to manipulate binary data that is not stored in an ASCII based format may lead to data corruption.

The search operations (in, count(), find(), index(), rfind() and rindex()) all accept both integers in the range 0 to 255 (inclusive) as well as bytes and byte array sequences.

*Changed in version 3.3:* All of the search methods also accept an integer in the range 0 to 255 (inclusive) as their first argument.

Each bytes and bytearray instance provides a `decode()` convenience method that is the inverse of `str.encode()`:

```python
bytes.decode(encoding="utf-8", errors="strict")
bytearray.decode(encoding="utf-8", errors="strict")
```

Return a string decoded from the given bytes. Default encoding is 'utf-8'. *errors* may be given to set a different error handling scheme. The default for *errors* is 'strict', meaning that encoding errors raise a `UnicodeError`. Other possible values are 'ignore', 'replace' and any other name registered via `codecs.register_error()`, see section *Codec Base Classes*. For a list of possible encodings, see section *Standard Encodings*.

*Changed in version 3.1:* Added support for keyword arguments.
Since 2 hexadecimal digits correspond precisely to a single byte, hexadecimal numbers are a commonly used format for describing binary data. Accordingly, the bytes and bytearray types have an additional class method to read data in that format:

```python
classmethod bytes.fromhex(string)
classmethod bytearray.fromhex(string)
```

This `bytes` class method returns a bytes or bytearray object, decoding the given string object. The string must contain two hexadecimal digits per byte, spaces are ignored.

```python
>>> bytes.fromhex('2Ef0 F1f2 ')
'b'.\xf0\xf1\xf2'
```

The maketrans and translate methods differ in semantics from the versions available on strings:

```python
bytes.translate(table[, delete])
bytearray.translate(table[, delete])
```

Return a copy of the bytes or bytearray object where all bytes occurring in the optional argument `delete` are removed, and the remaining bytes have been mapped through the given translation table, which must be a bytes object of length 256.

You can use the `bytes.maketrans()` method to create a translation table.

Set the `table` argument to `None` for translations that only delete characters:

```python
>>> b'read this short text'.translate(None, b'aei')
b'rd ths shrt txt'
```
`static bytes.maketrans(from, to)`
`static bytearray.maketrans(from, to)`

This static method returns a translation table usable for `bytes.translate()` that will map each character in `from` into the character at the same position in `to`; `from` and `to` must be bytes objects and have the same length.

*New in version 3.1.*

### 4.8.4. Memory Views

`memoryview` objects allow Python code to access the internal data of an object that supports the *buffer protocol* without copying.

#### class memoryview(obj)

Create a `memoryview` that references `obj`. `obj` must support the buffer protocol. Built-in objects that support the buffer protocol include `bytes` and `bytearray`.

A `memoryview` has the notion of an *element*, which is the atomic memory unit handled by the originating object `obj`. For many simple types such as `bytes` and `bytearray`, an element is a single byte, but other types such as `array.array` may have bigger elements.

`len(view)` is equal to the length of `tolist`. If `view.ndim = 0`, the length is 1. If `view.ndim = 1`, the length is equal to the number of elements in the view. For higher dimensions, the length is equal to the length of the nested list representation of the view. The `itemsize` attribute will give you the number of bytes in a single element.
A memoryview supports slicing to expose its data. If format is one of the native format specifiers from the struct module, indexing will return a single element with the correct type. Full slicing will result in a subview:

```python
g>>> v = memoryview(b'abcefg')
g>>> v[1]
g98
g>>> v[-1]
g103
g>>> v[1:4]
<memory at 0x7f3ddc9f4350>
g>>> bytes(v[1:4])
b'bce'
```

Other native formats:

```python
g>>> import array
g>>> a = array.array('l', [-11111111, 22222222, -3
>>>
>>> a[0]
-11111111
>>> a[-1]
44444444
>>> a[2:3].tolist()
[-33333333]
>>> a[:2].tolist()
[-11111111, -33333333]
>>> a[::-1].tolist()
[44444444, -33333333, 22222222, -11111111]
```

New in version 3.3.

If the underlying object is writable, the memoryview supports slice assignment. Resizing is not allowed:

```python
g```
>>> data = bytearray(b'abcefg')
>>> v = memoryview(data)
>>> v.readonly
False
>>> v[0] = ord(b'z')
>>> data
bytearray(b'zbcefg')
>>> v[1:4] = b'123'
>>> data
bytearray(b'z123fg')
>>> v[2:3] = b'spam'
Traceback (most recent call last):
  File "<stdin>" , line 1, in <module>
ValueError: memoryview assignment: lvalue and rva
>>> v[2:6] = b'spam'
>>> data
bytearray(b'z1spam')

One-dimensional memoryviews of hashable (read-only) types with formats ‘B’, ‘b’ or ‘c’ are also hashable. The hash is defined as hash(m) == hash(m.tobytes()):

>>> v = memoryview(b'abcefg')
>>> hash(v) == hash(b'abcefg')
True
>>> hash(v[2:4]) == hash(b'ce')
True
>>> hash(v[::2]) == hash(b'abcefg'[::2])
True

*Changed in version 3.3:* One-dimensional memoryviews with formats ‘B’, ‘b’ or ‘c’ are now hashable.

memoryview has several methods:
A memoryview and a PEP 3118 exporter are equal if their shapes are equivalent and if all corresponding values are equal when the operands’ respective format codes are interpreted using struct syntax.

For the subset of struct format strings currently supported by tolist(), \( v \) and \( w \) are equal if \( v\text{.tolist()} == w\text{.tolist()} \):

```python
>>> import array
>>> a = array.array('I', [1, 2, 3, 4, 5])
>>> b = array.array('d', [1.0, 2.0, 3.0, 4.0, 5.0])
>>> c = array.array('b', [5, 3, 1])
>>> x = memoryview(a)
>>> y = memoryview(b)
>>> x == a == y == b
True
>>> x.tolist() == a.tolist() == y.tolist() == b.tolist()
True
>>> z = y[:::-2]
>>> z == c
True
>>> z.tolist() == c.tolist()
True
```

If either format string is not supported by the struct module, then the objects will always compare as unequal (even if the format strings and buffer contents are identical):

```python
>>> from ctypes import BigEndianStructure, c_long
>>> class BEPoint(BigEndianStructure):
...     _fields_ = [("x", c_long), ("y", c_long), ...
```
>>> point = BEPoint(100, 200)
>>> a = memoryview(point)
>>> b = memoryview(point)
>>> a == point
False
>>> a == b
False

Note that, as with floating point numbers, \texttt{v is w} does \textit{not} imply \texttt{v == w} for memoryview objects.

\textit{Changed in version 3.3:} Previous versions compared the raw memory disregarding the item format and the logical array structure.

tobytes()  
Return the data in the buffer as a bytestring. This is equivalent to calling the \texttt{bytes} constructor on the memoryview.

```python
>>> m = memoryview(b"abc")
>>> m.tobytes()
b'abc'
```

For non-contiguous arrays the result is equal to the flattened list representation with all elements converted to bytes. \texttt{tobytes()} supports all format strings, including those that are not in \texttt{struct} module syntax.

tolist()  
Return the data in the buffer as a list of elements.
>>> memoryview(b'abc').tolist()
[97, 98, 99]
>>> import array
>>> a = array.array('d', [1.1, 2.2, 3.3])
>>> m = memoryview(a)
>>> m.tolist()
[1.1, 2.2, 3.3]

Changed in version 3.3: tolist() now supports all single character native formats in struct module syntax as well as multi-dimensional representations.

release()
Release the underlying buffer exposed by the memoryview object. Many objects take special actions when a view is held on them (for example, a bytearray would temporarily forbid resizing); therefore, calling release() is handy to remove these restrictions (and free any dangling resources) as soon as possible.

After this method has been called, any further operation on the view raises a ValueError (except release() itself which can be called multiple times):

```python
>>> m = memoryview(b'abc')
>>> m.release()
>>> m[0]
Traceback (most recent call last):
  File "<stdin>", line 1, in <module>
ValueError: operation forbidden on released memory
```

The context management protocol can be used for a similar effect, using the with statement:
New in version 3.2.

`cast(format[, shape])`

Cast a memoryview to a new format or shape. `shape` defaults to `[byte_length//new_itemsize]`, which means that the result view will be one-dimensional. The return value is a new memoryview, but the buffer itself is not copied. Supported casts are 1D -> C-contiguous and C-contiguous -> 1D.

Both formats are restricted to single element native formats in `struct` syntax. One of the formats must be a byte format (‘B’, ‘b’ or ‘c’). The byte length of the result must be the same as the original length.

Cast 1D/long to 1D/unsigned bytes:
Cast 1D/unsigned bytes to 1D/char:

```python
>>> b = bytearray(b'zyz')
>>> x = memoryview(b)
>>> x[0] = b'a'
Traceback (most recent call last):
  File "<stdin>"", line 1, in <module>
ValueError: memoryview: invalid value for format 'B'
```

```python
>>> y = x.cast('c')
>>> y[0] = b'a'
>>> b
bytearray(b'ayz')
```

Cast 1D/bytes to 3D/int to 1D/signed char:

```python
>>> import struct
>>> buf = struct.pack("i"*12, *list(range(12)))
>>> x = memoryview(buf)
>>> y = x.cast('i', shape=[2,2,3])
>>> y.tolist()
[[[0, 1, 2], [3, 4, 5]], [[6, 7, 8], [9, 10, 11]]
>>> y.format
'i'
>>> y.itemsize
1
```
Cast 1D/unsigned char to 2D/unsigned long:

```python
>>> buf = struct.pack("L"*6, *list(range(6)))
>>> x = memoryview(buf)
>>> y = x.cast('L', shape=[2,3])
>>> len(y)
2
>>> y.nbytes
48
>>> y.tolist()
[[0, 1, 2], [3, 4, 5]]
```

New in version 3.3.

There are also several readonly attributes available:

```python
obj
```

The underlying object of the memoryview:

```python
>>> b = bytearray(b'xyz')
```
m = memoryview(b)
m.obj is b
True

New in version 3.3.

**nbytes**

\[
\text{nbytes} == \text{product(shape)} * \text{itemsize} == \text{len(m.tobytes())}.\]

This is the amount of space in bytes that the array would use in a contiguous representation. It is not necessarily equal to \text{len(m)}:

```python
>>> import array
>>> a = array.array('i', [1, 2, 3, 4, 5])
>>> m = memoryview(a)
>>> len(m)
5
>>> m.nbytes
20
>>> y = m[::2]
>>> len(y)
3
>>> y.nbytes
12
>>> len(y.tobytes())
12
```

Multi-dimensional arrays:

```python
>>> import struct
>>> buf = struct.pack("d"*12, *[1.5*x for x in x])
>>> x = memoryview(buf)
>>> y = x.cast('d', shape=[3, 4])
>>> y.tolist()
[[[0.0, 1.5, 3.0, 4.5], [6.0, 7.5, 9.0, 10.5]], [
```
New in version 3.3.

readonly
A bool indicating whether the memory is read only.

format
A string containing the format (in `struct` module style) for each element in the view. A memoryview can be created from exporters with arbitrary format strings, but some methods (e.g. `tolist()`) are restricted to native single element formats.

*Changed in version 3.3:* format `'B'` is now handled according to the `struct` module syntax. This means that `memoryview(b'abc')[0] == b'abc'[0] == 97`.

itemsizethe size in bytes of each element of the memoryview:

```python
>>> import array, struct
>>> m = memoryview(array.array('H', [32000, 32001]))
>>> m.itemsize
2
>>> m[0]
32000
>>> struct.calcsize('H') == m.itemsize
True
```

ndim
An integer indicating how many dimensions of a multi-
dimensional array the memory represents.

**shape**

A tuple of integers the length of `ndim` giving the shape of the memory as an N-dimensional array.

*Changed in version 3.3:* An empty tuple instead of None when `ndim = 0`.

**strides**

A tuple of integers the length of `ndim` giving the size in bytes to access each element for each dimension of the array.

*Changed in version 3.3:* An empty tuple instead of None when `ndim = 0`.

**suboffsets**

Used internally for PIL-style arrays. The value is informational only.

**c_contiguous**

A bool indicating whether the memory is C-contiguous.

*New in version 3.3.*

**f_contiguous**

A bool indicating whether the memory is Fortran contiguous.

*New in version 3.3.*

**contiguous**

A bool indicating whether the memory is contiguous.

*New in version 3.3.*
4.9. Set Types — `set`, `frozenset`

A `set` object is an unordered collection of distinct `hashable` objects. Common uses include membership testing, removing duplicates from a sequence, and computing mathematical operations such as intersection, union, difference, and symmetric difference. (For other containers see the built-in `dict`, `list`, and `tuple` classes, and the `collections` module.)

Like other collections, sets support `x in set`, `len(set)`, and `for x in set`. Being an unordered collection, sets do not record element position or order of insertion. Accordingly, sets do not support indexing, slicing, or other sequence-like behavior.

There are currently two built-in set types, `set` and `frozenset`. The `set` type is mutable — the contents can be changed using methods like `add()` and `remove()`. Since it is mutable, it has no hash value and cannot be used as either a dictionary key or as an element of another set. The `frozenset` type is immutable and `hashable` — its contents cannot be altered after it is created; it can therefore be used as a dictionary key or as an element of another set.

Non-empty sets (not frozensets) can be created by placing a comma-separated list of elements within braces, for example: `{'jack', 'sjoerd'}`, in addition to the `set` constructor.

The constructors for both classes work the same:

```python
class set([iterable])
class frozenset([iterable])
```

Return a new set or frozenset object whose elements are taken
from iterable. The elements of a set must be hashable. To represent sets of sets, the inner sets must be frozenset objects. If iterable is not specified, a new empty set is returned.

Instances of set and frozenset provide the following operations:

**len(s)**

    Return the cardinality of set s.

**x in s**

    Test x for membership in s.

**x not in s**

    Test x for non-membership in s.

**isdisjoint(other)**

    Return True if the set has no elements in common with other. Sets are disjoint if and only if their intersection is the empty set.

**issubset(other)**

    set <= other

    Test whether every element in the set is in other.

**set < other**

    Test whether the set is a proper subset of other, that is, set <= other and set != other.

**issuperset(other)**

    set >= other

    Test whether every element in other is in the set.

**set > other**
Test whether the set is a proper superset of other, that is, set >= other and set != other.

**union**(other, ...)
**set | other | ...**

Return a new set with elements from the set and all others.

**intersection**(other, ...)
**set & other & ...**

Return a new set with elements common to the set and all others.

**difference**(other, ...)
**set - other - ...**

Return a new set with elements in the set that are not in the others.

**symmetric_difference**(other)
**set ^ other**

Return a new set with elements in either the set or other but not both.

**copy()**

Return a new set with a shallow copy of s.

Note, the non-operator versions of **union()**, **intersection()**, **difference()**, and **symmetric_difference()**, **issubset()**, and **issuperset()** methods will accept any iterable as an argument. In contrast, their operator based counterparts require their arguments to be sets. This precludes error-prone constructions like set('abc') & 'cbs' in favor of the more readable set('abc').intersection('cbs').
Both `set` and `frozenset` support set to set comparisons. Two sets are equal if and only if every element of each set is contained in the other (each is a subset of the other). A set is less than another set if and only if the first set is a proper subset of the second set (is a subset, but is not equal). A set is greater than another set if and only if the first set is a proper superset of the second set (is a superset, but is not equal).

Instances of `set` are compared to instances of `frozenset` based on their members. For example, `set('abc') == frozenset('abc')` returns `True` and so does `set('abc') in set([frozenset('abc')])`.

The subset and equality comparisons do not generalize to a total ordering function. For example, any two nonempty disjoint sets are not equal and are not subsets of each other, so all of the following return `False`: `a<b`, `a==b`, or `a>b`.

Since sets only define partial ordering (subset relationships), the output of the `list.sort()` method is undefined for lists of sets.

Set elements, like dictionary keys, must be `hashable`.

Binary operations that mix `set` instances with `frozenset` return the type of the first operand. For example: `frozenset('ab') | set('bc')` returns an instance of `frozenset`.

The following table lists operations available for `set` that do not apply to immutable instances of `frozenset`:

- `update(other, ...)`
- `set |== other | ...`

  Update the set, adding elements from all others.
**intersection_update**(other, ...)
set &\textcolor{red}{=} other & \ldots
Update the set, keeping only elements found in it and all others.

**difference_update**(other, ...)
set -= other | \ldots
Update the set, removing elements found in others.

**symmetric_difference_update**(other)
set ^= other
Update the set, keeping only elements found in either set, but not in both.

**add**(elem)
Add element elem to the set.

**remove**(elem)
Remove element elem from the set. Raises KeyErrror if elem is not contained in the set.

**discard**(elem)
Remove element elem from the set if it is present.

**pop**()
Remove and return an arbitrary element from the set. Raises KeyErrror if the set is empty.

**clear**()
Remove all elements from the set.

Note, the non-operator versions of the **update()**, **intersection_update()**, **difference_update()**, and **symmetric_difference_update()** methods will accept any
iterable as an argument.

Note, the elem argument to the `__contains__`, `remove`, and `discard` methods may be a set. To support searching for an equivalent frozenset, the elem set is temporarily mutated during the search and then restored. During the search, the elem set should not be read or mutated since it does not have a meaningful value.
### 4.10. Mapping Types — dict

A *mapping* object maps *hashable* values to arbitrary objects. Mappings are mutable objects. There is currently only one standard mapping type, the *dictionary*. (For other containers see the built-in *list*, *set*, and *tuple* classes, and the *collections* module.)

A dictionary’s keys are *almost* arbitrary values. Values that are not *hashable*, that is, values containing lists, dictionaries or other mutable types (that are compared by value rather than by object identity) may not be used as keys. Numeric types used for keys obey the normal rules for numeric comparison: if two numbers compare equal (such as 1 and 1.0) then they can be used interchangeably to index the same dictionary entry. (Note however, that since computers store floating-point numbers as approximations it is usually unwise to use them as dictionary keys.)

Dictionaries can be created by placing a comma-separated list of key: value pairs within braces, for example: `{ 'jack': 4098, 'sjoerd': 4127}` or `{4098: 'jack', 4127: 'sjoerd'}`, or by the *dict* constructor.

```python
class dict(**kwarg)
class dict(mapping, **kwarg)
class dict(iterable, **kwarg)
```

Return a new dictionary initialized from an optional positional argument and a possibly empty set of keyword arguments.

If no positional argument is given, an empty dictionary is created. If a positional argument is given and it is a mapping object, a dictionary is created with the same key-value pairs as the mapping
object. Otherwise, the positional argument must be an *iterator* object. Each item in the iterable must itself be an iterator with exactly two objects. The first object of each item becomes a key in the new dictionary, and the second object the corresponding value. If a key occurs more than once, the last value for that key becomes the corresponding value in the new dictionary.

If keyword arguments are given, the keyword arguments and their values are added to the dictionary created from the positional argument. If a key being added is already present, the value from the keyword argument replaces the value from the positional argument.

To illustrate, the following examples all return a dictionary equal to 
{"one": 1, "two": 2, "three": 3}:

```python
given:
>>> a = dict(one=1, two=2, three=3)
>>> b = {'one': 1, 'two': 2, 'three': 3}
>>> c = dict(zip([('one', 'two', 'three')], [1, 2,
>>> d = dict(((two, 2), ('one', 1), ('three', 3)
>>> e = dict({'three': 3, 'one': 1, 'two': 2})

>>> a == b == c == d == e
True
```

Providing keyword arguments as in the first example only works for keys that are valid Python identifiers. Otherwise, any valid keys can be used.

These are the operations that dictionaries support (and therefore, custom mapping types should support too):

**len(d)**

Return the number of items in the dictionary `d`. 
d[key]
Return the item of d with key key. Raises a KeyError if key is not in the map.

If a subclass of dict defines a method __missing__( ), if the key key is not present, the d[key] operation calls that method with the key key as argument. The d[key] operation then returns or raises whatever is returned or raised by the __missing__(key) call if the key is not present. No other operations or methods invoke __missing__( ). If __missing__( ) is not defined, KeyError is raised. __missing__( ) must be a method; it cannot be an instance variable:

```python
>>> class Counter(dict):
...     def __missing__(self, key):
...         return 0
>>> c = Counter()
>>> c['red']
0
>>> c['red'] += 1
>>> c['red']
1
```

See collections.Counter for a complete implementation including other methods helpful for accumulating and managing tallies.

d[key] = value
Set d[key] to value.

del d[key]
Remove d[key] from d. Raises a KeyError if key is not in
the map.

**key in d**
Return True if *d* has a key *key*, else False.

**key not in d**
Equivalent to `not key in d`.

**iter(d)**
Return an iterator over the keys of the dictionary. This is a shortcut for `iter(d.keys())`.

**clear()**
Remove all items from the dictionary.

**copy()**
Return a shallow copy of the dictionary.

*classmethod* `fromkeys(seq[, value])`
Create a new dictionary with keys from *seq* and values set to *value*.

`fromkeys()` is a class method that returns a new dictionary. *value* defaults to None.

**get(key[, default])**
Return the value for *key* if *key* is in the dictionary, else *default*. If *default* is not given, it defaults to None, so that this method never raises a *KeyError*.

**items()**
Return a new view of the dictionary's items ((*key*, *value)
pairs). See the documentation of view objects.

**keys()**

Return a new view of the dictionary’s keys. See the documentation of view objects.

**pop(key[, default])**

If key is in the dictionary, remove it and return its value, else return default. If default is not given and key is not in the dictionary, a KeyError is raised.

**popitem()**

Remove and return an arbitrary (key, value) pair from the dictionary.

popitem() is useful to destructively iterate over a dictionary, as often used in set algorithms. If the dictionary is empty, calling popitem() raises a KeyError.

**setdefault(key[, default])**

If key is in the dictionary, return its value. If not, insert key with a value of default and return default. default defaults to None.

**update([other])**

Update the dictionary with the key/value pairs from other, overwriting existing keys. Return None.

update() accepts either another dictionary object or an iterable of key/value pairs (as tuples or other iterables of length two). If keyword arguments are specified, the dictionary is then updated with those key/value pairs: d.update(red=1, blue=2).
values()

Return a new view of the dictionary’s values. See the documentation of view objects.

See also: types.MappingProxyType can be used to create a read-only view of a dict.

4.10.1. Dictionary view objects

The objects returned by dict.keys(), dict.values() and dict.items() are view objects. They provide a dynamic view on the dictionary’s entries, which means that when the dictionary changes, the view reflects these changes.

Dictionary views can be iterated over to yield their respective data, and support membership tests:

len(dictview)

Return the number of entries in the dictionary.

iter(dictview)

Return an iterator over the keys, values or items (represented as tuples of (key, value)) in the dictionary.

Keys and values are iterated over in an arbitrary order which is non-random, varies across Python implementations, and depends on the dictionary’s history of insertions and deletions. If keys, values and items views are iterated over with no intervening modifications to the dictionary, the order of items will directly correspond. This allows the creation of (value, key) pairs using zip(): pairs = zip(d.values(), d.keys()). Another way to create the same list is pairs = [(v, k) for (k, v) in
Iterating views while adding or deleting entries in the dictionary may raise a `RuntimeError` or fail to iterate over all entries.

**x in dictview**

Return `True` if `x` is in the underlying dictionary's keys, values or items (in the latter case, `x` should be a `(key, value)` tuple).

Keys views are set-like since their entries are unique and hashable. If all values are hashable, so that `(key, value)` pairs are unique and hashable, then the items view is also set-like. (Values views are not treated as set-like since the entries are generally not unique.) For set-like views, all of the operations defined for the abstract base class `collections.abc.Set` are available (for example, `==`, `<`, or `^`).

An example of dictionary view usage:

```python
>>> dishes = {'eggs': 2, 'sausage': 1, 'bacon': 1, 'spam': 500}
>>> keys = dishes.keys()
>>> values = dishes.values()

>>> # iteration
>>> n = 0
>>> for val in values:
...    n += val
>>> print(n)
504

>>> # keys and values are iterated over in the same
>>> list(keys)
['eggs', 'bacon', 'sausage', 'spam']
>>> list(values)
[2, 1, 1, 500]
```
>>> # view objects are dynamic and reflect dict changes
>>> del dishes['eggs']
>>> del dishes['sausage']
>>> list(keys)
['spam', 'bacon']

>>> # set operations
>>> keys & {'eggs', 'bacon', 'salad'}
{'bacon'}
>>> keys ^ {'sausage', 'juice'}
{'juice', 'sausage', 'bacon', 'spam'}
4.11. Context Manager Types

Python’s `with` statement supports the concept of a runtime context defined by a context manager. This is implemented using a pair of methods that allow user-defined classes to define a runtime context that is entered before the statement body is executed and exited when the statement ends:

```python
class contextmanager:
    def __enter__(self):
        Enter the runtime context and return either this object or another object related to the runtime context. The value returned by this method is bound to the identifier in the `as` clause of `with` statements using this context manager.

        An example of a context manager that returns itself is a `file object`. File objects return themselves from `__enter__()` to allow `open()` to be used as the context expression in a `with` statement.

        An example of a context manager that returns a related object is the one returned by `decimal.localcontext()`. These managers set the active decimal context to a copy of the original decimal context and then return the copy. This allows changes to be made to the current decimal context in the body of the `with` statement without affecting code outside the `with` statement.

    def __exit__(self, exc_type, exc_val, exc_tb):
        Exit the runtime context and return a Boolean flag indicating if any exception that occurred should be suppressed. If an exception occurred while executing the body of the `with` statement, the arguments contain the exception type, value and traceback information. Otherwise, all three arguments are None.
```
Returning a true value from this method will cause the \texttt{with} statement to suppress the exception and continue execution with the statement immediately following the \texttt{with} statement. Otherwise the exception continues propagating after this method has finished executing. Exceptions that occur during execution of this method will replace any exception that occurred in the body of the \texttt{with} statement.

The exception passed in should never be reraised explicitly - instead, this method should return a false value to indicate that the method completed successfully and does not want to suppress the raised exception. This allows context management code (such as \texttt{contextlib.nested}) to easily detect whether or not an \texttt{__exit__()} method has actually failed.

Python defines several context managers to support easy thread synchronisation, prompt closure of files or other objects, and simpler manipulation of the active decimal arithmetic context. The specific types are not treated specially beyond their implementation of the context management protocol. See the \texttt{contextlib} module for some examples.

Python’s \texttt{generators} and the \texttt{contextlib.contextmanager} decorator provide a convenient way to implement these protocols. If a generator function is decorated with the \texttt{contextlib.contextmanager} decorator, it will return a context manager implementing the necessary \texttt{__enter__()} and \texttt{__exit__()} methods, rather than the iterator produced by an undecorated generator function.

Note that there is no specific slot for any of these methods in the type structure for Python objects in the Python/C API. Extension types
wanting to define these methods must provide them as a normal Python accessible method. Compared to the overhead of setting up the runtime context, the overhead of a single class dictionary lookup is negligible.
4.12. Other Built-in Types

The interpreter supports several other kinds of objects. Most of these support only one or two operations.

4.12.1. Modules

The only special operation on a module is attribute access: \texttt{m.name}, where \texttt{m} is a module and \texttt{name} accesses a name defined in \texttt{m}'s symbol table. Module attributes can be assigned to. (Note that the \texttt{import} statement is not, strictly speaking, an operation on a module object; \texttt{import foo} does not require a module object named \texttt{foo} to exist, rather it requires an (external) \textit{definition} for a module named \texttt{foo} somewhere.)

A special attribute of every module is \texttt{__dict__}. This is the dictionary containing the module's symbol table. Modifying this dictionary will actually change the module's symbol table, but direct assignment to the \texttt{__dict__} attribute is not possible (you can write \texttt{m.__dict__['a'] = 1}, which defines \texttt{m.a} to be 1, but you can't write \texttt{m.__dict__ = {}}). Modifying \texttt{__dict__} directly is not recommended.

Modules built into the interpreter are written like this: \texttt{<module 'sys' (built-in)>}. If loaded from a file, they are written as \texttt{<module 'os' from '/usr/local/lib/pythonX.Y/os.pyc'>}.

4.12.2. Classes and Class Instances

See \textit{Objects, values and types} and \textit{Class definitions} for these.
4.12.3. Functions

Function objects are created by function definitions. The only operation on a function object is to call it: `func(argument-list)`.

There are really two flavors of function objects: built-in functions and user-defined functions. Both support the same operation (to call the function), but the implementation is different, hence the different object types.

See *Function definitions* for more information.

4.12.4. Methods

Methods are functions that are called using the attribute notation. There are two flavors: built-in methods (such as `append()` on lists) and class instance methods. Built-in methods are described with the types that support them.

If you access a method (a function defined in a class namespace) through an instance, you get a special object: a *bound method* (also called *instance method*) object. When called, it will add the `self` argument to the argument list. Bound methods have two special read-only attributes: `m.__self__` is the object on which the method operates, and `m.__func__` is the function implementing the method. Calling `m(arg-1, arg-2, ..., arg-n)` is completely equivalent to calling `m.__func__(m.__self__, arg-1, arg-2, ..., arg-n)`.

Like function objects, bound method objects support getting arbitrary attributes. However, since method attributes are actually stored on the
underlying function object (meth.__func__), setting method attributes on bound methods is disallowed. Attempting to set an attribute on a method results in an AttributeError being raised. In order to set a method attribute, you need to explicitly set it on the underlying function object:

```python
>>> class C:
...     def method(self):
...         pass
...
>>> c = C()
>>> c.method.whoami = 'my name is method'  # can't set on the method
Traceback (most recent call last):
  File "<stdin>", line 1, in <module>
AttributeError: 'method' object has no attribute 'whoami'
>>> c.method.__func__.whoami = 'my name is method'
>>> c.method.whoami
'my name is method'
```

See *The standard type hierarchy* for more information.

### 4.12.5. Code Objects

Code objects are used by the implementation to represent "pseudo-compiled" executable Python code such as a function body. They differ from function objects because they don’t contain a reference to their global execution environment. Code objects are returned by the built-in `compile()` function and can be extracted from function objects through their `__code__` attribute. See also the `code` module.

A code object can be executed or evaluated by passing it (instead of a source string) to the `exec()` or `eval()` built-in functions.
See *The standard type hierarchy* for more information.

4.12.6. Type Objects

Type objects represent the various object types. An object’s type is accessed by the built-in function `type()`. There are no special operations on types. The standard module `types` defines names for all standard built-in types.

Types are written like this: `<class 'int'>`.

4.12.7. The Null Object

This object is returned by functions that don’t explicitly return a value. It supports no special operations. There is exactly one null object, named `None` (a built-in name). `type(None)()` produces the same singleton.

It is written as `None`.

4.12.8. The Ellipsis Object

This object is commonly used by slicing (see *Slicings*). It supports no special operations. There is exactly one ellipsis object, named `Ellipsis` (a built-in name). `type(Ellipsis)()` produces the `Ellipsis` singleton.

It is written as `Ellipsis` or `...`.

4.12.9. The NotImplemented Object
This object is returned from comparisons and binary operations when they are asked to operate on types they don't support. See *Comparisons* for more information. There is exactly one `NotImplemented` object. `type(NotImplemented)()` produces the singleton instance.

It is written as `NotImplemented`.

### 4.12.10. Boolean Values

Boolean values are the two constant objects `False` and `True`. They are used to represent truth values (although other values can also be considered false or true). In numeric contexts (for example when used as the argument to an arithmetic operator), they behave like the integers 0 and 1, respectively. The built-in function `bool()` can be used to convert any value to a Boolean, if the value can be interpreted as a truth value (see section *Truth Value Testing* above).

They are written as `False` and `True`, respectively.

### 4.12.11. Internal Objects

See *The standard type hierarchy* for this information. It describes stack frame objects, traceback objects, and slice objects.
4.13. Special Attributes

The implementation adds a few special read-only attributes to several object types, where they are relevant. Some of these are not reported by the `dir()` built-in function.

**object.** __dict__

A dictionary or other mapping object used to store an object's (writable) attributes.

**instance.** __class__

The class to which a class instance belongs.

**class.** __bases__

The tuple of base classes of a class object.

**class.** __name__

The name of the class or type.

**class.** __qualname__

The *qualified name* of the class or type.

*New in version 3.3.*

**class.** __mro__

This attribute is a tuple of classes that are considered when looking for base classes during method resolution.

**class.** mro()

This method can be overridden by a metaclass to customize the method resolution order for its instances. It is called at class instantiation, and its result is stored in __mro__. 
class.__subclasses__()  
  Each class keeps a list of weak references to its immediate subclasses. This method returns a list of all those references still alive. Example:

```python
>>> int.__subclasses__()
[<class 'bool'>]
```

Footnotes

[1] Additional information on these special methods may be found in the Python Reference Manual (*Basic customization*).

[2] As a consequence, the list `[1, 2]` is considered equal to `[1.0, 2.0]`, and similarly for tuples.

[3] They must have since the parser can’t tell the type of the operands.

[4] `(1, 2, 3, 4)` Cased characters are those with general category property being one of “Lu” (Letter, uppercase), “Ll” (Letter, lowercase), or “Lt” (Letter, titlecase).

[5] To format only a tuple you should therefore provide a singleton tuple whose only element is the tuple to be formatted.
5. Built-in Exceptions

In Python, all exceptions must be instances of a class that derives from `BaseException`. In a `try` statement with an `except` clause that mentions a particular class, that clause also handles any exception classes derived from that class (but not exception classes from which it is derived). Two exception classes that are not related via subclassing are never equivalent, even if they have the same name.

The built-in exceptions listed below can be generated by the interpreter or built-in functions. Except where mentioned, they have an “associated value” indicating the detailed cause of the error. This may be a string or a tuple of several items of information (e.g., an error code and a string explaining the code). The associated value is usually passed as arguments to the exception class’s constructor.

User code can raise built-in exceptions. This can be used to test an exception handler or to report an error condition “just like” the situation in which the interpreter raises the same exception; but beware that there is nothing to prevent user code from raising an inappropriate error.

The built-in exception classes can be sub-classed to define new exceptions; programmers are encouraged to at least derive new exceptions from the `Exception` class and not `BaseException`. More information on defining exceptions is available in the Python Tutorial under *User-defined Exceptions*.

When raising (or re-raising) an exception in an `except` clause `__context__` is automatically set to the last exception caught; if the new exception is not handled the traceback that is eventually
displayed will include the originating exception(s) and the final exception.

When raising a new exception (rather than using a bare `raise` to re-raise the exception currently being handled), the implicit exception context can be supplemented with an explicit cause by using `from` with `raise`:

```
raise new_exc from original_exc
```

The expression following `from` must be an exception or `None`. It will be set as `__cause__` on the raised exception. Setting `__cause__` also implicitly sets the `__suppress_context__` attribute to `True`, so that using `raise new_exc from None` effectively replaces the old exception with the new one for display purposes (e.g. converting `KeyError` to `AttributeError`, while leaving the old exception available in `__context__` for introspection when debugging.

The default traceback display code shows these chained exceptions in addition to the traceback for the exception itself. An explicitly chained exception in `__cause__` is always shown when present. An implicitly chained exception in `__context__` is shown only if `__cause__` is `None` and `__suppress_context__` is false.

In either case, the exception itself is always shown after any chained exceptions so that the final line of the traceback always shows the last exception that was raised.
5.1. Base classes

The following exceptions are used mostly as base classes for other exceptions.

exception **BaseException**

The base class for all built-in exceptions. It is not meant to be directly inherited by user-defined classes (for that, use `Exception`). If `str()` is called on an instance of this class, the representation of the argument(s) to the instance are returned, or the empty string when there were no arguments.

**args**

The tuple of arguments given to the exception constructor. Some built-in exceptions (like `IOError`) expect a certain number of arguments and assign a special meaning to the elements of this tuple, while others are usually called only with a single string giving an error message.

**with_traceback**(tb)

This method sets `tb` as the new traceback for the exception and returns the exception object. It is usually used in exception handling code like this:

```python
try:
    ...
except SomeException:
    tb = sys.exc_info()[2]
    raise OtherException(...).with_traceback(tb)
```

exception **Exception**
All built-in, non-system-exiting exceptions are derived from this class. All user-defined exceptions should also be derived from this class.

**exception** ArithmeticError

The base class for those built-in exceptions that are raised for various arithmetic errors: OverflowError, ZeroDivisionError, FloatingPointError.

**exception** BufferError

Raised when a buffer related operation cannot be performed.

**exception** LookupError

The base class for the exceptions that are raised when a key or index used on a mapping or sequence is invalid: IndexError, KeyError. This can be raised directly by codecs.lookup().
5.2. Concrete exceptions

The following exceptions are the exceptions that are usually raised.

**exception** `AssertionError`
Raised when an `assert` statement fails.

**exception** `AttributeError`
Raised when an attribute reference (see *Attribute references*) or assignment fails. (When an object does not support attribute references or attribute assignments at all, `TypeError` is raised.)

**exception** `EOFError`
Raised when the `input()` function hits an end-of-file condition (EOF) without reading any data. (N.B.: the `io.IOBase.read()` and `io.IOBase.readline()` methods return an empty string when they hit EOF.)

**exception** `FloatingPointError`
Raised when a floating point operation fails. This exception is always defined, but can only be raised when Python is configured with the `--with-fpectl` option, or the WANT_SIGFPE_HANDLER symbol is defined in the `pyconfig.h` file.

**exception** `GeneratorExit`
Raise when a `generator`'s `close()` method is called. It directly inherits from `BaseException` instead of `Exception` since it is technically not an error.

**exception** `ImportError`
Raised when an `import` statement fails to find the module
definition or when a from ... import fails to find a name that is to be imported.

The name and path attributes can be set using keyword-only arguments to the constructor. When set they represent the name of the module that was attempted to be imported and the path to any file which triggered the exception, respectively.

*Changed in version 3.3:* Added the name and path attributes.

*exception IndexError*

Raised when a sequence subscript is out of range. (Slice indices are silently truncated to fall in the allowed range; if an index is not an integer, TypeError is raised.)

*exception KeyError*

Raised when a mapping (dictionary) key is not found in the set of existing keys.

*exception KeyboardInterrupt*

Raised when the user hits the interrupt key (normally Control-C or Delete). During execution, a check for interrupts is made regularly. The exception inherits from BaseException so as to not be accidentally caught by code that catches Exception and thus prevent the interpreter from exiting.

*exception MemoryError*

Raised when an operation runs out of memory but the situation may still be rescued (by deleting some objects). The associated value is a string indicating what kind of (internal) operation ran out of memory. Note that because of the underlying memory management architecture (C’s malloc() function), the interpreter
may not always be able to completely recover from this situation; it nevertheless raises an exception so that a stack traceback can be printed, in case a run-away program was the cause.

**exception NameError**

Raised when a local or global name is not found. This applies only to unqualified names. The associated value is an error message that includes the name that could not be found.

**exception NotImplementedWarning**

This exception is derived from **RuntimeError**. In user defined base classes, abstract methods should raise this exception when they require derived classes to override the method.

**exception OSError**

This exception is raised when a system function returns a system-related error, including I/O failures such as “file not found” or “disk full” (not for illegal argument types or other incidental errors). Often a subclass of **OSError** will actually be raised as described in OS exceptions below. The **errno** attribute is a numeric error code from the C variable errno.

Under Windows, the **winerror** attribute gives you the native Windows error code. The **errno** attribute is then an approximate translation, in POSIX terms, of that native error code.

Under all platforms, the **strerror** attribute is the corresponding error message as provided by the operating system (as formatted by the C functions perror() under POSIX, and FormatMessage() Windows).

For exceptions that involve a file system path (such as **open()** or
os.unlink()), the exception instance will contain an additional attribute, filename, which is the file name passed to the function.

*Changed in version 3.3:* EnvironmentError, IOError, WindowsError, VMSError, socket.error, select.error and mmap.error have been merged into OSError.

**exception OverflowError**
Raised when the result of an arithmetic operation is too large to be represented. This cannot occur for integers (which would rather raise MemoryError than give up). Because of the lack of standardization of floating point exception handling in C, most floating point operations also aren’t checked.

**exception ReferenceError**
This exception is raised when a weak reference proxy, created by the weakref.proxy() function, is used to access an attribute of the referent after it has been garbage collected. For more information on weak references, see the weakref module.

**exception RuntimeError**
Raised when an error is detected that doesn’t fall in any of the other categories. The associated value is a string indicating what precisely went wrong. (This exception is mostly a relic from a previous version of the interpreter; it is not used very much any more.)

**exception StopIteration**
Raised by built-in function `next()` and an `iterator`'s `__next__()` method to signal that there are no further items produced by the iterator.
The exception object has a single attribute `value`, which is given as an argument when constructing the exception, and defaults to `None`.

When a generator function returns, a new `StopIteration` instance is raised, and the value returned by the function is used as the `value` parameter to the constructor of the exception.

*Changed in version 3.3:* Added `value` attribute and the ability for generator functions to use it to return a value.

**exception** `SyntaxError`

Raised when the parser encounters a syntax error. This may occur in an `import` statement, in a call to the built-in functions `exec()` or `eval()`, or when reading the initial script or standard input (also interactively).

Instances of this class have attributes `filename`, `lineno`, `offset` and `text` for easier access to the details. `str()` of the exception instance returns only the message.

**exception** `IndentationError`

Base class for syntax errors related to incorrect indentation. This is a subclass of `SyntaxError`.

**exception** `TabError`

Raised when indentation contains an inconsistent use of tabs and spaces. This is a subclass of `IndentationError`.

**exception** `SystemError`

Raised when the interpreter finds an internal error, but the situation does not look so serious to cause it to abandon all hope. The associated value is a string indicating what went wrong (in low-
You should report this to the author or maintainer of your Python interpreter. Be sure to report the version of the Python interpreter (\texttt{sys.version}; it is also printed at the start of an interactive Python session), the exact error message (the exception's associated value) and if possible the source of the program that triggered the error.

\textit{exception} \texttt{SystemExit}

This exception is raised by the \texttt{sys.exit()} function. When it is not handled, the Python interpreter exits; no stack traceback is printed. If the associated value is an integer, it specifies the system exit status (passed to C's \texttt{exit()} function); if it is \texttt{None}, the exit status is zero; if it has another type (such as a string), the object's value is printed and the exit status is one.

Instances have an attribute \texttt{code} which is set to the proposed exit status or error message (defaulting to \texttt{None}). Also, this exception derives directly from \texttt{BaseException} and not \texttt{Exception}, since it is not technically an error.

A call to \texttt{sys.exit()} is translated into an exception so that clean-up handlers (\texttt{finally} clauses of \texttt{try} statements) can be executed, and so that a debugger can execute a script without running the risk of losing control. The \texttt{os._exit()} function can be used if it is absolutely positively necessary to exit immediately (for example, in the child process after a call to \texttt{os.fork()}).

The exception inherits from \texttt{BaseException} instead of \texttt{Exception} so that it is not accidentally caught by code that catches \texttt{Exception}. This allows the exception to properly
propagate up and cause the interpreter to exit.

exception **TypeError**
Raised when an operation or function is applied to an object of inappropriate type. The associated value is a string giving details about the type mismatch.

exception **UnboundLocalError**
Raised when a reference is made to a local variable in a function or method, but no value has been bound to that variable. This is a subclass of **NameError**.

exception **UnicodeError**
Raised when a Unicode-related encoding or decoding error occurs. It is a subclass of **ValueError**.

**UnicodeError** has attributes that describe the encoding or decoding error. For example, `err.object[err.start:err.end]` gives the particular invalid input that the codec failed on.

**encoding**
The name of the encoding that raised the error.

**reason**
A string describing the specific codec error.

**object**
The object the codec was attempting to encode or decode.

**start**
The first index of invalid data in **object**.
end

The index after the last invalid data in object.

exception UnicodeEncodeError
Raised when a Unicode-related error occurs during encoding. It is a subclass of UnicodeError.

exception UnicodeDecodeError
Raised when a Unicode-related error occurs during decoding. It is a subclass of UnicodeError.

exception UnicodeTranslateError
Raised when a Unicode-related error occurs during translating. It is a subclass of UnicodeError.

exception ValueError
Raised when a built-in operation or function receives an argument that has the right type but an inappropriate value, and the situation is not described by a more precise exception such as IndexError.

exception ZeroDivisionError
Raised when the second argument of a division or modulo operation is zero. The associated value is a string indicating the type of the operands and the operation.

The following exceptions are kept for compatibility with previous versions; starting from Python 3.3, they are aliases of OSError.

exception EnvironmentError

exception IOError
exception **VMSError**
   Only available on VMS.

exception **WindowsError**
   Only available on Windows.

### 5.2.1. OS exceptions

The following exceptions are subclasses of **OSError**, they get raised depending on the system error code.

exception **BlockingIOError**
   Raised when an operation would block on an object (e.g. socket) set for non-blocking operation. Corresponds to errno EAGAIN, EALREADY, EW OULDBLOCK and E INPROGRESS.

   In addition to those of **OSError**, **BlockingIOError** can have one more attribute:

   **characters_written**
   An integer containing the number of characters written to the stream before it blocked. This attribute is available when using the buffered I/O classes from the **io** module.

exception **ChildProcessError**
   Raised when an operation on a child process failed. Corresponds to errno ECHILD.

exception **ConnectionError**
   A base class for connection-related issues.

   Subclasses are **BrokenPipeError**,
ConnectionAbortedError, ConnectionRefusedError and ConnectionResetError.

*exception BrokenPipeError*
A subclass of ConnectionError, raised when trying to write on a pipe while the other end has been closed, or trying to write on a socket which has been shutdown for writing. Corresponds to errno EPIPE and ESHUTDOWN.

*exception ConnectionAbortedError*
A subclass of ConnectionError, raised when a connection attempt is aborted by the peer. Corresponds to errno ECONNABORTED.

*exception ConnectionRefusedError*
A subclass of ConnectionError, raised when a connection attempt is refused by the peer. Corresponds to errno ECONNREFUSED.

*exception ConnectionResetError*
A subclass of ConnectionError, raised when a connection is reset by the peer. Corresponds to errno ECONNRESET.

*exception FileExistsError*
Raised when trying to create a file or directory which already exists. Corresponds to errno EEXIST.

*exception FileNotFoundError*
Raised when a file or directory is requested but doesn’t exist. Corresponds to errno ENOENT.

*exception InterruptedError*
Raised when a system call is interrupted by an incoming signal. Corresponds to errno EINTR.

**exception** IsADirectoryError

Raised when a file operation (such as `os.remove()`) is requested on a directory. Corresponds to errno EISDIR.

**exception** NotADirectoryError

Raised when a directory operation (such as `os.listdir()`) is requested on something which is not a directory. Corresponds to errno ENOTDIR.

**exception** PermissionError

Raised when trying to run an operation without the adequate access rights - for example filesystem permissions. Corresponds to errno EACCES and EPERM.

**exception** ProcessLookupError

Raised when a given process doesn’t exist. Corresponds to errno ESRCH.

**exception** TimeoutError

Raised when a system function timed out at the system level. Corresponds to errno ETIMEDOUT.

*New in version 3.3:* All the above OSError subclasses were added.

**See also:** [PEP 3151](https://www.python.org/dev/peps/pep-03151/) - Reworking the OS and IO exception hierarchy
5.3. Warnings

The following exceptions are used as warning categories; see the \texttt{warnings} module for more information.

\texttt{exception Warning}

Base class for warning categories.

\texttt{exception UserWarning}

Base class for warnings generated by user code.

\texttt{exceptionDeprecationWarning}

Base class for warnings about deprecated features.

\texttt{exception PendingDeprecationWarning}

Base class for warnings about features which will be deprecated in the future.

\texttt{exception SyntaxWarning}

Base class for warnings about dubious syntax.

\texttt{exception RuntimeException}

Base class for warnings about dubious runtime behavior.

\texttt{exception FutureWarning}

Base class for warnings about constructs that will change semantically in the future.

\texttt{exception ImportWarning}

Base class for warnings about probable mistakes in module imports.

\texttt{exception UnicodeWarning}
Base class for warnings related to Unicode.

*exception* `BytesWarning`

Base class for warnings related to `bytes` and `bytearray`.

*exception* `ResourceWarning`

Base class for warnings related to resource usage.

*New in version 3.2.*
5.4. Exception hierarchy

The class hierarchy for built-in exceptions is:

```
BaseException
    +-- SystemExit
    +-- KeyboardInterrupt
    +-- GeneratorExit
    +-- Exception
      |   +-- StopIteration
      |   +-- ArithmeticError
      |       |   +-- FloatingPointError
      |       |   +-- OverflowError
      |       |   +-- ZeroDivisionError
      |   +-- AssertionError
      |   +-- AttributeError
      |   +-- BufferError
      |   +-- EOFError
      |   +-- ImportError
      |   +-- LookupError
      |       |   +-- IndexError
      |       |   +-- KeyError
      |   +-- MemoryError
      |   +-- NameError
      |       |   +-- UnboundLocalError
      +-- OSError
          |   +-- BlockingIOError
          |   +-- ChildProcessError
          |       |   +-- ConnectionError
          |       |       |   +-- BrokenPipeError
          |       |       |   +-- ConnectionAbortedError
          |       |       |   +-- ConnectionRefusedError
          |       |       |   +-- ConnectionResetError
          |   +-- FileExistsError
          |   +-- FileNotFoundError
```
Created using Sphinx 1.0.7.
6. Text Processing Services

The modules described in this chapter provide a wide range of string manipulation operations and other text processing services.

The `codecs` module described under *Binary Data Services* is also highly relevant to text processing. In addition, see the documentation for Python’s built-in string type in *Text Sequence Type — str*.

*String Methods*
6.1.1. String constants

The constants defined in this module are:

string. **ascii_letters**
The concatenation of the **ascii_lowercase** and **ascii_uppercase** constants described below. This value is not locale-dependent.

string. **ascii_lowercase**
The lowercase letters 'abcdefghijklmnopqrstuvwxyz'. This value is not locale-dependent and will not change.

string. **ascii_uppercase**
The uppercase letters 'ABCDEFGHIJKLMNOPQRSTUVWXYZ'. This value is not locale-dependent and will not change.

string. **digits**
The string '0123456789'.

string. **hexdigits**
The string '0123456789abcdefABCDEF'.

string. **octdigits**
The string '01234567'.

string. **punctuation**
String of ASCII characters which are considered punctuation characters in the C locale.

string. **printable**
String of ASCII characters which are considered printable. This is a
combination of digits, ascii_letters, punctuation, and whitespace.

string. whitespace
A string containing all ASCII characters that are considered whitespace. This includes the characters space, tab, linefeed, return, formfeed, and vertical tab.
6.1.2. String Formatting

The built-in string class provides the ability to do complex variable substitutions and value formatting via the `format()` method described in PEP 3101. The `Formatter` class in the `string` module allows you to create and customize your own string formatting behaviors using the same implementation as the built-in `format()` method.

**class string.Formatter**

The `Formatter` class has the following public methods:

```python
format(format_string, *args, **kwargs)
```

`format()` is the primary API method. It takes a format string and an arbitrary set of positional and keyword arguments. `format()` is just a wrapper that calls `vformat()`.

```python
vformat(format_string, args, kwargs)
```

This function does the actual work of formatting. It is exposed as a separate function for cases where you want to pass in a predefined dictionary of arguments, rather than unpacking and repacking the dictionary as individual arguments using the `*args` and `**kwargs` syntax. `vformat()` does the work of breaking up the format string into character data and replacement fields. It calls the various methods described below.

In addition, the `Formatter` defines a number of methods that are intended to be replaced by subclasses:

```python
parse(format_string)
```
Loop over the format_string and return an iterable of tuples
(literal_text, field_name, format_spec, conversion). This is used
by vformat() to break the string into either literal text, or
replacement fields.

The values in the tuple conceptually represent a span of literal
text followed by a single replacement field. If there is no literal
text (which can happen if two replacement fields occur
consecutively), then literal_text will be a zero-length string. If
there is no replacement field, then the values of field_name,
format_spec and conversion will be None.

get_field(field_name, args, kwargs)
Given field_name as returned by parse() (see above),
convert it to an object to be formatted. Returns a tuple (obj,
used_key). The default version takes strings of the form defined
in PEP 3101, such as “0[name]” or “label.title”. args and kwargs
are as passed in to vformat(). The return value used_key
has the same meaning as the key parameter to get_value().

get_value(key, args, kwargs)
Retrieve a given field value. The key argument will be either an
integer or a string. If it is an integer, it represents the index of
the positional argument in args; if it is a string, then it
represents a named argument in kwargs.

The args parameter is set to the list of positional arguments to
vformat(), and the kwargs parameter is set to the dictionary
of keyword arguments.

For compound field names, these functions are only called for
the first component of the field name; Subsequent components
are handled through normal attribute and indexing operations.

So for example, the field expression ‘0.name’ would cause `get_value()` to be called with a key argument of 0. The name attribute will be looked up after `get_value()` returns by calling the built-in `getattr()` function.

If the index or keyword refers to an item that does not exist, then an `IndexError` or `KeyError` should be raised.

**check_unused_args(used_args, args, kwargs)**

Implement checking for unused arguments if desired. The arguments to this function is the set of all argument keys that were actually referred to in the format string (integers for positional arguments, and strings for named arguments), and a reference to the `args` and `kwargs` that was passed to `vformat`. The set of unused args can be calculated from these parameters. `check_unused_args()` is assumed to raise an exception if the check fails.

**format_field(value, format_spec)**

`format_field()` simply calls the global `format()` built-in. The method is provided so that subclasses can override it.

**convert_field(value, conversion)**

Converts the value (returned by `get_field()`) given a conversion type (as in the tuple returned by the `parse()` method). The default version understands ‘s’ (str), ‘r’ (repr) and ‘a’ (ascii) conversion types.
6.1.3. Format String Syntax

The `str.format()` method and the `Formatter` class share the same syntax for format strings (although in the case of `Formatter`, subclasses can define their own format string syntax).

Format strings contain “replacement fields” surrounded by curly braces `{}`. Anything that is not contained in braces is considered literal text, which is copied unchanged to the output. If you need to include a brace character in the literal text, it can be escaped by doubling: `{}`.

The grammar for a replacement field is as follows:

```plaintext
replacement_field ::= "{" [field_name] ["!" conversion] field_name ::= arg_name ("." attribute_name) arg_name ::= [identifier | integer] attribute_name ::= identifier element_index ::= integer | index_string index_string ::= <any source character except \[\]> conversion ::= "r" | "s" | "a" format_spec ::= <described in the next section>
```

In less formal terms, the replacement field can start with a `field_name` that specifies the object whose value is to be formatted and inserted into the output instead of the replacement field. The `field_name` is optionally followed by a `conversion` field, which is preceded by an exclamation point `!`, and a `format_spec`, which is preceded by a colon `:`. These specify a non-default format for the replacement value.

See also the *Format Specification Mini-Language* section.
The field_name itself begins with an arg_name that is either a number or a keyword. If it’s a number, it refers to a positional argument, and if it’s a keyword, it refers to a named keyword argument. If the numerical arg_names in a format string are 0, 1, 2, ... in sequence, they can all be omitted (not just some) and the numbers 0, 1, 2, ... will be automatically inserted in that order. Because arg_name is not quote-delimited, it is not possible to specify arbitrary dictionary keys (e.g., the strings '10' or ': -]') within a format string. The arg_name can be followed by any number of index or attribute expressions. An expression of the form ".name" selects the named attribute using getattr(), while an expression of the form '[index]' does an index lookup using __getitem__().

*Changed in version 3.1:* The positional argument specifiers can be omitted, so '{ }' is equivalent to '{0} {1}'.

Some simple format string examples:

```
"First, thou shalt count to {0}"    # References first positional argument
"Bring me a {}"                     # Implicitly references the first positional argument
"From {} to {}"                     # Same as "From {0} to {1}
"My quest is {name}"               # References keyword argument
"Weight in tons {0.weight}"         # 'weight' attribute of first positional argument
"Units destroyed: {players[0]}"     # First element of keyword argument players
```

The conversion field causes a type coercion before formatting. Normally, the job of formatting a value is done by the __format__() method of the value itself. However, in some cases it is desirable to force a type to be formatted as a string, overriding its own definition of formatting. By converting the value to a string before calling __format__(), the normal formatting logic is bypassed.
Three conversion flags are currently supported: `!s` which calls `str()` on the value, `!r` which calls `repr()` and `!a` which calls `ascii()`.

Some examples:

```
"Harold's a clever {0!s}"     # Calls str() on the argument first
"Bring out the holy {name!r}"  # Calls repr() on the argument first
"More {!a}"                     # Calls ascii() on the argument first
```

The `format_spec` field contains a specification of how the value should be presented, including such details as field width, alignment, padding, decimal precision and so on. Each value type can define its own “formatting mini-language” or interpretation of the `format_spec`.

Most built-in types support a common formatting mini-language, which is described in the next section.

A `format_spec` field can also include nested replacement fields within it. These nested replacement fields can contain only a field name; conversion flags and format specifications are not allowed. The replacement fields within the `format_spec` are substituted before the `format_spec` string is interpreted. This allows the formatting of a value to be dynamically specified.

See the `Format examples` section for some examples.

### 6.1.3.1. Format Specification Mini-Language

“Format specifications” are used within replacement fields contained within a format string to define how individual values are presented (see `Format String Syntax`). They can also be passed directly to the
built-in `format()` function. Each formattable type may define how the format specification is to be interpreted.

Most built-in types implement the following options for format specifications, although some of the formatting options are only supported by the numeric types.

A general convention is that an empty format string (""") produces the same result as if you had called `str()` on the value. A non-empty format string typically modifies the result.

The general form of a standard format specifier is:

```plaintext
format_spec ::= [[fill]align][sign][#][0][width][,]
fill ::= <any character>
align ::= "<" | ">" | ":-" | ":^"
sign ::= "+" | "-" | "" width ::= integer
precision ::= integer
type ::= "b" | "c" | "d" | "e" | "E" | "f"
```

If a valid `align` value is specified, it can be preceeded by a `fill` character that can be any character and defaults to a space if omitted. Note that it is not possible to use `{` and `}` as `fill` char while using the `str.format()` method; this limitation however doesn’t affect the `format()` function.

The meaning of the various alignment options is as follows:

<table>
<thead>
<tr>
<th>Option</th>
<th>Meaning</th>
</tr>
</thead>
<tbody>
<tr>
<td>'&lt;'</td>
<td>Forces the field to be left-aligned within the available space (this is the default for most objects).</td>
</tr>
<tr>
<td>'&gt;'</td>
<td>Forces the field to be right-aligned within the available space.</td>
</tr>
</tbody>
</table>
space (this is the default for numbers).

<table>
<thead>
<tr>
<th>Option</th>
<th>Meaning</th>
</tr>
</thead>
<tbody>
<tr>
<td>`='</td>
<td>Forces the padding to be placed after the sign (if any) but before the digits. This is used for printing fields in the form <code>+000000120</code>. This alignment option is only valid for numeric types.</td>
</tr>
<tr>
<td><code>^</code></td>
<td>Forces the field to be centered within the available space.</td>
</tr>
</tbody>
</table>

Note that unless a minimum field width is defined, the field width will always be the same size as the data to fill it, so that the alignment option has no meaning in this case.

The `sign` option is only valid for number types, and can be one of the following:

<table>
<thead>
<tr>
<th>Option</th>
<th>Meaning</th>
</tr>
</thead>
<tbody>
<tr>
<td>`+'</td>
<td>indicates that a sign should be used for both positive as well as negative numbers.</td>
</tr>
<tr>
<td><code>-</code></td>
<td>indicates that a sign should be used only for negative numbers (this is the default behavior).</td>
</tr>
<tr>
<td>space</td>
<td>indicates that a leading space should be used on positive numbers, and a minus sign on negative numbers.</td>
</tr>
</tbody>
</table>

The `#` option causes the “alternate form” to be used for the conversion. The alternate form is defined differently for different types. This option is only valid for integer, float, complex and Decimal types. For integers, when binary, octal, or hexadecimal output is used, this option adds the prefix respective `0b`, `0o`, or `0x` to the output value. For floats, complex and Decimal the alternate form causes the result of the conversion to always contain a decimal-point character, even if no digits follow it. Normally, a decimal-point character appears
in the result of these conversions only if a digit follows it. In addition, for 'g' and 'G' conversions, trailing zeros are not removed from the result.

The ',,' option signals the use of a comma for a thousands separator. For a locale aware separator, use the 'n' integer presentation type instead.

*Changed in version 3.1*: Added the ',,' option (see also PEP 378).

*width* is a decimal integer defining the minimum field width. If not specified, then the field width will be determined by the content.

Preceding the *width* field by a zero ('0') character enables sign-aware zero-padding for numeric types. This is equivalent to a *fill* character of '0' with an *alignment* type of '='.

The *precision* is a decimal number indicating how many digits should be displayed after the decimal point for a floating point value formatted with 'f' and 'F', or before and after the decimal point for a floating point value formatted with 'g' or 'G'. For non-number types the field indicates the maximum field size - in other words, how many characters will be used from the field content. The *precision* is not allowed for integer values.

Finally, the *type* determines how the data should be presented.

The available string presentation types are:

<table>
<thead>
<tr>
<th>Type</th>
<th>Meaning</th>
</tr>
</thead>
<tbody>
<tr>
<td>'s'</td>
<td>String format. This is the default type for strings and may be omitted.</td>
</tr>
<tr>
<td>None</td>
<td>The same as 's'.</td>
</tr>
</tbody>
</table>
The available integer presentation types are:

<table>
<thead>
<tr>
<th>Type</th>
<th>Meaning</th>
</tr>
</thead>
<tbody>
<tr>
<td>'b'</td>
<td>Binary format. Outputs the number in base 2.</td>
</tr>
<tr>
<td>'c'</td>
<td>Character. Converts the integer to the corresponding unicode character before printing.</td>
</tr>
<tr>
<td>'d'</td>
<td>Decimal Integer. Outputs the number in base 10.</td>
</tr>
<tr>
<td>'o'</td>
<td>Octal format. Outputs the number in base 8.</td>
</tr>
<tr>
<td>'x'</td>
<td>Hex format. Outputs the number in base 16, using lower-case letters for the digits above 9.</td>
</tr>
<tr>
<td>'X'</td>
<td>Hex format. Outputs the number in base 16, using upper-case letters for the digits above 9.</td>
</tr>
<tr>
<td>'n'</td>
<td>Number. This is the same as 'd', except that it uses the current locale setting to insert the appropriate number separator characters.</td>
</tr>
<tr>
<td>None</td>
<td>The same as 'd'.</td>
</tr>
</tbody>
</table>

In addition to the above presentation types, integers can be formatted with the floating point presentation types listed below (except 'n' and None). When doing so, `float()` is used to convert the integer to a floating point number before formatting.

The available presentation types for floating point and decimal values are:

<table>
<thead>
<tr>
<th>Type</th>
<th>Meaning</th>
</tr>
</thead>
<tbody>
<tr>
<td>'e'</td>
<td>Exponent notation. Prints the number in scientific notation using the letter ‘e’ to indicate the exponent. The default precision is 6.</td>
</tr>
<tr>
<td>'E'</td>
<td>Exponent notation. Same as 'e' except it uses an upper case ‘E’ as the separator character.</td>
</tr>
<tr>
<td>'f'</td>
<td>Fixed point. Displays the number as a fixed-point number. The default precision is 6.</td>
</tr>
<tr>
<td>----</td>
<td>-----------------------------------------------------------------------------------</td>
</tr>
<tr>
<td>'F'</td>
<td>Fixed point. Same as 'f', but converts nan to NAN and inf to INF.</td>
</tr>
<tr>
<td></td>
<td>General format. For a given precision $p \geq 1$, this rounds the number to $p$ significant digits and then formats the result in either fixed-point format or in scientific notation, depending on its magnitude.</td>
</tr>
<tr>
<td>'g'</td>
<td>General format. For a given precision $p \geq 1$, this rounds the number to $p$ significant digits and then formats the result in either fixed-point format or in scientific notation, depending on its magnitude. The precise rules are as follows: suppose that the result formatted with presentation type 'e' and precision $p-1$ would have exponent $\text{exp}$. Then if $-4 \leq \text{exp} &lt; p$, the number is formatted with presentation type 'f' and precision $p-1-\text{exp}$. Otherwise, the number is formatted with presentation type 'e' and precision $p-1$. In both cases insignificant trailing zeros are removed from the significand, and the decimal point is also removed if there are no remaining digits following it. Positive and negative infinity, positive and negative zero, and nans, are formatted as inf, -inf, 0, -0 and nan respectively, regardless of the precision. A precision of 0 is treated as equivalent to a precision of 1. The default precision is 6.</td>
</tr>
<tr>
<td>'G'</td>
<td>General format. Same as 'g' except switches to 'E' if the number gets too large. The representations of infinity and NaN are uppercased, too.</td>
</tr>
<tr>
<td>'n'</td>
<td>Number. This is the same as 'g', except that it uses the current locale setting to insert the appropriate</td>
</tr>
</tbody>
</table>
number separator characters.

<p>| | |</p>
<table>
<thead>
<tr>
<th></th>
<th></th>
</tr>
</thead>
<tbody>
<tr>
<td>'%'</td>
<td>Percentage. Multiplies the number by 100 and displays in fixed ('f') format, followed by a percent sign.</td>
</tr>
<tr>
<td>None</td>
<td>Similar to 'g', except with at least one digit past the decimal point and a default precision of 12. This is intended to match <code>str()</code>, except you can add the other format modifiers.</td>
</tr>
</tbody>
</table>

### 6.1.3.2. Format examples

This section contains examples of the new format syntax and comparison with the old `%`-formatting.

In most of the cases the syntax is similar to the old `%`-formatting, with the addition of the `{}` and with `:` used instead of `%`. For example, `%03.2f` can be translated to `{:03.2f}`.

The new format syntax also supports new and different options, shown in the follow examples.

Accessing arguments by position:

```python
>>> '{0}, {1}, {2}'.format('a', 'b', 'c')
'a, b, c'
>>> '{}, {}, {}'.format('a', 'b', 'c')  # 3.1+ only
'a, b, c'
>>> '{2}, {1}, {0}'.format('a', 'b', 'c')
'c, b, a'
>>> '{2}, {1}, {0}'.format('*abc')  # unpacking
'c, b, a'
>>> '{0}{1}{0}'.format('abra', 'cad')  # arguments
'abracadabra'
```
Accessing arguments by name:

```python
>>> 'Coordinates: {latitude}, {longitude}'.format(latitude=37.24N, longitude=-115.81W)
'Coordinates: 37.24N, -115.81W'
>>> coord = {'latitude': '37.24N', 'longitude': '-115.81W'}
>>> 'Coordinates: {latitude}, {longitude}'.format(**coord)
'Coordinates: 37.24N, -115.81W'
```

Accessing arguments' attributes:

```python
>>> c = 3-5j
>>> ('The complex number {0} is formed from the real part {0.real} ' + 'and the imaginary part {0.imag}.').format(c)
'The complex number (3-5j) is formed from the real part 3.0 and the imaginary part -5.0.'
>>> class Point:
...     def __init__(self, x, y):
...         self.x, self.y = x, y
...     def __str__(self):
...         return 'Point({self.x}, {self.y})'.format(**self)
... >>> str(Point(4, 2))
'Point(4, 2)'
```

Accessing arguments' items:

```python
>>> coord = (3, 5)
>>> 'X: {0[0]}; Y: {0[1]}'.format(coord)
'X: 3; Y: 5'
```

Replacing `%s` and `%r`:

```python
>>> "repr() shows quotes: {!r}; str() doesn't: {!s}".format("test1", "test2")
'repr() shows quotes: 'test1'; str() doesn't: test2'
```
Aligning the text and specifying a width:

```python
>>> '{:<30}'.format('left aligned')
'left aligned'
>>> '{:>30}'.format('right aligned')
'  right aligned'
>>> '{:^30}'.format('centered')
'    centered'
>>> '{:*^30}'.format('centered')  # use '*' as a fill char
'***********centered***********'
```

Replacing %+f, %-f, and %f and specifying a sign:

```python
>>> '{:+f}; {:+f}'.format(3.14, -3.14)  # show it always
'+3.140000; -3.140000'
>>> '{: f}; {: f}'.format(3.14, -3.14)  # show a space
'3.140000; -3.140000'
>>> '{:-f}; {-f}'.format(3.14, -3.14)  # show only the minus
'3.140000; -3.140000'
```

Replacing %x and %o and converting the value to different bases:

```python
>>> # format also supports binary numbers
>>> "int: {0:d}; hex: {0:x}; oct: {0:o}; bin: {0:b};" .format(42)
'int: 42; hex: 2a; oct: 52; bin: 101010'
>>> # with 0x, 0o, or 0b as prefix:
>>> "int: {0:d}; hex: {0:#x}; oct: {0:#o}; bin: {0:#b};" .format(42)
'int: 42; hex: 0x2a; oct: 0o52; bin: 0b101010'
```

Using the comma as a thousands separator:

```python
>>> '{:,}'.format(1234567890)
'1,234,567,890'
```
Expressing a percentage:

```python
>>> points = 19
>>> total = 22
>>> 'Correct answers: {:.2%}'.format(points/total)
'Correct answers: 86.36%'
```

Using type-specific formatting:

```python
>>> import datetime
>>> d = datetime.datetime(2010, 7, 4, 12, 15, 58)
>>> '{:%Y-%m-%d %H:%M:%S}'.format(d)
'2010-07-04 12:15:58'
```

Nesting arguments and more complex examples:

```python
>>> for align, text in zip('<>^', ['left', 'center', ...
                          '{0:{fill}{align}16}'.format(text, fill=align
                            ...
                          'left<<<<<<<<<<<<'
                          '^^^center^^^^^'
                          '>>>>>>>>>>>right'
>>> octets = [192, 168, 0, 1]
>>> '{:02X}{:02X}{:02X}{:02X}'.format(*octets)
'C0A80001'
>>> int(_, 16)
3232235521
>>> width = 5
>>> for num in range(5,12):
...     for base in 'dXob':
...         print('{0:{width}{base}}'.format(num, base
...     print()
...     5 5 5 101```
<p>| | | | | |</p>
<table>
<thead>
<tr>
<th></th>
<th></th>
<th></th>
<th></th>
<th></th>
</tr>
</thead>
<tbody>
<tr>
<td>6</td>
<td>6</td>
<td>6</td>
<td>110</td>
<td></td>
</tr>
<tr>
<td>7</td>
<td>7</td>
<td>7</td>
<td>111</td>
<td></td>
</tr>
<tr>
<td>8</td>
<td>8</td>
<td>10</td>
<td>1000</td>
<td></td>
</tr>
<tr>

</tbody>
</table>
6.1.4. Template strings

Templates provide simpler string substitutions as described in PEP 292. Instead of the normal %-based substitutions, Templates support $-based substitutions, using the following rules:

- $$ is an escape; it is replaced with a single $.
- $identifier$ names a substitution placeholder matching a mapping key of "identifier". By default, "identifier" must spell a Python identifier. The first non-identifier character after the $ character terminates this placeholder specification.
- ${identifier} is equivalent to $identifier$. It is required when valid identifier characters follow the placeholder but are not part of the placeholder, such as "${noun}ification".

Any other appearance of $ in the string will result in a ValueError being raised.

The string module provides a Template class that implements these rules. The methods of Template are:

```
class string.Template(template)

    The constructor takes a single argument which is the template string.

substitute(mapping, **kwds)

    Performs the template substitution, returning a new string. mapping is any dictionary-like object with keys that match the placeholders in the template. Alternatively, you can provide keyword arguments, where the keywords are the placeholders. When both mapping and kwds are given and there are duplicates, the placeholders from kwds take precedence.
```
**safe_substitute**(mapping, **kwds)**

Like **substitute()**, except that if placeholders are missing from **mapping** and **kwds**, instead of raising a **KeyError** exception, the original placeholder will appear in the resulting string intact. Also, unlike with **substitute()**, any other appearances of the $ will simply return $ instead of raising **ValueError**.

While other exceptions may still occur, this method is called “safe” because substitutions always tries to return a usable string instead of raising an exception. In another sense, **safe_substitute()** may be anything other than safe, since it will silently ignore malformed templates containing dangling delimiters, unmatched braces, or placeholders that are not valid Python identifiers.

**Template** instances also provide one public data attribute:

**template**

This is the object passed to the constructor’s **template** argument. In general, you shouldn’t change it, but read-only access is not enforced.

Here is an example of how to use a Template:

```python
>>> from string import Template
>>> s = Template('$who likes $what')
>>> s.substitute(who='tim', what='kung pao')
'tim likes kung pao'
>>> d = dict(who='tim')
>>> Template('Give $who $100').substitute(d)
Traceback (most recent call last):
...
Advanced usage: you can derive subclasses of `Template` to customize the placeholder syntax, delimiter character, or the entire regular expression used to parse template strings. To do this, you can override these class attributes:

- **delimiter** – This is the literal string describing a placeholder introducing delimiter. The default value is $. Note that this should not be a regular expression, as the implementation will call `re.escape()` on this string as needed.

- **idpattern** – This is the regular expression describing the pattern for non-braced placeholders (the braces will be added automatically as appropriate). The default value is the regular expression `[_a-z][_a-z0-9]*`.

- **flags** – The regular expression flags that will be applied when compiling the regular expression used for recognizing substitutions. The default value is `re.IGNORECASE`. Note that `re.VERBOSE` will always be added to the flags, so custom `idpatterns` must follow conventions for verbose regular expressions.

    *New in version 3.2.*

Alternatively, you can provide the entire regular expression pattern by
overriding the class attribute *pattern*. If you do this, the value must be a regular expression object with four named capturing groups. The capturing groups correspond to the rules given above, along with the invalid placeholder rule:

- *escaped* – This group matches the escape sequence, e.g. `$$`, in the default pattern.
- *named* – This group matches the unbraced placeholder name; it should not include the delimiter in capturing group.
- *braced* – This group matches the brace enclosed placeholder name; it should not include either the delimiter or braces in the capturing group.
- *invalid* – This group matches any other delimiter pattern (usually a single delimiter), and it should appear last in the regular expression.
6.1.5. Helper functions

**string.capwords(s, sep=None)**

Split the argument into words using `str.split()`, capitalize each word using `str.capitalize()`, and join the capitalized words using `str.join()`. If the optional second argument `sep` is absent or `None`, runs of whitespace characters are replaced by a single space and leading and trailing whitespace are removed, otherwise `sep` is used to split and join the words.
6.2. **re** — Regular expression operations

This module provides regular expression matching operations similar to those found in Perl.

Both patterns and strings to be searched can be Unicode strings as well as 8-bit strings. However, Unicode strings and 8-bit strings cannot be mixed: that is, you cannot match an Unicode string with a byte pattern or vice-versa; similarly, when asking for a substitution, the replacement string must be of the same type as both the pattern and the search string.

Regular expressions use the backslash character ('\') to indicate special forms or to allow special characters to be used without invoking their special meaning. This collides with Python's usage of the same character for the same purpose in string literals; for example, to match a literal backslash, one might have to write '\\\' as the pattern string, because the regular expression must be \\\n, and each backslash must be expressed as \\
 inside a regular Python string literal.

The solution is to use Python's raw string notation for regular expression patterns; backslashes are not handled in any special way in a string literal prefixed with 'r'. So r"\n" is a two-character string containing '\n' and 'n', while "\n" is a one-character string containing a newline. Usually patterns will be expressed in Python code using this raw string notation.

It is important to note that most regular expression operations are
available as module-level functions and methods on compiled regular expressions. The functions are shortcuts that don’t require you to compile a regex object first, but miss some fine-tuning parameters.

See also:

Mastering Regular Expressions
Book on regular expressions by Jeffrey Friedl, published by O’Reilly. The second edition of the book no longer covers Python at all, but the first edition covered writing good regular expression patterns in great detail.
6.2.1. Regular Expression Syntax

A regular expression (or RE) specifies a set of strings that matches it; the functions in this module let you check if a particular string matches a given regular expression (or if a given regular expression matches a particular string, which comes down to the same thing).

Regular expressions can be concatenated to form new regular expressions; if $A$ and $B$ are both regular expressions, then $AB$ is also a regular expression. In general, if a string $p$ matches $A$ and another string $q$ matches $B$, the string $pq$ will match $AB$. This holds unless $A$ or $B$ contain low precedence operations; boundary conditions between $A$ and $B$; or have numbered group references. Thus, complex expressions can easily be constructed from simpler primitive expressions like the ones described here. For details of the theory and implementation of regular expressions, consult the Friedl book referenced above, or almost any textbook about compiler construction.

A brief explanation of the format of regular expressions follows. For further information and a gentler presentation, consult the Regular Expression HOWTO.

Regular expressions can contain both special and ordinary characters. Most ordinary characters, like 'A', 'a', or '0', are the simplest regular expressions; they simply match themselves. You can concatenate ordinary characters, so last matches the string 'last'. (In the rest of this section, we'll write RE's in this special style, usually without quotes, and strings to be matched in single quotes.)

Some characters, like '|' or '(', are special. Special characters either stand for classes of ordinary characters, or affect how the
Regular expressions around them are interpreted. Regular expression pattern strings may not contain null bytes, but can specify the null byte using a `\number` notation such as `\x00`.

The special characters are:

- `'.'` (Dot.) In the default mode, this matches any character except a newline. If the DOTALL flag has been specified, this matches any character including a newline.

- `'^'` (Caret.) Matches the start of the string, and in MULTILINE mode also matches immediately after each newline.

- `'$'` Matches the end of the string or just before the newline at the end of the string, and in MULTILINE mode also matches before a newline. `foo` matches both ‘foo’ and ‘foobas’, while the regular expression `foo$` matches only ‘foo’. More interestingly, searching for `foo.$` in `foo
foo2
` matches ‘foo2’ normally, but ‘foo1’ in MULTILINE mode; searching for a single $ in `foo
` will find two (empty) matches: one just before the newline, and one at the end of the string.

- `'*'` Causes the resulting RE to match 0 or more repetitions of the preceding RE, as many repetitions as are possible. `ab*` will match ‘a’, ‘ab’, or ‘a’ followed by any number of ‘b’s.

- `'+'` Causes the resulting RE to match 1 or more repetitions of the preceding RE. `ab+` will match ‘a’ followed by any non-zero number of ‘b’s; it will not match just ‘a’.

- `'?` Causes the resulting RE to match 0 or 1 repetitions of the
preceding RE. \texttt{ab?} will match either \texttt{a} or \texttt{ab}.

\texttt{*?}, \texttt{+?}, \texttt{??}

The \texttt{*?}, \texttt{+?}, and \texttt{??} qualifiers are all \textit{greedy}; they match as much text as possible. Sometimes this behaviour isn't desired; if the RE \texttt{<.*>} is matched against \texttt{'<H1>title</H1>'}, it will match the entire string, and not just \texttt{'<H1>'}. Adding \texttt{?} after the qualifier makes it perform the match in \textit{non-greedy} or \textit{minimal} fashion; as \textit{few} characters as possible will be matched. Using \texttt{.*?} in the previous expression will match only \texttt{'<H1>'}.

\texttt{\{m\}}

Specifies that exactly \textit{m} copies of the previous RE should be matched; fewer matches cause the entire RE not to match. For example, \texttt{a\{6\}} will match exactly six \texttt{a} characters, but not five.

\texttt{\{m, n\}}

Causes the resulting RE to match from \textit{m} to \textit{n} repetitions of the preceding RE, attempting to match as many repetitions as possible. For example, \texttt{a\{3, 5\}} will match from 3 to 5 \texttt{a} characters. Omitting \textit{m} specifies a lower bound of zero, and omitting \textit{n} specifies an infinite upper bound. As an example, \texttt{a\{4, \}b} will match \texttt{aaaab} or a thousand \texttt{a} characters followed by a \texttt{b}, but not \texttt{aaab}. The comma may not be omitted or the modifier would be confused with the previously described form.

\texttt{\{m, n\}?}

Causes the resulting RE to match from \textit{m} to \textit{n} repetitions of the preceding RE, attempting to match as \textit{few} repetitions as possible. This is the non-greedy version of the previous qualifier. For example, on the 6-character string \texttt{'aaaaaa'}, \texttt{a\{3, 5\}} will match 5 \texttt{a} characters, while \texttt{a\{3, 5\}?} will only match 3 characters.

\texttt{\'}

Either escapes special characters (permitting you to match characters like \texttt{*}, \texttt{?}, and so forth), or signals a special
sequence; special sequences are discussed below.

If you're not using a raw string to express the pattern, remember that Python also uses the backslash as an escape sequence in string literals; if the escape sequence isn't recognized by Python's parser, the backslash and subsequent character are included in the resulting string. However, if Python would recognize the resulting sequence, the backslash should be repeated twice. This is complicated and hard to understand, so it's highly recommended that you use raw strings for all but the simplest expressions.

[]
Used to indicate a set of characters. In a set:

- Characters can be listed individually, e.g. `[amk]` will match 'a', 'm', or 'k'.
- Ranges of characters can be indicated by giving two characters and separating them by a '-', for example `[a-z]` will match any lowercase ASCII letter, `[0-5][0-9]` will match all the two-digits numbers from 00 to 59, and `[0-9A-Fa-f]` will match any hexadecimal digit. If `-` is escaped (e.g. `[a\-z]`) or if it's placed as the first or last character (e.g. `[a-]`), it will match a literal '-'.
- Special characters lose their special meaning inside sets. For example, `[(+*)]` will match any of the literal characters '(' , '+', '*', or ')'.
- Character classes such as `\w` or `\S` (defined below) are also accepted inside a set, although the characters they match depends on whether ASCII or Locale mode is in force.
- Characters that are not within a range can be matched by complementing the set. If the first character of the set is `[^]`, all the characters that are not in the set will be matched. For example, `[^5]` will match any character except '5', and
[^\^] will match any character except '^'. ^ has no special meaning if it's not the first character in the set.

- To match a literal ']' inside a set, precede it with a backslash, or place it at the beginning of the set. For example, both [()]{} and [](){} will both match a parenthesis.

'|'

A|B, where A and B can be arbitrary REs, creates a regular expression that will match either A or B. An arbitrary number of REs can be separated by the '|' in this way. This can be used inside groups (see below) as well. As the target string is scanned, REs separated by '|' are tried from left to right. When one pattern completely matches, that branch is accepted. This means that once A matches, B will not be tested further, even if it would produce a longer overall match. In other words, the '|' operator is never greedy. To match a literal '|', use \|, or enclose it inside a character class, as in [\|].

(...) Matches whatever regular expression is inside the parentheses, and indicates the start and end of a group; the contents of a group can be retrieved after a match has been performed, and can be matched later in the string with the \number special sequence, described below. To match the literals '(', or ')', use \( or \), or enclose them inside a character class: [\(\)]\).

(????) This is an extension notation (a '?' following a '(' is not meaningful otherwise). The first character after the '?' determines what the meaning and further syntax of the construct is. Extensions usually do not create a new group; (??P<name>...) is the only exception to this rule. Following are the currently supported extensions.
(One or more letters from the set 'a', 'i', 'L', 'm', 's', 'u', 'x'.) The group matches the empty string; the letters set the corresponding flags: \texttt{re.A} (ASCII-only matching), \texttt{re.I} (ignore case), \texttt{re.L} (locale dependent), \texttt{re.M} (multi-line), \texttt{re.S} (dot matches all), and \texttt{re.X} (verbose), for the entire regular expression. (The flags are described in \textit{Module Contents}.) This is useful if you wish to include the flags as part of the regular expression, instead of passing a flag argument to the \texttt{re.compile()} function.

Note that the \texttt{(?:...)} flag changes how the expression is parsed. It should be used first in the expression string, or after one or more whitespace characters. If there are non-whitespace characters before the flag, the results are undefined.

(\texttt{?:...})

A non-capturing version of regular parentheses. Matches whatever regular expression is inside the parentheses, but the substring matched by the group \textit{cannot} be retrieved after performing a match or referenced later in the pattern.

(\texttt{(?P<name>...)}

Similar to regular parentheses, but the substring matched by the group is accessible via the symbolic group name \textit{name}. Group names must be valid Python identifiers, and each group name must be defined only once within a regular expression. A symbolic group is also a numbered group, just as if the group were not named.

Named groups can be referenced in three contexts. If the pattern is (\texttt{(?P<quote>["']).*?(?P=quote)} (i.e. matching a string quoted with either single or double quotes):
<table>
<thead>
<tr>
<th>Context of reference to group “quote”</th>
<th>Ways to reference it</th>
</tr>
</thead>
<tbody>
<tr>
<td>in the same pattern itself</td>
<td>• (?P=quote) (as shown)</td>
</tr>
<tr>
<td></td>
<td>• \1</td>
</tr>
<tr>
<td>when processing match object m</td>
<td>• m.group('quote')</td>
</tr>
<tr>
<td></td>
<td>• m.end('quote')</td>
</tr>
<tr>
<td>in a string passed to the repl argument of re.sub()</td>
<td>• \g&lt;quote&gt;</td>
</tr>
<tr>
<td></td>
<td>• \g&lt;1&gt;</td>
</tr>
<tr>
<td></td>
<td>• \1</td>
</tr>
</tbody>
</table>

(?P=name)
A backreference to a named group; it matches whatever text was matched by the earlier group named *name*.

(?#...)
A comment; the contents of the parentheses are simply ignored.

(=?...)
Matches if ... matches next, but doesn’t consume any of the string. This is called a lookahead assertion. For example, *Isaac (?=Asimov)* will match 'Isaac' only if it’s followed by 'Asimov'.

(?!...)
Matches if ... doesn’t match next. This is a negative lookahead assertion. For example, *Isaac (?!Asimov)* will match 'Isaac' only if it’s *not* followed by 'Asimov'.

(<=...)
Matches if the current position in the string is preceded by a match for ... that ends at the current position. This is called a *positive*
**lookbehind assertion.** `(<=abc)def` will find a match in `abcdef`, since the lookbehind will back up 3 characters and check if the contained pattern matches. The contained pattern must only match strings of some fixed length, meaning that `abc` or `a|b` are allowed, but `a*` and `a{3,4}` are not. Note that patterns which start with positive lookbehind assertions will not match at the beginning of the string being searched; you will most likely want to use the `search()` function rather than the `match()` function:

```python
>>> import re
>>> m = re.search('(<=abc)def', 'abcdef')
>>> m.group(0)
'def'
```

This example looks for a word following a hyphen:

```python
>>> m = re.search('(<=-)\w+', 'spam-egg')
>>> m.group(0)
'egg'
```

`(?<!...)` Matches if the current position in the string is not preceded by a match for `...`. This is called a **negative lookbehind assertion**. Similar to positive lookbehind assertions, the contained pattern must only match strings of some fixed length. Patterns which start with negative lookbehind assertions may match at the beginning of the string being searched.

`(?(id/name)yes-pattern|no-pattern)` Will try to match with `yes-pattern` if the group with given `id` or `name` exists, and with `no-pattern` if it doesn't. `no-pattern` is optional and can be omitted. For example, `(<)?((\w+@\w+(?:\.:\.:\w+)+)(?1)>|$)` is a poor email matching pattern, which will match with `'<user@host.com>'` as well as...
'user@host.com', but not with '<user@host.com>' nor 'user@host.com>'.

The special sequences consist of '\ ' and a character from the list below. If the ordinary character is not on the list, then the resulting RE will match the second character. For example, \$ matches the character '$'.

\number
Matches the contents of the group of the same number. Groups are numbered starting from 1. For example, (.+) \1 matches 'the the' or '55 55', but not 'thethe' (note the space after the group). This special sequence can only be used to match one of the first 99 groups. If the first digit of number is 0, or number is 3 octal digits long, it will not be interpreted as a group match, but as the character with octal value number. Inside the '[[ ' and ' ]]' of a character class, all numeric escapes are treated as characters.

\A
Matches only at the start of the string.

\b
Matches the empty string, but only at the beginning or end of a word. A word is defined as a sequence of Unicode alphanumeric or underscore characters, so the end of a word is indicated by whitespace or a non-alphanumeric, non-underscore Unicode character. Note that formally, \b is defined as the boundary between a \w and a \W character (or vice versa), or between \w and the beginning/end of the string. This means that r'\bfoo\b' matches 'foo', 'foo.', '(foo)', 'bar foo baz' but not 'foobar' or 'foo3'.

By default Unicode alphanumerics are the ones used, but this can be changed by using the ASCII flag. Inside a character range, \
represents the backspace character, for compatibility with Python’s string literals.

\B

Matches the empty string, but only when it is not at the beginning or end of a word. This means that `r'py\B'` matches 'python', 'py3', 'py2', but not 'py', 'py.', or 'py!'. `\B` is just the opposite of `\b`, so word characters are Unicode alphanumerics or the underscore, although this can be changed by using the ASCII flag.

\d

For Unicode (str) patterns:

_matches any Unicode decimal digit (that is, any character in Unicode character category \[Nd\]). This includes \[0-9\], and also many other digit characters. If the ASCII flag is used only \[0-9\] is matched (but the flag affects the entire regular expression, so in such cases using an explicit \[0-9\] may be a better choice).

For 8-bit (bytes) patterns:

_matches any decimal digit; this is equivalent to \[0-9\].

\D

Matches any character which is not a Unicode decimal digit. This is the opposite of `\d`. If the ASCII flag is used this becomes the equivalent of \[^0-9\] (but the flag affects the entire regular expression, so in such cases using an explicit \[^0-9\] may be a better choice).

\s

For Unicode (str) patterns:

_matches Unicode whitespace characters (which includes \[\t\n\r\f\v\], and also many other characters, for example the non-breaking spaces mandated by typography rules in
many languages). If the ASCII flag is used, only \[ \t\n\r\f\v \] is matched (but the flag affects the entire regular expression, so in such cases using an explicit \[ \t\n\r\f\v \] may be a better choice).

For 8-bit (bytes) patterns:
Matches characters considered whitespace in the ASCII character set; this is equivalent to \[ \t\n\r\f\v \].

\S
Matches any character which is not a Unicode whitespace character. This is the opposite of \s. If the ASCII flag is used this becomes the equivalent of \[^\t\n\r\f\v \] (but the flag affects the entire regular expression, so in such cases using an explicit \[^\t\n\r\f\v \] may be a better choice).

\w
For Unicode (str) patterns:
Matches Unicode word characters; this includes most characters that can be part of a word in any language, as well as numbers and the underscore. If the ASCII flag is used, only \[a-zA-Z0-9_\] is matched (but the flag affects the entire regular expression, so in such cases using an explicit \[a-zA-Z0-9_\] may be a better choice).

For 8-bit (bytes) patterns:
Matches characters considered alphanumeric in the ASCII character set; this is equivalent to \[a-zA-Z0-9_\].

\W
Matches any character which is not a Unicode word character. This is the opposite of \w. If the ASCII flag is used this becomes the equivalent of \[^a-zA-Z0-9_\] (but the flag affects the entire regular expression, so in such cases using an explicit \[^a-zA-Z0-9_\] may be a better choice).
\Z

Matches only at the end of the string.

Most of the standard escapes supported by Python string literals are also accepted by the regular expression parser:

```
a \b \f \n \r \t \u \U \
v \x \\`
```

(Note that \b is used to represent word boundaries, and means “backspace” only inside character classes.)

'\u' and '\U' escape sequences are only recognized in Unicode patterns. In bytes patterns they are not treated specially.

Octal escapes are included in a limited form. If the first digit is a 0, or if there are three octal digits, it is considered an octal escape. Otherwise, it is a group reference. As for string literals, octal escapes are always at most three digits in length.

*Changed in version 3.3:* The '\u' and '\U' escape sequences have been added.
6.2.2. Module Contents

The module defines several functions, constants, and an exception. Some of the functions are simplified versions of the full featured methods for compiled regular expressions. Most non-trivial applications always use the compiled form.

\texttt{re.compile(pattern, flags=0)}

Compile a regular expression pattern into a regular expression object, which can be used for matching using its \texttt{match()} and \texttt{search()} methods, described below.

The expression’s behaviour can be modified by specifying a \texttt{flags} value. Values can be any of the following variables, combined using bitwise OR (the | operator).

The sequence

\begin{verbatim}
prog = re.compile(pattern)
result = prog.match(string)
\end{verbatim}

is equivalent to

\begin{verbatim}
result = re.match(pattern, string)
\end{verbatim}

but using \texttt{re.compile()} and saving the resulting regular expression object for reuse is more efficient when the expression will be used several times in a single program.

\textbf{Note: } The compiled versions of the most recent patterns passed to \texttt{re.match()}, \texttt{re.search()} or \texttt{re.compile()} are cached, so programs that use only a few regular expressions at a time
needn’t worry about compiling regular expressions.

**re.A**
**re.ASCII**
Make \w, \W, \b, \B, \d, \D, \s and \S perform ASCII-only matching instead of full Unicode matching. This is only meaningful for Unicode patterns, and is ignored for byte patterns.

Note that for backward compatibility, the re.U flag still exists (as well as its synonym re.UNICODE and its embedded counterpart (?u)), but these are redundant in Python 3 since matches are Unicode by default for strings (and Unicode matching isn’t allowed for bytes).

**re.DEBUG**
Display debug information about compiled expression.

**re.I**
**re.IGNORECASE**
Perform case-insensitive matching; expressions like [A-Z] will match lowercase letters, too. This is not affected by the current locale and works for Unicode characters as expected.

**re.L**
**re.LOCALE**
Make \w, \W, \b, \B, \s and \S dependent on the current locale. The use of this flag is discouraged as the locale mechanism is very unreliable, and it only handles one “culture” at a time anyway; you should use Unicode matching instead, which is the default in Python 3 for Unicode (str) patterns.

**re.M**
**re.MULTILINE**
When specified, the pattern character `'^'` matches at the beginning of the string and at the beginning of each line (immediately following each newline); and the pattern character `'$'` matches at the end of the string and at the end of each line (immediately preceding each newline). By default, `'^'` matches only at the beginning of the string, and `'$'` only at the end of the string and immediately before the newline (if any) at the end of the string.

**re.S**

**re.DOTALL**

Make the `.'` special character match any character at all, including a newline; without this flag, `.'` will match anything except a newline.

**re.X**

**re.VERBOSE**

This flag allows you to write regular expressions that look nicer. Whitespace within the pattern is ignored, except when in a character class or preceded by an unescaped backslash, and, when a line contains a `'#'` neither in a character class or preceded by an unescaped backslash, all characters from the leftmost such `'#'` through the end of the line are ignored.

That means that the two following regular expression objects that match a decimal number are functionally equal:

```python
a = re.compile(r"\d + # the integral part \.
    # the decimal point \d * # some fractional digits"

b = re.compile(r"\d\+.\d*"
```

re.\texttt{search}(\textit{pattern}, \textit{string}, flags=0)
Scan through \textit{string} looking for a location where the regular expression \textit{pattern} produces a match, and return a corresponding \textit{match object}. Return \texttt{None} if no position in the string matches the pattern; note that this is different from finding a zero-length match at some point in the string.

re.\texttt{match}(\textit{pattern}, \textit{string}, flags=0)
If zero or more characters at the beginning of \textit{string} match the regular expression \textit{pattern}, return a corresponding \textit{match object}. Return \texttt{None} if the string does not match the pattern; note that this is different from a zero-length match.

Note that even in \texttt{MULTILINE} mode, \texttt{re.match()} will only match at the beginning of the string and not at the beginning of each line.

If you want to locate a match anywhere in \textit{string}, use \texttt{search()} instead (see also \texttt{search()} vs. \texttt{match()}).

re.\texttt{split}(\textit{pattern}, \textit{string}, maxsplit=0, flags=0)
Split \textit{string} by the occurrences of \textit{pattern}. If capturing parentheses are used in \textit{pattern}, then the text of all groups in the pattern are also returned as part of the resulting list. If \textit{maxsplit} is nonzero, at most \textit{maxsplit} splits occur, and the remainder of the string is returned as the final element of the list.

```python
>>> re.split('\\W+', 'Words, words, words.')
['Words', 'words', 'words', '']
>>> re.split('(\\W+)', 'Words, words, words.')
['Words', ',', ',', 'words', ',', ',', 'words', ',', '.', '', '']
>>> re.split('\\W+', 'Words, words, words.', 1)
['Words', 'words, words.]
>>> re.split('[a-f]+', '0a3B9', flags=re.IGNORECASE
```
If there are capturing groups in the separator and it matches at the start of the string, the result will start with an empty string. The same holds for the end of the string:

```python
>>> re.split('(\W+)', '...words, words...')
['', '...', 'words', ',', ',', 'words', '...', '']
```

That way, separator components are always found at the same relative indices within the result list.

Note that `split` will never split a string on an empty pattern match. For example:

```python
>>> re.split('x*', 'foo')
['foo']
>>> re.split("(?m)^$", "foo

bar
")
['foo

bar
']
```

Changed in version 3.1: Added the optional flags argument.

`re.findall(pattern, string, flags=0)`
Return all non-overlapping matches of `pattern` in `string`, as a list of strings. The `string` is scanned left-to-right, and matches are returned in the order found. If one or more groups are present in the pattern, return a list of groups; this will be a list of tuples if the pattern has more than one group. Empty matches are included in the result unless they touch the beginning of another match.

`re.finditer(pattern, string, flags=0)`
Return an `iterator` yielding `match objects` over all non-overlapping matches for the RE `pattern` in `string`. The `string` is scanned left-to-
right, and matches are returned in the order found. Empty matches are included in the result unless they touch the beginning of another match.

```
re.sub(pattern, repl, string, count=0, flags=0)
```

Return the string obtained by replacing the leftmost non-overlapping occurrences of `pattern` in `string` by the replacement `repl`. If the pattern isn’t found, `string` is returned unchanged. `repl` can be a string or a function; if it is a string, any backslash escapes in it are processed. That is, `\n` is converted to a single newline character, `\r` is converted to a carriage return, and so forth. Unknown escapes such as `\j` are left alone. Backreferences, such as `\6`, are replaced with the substring matched by group 6 in the pattern. For example:

```python
>>> re.sub(r'\d{1,2}', dashrepl, 'pro--gram files')
'Baked Beans & Spam'
```

If `repl` is a function, it is called for every non-overlapping occurrence of `pattern`. The function takes a single match object argument, and returns the replacement string. For example:

```python
>>> def dashrepl(matchobj):
...     if matchobj.group(0) == '-': return ''
...     else: return '-'

>>> re.sub(r'\s+([a-zA-Z_][a-zA-Z_0-9]*)\s*', 'static PyObject*\npy_1(void)\n{', ...
'...  
static PyObject*\npy_myfunc(void)\n{"...''

>>> re.sub(r'\s+([a-zA-Z_][a-zA-Z_0-9]*)\s*', 'static PyObject*\npy_1(void)\n{', ...
'...  
static PyObject*\npy_myfunc(void)\n{"...''
```

```python
>>> re.sub(r'\s+([a-zA-Z_][a-zA-Z_0-9]*)\s*', 'static PyObject*\npy_1(void)\n{', ...
'...  
static PyObject*\npy_myfunc(void)\n{"...''
```
The pattern may be a string or an RE object.

The optional argument *count* is the maximum number of pattern occurrences to be replaced; *count* must be a non-negative integer. If omitted or zero, all occurrences will be replaced. Empty matches for the pattern are replaced only when not adjacent to a previous match, so `sub('x*', '-', 'abc')` returns `-a-b-c-`.

In string-type *repl* arguments, in addition to the character escapes and backreferences described above, \g<name> will use the substring matched by the group named *name*, as defined by the (? P<name>...) syntax. \g<number> uses the corresponding group number; \g<2> is therefore equivalent to \2, but isn’t ambiguous in a replacement such as \g<2>0. \20 would be interpreted as a reference to group 20, not a reference to group 2 followed by the literal character '0'. The backreference \g<0> substitutes in the entire substring matched by the RE.

*Changed in version 3.1:* Added the optional flags argument.

**re.subn**(*pattern*, *repl*, *string*, *count=0*, *flags=0*)

Perform the same operation as `sub()`, but return a tuple `(new_string, number_of_subs_made)`.  

*Changed in version 3.1:* Added the optional flags argument.

**re.escape**(*string*)

Escape all the characters in pattern except ASCII letters, numbers and ' _ '. This is useful if you want to match an arbitrary literal string that may have regular expression metacharacters in it.

*Changed in version 3.3:* The ' _ ' character is no longer escaped.
**re.** `purge()`

Clear the regular expression cache.

**exception re.** `error`

Exception raised when a string passed to one of the functions here is not a valid regular expression (for example, it might contain unmatched parentheses) or when some other error occurs during compilation or matching. It is never an error if a string contains no match for a pattern.
6.2.3. Regular Expression Objects

Compiled regular expression objects support the following methods and attributes:

```python
regex.search(string[, pos[, endpos]])
```

Scan through `string` looking for a location where this regular expression produces a match, and return a corresponding `match object`. Return None if no position in the string matches the pattern; note that this is different from finding a zero-length match at some point in the string.

The optional second parameter `pos` gives an index in the string where the search is to start; it defaults to 0. This is not completely equivalent to slicing the string; the `'^'` pattern character matches at the real beginning of the string and at positions just after a newline, but not necessarily at the index where the search is to start.

The optional parameter `endpos` limits how far the string will be searched; it will be as if the string is `endpos` characters long, so only the characters from `pos` to `endpos - 1` will be searched for a match. If `endpos` is less than `pos`, no match will be found; otherwise, if `rx` is a compiled regular expression object, `rx.search(string, 0, 50)` is equivalent to `rx.search(string[:50], 0)`.

```python
>>> pattern = re.compile("d")
>>> pattern.search("dog")   # Match at index 0
<_sre.SRE_Match object at ...>  
>>> pattern.search("dog", 1)     # No match; search
```

`regex.match(string[, pos[, endpos]])`

If zero or more characters at the *beginning* of *string* match this regular expression, return a corresponding *match object*. Return None if the string does not match the pattern; note that this is different from a zero-length match.

The optional *pos* and *endpos* parameters have the same meaning as for the `search()` method.

```python
>>> pattern = re.compile("o")
>>> pattern.match("dog")       # No match as "o" is not at the start of "dog".
>>> pattern.match("dog", 1)    # Match as "o" is the 2nd character of "dog".
<_sre.SRE_Match object at ...>|
```

If you want to locate a match anywhere in *string*, use `search()` instead (see also `search() vs. match()`).

`regex.split(string, maxsplit=0)`

Identical to the `split()` function, using the compiled pattern.

`regex.findall(string[, pos[, endpos]])`

Similar to the `findall()` function, using the compiled pattern, but also accepts optional *pos* and *endpos* parameters that limit the search region like for `match()`.

`regex.finditer(string[, pos[, endpos]])`

Similar to the `finditer()` function, using the compiled pattern, but also accepts optional *pos* and *endpos* parameters that limit the search region like for `match()`.

`regex.sub(repl, string, count=0)`
Identical to the `sub()` function, using the compiled pattern.

`regex.subn(repl, string, count=0)`
Identical to the `subn()` function, using the compiled pattern.

`regex.flags`
The regex matching flags. This is a combination of the flags given to `compile()`, any `(?...)` inline flags in the pattern, and implicit flags such as UNICODE if the pattern is a Unicode string.

`regex.groups`
The number of capturing groups in the pattern.

`regex.groupindex`
A dictionary mapping any symbolic group names defined by `(P<id>)` to group numbers. The dictionary is empty if no symbolic groups were used in the pattern.

`regex.pattern`
The pattern string from which the RE object was compiled.
6.2.4. Match Objects

Match objects always have a boolean value of True. Since `match()` and `search()` return None when there is no match, you can test whether there was a match with a simple `if` statement:

```python
match = re.search(pattern, string)
if match:
    process(match)
```

Match objects support the following methods and attributes:

**match.`expand(template)`**

Return the string obtained by doing backslash substitution on the template string `template`, as done by the `sub()` method. Escapes such as `\n` are converted to the appropriate characters, and numeric backreferences (`\1, \2`) and named backreferences (`\g<1>, \g<name>`) are replaced by the contents of the corresponding group.

**match.`group([group1,...])`**

Returns one or more subgroups of the match. If there is a single argument, the result is a single string; if there are multiple arguments, the result is a tuple with one item per argument. Without arguments, `group1` defaults to zero (the whole match is returned). If a `groupN` argument is zero, the corresponding return value is the entire matching string; if it is in the inclusive range `[1..99]`, it is the string matching the corresponding parenthesized group. If a group number is negative or larger than the number of groups defined in the pattern, an `IndexError` exception is raised. If a group is contained in a part of the pattern that did not match,
the corresponding result is None. If a group is contained in a part of the pattern that matched multiple times, the last match is returned.

```python
>>> m = re.match(r"(\w+) (\w+)", "Isaac Newton, physicist")
>>> m.group(0)  # The entire match
'Isaac Newton'
>>> m.group(1)  # The first parenthesized subgroup
'Isaac'
>>> m.group(2)  # The second parenthesized subgroup
'Newton'
>>> m.group(1, 2)  # Multiple arguments give us a tuple.
('Isaac', 'Newton')
```

If the regular expression uses the `(\P<name>...)` syntax, the groupN arguments may also be strings identifying groups by their group name. If a string argument is not used as a group name in the pattern, an `IndexError` exception is raised.

A moderately complicated example:

```python
>>> m = re.match(r"(?P<first_name>\w+) (?P<last_name>\w+)", "Isaac Newton, physicist")
>>> m.group('first_name')  # 'Malcolm'
'Malcolm'
>>> m.group('last_name')  # 'Reynolds'
'Reynolds'
```

Named groups can also be referred to by their index:

```python
>>> m.group(1)  # 'Malcolm'
'Malcolm'
>>> m.group(2)  # 'Reynolds'
'Reynolds'
```
If a group matches multiple times, only the last match is accessible:

```python
>>> m = re.match(r"(.+)", "a1b2c3")  # Matches 3 times.
>>> m.group(1)  # Returns only the last match.
'c3'
```

**match.groups**(default=None)

Return a tuple containing all the subgroups of the match, from 1 up to however many groups are in the pattern. The *default* argument is used for groups that did not participate in the match; it defaults to None.

For example:

```python
>>> m = re.match(r"(\d+)\.?\d+\d+\d+", "24.1632")
>>> m.groups()
('24', '1632')
```

If we make the decimal place and everything after it optional, not all groups might participate in the match. These groups will default to None unless the *default* argument is given:

```python
>>> m = re.match(r"(\d+)\.?\d+\d+\d+", "24")
>>> m.groups()  # Second group defaults to None.
('24', None)
>>> m.groups('0')  # Now, the second group defaults to '0'.
('24', '0')
```

**match.groupdict**(default=None)

Return a dictionary containing all the named subgroups of the match, keyed by the subgroup name. The *default* argument is used for groups that did not participate in the match; it defaults to None.
For example:

```python
>>> m = re.match(r"(?P<first_name>\w+) (?P<last_name>\w+)", "Malcolm Reynolds")
>>> m.groupdict()
{'first_name': 'Malcolm', 'last_name': 'Reynolds'}
```

`match.start([group])`

`match.end([group])`

Return the indices of the start and end of the substring matched by `group`; `group` defaults to zero (meaning the whole matched substring). Return `-1` if `group` exists but did not contribute to the match. For a match object `m`, and a group `g` that did contribute to the match, the substring matched by group `g` (equivalent to `m.group(g)`) is

```python
m.string[m.start(g):m.end(g)]
```

Note that `m.start(group)` will equal `m.end(group)` if `group` matched a null string. For example, after `m = re.search('b(c?)', 'cba'), m.start(0)` is 1, `m.end(0)` is 2, `m.start(1)` and `m.end(1)` are both 2, and `m.start(2)` raises an `IndexError` exception.

An example that will remove `remove_this` from email addresses:

```python
>>> email = "tony@tiremove_thisger.net"
>>> m = re.search("remove_this", email)
>>> email[:m.start()] + email[m.end():]
'tony@tiger.net'
```

`match.span([group])`

For a match `m`, return the 2-tuple `(m.start(group),`
m.end(group)). Note that if group did not contribute to the match, this is \((-1, -1)\). group defaults to zero, the entire match.

**match.pos**

The value of pos which was passed to the `search()` or `match()` method of a *regex object*. This is the index into the string at which the RE engine started looking for a match.

**match.endpos**

The value of endpos which was passed to the `search()` or `match()` method of a *regex object*. This is the index into the string beyond which the RE engine will not go.

**match.lastindex**

The integer index of the last matched capturing group, or None if no group was matched at all. For example, the expressions \((a)b\), \(((a)(b))\), and \(((ab))\) will have `lastindex == 1` if applied to the string `'ab'`, while the expression \((a)(b)\) will have `lastindex == 2`, if applied to the same string.

**match.lastgroup**

The name of the last matched capturing group, or None if the group didn’t have a name, or if no group was matched at all.

**match.re**

The regular expression object whose `match()` or `search()` method produced this match instance.

**match.string**

The string passed to `match()` or `search()`.
6.2.5. Regular Expression Examples

6.2.5.1. Checking for a Pair

In this example, we'll use the following helper function to display match objects a little more gracefully:

```python
def displaymatch(match):
    if match is None:
        return None
    return '<Match: %r, groups=%r>' % (match.group(),)
```

Suppose you are writing a poker program where a player's hand is represented as a 5-character string with each character representing a card, “a” for ace, “k” for king, “q” for queen, “j” for jack, “t” for 10, and “2” through “9” representing the card with that value.

To see if a given string is a valid hand, one could do the following:

```python
>>> valid = re.compile(r'^[a2-9tjqk]{5}$')
>>> displaymatch(valid.match("akt5q"))  # Valid.
"<Match: 'akt5q', groups=()>
>>> displaymatch(valid.match("akt5e"))  # Invalid.
>>> displaymatch(valid.match("akt"))    # Invalid.
>>> displaymatch(valid.match("727ak"))  # Valid.
"<Match: '727ak', groups=()>
```

That last hand, "727ak", contained a pair, or two of the same valued cards. To match this with a regular expression, one could use backreferences as such:

```python
>>> pair = re.compile(r".*(.).*\1")
>>> displaymatch(pair.match("717ak"))  # Pair of
```
To find out what card the pair consists of, one could use the `group()` method of the match object in the following manner:

```python
>>> pair.match("717ak").group(1)
'7'
```

# Error because re.match() returns None, which doesn't have a group() method:

```python
>>> pair.match("718ak").group(1)
Traceback (most recent call last):
  File "<pyshell#23>", line 1, in <module>
    re.match(r"\.(.).*\1", "718ak").group(1)
AttributeError: 'NoneType' object has no attribute 'group'
```

```python
>>> pair.match("354aa").group(1)
'a'
```

6.2.5.2. Simulating `scanf()`

Python does not currently have an equivalent to `scanf()`. Regular expressions are generally more powerful, though also more verbose, than `scanf()` format strings. The table below offers some more-or-less equivalent mappings between `scanf()` format tokens and regular expressions.

<table>
<thead>
<tr>
<th><code>scanf()</code> Token</th>
<th>Regular Expression</th>
</tr>
</thead>
<tbody>
<tr>
<td>%c</td>
<td>.</td>
</tr>
<tr>
<td>%5c</td>
<td>.{5}</td>
</tr>
</tbody>
</table>
To extract the filename and numbers from a string like

```
/usr/sbin/sendmail - 0 errors, 4 warnings
```

you would use a `scanf()` format like

```
%s - %d errors, %d warnings
```

The equivalent regular expression would be

```
(\S+) - (\d+) errors, (\d+) warnings
```

### 6.2.5.3. search() vs. match()

Python offers two different primitive operations based on regular expressions: `re.match()` checks for a match only at the beginning of the string, while `re.search()` checks for a match anywhere in the string (this is what Perl does by default).

For example:
Regular expressions beginning with `^` can be used with `search()` to restrict the match at the beginning of the string:

```python
>>> re.match("c", "abcdef") # No match
>>> re.search("c", "abcdef") # Match
<_sre.SRE_Match object at ...>
```

Note however that in MULTILINE mode `match()` only matches at the beginning of the string, whereas using `search()` with a regular expression beginning with `^` will match at the beginning of each line.

```python
>>> re.match("X", "A\nB\nX", re.MULTILINE) # No match
>>> re.search("^X", "A\nB\nX", re.MULTILINE) # Match
<_sre.SRE_Match object at ...>
```

### 6.2.5.4. Making a Phonebook

`split()` splits a string into a list delimited by the passed pattern. The method is invaluable for converting textual data into data structures that can be easily read and modified by Python as demonstrated in the following example that creates a phonebook.

First, here is the input. Normally it may come from a file, here we are using triple-quoted string syntax:

```python
>>> text = """Ross McFluff: 834.345.1254 155 Elm Street""
```
The entries are separated by one or more newlines. Now we convert the string into a list with each nonempty line having its own entry:

```python
>>> entries = re.split("\n+", text)
`entries`
['Ross McFluff: 834.345.1254 155 Elm Street',
'Ronald Heathmore: 892.345.3428 436 Finley Avenue',
'Frank Burger: 925.541.7625 662 South Dogwood Way',
'Heather Albrecht: 548.326.4584 919 Park Place']
```

Finally, split each entry into a list with first name, last name, telephone number, and address. We use the maxsplit parameter of `split()` because the address has spaces, our splitting pattern, in it:

```python
>>> [re.split(":?:\s+", entry, 3) for entry in entries]
[['Ross', 'McFluff', '834.345.1254', '155 Elm Street'],
['Ronald', 'Heathmore', '892.345.3428', '436 Finley Avenue'],
['Frank', 'Burger', '925.541.7625', '662 South Dogwood Way'],
['Heather', 'Albrecht', '548.326.4584', '919 Park Place']
```

The `:?:` pattern matches the colon after the last name, so that it does not occur in the result list. With a `maxsplit` of 4, we could separate the house number from the street name:

```python
>>> [re.split(":?:\s+", entry, 4) for entry in entries]
[['Ross', 'McFluff', '834.345.1254', '155', 'Elm Street'],
['Ronald', 'Heathmore', '892.345.3428', '436', 'Finley Avenue'],
['Frank', 'Burger', '925.541.7625', '662', 'South Dogwood Way'],
['Heather', 'Albrecht', '548.326.4584', '919', 'Park Place']
```
6.2.5.5. Text Munging

`sub()` replaces every occurrence of a pattern with a string or the result of a function. This example demonstrates using `sub()` with a function to “munge” text, or randomize the order of all the characters in each word of a sentence except for the first and last characters:

```python
>>> def repl(m):
...     inner_word = list(m.group(2))
...     random.shuffle(inner_word)
...     return m.group(1) + ''.join(inner_word) + m.group(3)

>>> text = "Professor Abdolmalek, please report your absences promptly."

>>> re.sub(r"(\w)(\w+)(\w)", repl, text)
'Pofsroser Aoelambelk, plasee reoprt yuor asnbeces p'
```

6.2.5.6. Finding all Adverbs

`findall()` matches all occurrences of a pattern, not just the first one as `search()` does. For example, if one was a writer and wanted to find all of the adverbs in some text, he or she might use `findall()` in the following manner:

```python
>>> text = "He was carefully disguised but captured quickly by police."

>>> re.findall(r"\w+ly", text)
['carefully', 'quickly']
```
6.2.5.7. Finding all Adverbs and their Positions

If one wants more information about all matches of a pattern than the matched text, `finditer()` is useful as it provides *match objects* instead of strings. Continuing with the previous example, if one was a writer who wanted to find all of the adverbs *and their positions* in some text, he or she would use `finditer()` in the following manner:

```python
>>> text = "He was carefully disguised but captured quickly by police."
>>> for m in re.finditer(r"\w+ly", text):
...       print('%02d-%02d: %s' % (m.start(), m.end(), 07-16: carefully
40-47: quickly
```

6.2.5.8. Raw String Notation

Raw string notation (r"text") keeps regular expressions sane. Without it, every backslash (\') in a regular expression would have to be prefixed with another one to escape it. For example, the two following lines of code are functionally identical:

```python
>>> re.match(r"\W(.)\1\W", " ff ")
<_sre.SRE_Match object at ...>
>>> re.match("\W(.)\1\W", " ff ")
<_sre.SRE_Match object at ...>
```

When one wants to match a literal backslash, it must be escaped in the regular expression. With raw string notation, this means r"\". Without raw string notation, one must use "\\"", making the following lines of code functionally identical:
6.2.5.9. Writing a Tokenizer

A tokenizer or scanner analyzes a string to categorize groups of characters. This is a useful first step in writing a compiler or interpreter.

The text categories are specified with regular expressions. The technique is to combine those into a single master regular expression and to loop over successive matches:

```python
import collections
import re

Token = collections.namedtuple('Token', ['typ', 'value'])

def tokenize(s):
    keywords = {'IF', 'THEN', 'ENDIF', 'FOR', 'NEXT'}
    token_specification = [
        ('NUMBER', r'[\d.]+'), # Integer or decimal number
        ('ASSIGN', r':='), # Assignment operator
        ('END', r';'), # Statement terminator
        ('ID', r'[A-Za-z]+'), # Identifiers
        ('OP', r'[\+\-\*\/]+'), # Arithmetic operators
        ('NEWLINE', r'\n'), # Line endings
        ('SKIP', r'[ \t]+'), # Skip over spaces and tabs
    ]
    tok_regex = '|'.join('(?P<%s>%s)' % pair for pair in token_specification)
    get_token = re.compile(tok_regex).match
    line = 1
    pos = line_start = 0
    mo = get_token(s)
```
while mo is not None:
    typ = mo.lastgroup
    if typ == 'NEWLINE':
        line_start = pos
        line += 1
    elif typ != 'SKIP':
        val = mo.group(typ)
        if typ == 'ID' and val in keywords:
            typ = val
        yield Token(typ, val, line, mo.start()-line_start)
    pos = mo.end()
    mo = get_token(s, pos)
    if pos != len(s):
        raise RuntimeError('Unexpected character %r

statements = ''
    IF quantity THEN
        total := total + price * quantity;
        tax := price * 0.05;
    ENDIF;
    ''

for token in tokenize(statements):
    print(token)

The tokenizer produces the following output:

Token(typ='IF', value='IF', line=2, column=5)
Token(typ='ID', value='quantity', line=2, column=8)
Token(typ='THEN', value='THEN', line=2, column=17)
Token(typ='ID', value='total', line=3, column=9)
Token(typ='ASSIGN', value=':=', line=3, column=15)
Token(typ='ID', value='total', line=3, column=18)
Token(typ='OP', value='+', line=3, column=24)
Token(typ='ID', value='price', line=3, column=26)
Token(typ='OP', value='*', line=3, column=32)
Token(typ='ID', value='quantity', line=3, column=34)
Token(typ='END', value=';', line=3, column=42)
Token(typ='ID', value='tax', line=4, column=9)
Token(typ='ASSIGN', value=':', line=4, column=13)
Token(typ='ID', value='price', line=4, column=16)
Token(typ='OP', value='*', line=4, column=22)
Token(typ='NUMBER', value='0.05', line=4, column=24)
Token(typ='END', value=';', line=4, column=28)
Token(typ='ENDIF', value='ENDIF', line=5, column=5)
Token(typ='END', value=';', line=5, column=10)
6.3. **difflib** — Helpers for computing deltas

This module provides classes and functions for comparing sequences. It can be used for example, for comparing files, and can produce difference information in various formats, including HTML and context and unified diffs. For comparing directories and files, see also, the `filecmp` module.

**class difflib.SequenceMatcher**

This is a flexible class for comparing pairs of sequences of any type, so long as the sequence elements are *hashable*. The basic algorithm predates, and is a little fancier than, an algorithm published in the late 1980’s by Ratcliff and ObershLP under the hyperbolic name “gestalt pattern matching.” The idea is to find the longest contiguous matching subsequence that contains no “junk” elements (the Ratcliff and ObershLP algorithm doesn’t address junk). The same idea is then applied recursively to the pieces of the sequences to the left and to the right of the matching subsequence. This does not yield minimal edit sequences, but does tend to yield matches that “look right” to people.

**Timing:** The basic Ratcliff-ObershLP algorithm is cubic time in the worst case and quadratic time in the expected case. `SequenceMatcher` is quadratic time for the worst case and has expected-case behavior dependent in a complicated way on how many elements the sequences have in common; best case time is linear.

**Automatic junk heuristic:** `SequenceMatcher` supports a
heuristic that automatically treats certain sequence items as junk. The heuristic counts how many times each individual item appears in the sequence. If an item's duplicates (after the first one) account for more than 1% of the sequence and the sequence is at least 200 items long, this item is marked as “popular” and is treated as junk for the purpose of sequence matching. This heuristic can be turned off by setting the autojunk argument to False when creating the SequenceMatcher.

New in version 3.2: The autojunk parameter.

class difflib.Differ

This is a class for comparing sequences of lines of text, and producing human-readable differences or deltas. Differ uses SequenceMatcher both to compare sequences of lines, and to compare sequences of characters within similar (near-matching) lines.

Each line of a Differ delta begins with a two-letter code:

<table>
<thead>
<tr>
<th>Code</th>
<th>Meaning</th>
</tr>
</thead>
<tbody>
<tr>
<td><code>- </code></td>
<td>line unique to sequence 1</td>
</tr>
<tr>
<td><code>+ </code></td>
<td>line unique to sequence 2</td>
</tr>
<tr>
<td><code>- </code></td>
<td>line common to both sequences</td>
</tr>
<tr>
<td><code>? </code></td>
<td>line not present in either input sequence</td>
</tr>
</tbody>
</table>

Lines beginning with `?` attempt to guide the eye to intraline differences, and were not present in either input sequence. These lines can be confusing if the sequences contain tab characters.

class difflib.HtmlDiff
This class can be used to create an HTML table (or a complete HTML file containing the table) showing a side by side, line by line comparison of text with inter-line and intra-line change highlights. The table can be generated in either full or contextual difference mode.

The constructor for this class is:

```python
__init__(tabsize=8, wrapcolumn=None, linejunk=None, charjunk=IS_CHARACTER_JUNK)
```

Initializes instance of `HtmlDiff`.

- `tabsize` is an optional keyword argument to specify tab stop spacing and defaults to 8.
- `wrapcolumn` is an optional keyword to specify column number where lines are broken and wrapped, defaults to None where lines are not wrapped.
- `linejunk` and `charjunk` are optional keyword arguments passed into `ndiff()` (used by `HtmlDiff` to generate the side by side HTML differences). See `ndiff()` documentation for argument default values and descriptions.

The following methods are public:

```python
make_file(fromlines, tolines, fromdesc='', todesc='', context=False, numlines=5)
```

Compares `fromlines` and `tolines` (lists of strings) and returns a string which is a complete HTML file containing a table showing line by line differences with inter-line and intra-line changes highlighted.
fromdesc and todesc are optional keyword arguments to specify from/to file column header strings (both default to an empty string).

context and numlines are both optional keyword arguments. Set context to True when contextual differences are to be shown, else the default is False to show the full files. numlines defaults to 5. When context is True numlines controls the number of context lines which surround the difference highlights. When context is False numlines controls the number of lines which are shown before a difference highlight when using the “next” hyperlinks (setting to zero would cause the “next” hyperlinks to place the next difference highlight at the top of the browser without any leading context).

\[\text{make\_table}(\text{fromlines}, \text{tolines}, \text{fromdesc='', todesc='', context=False, numlines=5})\]

Compares fromlines and tolines (lists of strings) and returns a string which is a complete HTML table showing line by line differences with inter-line and intra-line changes highlighted.

The arguments for this method are the same as those for the make_file() method.

Tools/scripts/diff.py is a command-line front-end to this class and contains a good example of its use.

\[\text{difflib.context\_diff(a, b, fromfile='', tofile='', fromfiledate='', tofiledate='', n=3, lineterm='\ln')}\]

Compare a and b (lists of strings); return a delta (a generator generating the delta lines) in context diff format.

Context diffs are a compact way of showing just the lines that have
changed plus a few lines of context. The changes are shown in a before/after style. The number of context lines is set by $n$ which defaults to three.

By default, the diff control lines (those with *** or ---) are created with a trailing newline. This is helpful so that inputs created from `io.IOBase.readlines()` result in diffs that are suitable for use with `io.IOBase.writelines()` since both the inputs and outputs have trailing newlines.

For inputs that do not have trailing newlines, set the `lineterm` argument to "" so that the output will be uniformly newline free.

The context diff format normally has a header for filenames and modification times. Any or all of these may be specified using strings for `fromfile`, `tofile`, `fromfiledate`, and `todatedate`. The modification times are normally expressed in the ISO 8601 format. If not specified, the strings default to blanks.

```python
>>> s1 = ['bacon
', 'eggs
', 'ham
', 'guido
'
>>> s2 = ['python
', 'eggy
', 'hamster
', 'guido

>> for line in context_diff(s1, s2, fromfile='be...
    sys.stdout.write(line)
***  before.py
---  after.py
***************
***  1,4  ****
!  bacon
!  eggs
!  ham
  guided
---  1,4  ----
!  python
!  eggy
!  hamster
```
See *A command-line interface to difflib* for a more detailed example.

`difflib.get_close_matches(word, possibilities, n=3, cutoff=0.6)`

Return a list of the best “good enough” matches. *word* is a sequence for which close matches are desired (typically a string), and *possibilities* is a list of sequences against which to match *word* (typically a list of strings).

Optional argument *n* (default 3) is the maximum number of close matches to return; *n* must be greater than 0.

Optional argument *cutoff* (default 0.6) is a float in the range [0, 1]. Possibilities that don’t score at least that similar to *word* are ignored.

The best (no more than *n*) matches among the possibilities are returned in a list, sorted by similarity score, most similar first.

```python
>>> get_close_matches('appel', ['ape', 'apple', 'apple', 'ape'])
['apple', 'ape']
>>> import keyword
>>> get_close_matches('wheel', keyword.kwlist)  
['while']
>>> get_close_matches('apple', keyword.kwlist)  
[]
>>> get_close_matches('accept', keyword.kwlist)  
['except']
```

difflib.**ndiff**(a, b, linejunk=None,
Compare \( a \) and \( b \) (lists of strings); return a Differ-style delta (a generator generating the delta lines).

Optional keyword parameters linejunk and charjunk are for filter functions (or None):

linejunk: A function that accepts a single string argument, and returns true if the string is junk, or false if not. The default is None. There is also a module-level function IS_LINE_JUNK(), which filters out lines without visible characters, except for at most one pound character ("#") – however the underlying SequenceMatcher class does a dynamic analysis of which lines are so frequent as to constitute noise, and this usually works better than using this function.

charjunk: A function that accepts a character (a string of length 1), and returns if the character is junk, or false if not. The default is module-level function IS_CHARACTER_JUNK(), which filters out whitespace characters (a blank or tab; note: bad idea to include newline in this!).

Tools/scripts/ndiff.py is a command-line front-end to this function.

```python
>>> diff = ndiff('one\ntwo\nthree
'.splitlines(1)
... 'ore\ntree\nemu
'.splitlines(1))
>>> print(''.join(diff), end="")
- one
  ^
+ ore
  ^
- two
- three
```
difflib.\texttt{restore}(\texttt{sequence}, \texttt{which})

Return one of the two sequences that generated a delta.

Given a \texttt{sequence} produced by \texttt{Differ.compare()} or \texttt{ndiff()}, extract lines originating from file 1 or 2 (parameter \texttt{which}), stripping off line prefixes.

Example:

```python
>>> diff = ndiff('one\ntwo\nthree\n'.splitlines(1)
...                   'ore\ntree\nemu\n'.splitlines(1))
>>> diff = list(diff) # materialize the generated delta
>>> print(''.join(restore(diff, 1)), end='')
one
two
three
>>> print(''.join(restore(diff, 2)), end='')
ore
tree
emu
```

difflib.\texttt{unified\_diff}(a, b, fromfile='', tofile='', fromfiledate='', tofiledate='', n=3, lineterm=\texttt{'\n'})

Compare \(a\) and \(b\) (lists of strings); return a delta (a \texttt{generator} generating the delta lines) in unified diff format.

Unified diffs are a compact way of showing just the lines that have changed plus a few lines of context. The changes are shown in an inline style (instead of separate before/after blocks). The number of
context lines is set by \( n \) which defaults to three.

By default, the diff control lines (those with \(--\), \(+++\), or \(@@\)) are created with a trailing newline. This is helpful so that inputs created from `io.IOBase.readlines()` result in diffs that are suitable for use with `io.IOBase.writelines()` since both the inputs and outputs have trailing newlines.

For inputs that do not have trailing newlines, set the `lineterm` argument to "" so that the output will be uniformly newline free.

The context diff format normally has a header for filenames and modification times. Any or all of these may be specified using strings for `fromfile`, `tofile`, `fromfiledate`, and `tofiledate`. The modification times are normally expressed in the ISO 8601 format. If not specified, the strings default to blanks.

```python
>>> s1 = ['bacon
', 'eggs
', 'ham
', 'guido
']
>>> s2 = ['python
', 'eggy
', 'hamster
', 'guido
']
>>> for line in unified_diff(s1, s2, fromfile='before.py'):
...     sys.stdout.write(line)
--- before.py
+++ after.py
@@ -1,4 +1,4 @@
-bacon
-eggs
-ham
+python
+eggy
+hamster
-guido
```

See *A command-line interface to difflib* for a more detailed example.
difflib.IS_LINE_JUNK(line)

Return true for ignorable lines. The line line is ignorable if line is blank or contains a single '#', otherwise it is not ignorable. Used as a default for parameter linejunk in ndiff() in older versions.

difflib.IS_CHARACTER_JUNK(ch)

Return true for ignorable characters. The character ch is ignorable if ch is a space or tab, otherwise it is not ignorable. Used as a default for parameter charjunk in ndiff().

Pattern Matching: The Gestalt Approach
Discussion of a similar algorithm by John W. Ratcliff and D. E. Metzener. This was published in Dr. Dobb's Journal in July, 1988.
6.3.1. SequenceMatcher Objects

The `SequenceMatcher` class has this constructor:

```python
class difflib.SequenceMatcher(isjunk=None, a='', b='', autojunk=True)
```

Optional argument `isjunk` must be `None` (the default) or a one-argument function that takes a sequence element and returns true if and only if the element is “junk” and should be ignored. Passing `None` for `isjunk` is equivalent to passing `lambda x: 0`; in other words, no elements are ignored. For example, pass:

```python
lambda x: x in "\t"
```

if you’re comparing lines as sequences of characters, and don’t want to synch up on blanks or hard tabs.

The optional arguments `a` and `b` are sequences to be compared; both default to empty strings. The elements of both sequences must be `hashable`.

The optional argument `autojunk` can be used to disable the automatic junk heuristic.

*New in version 3.2:* The `autojunk` parameter.

SequenceMatcher objects get three data attributes: `bjunk` is the set of elements of `b` for which `isjunk` is True; `bpopular` is the set of non-junk elements considered popular by the heuristic (if it is not disabled); `b2j` is a dict mapping the remaining elements of `b` to a list of positions where they occur. All three are reset whenever `b` is reset with `set_seqs()` or `set_seq2()`.
New in version 3.2: The \texttt{bjunk} and \texttt{bpopular} attributes.

\texttt{SequenceMatcher} objects have the following methods:

\texttt{set_seqs}(a, b)

Set the two sequences to be compared.

\texttt{SequenceMatcher} computes and caches detailed information about the second sequence, so if you want to compare one sequence against many sequences, use \texttt{set_seq2()} to set the commonly used sequence once and call \texttt{set_seq1()} repeatedly, once for each of the other sequences.

\texttt{set_seq1}(a)

Set the first sequence to be compared. The second sequence to be compared is not changed.

\texttt{set_seq2}(b)

Set the second sequence to be compared. The first sequence to be compared is not changed.

\texttt{find_longest_match}(alo, ahi, blo, bhi)

Find longest matching block in \texttt{a[alo:ahi]} and \texttt{b[blo:bhi]}.

If \texttt{isjunk} was omitted or \texttt{None}, \texttt{find_longest_match()} returns \((i, j, k)\) such that \texttt{a[i:i+k]} is equal to \texttt{b[j:j+k]}, where \texttt{alo} \(\leq i \leq i+k \leq ahi\) and \texttt{blo} \(\leq j \leq j+k \leq bhi\). For all \((i', j', k')\) meeting those conditions, the additional conditions \(k \geq k', i \leq i',\) and if \(i = i', j \leq j'\) are also met. In other words, of all maximal matching blocks, return one that starts earliest in \texttt{a},
and of all those maximal matching blocks that start earliest in \(a\), return the one that starts earliest in \(b\).

```python
>>> s = SequenceMatcher(None, "abcd", "abcd abc``
```d
>>> s.find_longest_match(0, 5, 0, 9)
Match(a=0, b=4, size=5)
```

If \(isjunk\) was provided, first the longest matching block is determined as above, but with the additional restriction that no junk element appears in the block. Then that block is extended as far as possible by matching (only) junk elements on both sides. So the resulting block never matches on junk except as identical junk happens to be adjacent to an interesting match.

Here's the same example as before, but considering blanks to be junk. That prevents 'abcd' from matching the 'abcd' at the tail end of the second sequence directly. Instead only the 'abcd' can match, and matches the leftmost 'abcd' in the second sequence:

```python
>>> s = SequenceMatcher(lambda x: x==" ", "abcd``
```d
>>> s.find_longest_match(0, 5, 0, 9)
Match(a=1, b=0, size=4)
```

If no blocks match, this returns (alo, blo, \(0\)).

This method returns a named tuple \(Match(a, b, size)\).

**get_matching_blocks()**

Return list of triples describing matching subsequences. Each triple is of the form \((i, j, n)\), and means that \(a[i:i+n] == b[j:j+n]\). The triples are monotonically increasing in \(i\)
and j.

The last triple is a dummy, and has the value (len(a), len(b), 0). It is the only triple with n == 0. If (i, j, n) and (i', j', n') are adjacent triples in the list, and the second is not the last triple in the list, then i+n != i' or j+n != j'; in other words, adjacent triples always describe non-adjacent equal blocks.

```python
>>> s = SequenceMatcher(None, "abxcd", "abcd")
>>> s.get_matching_blocks()
[Match(a=0, b=0, size=2), Match(a=3, b=2, size=2), Match(a=5, b=4, size=0)]
```

### get_opcodes()

Return list of 5-tuples describing how to turn a into b. Each tuple is of the form (tag, i1, i2, j1, j2). The first tuple has i1 == j1 == 0, and remaining tuples have i1 equal to the i2 from the preceding tuple, and, likewise, j1 equal to the previous j2.

The tag values are strings, with these meanings:

<table>
<thead>
<tr>
<th>Value</th>
<th>Meaning</th>
</tr>
</thead>
<tbody>
<tr>
<td>'replace'</td>
<td>a[i1:i2] should be replaced by b[j1:j2].</td>
</tr>
<tr>
<td>'delete'</td>
<td>a[i1:i2] should be deleted. Note that j1 == j2 in this case.</td>
</tr>
<tr>
<td>'insert'</td>
<td>b[j1:j2] should be inserted at a[i1:i1]. Note that i1 == i2 in this case.</td>
</tr>
<tr>
<td>'equal'</td>
<td>a[i1:i2] == b[j1:j2] (the sub-sequences are equal).</td>
</tr>
</tbody>
</table>
For example:

```python
>>> a = "qabxcd"
>>> b = "abycdf"
>>> s = SequenceMatcher(None, a, b)
>>> for tag, i1, i2, j1, j2 in s.get_opcodes():
    print('{:7}  a[{}:{}]	-->	b[{}:{}]	{!r:>8}	-->	{!r}'.format(
        tag, i1, i2, j1, j2, a[i1:i2], b[j1:j2]))
```

**get_grouped_opcodes**(n=3)

Return a *generator* of groups with up to *n* lines of context.

Starting with the groups returned by `get_opcodes()` , this method splits out smaller change clusters and eliminates intervening ranges which have no changes.

The groups are returned in the same format as `get_opcodes()` .

**ratio()**

Return a measure of the sequences' similarity as a float in the range [0, 1].

Where T is the total number of elements in both sequences, and M is the number of matches, this is 2.0*M / T. Note that this is **1.0** if the sequences are identical, and **0.0** if they have nothing in common.

This is expensive to compute if `get_matching_blocks()` or
get_opcodes() hasn’t already been called, in which case you may want to try quick_ratio() or real_quick_ratio() first to get an upper bound.

**quick_ratio()**
Return an upper bound on ratio() relatively quickly.

**real_quick_ratio()**
Return an upper bound on ratio() very quickly.

The three methods that return the ratio of matching to total characters can give different results due to differing levels of approximation, although quick_ratio() and real_quick_ratio() are always at least as large as ratio():

```python
>>> s = SequenceMatcher(None, "abcd", "bcde")
>>> s.ratio()
0.75
>>> s.quick_ratio()
0.75
>>> s.real_quick_ratio()
1.0
```
6.3.2. SequenceMatcher Examples

This example compares two strings, considering blanks to be “junk”:

```python
>>> s = SequenceMatcher(lambda x: x == " ",
                        "private Thread currentThread;
                        "private volatile Thread cur
```  

ratio() returns a float in [0, 1], measuring the similarity of the sequences. As a rule of thumb, a ratio() value over 0.6 means the sequences are close matches:

```python
>>> print(round(s.ratio(), 3))
0.866
```

If you’re only interested in where the sequences match, get_matching_blocks() is handy:

```python
>>> for block in s.get_matching_blocks():
...     print("a[%d] and b[%d] match for %d elements
...     a[0] and b[0] match for 8 elements
...     a[8] and b[17] match for 21 elements
...     a[29] and b[38] match for 0 elements
```  

Note that the last tuple returned by get_matching_blocks() is always a dummy, (len(a), len(b), 0), and this is the only case in which the last tuple element (number of elements matched) is 0.

If you want to know how to change the first sequence into the second, use get_opcodes():

```python
>>> for opcode in s.get_opcodes():
```

```python
...    print("%6s a[%d:%d] b[%d:%d]" % opcode)
    equal a[0:8] b[0:8]
    insert a[8:8] b[8:17]
    equal a[8:29] b[17:38]
```

**See also:**

- The `get_close_matches()` function in this module which shows how simple code building on `SequenceMatcher` can be used to do useful work.
- Simple version control recipe for a small application built with `SequenceMatcher`. 

6.3.3. Differ Objects

Note that Differ-generated deltas make no claim to be minimal diffs. To the contrary, minimal diffs are often counter-intuitive, because they synch up anywhere possible, sometimes accidental matches 100 pages apart. Restricting synch points to contiguous matches preserves some notion of locality, at the occasional cost of producing a longer diff.

The Differ class has this constructor:

```python
class difflib.Differ(linejunk=None, charjunk=None)

Optional keyword parameters linejunk and charjunk are for filter functions (or None):

linejunk: A function that accepts a single string argument, and returns true if the string is junk. The default is None, meaning that no line is considered junk.

charjunk: A function that accepts a single character argument (a string of length 1), and returns true if the character is junk. The default is None, meaning that no character is considered junk.

Differ objects are used (deltas generated) via a single method:

```python
compare(a, b)
```

Compare two sequences of lines, and generate the delta (a sequence of lines).

Each sequence must contain individual single-line strings ending with newlines. Such sequences can be obtained from the `readlines()` method of file-like objects. The delta
generated also consists of newline-terminated strings, ready to be printed as-is via the `writelines()` method of a file-like object.
6.3.4. Differ Example

This example compares two texts. First we set up the texts, sequences of individual single-line strings ending with newlines (such sequences can also be obtained from the `readlines()` method of file-like objects):

```python
>>> text1 = '''
1. Beautiful is better than ugly.
...
2. Explicit is better than implicit.
...
3. Simple is better than complex.
...
4. Complex is better than complicated.
... '''.splitlines(1)
>>> len(text1)
4
>>> text1[0][-1]
'\n'
>>> text2 = '''
1. Beautiful is better than ugly.
...
3. Simple is better than complex.
...
4. Complicated is better than complex.
...
5. Flat is better than nested.
... '''.splitlines(1)

Next we instantiate a Differ object:

```python
>>> d = Differ()
```

Note that when instantiating a `Differ` object we may pass functions to filter out line and character “junk.” See the `Differ()` constructor for details.

Finally, we compare the two:

```python
>>> result = list(d.compare(text1, text2))
```
result is a list of strings, so let's pretty-print it:

```python
>>> from pprint import pprint
>>> pprint(result)
['  1. Beautiful is better than ugly.
' - 2. Explicit is better than implicit.
' - 3. Simple is better than complex.
' + 3. Simple is better than complex.
' ? ++
' - 4. Complex is better than complicated.
' ? ^ ---- ^
' + 4. Complicated is better than complex.
' ? ++++ ^
' + 5. Flat is better than nested.
]
```

As a single multi-line string it looks like this:

```python
>>> import sys
>>> sys.stdout.writelines(result)
  1. Beautiful is better than ugly.
- 2. Explicit is better than implicit.
- 3. Simple is better than complex.
+ 3. Simple is better than complex.
? ++
- 4. Complex is better than complicated.
? ^ ---- ^
+ 4. Complicated is better than complex.
? ++++ ^
+ 5. Flat is better than nested.
```
6.3.5. A command-line interface to difflib

This example shows how to use difflib to create a diff-like utility. It is also contained in the Python source distribution, as Tools/scripts/diff.py.

"""
Command line interface to difflib.py providing diffs in four formats:
* ndiff: lists every line and highlights interline changes.
* context: highlights clusters of changes in a before/after format.
* unified: highlights clusters of changes in an inline format.
* html: generates side by side comparison with change highlights.
"""

```python
import sys, os, time, difflib, optparse

def main():
    # Configure the option parser
    usage = "usage: %prog [options] fromfile tofile"
    parser = optparse.OptionParser(usage)
    parser.add_option("-c", action="store_true", default=False, help='Produce a context format diff (default)
    parser.add_option("-u", action="store_true", default=False, help='Produce a unified format diff
    parser.add_option("-m", action="store_true", default=False, help='Produce HTML side by side diff (can use -c)
    parser.add_option("-n", action="store_true", default=False, help='Produce a ndiff format diff
    parser.add_option("-l", "--lines", type="int", default=3, help='Set number of context lines (default 3)

    (options, args) = parser.parse_args()

    if len(args) == 0:
        parser.print_help()
```

sys.exit(1)
if len(args) != 2:
    parser.error("need to specify both a fromfile and a tofile")

n = options.lines
fromfile, tofile = args # as specified in the usage string

# we're passing these as arguments to the diff function
fromdate = time.ctime(os.stat(fromfile).st_mtime)
todate = time.ctime(os.stat(tofile).st_mtime)
with open(fromfile) as fromf, open(tofile) as tof:
    fromlines, tolines = list(fromf), list(tof)

if options.u:
    diff = difflib.unified_diff(fromlines, tolines, fromdate, todate)
elif options.n:
    diff = difflib.ndiff(fromlines, tolines)
elif options.m:
    diff = difflib.HtmlDiff().make_file(fromlines, tolines, numlines)
else:
    diff = difflib.context_diff(fromlines, tolines, fromdate, todate)

# we're using writelines because diff is a generator
sys.stdout.writelines(diff)

if __name__ == '__main__':
    main()

Last updated on Nov 11, 2013. Found a bug?

Created using Sphinx 1.0.7.
6.4. `textwrap` — Text wrapping and filling

Source code: Lib/textwrap.py

The `textwrap` module provides two convenience functions, `wrap()` and `fill()`, as well as `TextWrapper`, the class that does all the work, and two utility functions, `dedent()` and `indent()`. If you’re just wrapping or filling one or two text strings, the convenience functions should be good enough; otherwise, you should use an instance of `TextWrapper` for efficiency.

`textwrap.wrap(text, width=70, **kwargs)`

Wraps the single paragraph in `text` (a string) so every line is at most `width` characters long. Returns a list of output lines, without final newlines.

Optional keyword arguments correspond to the instance attributes of `TextWrapper`, documented below. `width` defaults to 70.

See the `TextWrapper.wrap()` method for additional details on how `wrap()` behaves.

`textwrap.fill(text, width=70, **kwargs)`

Wraps the single paragraph in `text`, and returns a single string containing the wrapped paragraph. `fill()` is shorthand for

```
"\n".join(wrap(text, ...))
```

In particular, `fill()` accepts exactly the same keyword
arguments as \texttt{\texttt{wrap}}().

Both \texttt{\texttt{wrap}}() and \texttt{\texttt{fill}}() work by creating a \texttt{TextWrapper} instance and calling a single method on it. That instance is not reused, so for applications that \texttt{\texttt{wrap/fill}} many text strings, it will be more efficient for you to create your own \texttt{TextWrapper} object.

Text is preferably wrapped on whitespaces and right after the hyphens in hyphenated words; only then will long words be broken if necessary, unless \texttt{TextWrapper\texttt{.break_long_words}} is set to false.

Two additional utility function, \texttt{\texttt{dedent}}() and \texttt{\texttt{indent}}(), are provided to remove indentation from strings that have unwanted whitespace to the left of the text and to add an arbitrary prefix to selected lines in a block of text.

\texttt{\texttt{textwrap.dedent}}(\textit{text})

Remove any common leading whitespace from every line in \textit{text}.

This can be used to make triple-quoted strings line up with the left edge of the display, while still presenting them in the source code in indented form.

Note that tabs and spaces are both treated as whitespace, but they are not equal: the lines "\texttt{\texttt{hello}}" and "\texttt{\texttt{\thello}}" are considered to have no common leading whitespace.

For example:

\begin{verbatim}
def test():
    # end first line with \ to avoid the empty li
s = ''\\
    hello
        world
\end{verbatim}
textwrap.\texttt{indent}(\texttt{text, prefix, predicate=None})

Add \texttt{prefix} to the beginning of selected lines in \texttt{text}.

Lines are separated by calling \texttt{text.splitlines(True)}.

By default, \texttt{prefix} is added to all lines that do not consist solely of whitespace (including any line endings).

For example:

```python
>>> s = 'hello

world'
```

```python
>>> indent(s, '  ')  
' hello

 world'
```

The optional \texttt{predicate} argument can be used to control which lines are indented. For example, it is easy to add \texttt{prefix} to even empty and whitespace-only lines:

```python
>>> print(indent(s, '+ ', \texttt{lambda line: True}))
+ hello
+
+
+ world
```

\texttt{class textwrap.TextWrapper(**kwargs)}

The \texttt{TextWrapper} constructor accepts a number of optional keyword arguments. Each keyword argument corresponds to an instance attribute, so for example

```python
wrapper = TextWrapper(initial_indent='* ')
```
is the same as

```python
wrapper = TextWrapper()
wrapper.initial_indent = "* "
```

You can re-use the same `TextWrapper` object many times, and you can change any of its options through direct assignment to instance attributes between uses.

The `TextWrapper` instance attributes (and keyword arguments to the constructor) are as follows:

**width**

(default: 70) The maximum length of wrapped lines. As long as there are no individual words in the input text longer than `width`, `TextWrapper` guarantees that no output line will be longer than `width` characters.

**expand_tabs**

(default: True) If true, then all tab characters in `text` will be expanded to spaces using the `expandtabs()` method of `text`.

**tabsize**

(default: 8) If `expand_tabs` is true, then all tab characters in `text` will be expanded to zero or more spaces, depending on the current column and the given tab size.

*New in version 3.3.*

**replace_whitespace**

(default: True) If true, after tab expansion but before wrapping, the `wrap()` method will replace each whitespace character
with a single space. The whitespace characters replaced are as follows: tab, newline, vertical tab, formfeed, and carriage return (\t\n\v\f\r).

**Note:** If `expand_tabs` is false and `replace_whitespace` is true, each tab character will be replaced by a single space, which is *not* the same as tab expansion.

**Note:** If `replace_whitespace` is false, newlines may appear in the middle of a line and cause strange output. For this reason, text should be split into paragraphs (using `str.splitlines()` or similar) which are wrapped separately.

**drop_whitespace**
(default: True) If true, whitespace at the beginning and ending of every line (after wrapping but before indenting) is dropped. Whitespace at the beginning of the paragraph, however, is not dropped if non-whitespace follows it. If whitespace being dropped takes up an entire line, the whole line is dropped.

**initial_indent**
(default: '') String that will be prepended to the first line of wrapped output. Counts towards the length of the first line. The empty string is not indented.

**subsequent_indent**
(default: '') String that will be prepended to all lines of wrapped output except the first. Counts towards the length of each line except the first.

**fix_sentence_endings**
(default: False) If true, TextWrapper attempts to detect sentence endings and ensure that sentences are always separated by exactly two spaces. This is generally desired for text in a monospaced font. However, the sentence detection algorithm is imperfect: it assumes that a sentence ending consists of a lowercase letter followed by one of '.','!','?', possibly followed by one of '"' or '"', followed by a space. One problem with this is algorithm is that it is unable to detect the difference between “Dr.” in

```
[... ] Dr. Frankenstein's monster [... ]
```

and “Spot.” in

```
[... ] See Spot. See Spot run [... ]
```

fix_sentence_endings is false by default.

Since the sentence detection algorithm relies on string.lowercase for the definition of “lowercase letter,” and a convention of using two spaces after a period to separate sentences on the same line, it is specific to English-language texts.

**break_long_words**

(default: True) If true, then words longer than width will be broken in order to ensure that no lines are longer than width. If it is false, long words will not be broken, and some lines may be longer than width. (Long words will be put on a line by themselves, in order to minimize the amount by which width is exceeded.)
break_on_hyphens

(default: True) If true, wrapping will occur preferably on whitespaces and right after hyphens in compound words, as it is customary in English. If false, only whitespaces will be considered as potentially good places for line breaks, but you need to set break_long_words to false if you want truly inseparable words. Default behaviour in previous versions was to always allow breaking hyphenated words.

TextWrapper also provides two public methods, analogous to the module-level convenience functions:

wrap(text)
Wraps the single paragraph in text (a string) so every line is at most width characters long. All wrapping options are taken from instance attributes of the TextWrapper instance. Returns a list of output lines, without final newlines. If the wrapped output has no content, the returned list is empty.

fill(text)
Wraps the single paragraph in text, and returns a single string containing the wrapped paragraph.
6.5. `unicodedata` — Unicode Database

This module provides access to the Unicode Character Database (UCD) which defines character properties for all Unicode characters. The data contained in this database is compiled from the UCD version 6.1.0.

The module uses the same names and symbols as defined by Unicode Standard Annex #44, “Unicode Character Database”. It defines the following functions:

`unicodedata.lookup(name)`
Look up character by name. If a character with the given name is found, return the corresponding character. If not found, `KeyError` is raised.

*Changed in version 3.3:* Support for name aliases [1] and named sequences [2] has been added.

`unicodedata.name(chr[, default])`
Returns the name assigned to the character `chr` as a string. If no name is defined, `default` is returned, or, if not given, `ValueError` is raised.

`unicodedata.decimal(chr[, default])`
Returns the decimal value assigned to the character `chr` as integer. If no such value is defined, `default` is returned, or, if not given, `ValueError` is raised.
unicodedata.digit(chr[, default])
Returns the digit value assigned to the character chr as integer. If no such value is defined, default is returned, or, if not given, ValueError is raised.

unicodedata.numeric(chr[, default])
Returns the numeric value assigned to the character chr as float. If no such value is defined, default is returned, or, if not given, ValueError is raised.

unicodedata.category(chr)
Returns the general category assigned to the character chr as string.

unicodedata.bidirectional(chr)
Returns the bidirectional class assigned to the character chr as string. If no such value is defined, an empty string is returned.

unicodedata.combining(chr)
Returns the canonical combining class assigned to the character chr as integer. Returns 0 if no combining class is defined.

unicodedata.east_asian_width(chr)
Returns the east asian width assigned to the character chr as string.

unicodedata.mirrored(chr)
Returns the mirrored property assigned to the character chr as integer. Returns 1 if the character has been identified as a "mirrored" character in bidirectional text, 0 otherwise.

unicodedata.decomposition(chr)
Returns the character decomposition mapping assigned to the character `chr` as string. An empty string is returned in case no such mapping is defined.

```python
unicodedata.normalize(form, unistr)
```

Return the normal form `form` for the Unicode string `unistr`. Valid values for `form` are ‘NFC’, ‘NFKC’, ‘NFD’, and ‘NFKD’.

The Unicode standard defines various normalization forms of a Unicode string, based on the definition of canonical equivalence and compatibility equivalence. In Unicode, several characters can be expressed in various way. For example, the character U+00C7 (LATIN CAPITAL LETTER C WITH CEDILLA) can also be expressed as the sequence U+0043 (LATIN CAPITAL LETTER C) U+0327 (COMBINING CEDILLA).

For each character, there are two normal forms: normal form C and normal form D. Normal form D (NFD) is also known as canonical decomposition, and translates each character into its decomposed form. Normal form C (NFC) first applies a canonical decomposition, then composes pre-combined characters again.

In addition to these two forms, there are two additional normal forms based on compatibility equivalence. In Unicode, certain characters are supported which normally would be unified with other characters. For example, U+2160 (ROMAN NUMERAL ONE) is really the same thing as U+0049 (LATIN CAPITAL LETTER I). However, it is supported in Unicode for compatibility with existing character sets (e.g. gb2312).

The normal form KD (NFKD) will apply the compatibility decomposition, i.e. replace all compatibility characters with their equivalents. The normal form KC (NFKC) first applies the
compatibility decomposition, followed by the canonical composition.

Even if two unicode strings are normalized and look the same to a human reader, if one has combining characters and the other doesn't, they may not compare equal.

In addition, the module exposes the following constant:

unicodedata.**unidata_version**

The version of the Unicode database used in this module.

unicodedata.**ucd_3_2_0**

This is an object that has the same methods as the entire module, but uses the Unicode database version 3.2 instead, for applications that require this specific version of the Unicode database (such as IDNA).

Examples:

```python
>>> import unicodedata
>>> unicodedata.lookup('LEFT CURLY BRACKET')
'{
>>> unicodedata.name('/')
'SOLIDUS'
>>> unicodedata.decimal('9')
9
>>> unicodedata.decimal('a')
Traceback (most recent call last):
  File "<stdin>", line 1, in ?
ValueError: not a decimal
>>> unicodedata.category('A')  # 'L'etter, 'u'ppercase
'Lu'
>>> unicodedata.bidirectional('٠')  # 'A'rabic, 'AN'
```

6.6. **stringprep** — Internet String Preparation

When identifying things (such as host names) in the internet, it is often necessary to compare such identifications for “equality”. Exactly how this comparison is executed may depend on the application domain, e.g. whether it should be case-insensitive or not. It may be also necessary to restrict the possible identifications, to allow only identifications consisting of “printable” characters.

**RFC 3454** defines a procedure for “preparing” Unicode strings in internet protocols. Before passing strings onto the wire, they are processed with the preparation procedure, after which they have a certain normalized form. The RFC defines a set of tables, which can be combined into profiles. Each profile must define which tables it uses, and what other optional parts of the **stringprep** procedure are part of the profile. One example of a **stringprep** profile is **nameprep**, which is used for internationalized domain names.

The module **stringprep** only exposes the tables from RFC 3454. As these tables would be very large to represent them as dictionaries or lists, the module uses the Unicode character database internally. The module source code itself was generated using the **mkstringprep.py** utility.

As a result, these tables are exposed as functions, not as data structures. There are two kinds of tables in the RFC: sets and mappings. For a set, **stringprep** provides the “characteristic function”, i.e. a function that returns true if the parameter is part of the set. For mappings, it provides the mapping function: given the key, it
returns the associated value. Below is a list of all functions available in the module.

**stringprep.in_table_a1(code)**
- Determine whether *code* is in tableA.1 (Unassigned code points in Unicode 3.2).

**stringprep.in_table_b1(code)**
- Determine whether *code* is in tableB.1 (Commonly mapped to nothing).

**stringprep.map_table_b2(code)**
- Return the mapped value for *code* according to tableB.2 (Mapping for case-folding used with NFKC).

**stringprep.map_table_b3(code)**
- Return the mapped value for *code* according to tableB.3 (Mapping for case-folding used with no normalization).

**stringprep.in_table_c11(code)**
- Determine whether *code* is in tableC.1.1 (ASCII space characters).

**stringprep.in_table_c12(code)**
- Determine whether *code* is in tableC.1.2 (Non-ASCII space characters).

**stringprep.in_table_c11_c12(code)**
- Determine whether *code* is in tableC.1 (Space characters, union of C.1.1 and C.1.2).

**stringprep.in_table_c21(code)**
- Determine whether *code* is in tableC.2.1 (ASCII control characters).
stringprep.in_table_c22(code)
Determine whether code is in tableC.2.2 (Non-ASCII control characters).

stringprep.in_table_c21_c22(code)
Determine whether code is in tableC.2 (Control characters, union of C.2.1 and C.2.2).

stringprep.in_table_c3(code)
Determine whether code is in tableC.3 (Private use).

stringprep.in_table_c4(code)
Determine whether code is in tableC.4 (Non-character code points).

stringprep.in_table_c5(code)
Determine whether code is in tableC.5 (Surrogate codes).

stringprep.in_table_c6(code)
Determine whether code is in tableC.6 (Inappropriate for plain text).

stringprep.in_table_c7(code)
Determine whether code is in tableC.7 (Inappropriate for canonical representation).

stringprep.in_table_c8(code)
Determine whether code is in tableC.8 (Change display properties or are deprecated).

stringprep.in_table_c9(code)
Determine whether code is in tableC.9 (Tagging characters).

stringprep.in_table_d1(code)
Determine whether `code` is in tableD.1 (Characters with bidirectional property “R” or “AL”).

```python
stringprep.in_table_d2(code)
```

Determine whether `code` is in tableD.2 (Characters with bidirectional property “L”).
6.7. **readline** — GNU readline interface

*Platforms:* Unix

The **readline** module defines a number of functions to facilitate completion and reading/writing of history files from the Python interpreter. This module can be used directly or via the **rlcompleter** module. Settings made using this module affect the behaviour of both the interpreter’s interactive prompt and the prompts offered by the built-in `input()` function.

**Note:** On MacOS X the **readline** module can be implemented using the **libedit** library instead of GNU readline.

The configuration file for **libedit** is different from that of GNU readline. If you programmatically load configuration strings you can check for the text “libedit” in **readline.**`.doc` to differentiate between GNU readline and libedit.

The **readline** module defines the following functions:

- **readline.**`parse_and_bind`(string)
  
  Parse and execute single line of a readline init file.

- **readline.**`get_line_buffer`()
  
  Return the current contents of the line buffer.

- **readline.**`insert_text`(string)
  
  Insert text into the command line.
readline. **read_init_file**([filename])

Parse a readline initialization file. The default filename is the last filename used.

readline. **read_history_file**([filename])

Load a readline history file. The default filename is ~/.history.

readline. **write_history_file**([filename])

Save a readline history file. The default filename is ~/.history.

readline. **clear_history**()

Clear the current history. (Note: this function is not available if the installed version of GNU readline doesn’t support it.)

readline. **get_history_length**()

Return the desired length of the history file. Negative values imply unlimited history file size.

readline. **set_history_length**(length)

Set the number of lines to save in the history file. write_history_file() uses this value to truncate the history file when saving. Negative values imply unlimited history file size.

readline. **get_current_history_length**()

Return the number of lines currently in the history. (This is different from get_history_length(), which returns the maximum number of lines that will be written to a history file.)

readline. **get_history_item**(index)

Return the current contents of history item at index.

readline. **remove_history_item**(pos)
Remove history item specified by its position from the history.

```
readline.replace_history_item(pos, line)
```

Replace history item specified by its position with the given line.

```
readline.redisplay()
```

Change what’s displayed on the screen to reflect the current contents of the line buffer.

```
readline.set_startup_hook([function])
```

Set or remove the startup_hook function. If `function` is specified, it will be used as the new startup_hook function; if omitted or None, any hook function already installed is removed. The startup_hook function is called with no arguments just before readline prints the first prompt.

```
readline.set_pre_input_hook([function])
```

Set or remove the pre_input_hook function. If `function` is specified, it will be used as the new pre_input_hook function; if omitted or None, any hook function already installed is removed. The pre_input_hook function is called with no arguments after the first prompt has been printed and just before readline starts reading input characters.

```
readline.set_completer([function])
```

Set or remove the completer function. If `function` is specified, it will be used as the new completer function; if omitted or None, any completer function already installed is removed. The completer function is called as `function(text, state)`, for state in 0, 1, 2, ..., until it returns a non-string value. It should return the next possible completion starting with `text`. 
readline. `get_completer()`
Get the completer function, or None if no completer function has been set.

readline. `get_completion_type()`
Get the type of completion being attempted.

readline. `get_begidx()`
Get the beginning index of the readline tab-completion scope.

readline. `get_endidx()`
Get the ending index of the readline tab-completion scope.

readline. `set_completer_delims(string)`
Set the readline word delimiters for tab-completion.

readline. `get_completer_delims()`
Get the readline word delimiters for tab-completion.

readline. `set_completion_display_matches_hook([function])`
Set or remove the completion display function. If `function` is specified, it will be used as the new completion display function; if omitted or None, any completion display function already installed is removed. The completion display function is called as `function(substitution, [matches], longest_match_length)` once each time matches need to be displayed.

readline. `add_history(line)`
Append a line to the history buffer, as if it was the last line typed.

<th><strong>Module</strong></th>
<th><code>rlcompleter</code></th>
</tr>
</thead>
<tbody>
<tr>
<td><strong>Completion</strong></td>
<td>Completion of Python identifiers at the interactive prompt.</td>
</tr>
</tbody>
</table>
6.7.1. Example

The following example demonstrates how to use the `readline` module's history reading and writing functions to automatically load and save a history file named `.pyhist` from the user's home directory. The code below would normally be executed automatically during interactive sessions from the user's `PYTHONSTARTUP` file.

```python
import os
import readline
histfile = os.path.join(os.path.expanduser("~"), ".pyhist")
try:
exterior.eadline.ead_history_file(histfile)
except FileNotFoundError:
    pass
import atexit
atexit.register(readline.write_history_file, histfile)
del os, histfile
```

The following example extends the `code.InteractiveConsole` class to support history save/restore.

```python
import code
import readline
import atexit
import os

class HistoryConsole(code.InteractiveConsole):
    def __init__(self, locals=None, filename="<console>", histfile=os.path.expanduser("~/.console-history")):
        code.InteractiveConsole.__init__(self, locals)
        self.init_history(histfile)
```
```python
def init_history(self, histfile):
    readline.parse_and_bind("tab: complete")
    if hasattr(readline, "read_history_file"):
        try:
            readline.read_history_file(histfile)
        except FileNotFoundError:
            pass
    atexit.register(self.save_history, histfile)

def save_history(self, histfile):
    readline.write_history_file(histfile)
```

Created using Sphinx 1.0.7.
6.8. `rlcompleter` — Completion function for GNU readline

**Source code:** Lib/rlcompleter.py

The `rlcompleter` module defines a completion function suitable for the `readline` module by completing valid Python identifiers and keywords.

When this module is imported on a Unix platform with the `readline` module available, an instance of the Completer class is automatically created and its `complete()` method is set as the `readline` completer.

Example:

```python
>>> import rlcompleter
>>> import readline

>>> readline.parse_and_bind("tab: complete")

>>> readline.<TAB PRESSED>
```

```python
readline.__doc__
readline.get_line_buffer()
readline.__file__
readline.insert_text(
readline.__name__
readline.parse_and_bind(

>>> readline.
```

The `rlcompleter` module is designed for use with Python's interactive mode. A user can add the following lines to his or her initialization file (identified by the `PYTHONSTARTUP` environment variable) to get automatic Tab completion:
try:
    import readline
except ImportError:
    print("Module readline not available.")
else:
    import rlcompleter
    readline.parse_and_bind("tab: complete")

On platforms without readline, the Completer class defined by this module can still be used for custom purposes.
6.8.1. Completer Objects

Completer objects have the following method:

Completer.complete(text, state)

Return the state th completion for text.

If called for text that doesn't include a period character ('.'), it will complete from names currently defined in __main__, builtins and keywords (as defined by the keyword module).

If called for a dotted name, it will try to evaluate anything without obvious side-effects (functions will not be evaluated, but it can generate calls to __getattr__() up to the last part, and find matches for the rest via the dir() function. Any exception raised during the evaluation of the expression is caught, silenced and None is returned.
7. Binary Data Services

The modules described in this chapter provide some basic services operations for manipulation of binary data. Other operations on binary data, specifically in relation to file formats and network protocols, are described in the relevant sections.

Some libraries described under *Text Processing Services* also work with either ASCII-compatible binary formats (for example, *re*) or all binary data (for example, *difflib*).

In addition, see the documentation for Python’s built-in binary data types in *Binary Sequence Types — bytes, bytearray, memoryview*.

7.2.6. `encodings.mbc` — Windows ANSI codepage
7.2.7. `encodings.utf_8_sig` — UTF-8 codec with BOM signature
7.1. **struct** — Interpret bytes as packed binary data

This module performs conversions between Python values and C structs represented as Python `bytes` objects. This can be used in handling binary data stored in files or from network connections, among other sources. It uses *Format Strings* as compact descriptions of the layout of the C structs and the intended conversion to/from Python values.

**Note:** By default, the result of packing a given C struct includes pad bytes in order to maintain proper alignment for the C types involved; similarly, alignment is taken into account when unpacking. This behavior is chosen so that the bytes of a packed struct correspond exactly to the layout in memory of the corresponding C struct. To handle platform-independent data formats or omit implicit pad bytes, use standard size and alignment instead of native size and alignment: see *Byte Order, Size, and Alignment* for details.
7.1.1. Functions and Exceptions

The module defines the following exception and functions:

*exception* struct.error

Exception raised on various occasions; argument is a string describing what is wrong.

struct.pack(fmt, v1, v2, ...)

Return a bytes object containing the values v1, v2, ... packed according to the format string fmt. The arguments must match the values required by the format exactly.

struct.pack_into(fmt, buffer, offset, v1, v2, ...)

Pack the values v1, v2, ... according to the format string fmt and write the packed bytes into the writable buffer buffer starting at position offset. Note that offset is a required argument.

struct.unpack(fmt, buffer)

Unpack from the buffer buffer (presumably packed by pack(fmt, ...)) according to the format string fmt. The result is a tuple even if it contains exactly one item. The buffer must contain exactly the amount of data required by the format (len(bytes) must equal calcsize(fmt)).

struct.unpack_from(fmt, buffer, offset=0)

Unpack from buffer starting at position offset, according to the format string fmt. The result is a tuple even if it contains exactly one item. buffer must contain at least the amount of data required by the format (len(buffer[offset:]) must be at least calcsize(fmt)).
struct.\texttt{calcsize}(\texttt{fmt})

Return the size of the struct (and hence of the bytes object produced by \texttt{pack(fmt, ...)}) corresponding to the format string \texttt{fmt}.
7.1.2. Format Strings

Format strings are the mechanism used to specify the expected layout when packing and unpacking data. They are built up from *Format Characters*, which specify the type of data being packed/unpacked. In addition, there are special characters for controlling the *Byte Order, Size, and Alignment*.

7.1.2.1. Byte Order, Size, and Alignment

By default, C types are represented in the machine's native format and byte order, and properly aligned by skipping pad bytes if necessary (according to the rules used by the C compiler).

Alternatively, the first character of the format string can be used to indicate the byte order, size and alignment of the packed data, according to the following table:

<table>
<thead>
<tr>
<th>Character</th>
<th>Byte order</th>
<th>Size</th>
<th>Alignment</th>
</tr>
</thead>
<tbody>
<tr>
<td>@</td>
<td>native</td>
<td>native</td>
<td>native</td>
</tr>
<tr>
<td>=</td>
<td>native</td>
<td>standard</td>
<td>none</td>
</tr>
<tr>
<td>&lt;</td>
<td>little-endian</td>
<td>standard</td>
<td>none</td>
</tr>
<tr>
<td>&gt;</td>
<td>big-endian</td>
<td>standard</td>
<td>none</td>
</tr>
<tr>
<td>!</td>
<td>network (= big-endian)</td>
<td>standard</td>
<td>none</td>
</tr>
</tbody>
</table>

If the first character is not one of these, '@' is assumed.

Native byte order is big-endian or little-endian, depending on the host system. For example, Intel x86 and AMD64 (x86-64) are little-endian; Motorola 68000 and PowerPC G5 are big-endian; ARM and Intel
Itanium feature switchable endianness (bi-endian). Use `sys.byteorder` to check the endianness of your system.

Native size and alignment are determined using the C compiler’s `sizeof` expression. This is always combined with native byte order.

Standard size depends only on the format character; see the table in the *Format Characters* section.

Note the difference between '@' and '=': both use native byte order, but the size and alignment of the latter is standardized.

The form '!' is available for those poor souls who claim they can't remember whether network byte order is big-endian or little-endian.

There is no way to indicate non-native byte order (force byte-swapping); use the appropriate choice of '<' or '>'.

Notes:

1. Padding is only automatically added between successive structure members. No padding is added at the beginning or the end of the encoded struct.
2. No padding is added when using non-native size and alignment, e.g. with '<', '>', '=', and '!'.
3. To align the end of a structure to the alignment requirement of a particular type, end the format with the code for that type with a repeat count of zero. See *Examples*.

### 7.1.2.2. Format Characters

Format characters have the following meaning; the conversion between C and Python values should be obvious given their types. The ‘Standard size’ column refers to the size of the packed value in
bytes when using standard size; that is, when the format string starts with one of '<', '>', '!' or '='. When using native size, the size of the packed value is platform-dependent.

<table>
<thead>
<tr>
<th>Format</th>
<th>C Type</th>

</table>
| p | char[] | bytes
| P | void * | integer | (6) |

Changed in version 3.3: Added support for the 'n' and 'N' formats.

Notes:

1. The '?' conversion code corresponds to the _Bool type defined by C99. If this type is not available, it is simulated using a char. In standard mode, it is always represented by one byte.

2. The 'q' and 'Q' conversion codes are available in native mode only if the platform C compiler supports C long long, or, on Windows, __int64. They are always available in standard modes.

3. When attempting to pack a non-integer using any of the integer conversion codes, if the non-integer has a __index__() method then that method is called to convert the argument to an integer before packing.

   Changed in version 3.2: Use of the __index__() method for non-integers is new in 3.2.

4. The 'n' and 'N' conversion codes are only available for the native size (selected as the default or with the '@' byte order character). For the standard size, you can use whichever of the other integer formats fits your application.

5. For the 'f' and 'd' conversion codes, the packed representation uses the IEEE 754 binary32 (for 'f') or binary64 (for 'd') format, regardless of the floating-point format used by the platform.
6. The 'P' format character is only available for the native byte ordering (selected as the default or with the '@' byte order character). The byte order character '=' chooses to use little- or big-endian ordering based on the host system. The struct module does not interpret this as native ordering, so the 'P' format is not available.

A format character may be preceded by an integral repeat count. For example, the format string '4h' means exactly the same as 'hhhh'.

Whitespace characters between formats are ignored; a count and its format must not contain whitespace though.

For the 's' format character, the count is interpreted as the length of the bytes, not a repeat count like for the other format characters; for example, '10s' means a single 10-byte string, while '10c' means 10 characters. If a count is not given, it defaults to 1. For packing, the string is truncated or padded with null bytes as appropriate to make it fit. For unpacking, the resulting bytes object always has exactly the specified number of bytes. As a special case, '0s' means a single, empty string (while '0c' means 0 characters).

When packing a value \( x \) using one of the integer formats ('b', 'B', 'h', 'H', 'i', 'I', 'l', 'L', 'q', 'Q'), if \( x \) is outside the valid range for that format then `struct.error` is raised.

*Changed in version 3.1:* In 3.0, some of the integer formats wrapped out-of-range values and raised `DeprecationWarning` instead of `struct.error`.

The 'p' format character encodes a “Pascal string”, meaning a short variable-length string stored in a *fixed number of bytes*, given by the
count. The first byte stored is the length of the string, or 255, whichever is smaller. The bytes of the string follow. If the string passed in to `pack()` is too long (longer than the count minus 1), only the leading `count-1` bytes of the string are stored. If the string is shorter than `count-1`, it is padded with null bytes so that exactly count bytes in all are used. Note that for `unpack()`, the `p` format character consumes `count` bytes, but that the string returned can never contain more than 255 bytes.

For the `?` format character, the return value is either `True` or `False`. When packing, the truth value of the argument object is used. Either 0 or 1 in the native or standard bool representation will be packed, and any non-zero value will be True when unpacking.

### 7.1.2.3. Examples

**Note:** All examples assume a native byte order, size, and alignment with a big-endian machine.

A basic example of packing/unpacking three integers:

```python
>>> from struct import *
>>> pack('hhl', 1, 2, 3)
\x00\x01\x00\x00\x02\x00\x00\x00\x03
>>> unpack('hhl', b'\x00\x01\x00\x02\x00\x00\x00\x03')
(1, 2, 3)
>>> calcsize('hhl')
8
```

Unpacked fields can be named by assigning them to variables or by wrapping the result in a named tuple:
```python
>>> record = b'raymond  \x32\x12\x08\x01\x08'
>>> name, serialnum, school, gradelevel = unpack('<10sHHb', record)
>>> from collections import namedtuple
>>> Student = namedtuple('Student', 'name serialnum school gradelevel')
>>> Student._make(unpack('<10sHHb', record))
Student(name=b'raymond ', serialnum=4658, school=264, gradelevel=8)
```

The ordering of format characters may have an impact on size since the padding needed to satisfy alignment requirements is different:

```python
>>> pack('ci', b'*', 0x12131415)
b'*\x00\x00\x00\x12\x13\x14\x15'
>>> pack('ic', 0x12131415, b'*')
b'\x12\x13\x14\x15*'n
>>> calcsize('ci')
8
>>> calcsize('ic')
5
```

The following format `'llh0l'` specifies two pad bytes at the end, assuming longs are aligned on 4-byte boundaries:

```python
>>> pack('llh0l', 1, 2, 3)
b'\x00\x00\x00\x01\x00\x00\x00\x00\x02\x00\x03\x00\x00'
```

This only works when native size and alignment are in effect; standard size and alignment does not enforce any alignment.

**See also:**

**Module** array

Packed binary storage of homogeneous data.

**Module** xdrlib
Packing and unpacking of XDR data.
7.1.3. Classes

The `struct` module also defines the following type:

```python
class struct.Struct(format)
```

Return a new Struct object which writes and reads binary data according to the format string `format`. Creating a Struct object once and calling its methods is more efficient than calling the `struct` functions with the same format since the format string only needs to be compiled once.

Compiled Struct objects support the following methods and attributes:

- **pack(v1, v2, ...)**
  Identical to the `pack()` function, using the compiled format. 
  `(len(result) will equal self.size.)`

- **pack_into(buffer, offset, v1, v2, ...)**
  Identical to the `pack_into()` function, using the compiled format.

- **unpack(buffer)**
  Identical to the `unpack()` function, using the compiled format. 
  `(len(buffer) must equal self.size).`

- **unpack_from(buffer, offset=0)**
  Identical to the `unpack_from()` function, using the compiled format. 
  `(len(buffer[offset:]) must be at least self.size).`
format
The format string used to construct this Struct object.

size
The calculated size of the struct (and hence of the bytes object produced by the \texttt{pack()} method) corresponding to \texttt{format}. 
7.2. **codecs** — Codec registry and base classes

This module defines base classes for standard Python codecs (encoders and decoders) and provides access to the internal Python codec registry which manages the codec and error handling lookup process.

It defines the following functions:

**codecs.**`encode`*(obj, encoding='utf-8', errors='strict')*

Encodes *obj* using the codec registered for *encoding*.

*Errors* may be given to set the desired error handling scheme. The default error handler is *strict* meaning that encoding errors raise *ValueError* (or a more codec specific subclass, such as *UnicodeEncodeError*). Refer to *Codec Base Classes* for more information on codec error handling.

**codecs.**`decode`*(obj, encoding='utf-8', errors='strict')*

Decodes *obj* using the codec registered for *encoding*.

*Errors* may be given to set the desired error handling scheme. The default error handler is *strict* meaning that decoding errors raise *ValueError* (or a more codec specific subclass, such as *UnicodeDecodeError*). Refer to *Codec Base Classes* for more information on codec error handling.

**codecs.**`register`(search_function)

Register a codec search function. Search functions are expected to
take one argument, the encoding name in all lower case letters, and return a CodecInfo object having the following attributes:

- **name** The name of the encoding;
- **encode** The stateless encoding function;
- **decode** The stateless decoding function;
- **incrementalencoder** An incremental encoder class or factory function;
- **incrementaldecoder** An incremental decoder class or factory function;
- **streamwriter** A stream writer class or factory function;
- **streamreader** A stream reader class or factory function.

The various functions or classes take the following arguments:

**encode** and **decode**: These must be functions or methods which have the same interface as the `encode()`/`decode()` methods of Codec instances (see `Codec Interface`). The functions/methods are expected to work in a stateless mode.

**incrementalencoder** and **incrementaldecoder**: These have to be factory functions providing the following interface:

```python
factory(errors='strict')
```

The factory functions must return objects providing the interfaces defined by the base classes `IncrementalEncoder` and `IncrementalDecoder`, respectively. Incremental codecs can maintain state.

**streamreader** and **streamwriter**: These have to be factory functions providing the following interface:

```python
factory(stream, errors='strict')
```
The factory functions must return objects providing the interfaces defined by the base classes `StreamReader` and `StreamWriter`, respectively. Stream codecs can maintain state.

Possible values for errors are

- `'strict'`: raise an exception in case of an encoding error
- `'replace'`: replace malformed data with a suitable replacement marker, such as '?' or '\ufffd'
- `'ignore'`: ignore malformed data and continue without further notice
- `'xmlcharrefreplace'`: replace with the appropriate XML character reference (for encoding only)
- `'backslashreplace'`: replace with backslashed escape sequences (for encoding only)
- `'surrogateescape'`: on decoding, replace with code points in the Unicode Private Use Area ranging from U+DC80 to U+DCFF. These private code points will then be turned back into the same bytes when the `surrogateescape` error handler is used when encoding the data. (See PEP 383 for more.)

as well as any other error handling name defined via `register_error()`.

In case a search function cannot find a given encoding, it should return `None`.

codecs. `lookup(encoding)`

Looks up the codec info in the Python codec registry and returns a `CodecInfo` object as defined above.

Encodings are first looked up in the registry's cache. If not found, the list of registered search functions is scanned. If no `CodecInfo`
object is found, a LookupError is raised. Otherwise, the CodecInfo object is stored in the cache and returned to the caller.

To simplify access to the various codecs, the module provides these additional functions which use lookup() for the codec lookup:

codecs.getencoder(encoding)
Look up the codec for the given encoding and return its encoder function.

Raises a LookupError in case the encoding cannot be found.

codecs.getdecoder(encoding)
Look up the codec for the given encoding and return its decoder function.

Raises a LookupError in case the encoding cannot be found.

codecs.getincrementalencoder(encoding)
Look up the codec for the given encoding and return its incremental encoder class or factory function.

Raises a LookupError in case the encoding cannot be found or the codec doesn’t support an incremental encoder.

codecs.getincrementaldecoder(encoding)
Look up the codec for the given encoding and return its incremental decoder class or factory function.

Raises a LookupError in case the encoding cannot be found or the codec doesn’t support an incremental decoder.

codecs.getreader(encoding)
Look up the codec for the given encoding and return its StreamReader class or factory function.

Raises a LookupError in case the encoding cannot be found.

codecs.getwriter(encoding)

Look up the codec for the given encoding and return its StreamWriter class or factory function.

Raises a LookupError in case the encoding cannot be found.

codecs.register_error(name, error_handler)

Register the error handling function error_handler under the name name. error_handler will be called during encoding and decoding in case of an error, when name is specified as the errors parameter.

For encoding error_handler will be called with a UnicodeEncodeError instance, which contains information about the location of the error. The error handler must either raise this or a different exception or return a tuple with a replacement for the unencodable part of the input and a position where encoding should continue. The replacement may be either str or bytes. If the replacement is bytes, the encoder will simply copy them into the output buffer. If the replacement is a string, the encoder will encode the replacement. Encoding continues on original input at the specified position. Negative position values will be treated as being relative to the end of the input string. If the resulting position is out of bound an IndexError will be raised.

Decoding and translating works similar, except UnicodeDecodeError or UnicodeTranslateError will be passed to the handler and that the replacement from the error handler will be put into the output directly.
codecs.**lookup_error**(name)

Return the error handler previously registered under the name `name`.

Raises a LookupError in case the handler cannot be found.

codecs.**strict_errors**(exception)

Implements the strict error handling: each encoding or decoding error raises a UnicodeError.

codecs.**replace_errors**(exception)

Implements the replace error handling: malformed data is replaced with a suitable replacement character such as '?' in bytestrings and '\ufffd' in Unicode strings.

codecs.**ignore_errors**(exception)

Implements the ignore error handling: malformed data is ignored and encoding or decoding is continued without further notice.

codecs.**xmlcharrefreplace_errors**(exception)

Implements the xmlcharrefreplace error handling (for encoding only): the unencodable character is replaced by an appropriate XML character reference.

codecs.**backslashreplace_errors**(exception)

Implements the backslashreplace error handling (for encoding only): the unencodable character is replaced by a backslashed escape sequence.

To simplify working with encoded files or stream, the module also defines these utility functions:
codecs.open(filename, mode[, encoding[, errors[, buffering]]])

Open an encoded file using the given mode and return a wrapped version providing transparent encoding/decoding. The default file mode is 'r' meaning to open the file in read mode.

**Note:** The wrapped version’s methods will accept and return strings only. Bytes arguments will be rejected.

**Note:** Files are always opened in binary mode, even if no binary mode was specified. This is done to avoid data loss due to encodings using 8-bit values. This means that no automatic conversion of b'\n' is done on reading and writing.

*encoding* specifies the encoding which is to be used for the file.

*errors* may be given to define the error handling. It defaults to 'strict' which causes a *ValueError* to be raised in case an encoding error occurs.

*buffering* has the same meaning as for the built-in open() function. It defaults to line buffered.

codecs.EncodedFile(file, data_encoding, file_encoding=None, errors='strict')

Return a wrapped version of file which provides transparent encoding translation.

Bytes written to the wrapped file are interpreted according to the given *data_encoding* and then written to the original file as bytes using the *file_encoding*.

If *file_encoding* is not given, it defaults to *data_encoding*.
errors may be given to define the error handling. It defaults to 'strict', which causes ValueError to be raised in case an encoding error occurs.

codecs.iterencode(iterator, encoding, errors='strict', **kwargs)
Uses an incremental encoder to iteratively encode the input provided by iterator. This function is a generator. errors (as well as any other keyword argument) is passed through to the incremental encoder.

codecs.iterdecode(iterator, encoding, errors='strict', **kwargs)
Uses an incremental decoder to iteratively decode the input provided by iterator. This function is a generator. errors (as well as any other keyword argument) is passed through to the incremental decoder.

The module also provides the following constants which are useful for reading and writing to platform dependent files:

codecs.BOM
codecs.BOM_BE
codecs.BOM_LE
codecs.BOM_UTF8
codecs.BOM_UTF16
codecs.BOM_UTF16_BE
codecs.BOM_UTF16_LE
codecs.BOM_UTF32
codecs.BOM_UTF32_BE
codecs.BOM_UTF32_LE

These constants define various encodings of the Unicode byte order mark (BOM) used in UTF-16 and UTF-32 data streams to indicate the byte order used in the stream or file and in UTF-8 as a Unicode signature. BOM_UTF16 is either BOM_UTF16_BE or
BOM_UTF16_LE depending on the platform’s native byte order, BOM is an alias for BOM_UTF16, BOM_LE for BOM_UTF16_LE and BOM_BE for BOM_UTF16_BE. The others represent the BOM in UTF-8 and UTF-32 encodings.
7.2.1. Codec Base Classes

The `codecs` module defines a set of base classes which define the interface and can also be used to easily write your own codecs for use in Python.

Each codec has to define four interfaces to make it usable as codec in Python: stateless encoder, stateless decoder, stream reader and stream writer. The stream reader and writers typically reuse the stateless encoder/decoder to implement the file protocols.

The `Codec` class defines the interface for stateless encoders/decoders.

To simplify and standardize error handling, the `encode()` and `decode()` methods may implement different error handling schemes by providing the `errors` string argument. The following string values are defined and implemented by all standard Python codecs:

<table>
<thead>
<tr>
<th>Value</th>
<th>Meaning</th>
</tr>
</thead>
<tbody>
<tr>
<td>'strict'</td>
<td>Raise <code>UnicodeError</code> (or a subclass); this is the default.</td>
</tr>
<tr>
<td>'ignore'</td>
<td>Ignore the character and continue with the next.</td>
</tr>
<tr>
<td>'replace'</td>
<td>Replace with a suitable replacement character; Python will use the official U+FFFD REPLACEMENT CHARACTER for the built-in Unicode codecs on decoding and ‘?’ on encoding.</td>
</tr>
<tr>
<td>'xmlcharrefreplace'</td>
<td>Replace with the appropriate XML character reference (only for encoding).</td>
</tr>
</tbody>
</table>
Replace with backslashed escape sequences (only for encoding).

Replace byte with surrogate U+DCxx, as defined in PEP 383.

In addition, the following error handlers are specific to a single codec:

<table>
<thead>
<tr>
<th>Value</th>
<th>Codec</th>
<th>Meaning</th>
</tr>
</thead>
<tbody>
<tr>
<td>'surrogatepass'</td>
<td>utf-8</td>
<td>Allow encoding and decoding of surrogate codes in UTF-8.</td>
</tr>
</tbody>
</table>

New in version 3.1: The 'surrogateescape' and 'surrogatepass' error handlers.

The set of allowed values can be extended via register_error().

7.2.1.1. Codec Objects

The Codec class defines these methods which also define the function interfaces of the stateless encoder and decoder:

Codec. **encode**(input[, errors])

Encodes the object input and returns a tuple (output object, length consumed). Encoding converts a string object to a bytes object using a particular character set encoding (e.g., cp1252 or iso-8859-1).

errors defines the error handling to apply. It defaults to 'strict' handling.

The method may not store state in the Codec instance. Use StreamCodec for codecs which have to keep state in order to
make encoding/decoding efficient.

The encoder must be able to handle zero length input and return an empty object of the output object type in this situation.

Codec. `decode(input[, errors])`
Decodes the object `input` and returns a tuple (output object, length consumed). Decoding converts a bytes object encoded using a particular character set encoding to a string object.

`input` must be a bytes object or one which provides the read-only character buffer interface – for example, buffer objects and memory mapped files.

`errors` defines the error handling to apply. It defaults to 'strict' handling.

The method may not store state in the Codec instance. Use StreamCodec for codecs which have to keep state in order to make encoding/decoding efficient.

The decoder must be able to handle zero length input and return an empty object of the output object type in this situation.

The `IncrementalEncoder` and `IncrementalDecoder` classes provide the basic interface for incremental encoding and decoding. Encoding/decoding the input isn’t done with one call to the stateless encoder/decoder function, but with multiple calls to the `encode()/decode()` method of the incremental encoder/decoder. The incremental encoder/decoder keeps track of the encoding/decoding process during method calls.

The joined output of calls to the `encode()/decode()` method is the
same as if all the single inputs were joined into one, and this input was encoded/decoded with the stateless encoder/decoder.

7.2.1.2. IncrementalEncoder Objects

The IncrementalEncoder class is used for encoding an input in multiple steps. It defines the following methods which every incremental encoder must define in order to be compatible with the Python codec registry.

class codecs.IncrementalEncoder([errors])

Constructor for an IncrementalEncoder instance.

All incremental encoders must provide this constructor interface. They are free to add additional keyword arguments, but only the ones defined here are used by the Python codec registry.

The IncrementalEncoder may implement different error handling schemes by providing the errors keyword argument. These parameters are predefined:

- 'strict' Raise ValueError (or a subclass); this is the default.
- 'ignore' Ignore the character and continue with the next.
- 'replace' Replace with a suitable replacement character
- 'xmlcharrefreplace' Replace with the appropriate XML character reference
- 'backslashreplace' Replace with backslashed escape sequences.

The errors argument will be assigned to an attribute of the same name. Assigning to this attribute makes it possible to switch between different error handling strategies during the lifetime of the
IncrementalEncoder object.

The set of allowed values for the errors argument can be extended with register_error().

**encode**(object[, final])

Encodes object (taking the current state of the encoder into account) and returns the resulting encoded object. If this is the last call to encode() final must be true (the default is false).

**reset()**

Reset the encoder to the initial state. The output is discarded: call encode('', final=True) to reset the encoder and to get the output.

IncrementalEncoder. **getstate()**

Return the current state of the encoder which must be an integer. The implementation should make sure that 0 is the most common state. (States that are more complicated than integers can be converted into an integer by marshaling/pickling the state and encoding the bytes of the resulting string into an integer).

IncrementalEncoder. **setstate**(state)

Set the state of the encoder to state. state must be an encoder state returned by getstate().

### 7.2.1.3. IncrementalDecoder Objects

The IncrementalDecoder class is used for decoding an input in multiple steps. It defines the following methods which every incremental decoder must define in order to be compatible with the Python codec registry.
class codecs.IncrementalDecoder([errors])

Constructor for an IncrementalDecoder instance.

All incremental decoders must provide this constructor interface. They are free to add additional keyword arguments, but only the ones defined here are used by the Python codec registry.

The IncrementalDecoder may implement different error handling schemes by providing the errors keyword argument. These parameters are predefined:

- `'strict'` Raise `ValueError` (or a subclass); this is the default.
- `'ignore'` Ignore the character and continue with the next.
- `'replace'` Replace with a suitable replacement character.

The errors argument will be assigned to an attribute of the same name. Assigning to this attribute makes it possible to switch between different error handling strategies during the lifetime of the IncrementalDecoder object.

The set of allowed values for the errors argument can be extended with `register_error()`.

decode(object[, final])

Decodes object (taking the current state of the decoder into account) and returns the resulting decoded object. If this is the last call to `decode()` `final` must be true (the default is false). If `final` is true the decoder must decode the input completely and must flush all buffers. If this isn’t possible (e.g. because of incomplete byte sequences at the end of the input) it must initiate error handling just like in the stateless case (which might raise an exception).
reset()
    Reset the decoder to the initial state.

getstate()
    Return the current state of the decoder. This must be a tuple
    with two items, the first must be the buffer containing the still
    undecoded input. The second must be an integer and can be
    additional state info. (The implementation should make sure
    that 0 is the most common additional state info.) If this
    additional state info is 0 it must be possible to set the decoder
    to the state which has no input buffered and 0 as the additional
    state info, so that feeding the previously buffered input to the
    decoder returns it to the previous state without producing any
    output. (Additional state info that is more complicated than
    integers can be converted into an integer by marshaling/pickling
    the info and encoding the bytes of the resulting string into an
    integer.)

setstate(state)
    Set the state of the encoder to state. state must be a decoder
    state returned by getstate().

The StreamWriter and StreamReader classes provide generic
working interfaces which can be used to implement new encoding
submodules very easily. See encodings.utf_8 for an example of
how this is done.

7.2.1.4. StreamWriter Objects

The StreamWriter class is a subclass of Codec and defines the
following methods which every stream writer must define in order to be
compatible with the Python codec registry.

```python
class codecs.StreamWriter(stream[, errors])
```

Constructor for a `StreamWriter` instance.

All stream writers must provide this constructor interface. They are free to add additional keyword arguments, but only the ones defined here are used by the Python codec registry.

`stream` must be a file-like object open for writing binary data.

The `StreamWriter` may implement different error handling schemes by providing the `errors` keyword argument. These parameters are predefined:

- `'strict'` Raise `ValueError` (or a subclass); this is the default.
- `'ignore'` Ignore the character and continue with the next.
- `'replace'` Replace with a suitable replacement character
- `'xmlcharrefreplace'` Replace with the appropriate XML character reference
- `'backslashreplace'` Replace with backslashed escape sequences.

The `errors` argument will be assigned to an attribute of the same name. Assigning to this attribute makes it possible to switch between different error handling strategies during the lifetime of the `StreamWriter` object.

The set of allowed values for the `errors` argument can be extended with `register_error()`.

```python
write(object)
```

Writes the object's contents encoded to the stream.
**writelines**(list)

Writes the concatenated list of strings to the stream (possibly by reusing the `write()` method).

**reset()

Flushes and resets the codec buffers used for keeping state.

Calling this method should ensure that the data on the output is put into a clean state that allows appending of new fresh data without having to rescan the whole stream to recover state.

In addition to the above methods, the `StreamWriter` must also inherit all other methods and attributes from the underlying stream.

### 7.2.1.5. StreamReader Objects

The `StreamReader` class is a subclass of Codec and defines the following methods which every stream reader must define in order to be compatible with the Python codec registry.

```python
class codecs.StreamReader(stream[, errors])
```

Constructor for a `StreamReader` instance.

All stream readers must provide this constructor interface. They are free to add additional keyword arguments, but only the ones defined here are used by the Python codec registry.

`stream` must be a file-like object open for reading (binary) data.

The `StreamReader` may implement different error handling schemes by providing the `errors` keyword argument. These parameters are defined:
- **'strict'** Raise `ValueError` (or a subclass); this is the default.
- **'ignore'** Ignore the character and continue with the next.
- **'replace'** Replace with a suitable replacement character.

The `errors` argument will be assigned to an attribute of the same name. Assigning to this attribute makes it possible to switch between different error handling strategies during the lifetime of the `StreamReader` object.

The set of allowed values for the `errors` argument can be extended with `register_error()`.

```python
read([size[, chars[, firstline]]])
```

Decodes data from the stream and returns the resulting object.

- `chars` indicates the number of characters to read from the stream. `read()` will never return more than `chars` characters, but it might return less, if there are not enough characters available.

- `size` indicates the approximate maximum number of bytes to read from the stream for decoding purposes. The decoder can modify this setting as appropriate. The default value -1 indicates to read and decode as much as possible. `size` is intended to prevent having to decode huge files in one step.

- `firstline` indicates that it would be sufficient to only return the first line, if there are decoding errors on later lines.

The method should use a greedy read strategy meaning that it should read as much data as is allowed within the definition of the encoding and the given size, e.g. if optional encoding endings or state markers are available on the stream, these
should be read too.

**readline([size[, keepends]])**
Read one line from the input stream and return the decoded data.

`size`, if given, is passed as size argument to the stream's `read()` method.

If `keepends` is false line-endings will be stripped from the lines returned.

**readlines([sizehint[, keepends]])**
Read all lines available on the input stream and return them as a list of lines.

Line-endings are implemented using the codec's decoder method and are included in the list entries if `keepends` is true.

`sizehint`, if given, is passed as the `size` argument to the stream's `read()` method.

**reset()**
Resets the codec buffers used for keeping state.

Note that no stream repositioning should take place. This method is primarily intended to be able to recover from decoding errors.

In addition to the above methods, the `StreamReader` must also inherit all other methods and attributes from the underlying stream.

The next two base classes are included for convenience. They are not needed by the codec registry, but may provide useful in practice.
7.2.1.6. StreamReaderWriter Objects

The **StreamReaderWriter** allows wrapping streams which work in both read and write modes.

The design is such that one can use the factory functions returned by the **lookup()** function to construct the instance.

```python
class codecs.StreamReaderWriter(stream, Reader, Writer, errors)
```

Creates a **StreamReaderWriter** instance. *stream* must be a file-like object. *Reader* and *Writer* must be factory functions or classes providing the **StreamReader** and **StreamWriter** interface resp. Error handling is done in the same way as defined for the stream readers and writers.

**StreamReaderWriter** instances define the combined interfaces of **StreamReader** and **StreamWriter** classes. They inherit all other methods and attributes from the underlying stream.

7.2.1.7. StreamRecoder Objects

The **StreamRecoder** provide a frontend - backend view of encoding data which is sometimes useful when dealing with different encoding environments.

The design is such that one can use the factory functions returned by the **lookup()** function to construct the instance.

```python
class codecs.StreamRecoder(stream, encode, decode, Reader, Writer, errors)
```
Creates a **StreamRecoder** instance which implements a two-way conversion: *encode* and *decode* work on the frontend (the input to `read()` and output of `write()`), while *Reader* and *Writer* work on the backend (reading and writing to the stream).

You can use these objects to do transparent direct recodings from e.g. Latin-1 to UTF-8 and back.

*stream* must be a file-like object. 

*encode, decode* must adhere to the Codec interface. *Reader, Writer* must be factory functions or classes providing objects of the **StreamReader** and **StreamWriter** interface respectively.

*encode* and *decode* are needed for the frontend translation, *Reader* and *Writer* for the backend translation.

Error handling is done in the same way as defined for the stream readers and writers.

**StreamRecoder** instances define the combined interfaces of **StreamReader** and **StreamWriter** classes. They inherit all other methods and attributes from the underlying stream.
7.2.2. Encodings and Unicode

Strings are stored internally as sequences of codepoints in range 0 - 10FFFF (see PEP 393 for more details about the implementation). Once a string object is used outside of CPU and memory, CPU endianness and how these arrays are stored as bytes become an issue. Transforming a string object into a sequence of bytes is called encoding and recreating the string object from the sequence of bytes is known as decoding. There are many different methods for how this transformation can be done (these methods are also called encodings). The simplest method is to map the codepoints 0-255 to the bytes 0x0-0xff. This means that a string object that contains codepoints above U+00FF can't be encoded with this method (which is called 'latin-1' or 'iso-8859-1'). `str.encode()` will raise a `UnicodeEncodeError` that looks like this: `UnicodeEncodeError: 'latin-1' codec can't encode character '\u1234' in position 3: ordinal not in range(256).

There's another group of encodings (the so called charmap encodings) that choose a different subset of all Unicode code points and how these codepoints are mapped to the bytes 0x0-0xff. To see how this is done simply open e.g. `encodings/cp1252.py` (which is an encoding that is used primarily on Windows). There's a string constant with 256 characters that shows you which character is mapped to which byte value.

All of these encodings can only encode 256 of the 1114112 codepoints defined in Unicode. A simple and straightforward way that can store each Unicode code point, is to store each codepoint as four consecutive bytes. There are two possibilities: store the bytes in big endian or in little endian order. These two encodings are called UTF-
32-BE and UTF-32-LE respectively. Their disadvantage is that if e.g. you use UTF-32-BE on a little endian machine you will always have to swap bytes on encoding and decoding. UTF-32 avoids this problem: bytes will always be in natural endianness. When these bytes are read by a CPU with a different endianness, then bytes have to be swapped though. To be able to detect the endianness of a UTF-16 or UTF-32 byte sequence, there's the so called BOM (“Byte Order Mark”). This is the Unicode character U+FEFF. This character can be prepended to every UTF-16 or UTF-32 byte sequence. The byte swapped version of this character (0xFFFE) is an illegal character that may not appear in a Unicode text. So when the first character in an UTF-16 or UTF-32 byte sequence appears to be a U+FFFE the bytes have to be swapped on decoding. Unfortunately the character U+FEFF had a second purpose as a ZERO WIDTH NO-BREAK SPACE: a character that has no width and doesn’t allow a word to be split. It can e.g. be used to give hints to a ligature algorithm. With Unicode 4.0 using U+FEFF as a ZERO WIDTH NO-BREAK SPACE has been deprecated (with U+2060 (WORD JOINER) assuming this role). Nevertheless Unicode software still must be able to handle U+FEFF in both roles: as a BOM it’s a device to determine the storage layout of the encoded bytes, and vanishes once the byte sequence has been decoded into a string; as a ZERO WIDTH NO-BREAK SPACE it’s a normal character that will be decoded like any other.

There’s another encoding that is able to encoding the full range of Unicode characters: UTF-8. UTF-8 is an 8-bit encoding, which means there are no issues with byte order in UTF-8. Each byte in a UTF-8 byte sequence consists of two parts: marker bits (the most significant bits) and payload bits. The marker bits are a sequence of zero to four 1 bits followed by a 0 bit. Unicode characters are encoded like this (with x being payload bits, which when concatenated give the Unicode
The least significant bit of the Unicode character is the rightmost x bit.

As UTF-8 is an 8-bit encoding no BOM is required and any U+FEFF character in the decoded string (even if it's the first character) is treated as a ZERO WIDTH NO-BREAK SPACE.

Without external information it's impossible to reliably determine which encoding was used for encoding a string. Each charmap encoding can decode any random byte sequence. However that's not possible with UTF-8, as UTF-8 byte sequences have a structure that doesn't allow arbitrary byte sequences. To increase the reliability with which a UTF-8 encoding can be detected, Microsoft invented a variant of UTF-8 (that Python 2.5 calls "utf-8-sig") for its Notepad program: Before any of the Unicode characters is written to the file, a UTF-8 encoded BOM (which looks like this as a byte sequence: 0xef, 0xbb, 0xbf) is written. As it's rather improbable that any charmap encoded file starts with these byte values (which would e.g. map to

LATIN SMALL LETTER I WITH DIAERESIS
RIGHT-POINTING DOUBLE ANGLE QUOTATION MARK
INVERTED QUESTION MARK

in iso-8859-1), this increases the probability that a utf-8-sig encoding can be correctly guessed from the byte sequence. So here the BOM is not used to be able to determine the byte order used for generating the byte sequence, but as a signature that helps in guessing the encoding. On encoding the utf-8-sig codec will write 0xef, 0xbb, 0xbf as the first three bytes to the file. On decoding utf-8-sig will skip those three bytes if they appear as the first three bytes in the file. In UTF-8, the use of the BOM is discouraged and should generally be avoided.
7.2.3. Standard Encodings

Python comes with a number of codecs built-in, either implemented as C functions or with dictionaries as mapping tables. The following table lists the codecs by name, together with a few common aliases, and the languages for which the encoding is likely used. Neither the list of aliases nor the list of languages is meant to be exhaustive. Notice that spelling alternatives that only differ in case or use a hyphen instead of an underscore are also valid aliases; therefore, e.g. 'utf-8' is a valid alias for the 'utf_8' codec.

<table>
<thead>
<tr>
<th>Codec</th>
<th>Aliases</th>
<th>Languages</th>
</tr>
</thead>
<tbody>
<tr>
<td></td>
<td></td>
<td></td>
</tr>
</tbody>
</table>

**CPython implementation detail:** Some common encodings can bypass the codecs lookup machinery to improve performance. These optimization opportunities are only recognized by CPython for a limited set of aliases: utf-8, utf8, latin-1, latin1, iso-8859-1, mbcs (Windows only), ascii, utf-16, and utf-32. Using alternative spellings for these encodings may result in slower execution.

Many of the character sets support the same languages. They vary in individual characters (e.g. whether the EURO SIGN is supported or not), and in the assignment of characters to code positions. For the European languages in particular, the following variants typically exist:

- an ISO 8859 codeset
- a Microsoft Windows code page, which is typically derived from a 8859 codeset, but replaces control characters with additional graphic characters
- an IBM EBCDIC code page
- an IBM PC code page, which is ASCII compatible

### 7.2.4. Python Specific Encodings

A number of predefined codecs are specific to Python, so their codec names have no meaning outside Python. These are listed in the tables below based on the expected input and output types (note that while text encodings are the most common use case for codecs, the underlying codec infrastructure supports arbitrary data transforms rather than just text encodings). For asymmetric codecs, the stated purpose describes the encoding direction.

The following codecs provide \texttt{str} to \texttt{bytes} encoding and \texttt{bytes-like object} to \texttt{str} decoding, similar to the Unicode text encodings.

<table>
<thead>
<tr>
<th>Codec</th>
<th>Aliases</th>
<th>Purpose</th>
</tr>
</thead>
<tbody>
<tr>
<td>idna</td>
<td></td>
<td>Implements <a href="https://tools.ietf.org/html/rfc3490">RFC 3490</a>, see also <code>encodings.idna</code></td>
</tr>
<tr>
<td>mbcs</td>
<td>dbcs</td>
<td>Windows only: Encode operand according to the ANSI codepage (CP_ACP)</td>
</tr>
<tr>
<td>palmos</td>
<td></td>
<td>Encoding of PalmOS 3.5</td>
</tr>
<tr>
<td>punycode</td>
<td></td>
<td>Implements <a href="https://tools.ietf.org/html/rfc3492">RFC 3492</a></td>
</tr>
<tr>
<td>raw_unicode_escape</td>
<td></td>
<td>Produce a string that is suitable as raw Unicode literal in Python source code</td>
</tr>
<tr>
<td>undefined</td>
<td></td>
<td>Raise an exception for all conversions. Can be used as the system encoding if no automatic coercion between byte and Unicode strings is desired.</td>
</tr>
<tr>
<td></td>
<td></td>
<td>Produce a string that is suitable</td>
</tr>
<tr>
<td>Codec</td>
<td>Purpose</td>
<td>Encoder/decoder</td>
</tr>
<tr>
<td>---------------</td>
<td>----------------------------------------------</td>
<td>--------------------------------------</td>
</tr>
<tr>
<td>base64_codec</td>
<td>Convert operand to MIME base64 (the result always includes a trailing '\n')</td>
<td>base64.b64encode(), base64.b64decode()</td>
</tr>
<tr>
<td>bz2_codec</td>
<td>Compress the operand using bz2</td>
<td>bz2.compress(), bz2.decompress()</td>
</tr>
<tr>
<td>hex_codec</td>
<td>Convert operand to hexadecimal representation, with two digits per byte</td>
<td>base64.b16encode(), base64.b16decode()</td>
</tr>
<tr>
<td>quopri_codec</td>
<td>Convert operand to MIME quoted printable</td>
<td>quopri.encodestring(), quopri.decodestring()</td>
</tr>
<tr>
<td>uu_codec</td>
<td>Convert the operand using uuencode</td>
<td>uu.encode(), uu.decode()</td>
</tr>
<tr>
<td>zlib_codec</td>
<td>Compress the operand using gzip</td>
<td>zlib.compress(), zlib.decompress()</td>
</tr>
</tbody>
</table>

The following codecs provide *bytes-like object* to *bytes* mappings.
Rather than accepting any `bytes-like object`, `base64_codec` accepts only `bytes` and `bytearray` for encoding and only `bytes`, `bytearray`, and ASCII-only instances of `str` for decoding.

The following codecs provide `str` to `str` mappings.

<table>
<thead>
<tr>
<th>Codec</th>
<th>Purpose</th>
</tr>
</thead>
<tbody>
<tr>
<td>rot_13</td>
<td>Returns the Caesar-cypher encryption of the operand</td>
</tr>
</tbody>
</table>

*New in version 3.2*: bytes-to-bytes and str-to-str codecs.
7.2.5. **encodings.idna** — Internationalized Domain Names in Applications

This module implements RFC 3490 (Internationalized Domain Names in Applications) and RFC 3492 (Nameprep: A Stringprep Profile for Internationalized Domain Names (IDN)). It builds upon the punycode encoding and stringprep.

These RFCs together define a protocol to support non-ASCII characters in domain names. A domain name containing non-ASCII characters (such as www.Alliancefrançaise.nu) is converted into an ASCII-compatible encoding (ACE, such as www.xn--alliancefranaise-npb.nu). The ACE form of the domain name is then used in all places where arbitrary characters are not allowed by the protocol, such as DNS queries, HTTP Host fields, and so on. This conversion is carried out in the application; if possible invisible to the user: The application should transparently convert Unicode domain labels to IDNA on the wire, and convert back ACE labels to Unicode before presenting them to the user.

Python supports this conversion in several ways: the idna codec performs conversion between Unicode and ACE, separating an input string into labels based on the separator characters defined in section 3.1 (1) of RFC 3490 and converting each label to ACE as required, and conversely separating an input byte string into labels based on the . separator and converting any ACE labels found into unicode. Furthermore, the socket module transparently converts Unicode host names to ACE, so that applications need not be concerned about converting host names themselves when they pass them to the socket
module. On top of that, modules that have host names as function parameters, such as `http.client` and `ftplib`, accept Unicode host names (`http.client` then also transparently sends an IDNA hostname in the `Host` field if it sends that field at all).

When receiving host names from the wire (such as in reverse name lookup), no automatic conversion to Unicode is performed: Applications wishing to present such host names to the user should decode them to Unicode.

The module `encodings.idna` also implements the nameprep procedure, which performs certain normalizations on host names, to achieve case-insensitivity of international domain names, and to unify similar characters. The nameprep functions can be used directly if desired.

`encodings.idna.nameprep(label)`

Return the nameprepped version of `label`. The implementation currently assumes query strings, so `AllowUnassigned` is true.

`encodings.idna.ToASCII(label)`

Convert a label to ASCII, as specified in [RFC 3490](https://tools.ietf.org/html/rfc3490). `UseSTD3ASCIIRules` is assumed to be false.

`encodings.idna.ToUnicode(label)`

Convert a label to Unicode, as specified in [RFC 3490](https://tools.ietf.org/html/rfc3490).
7.2.6. **encodings.mbc** — Windows ANSI codepage

Encode operand according to the ANSI codepage (CP_ACP).

Availability: Windows only.

*Changed in version 3.3:* Support any error handler.

*Changed in version 3.2:* Before 3.2, the `errors` argument was ignored; 'replace' was always used to encode, and 'ignore' to decode.
7.2.7. **encodings.utf_8_sig** — UTF-8 codec with BOM signature

This module implements a variant of the UTF-8 codec: On encoding a UTF-8 encoded BOM will be prepended to the UTF-8 encoded bytes. For the stateful encoder this is only done once (on the first write to the byte stream). For decoding an optional UTF-8 encoded BOM at the start of the data will be skipped.
8. Data Types

The modules described in this chapter provide a variety of specialized data types such as dates and times, fixed-type arrays, heap queues, synchronized queues, and sets.

Python also provides some built-in data types, in particular, `dict`, `list`, `set` and `frozenset`, and `tuple`. The `str` class is used to hold Unicode strings, and the `bytes` class is used to hold binary data.

The following modules are documented in this chapter:

- **8.1. datetime — Basic date and time types**
  - 8.1.1. Available Types
  - 8.1.2. timedelta Objects
  - 8.1.3. date Objects
  - 8.1.4. datetime Objects
  - 8.1.5. time Objects
  - 8.1.6. tzinfo Objects
  - 8.1.7. timezone Objects
  - 8.1.8. strftime() and strptime() Behavior
- **8.2. calendar — General calendar-related functions**
- **8.3. collections — Container datatypes**
  - 8.3.1. ChainMap objects
    - 8.3.1.1. ChainMap Examples and Recipes
  - 8.3.2. Counter objects
  - 8.3.3. deque objects
    - 8.3.3.1. deque Recipes
  - 8.3.4. defaultdict objects
    - 8.3.4.1. defaultdict Examples
  - 8.3.5. namedtuple() Factory Function for Tuples with
Named Fields

- 8.3.6. OrderedDict objects
  - 8.3.6.1. OrderedDict Examples and Recipes
- 8.3.7. UserDict objects
- 8.3.8. UserList objects
- 8.3.9. UserString objects

- 8.4. collections.abc — Abstract Base Classes for Containers
  - 8.4.1. Collections Abstract Base Classes

- 8.5. heapq — Heap queue algorithm
  - 8.5.1. Basic Examples
  - 8.5.2. Priority Queue Implementation Notes
  - 8.5.3. Theory

- 8.6. bisect — Array bisection algorithm
  - 8.6.1. Searching Sorted Lists
  - 8.6.2. Other Examples

- 8.7. array — Efficient arrays of numeric values

- 8.8. weakref — Weak references
  - 8.8.1. Weak Reference Objects
  - 8.8.2. Example

- 8.9. types — Dynamic type creation and names for built-in types
  - 8.9.1. Dynamic Type Creation
  - 8.9.2. Standard Interpreter Types

- 8.10. copy — Shallow and deep copy operations

- 8.11. pprint — Data pretty printer
  - 8.11.1. PrettyPrinter Objects
  - 8.11.2. Example

- 8.12. reprlib — Alternate repr() implementation
  - 8.12.1. Repr Objects
  - 8.12.2. Subclassing Repr Objects
8.1. `datetime` — Basic date and time types

The `datetime` module supplies classes for manipulating dates and times in both simple and complex ways. While date and time arithmetic is supported, the focus of the implementation is on efficient attribute extraction for output formatting and manipulation. For related functionality, see also the `time` and `calendar` modules.

There are two kinds of date and time objects: “naive” and “aware”.

An aware object has sufficient knowledge of applicable algorithmic and political time adjustments, such as time zone and daylight saving time information, to locate itself relative to other aware objects. An aware object is used to represent a specific moment in time that is not open to interpretation [1].

A naive object does not contain enough information to unambiguously locate itself relative to other date/time objects. Whether a naive object represents Coordinated Universal Time (UTC), local time, or time in some other timezone is purely up to the program, just like it is up to the program whether a particular number represents metres, miles, or mass. Naive objects are easy to understand and to work with, at the cost of ignoring some aspects of reality.

For applications requiring aware objects, `datetime` and `time` objects have an optional time zone information attribute, `tzinfo`, that can be set to an instance of a subclass of the abstract `tzinfo` class. These `tzinfo` objects capture information about the offset from UTC time, the time zone name, and whether Daylight Saving Time is in effect.
Note that only one concrete tzinfo class, the timezone class, is supplied by the datetime module. The timezone class can represent simple timezones with fixed offset from UTC, such as UTC itself or North American EST and EDT timezones. Supporting timezones at deeper levels of detail is up to the application. The rules for time adjustment across the world are more political than rational, change frequently, and there is no standard suitable for every application aside from UTC.

The datetime module exports the following constants:

datetime.MINYEAR

The smallest year number allowed in a date or datetime object. MINYEAR is 1.

datetime.MAXYEAR

The largest year number allowed in a date or datetime object. MAXYEAR is 9999.

See also:

Module calendar

General calendar related functions.

Module time

Time access and conversions.
8.1.1. Available Types

```
class datetime.date
    An idealized naive date, assuming the current Gregorian calendar always was, and always will be, in effect. Attributes: year, month, and day.

class datetime.time
    An idealized time, independent of any particular day, assuming that every day has exactly 24*60*60 seconds (there is no notion of “leap seconds” here). Attributes: hour, minute, second, microsecond, and tzinfo.

class datetime.datetime
    A combination of a date and a time. Attributes: year, month, day, hour, minute, second, microsecond, and tzinfo.

class datetime.timedelta
    A duration expressing the difference between two date, time, or datetime instances to microsecond resolution.

class datetime.tzinfo
    An abstract base class for time zone information objects. These are used by the datetime and time classes to provide a customizable notion of time adjustment (for example, to account for time zone and/or daylight saving time).

class datetime.timezone
    A class that implements the tzinfo abstract base class as a fixed offset from the UTC.
```
New in version 3.2.

Objects of these types are immutable.

Objects of the `date` type are always naive.

An object of type `time` or `datetime` may be naive or aware. A `datetime` object \( d \) is aware if \( d.tzinfo \) is not `None` and \( d.tzinfo.utcoffset(d) \) does not return `None`. If \( d.tzinfo \) is `None`, or if \( d.tzinfo \) is not `None` but \( d.tzinfo.utcoffset(d) \) returns `None`, \( d \) is naive. A `time` object \( t \) is aware if \( t.tzinfo \) is not `None` and \( t.tzinfo.utcoffset(None) \) does not return `None`. Otherwise, \( t \) is naive.

The distinction between naive and aware doesn't apply to `timedelta` objects.

Subclass relationships:
8.1.2. `timedelta` Objects

A `timedelta` object represents a duration, the difference between two dates or times.

```
class datetime.timedelta(days=0, seconds=0, microseconds=0, milliseconds=0, minutes=0, hours=0, weeks=0)
```

All arguments are optional and default to 0. Arguments may be integers or floats, and may be positive or negative.

Only `days`, `seconds` and `microseconds` are stored internally. Arguments are converted to those units:

- A millisecond is converted to 1000 microseconds.
- A minute is converted to 60 seconds.
- An hour is converted to 3600 seconds.
- A week is converted to 7 days.

and days, seconds and microseconds are then normalized so that the representation is unique, with

- $0 \leq \text{microseconds} < 1000000$
- $0 \leq \text{seconds} < 3600*24$ (the number of seconds in one day)
- $-999999999 \leq \text{days} \leq 999999999$

If any argument is a float and there are fractional microseconds, the fractional microseconds left over from all arguments are combined and their sum is rounded to the nearest microsecond. If no argument is a float, the conversion and normalization processes are exact (no information is lost).

If the normalized value of days lies outside the indicated range,
OverflowError is raised.

Note that normalization of negative values may be surprising at first. For example,

```python
>>> from datetime import timedelta
>>> d = timedelta(microseconds=-1)
>>> (d.days, d.seconds, d.microseconds)
(-1, 86399, 999999)
```

Class attributes are:

- **timedelta.min**
  - The most negative timedelta object, `timedelta(-999999999)`.

- **timedelta.max**
  - The most positive timedelta object, `timedelta(days=999999999, hours=23, minutes=59, seconds=59, microseconds=999999)`.

- **timedelta.resolution**
  - The smallest possible difference between non-equal timedelta objects, `timedelta(microseconds=1)`.

Note that, because of normalization, `timedelta.max > -timedelta.min`. `-timedelta.max` is not representable as a timedelta object.

Instance attributes (read-only):

<table>
<thead>
<tr>

<tr>
<td></td>
<td>The remainder is computed as a</td>
</tr>
</tbody>
</table>
\[ t1 = t2 \% t3 \]

**timedelta object.** (3)

\[ q, r = \text{divmod}(t1, t2) \]

Computes the quotient and the remainder: \( q = \frac{t1}{t2} \) (3) and \( r = t1 \% t2 \). \( q \) is an integer and \( r \) is a **timedelta** object.

**+t1**

Returns a **timedelta** object with the same value. (2)

**-t1**

equivalent to **timedelta**(-\( t1.\text{days} \), -\( t1.\text{seconds} \), -\( t1.\text{microseconds} \)), and to \( t1 \times -1 \). (1)(4)

**abs(t)**

equivalent to +\( t \) when \( t.\text{days} \) >= 0, and to -\( t \) when \( t.\text{days} \) < 0. (2)

**str(t)**

Returns a string in the form \[ D \text{ day[s]}, ]H:MM:SS [.UUUUUU], \] where \( D \) is negative for negative \( t \). (5)

**repr(t)**

Returns a string in the form \[ \text{datetime.timedelta}(D[, S[, U]]) \], where \( D \) is negative for negative \( t \). (5)

**Notes:**

1. This is exact, but may overflow.
2. This is exact, and cannot overflow.
3. Division by 0 raises **ZeroDivisionError**.
4. **-timedelta.max** is not representable as a **timedelta** object.
5. String representations of **timedelta** objects are normalized similarly to their internal representation. This leads to somewhat
unusual results for negative timedeltas. For example:

```python
>>> timedelta(hours=-5)
datetime.timedelta(-1, 68400)
>>> print(_)
-1 day, 19:00:00
```

In addition to the operations listed above `timedelta` objects support certain additions and subtractions with `date` and `datetime` objects (see below).

*Changed in version 3.2:* Floor division and true division of a `timedelta` object by another `timedelta` object are now supported, as are remainder operations and the `divmod()` function. True division and multiplication of a `timedelta` object by a `float` object are now supported.

Comparisons of `timedelta` objects are supported with the `timedelta` object representing the smaller duration considered to be the smaller timedelta. In order to stop mixed-type comparisons from falling back to the default comparison by object address, when a `timedelta` object is compared to an object of a different type, `TypeError` is raised unless the comparison is `==` or `!=`. The latter cases return `False` or `True`, respectively.

`timedelta` objects are `hashable` (usable as dictionary keys), support efficient pickling, and in Boolean contexts, a `timedelta` object is considered to be true if and only if it isn’t equal to `timedelta(0).

Instance methods:

`timedelta.total_seconds()`

Return the total number of seconds contained in the duration.
Equivalent to td / timedelta(seconds=1).

Note that for very large time intervals (greater than 270 years on most platforms) this method will lose microsecond accuracy.

New in version 3.2.

Example usage:

```python
>>> from datetime import timedelta
>>> year = timedelta(days=365)
>>> another_year = timedelta(weeks=40, days=84, hours=... minutes=50, seconds=600)
>>> year.total_seconds()
31536000.0
>>> year == another_year
True
>>> ten_years = 10 * year
>>> ten_years, ten_years.days // 365  
(datetime.timedelta(3650), 10)
>>> nine_years = ten_years - year
>>> nine_years, nine_years.days // 365 
(datetime.timedelta(3285), 9)
>>> three_years = nine_years // 3;
>>> three_years, three_years.days // 365 
(datetime.timedelta(1095), 3)
>>> abs(three_years - ten_years) == 2 * three_years
True
```
8.1.3. **date** Objects

A **date** object represents a date (year, month and day) in an idealized calendar, the current Gregorian calendar indefinitely extended in both directions. January 1 of year 1 is called day number 1, January 2 of year 1 is called day number 2, and so on. This matches the definition of the “proleptic Gregorian” calendar in Dershowitz and Reingold’s book Calendrical Calculations, where it’s the base calendar for all computations. See the book for algorithms for converting between proleptic Gregorian ordinals and many other calendar systems.

```python
class datetime.date(year, month, day)
```

All arguments are required. Arguments may be integers, in the following ranges:

- `MINYEAR <= year <= MAXYEAR`
- `1 <= month <= 12`
- `1 <= day <= number of days in the given month and year`

If an argument outside those ranges is given, **ValueError** is raised.

Other constructors, all class methods:

```python
classmethod date.today()
```

Return the current local date. This is equivalent to `date.fromtimestamp(time.time())`.

```python
classmethod date.fromtimestamp(timestamp)
```

Return the local date corresponding to the POSIX timestamp, such as is returned by `time.time()`. This may raise
OverflowError, if the timestamp is out of the range of values supported by the platform C localtime() function, and OSError on localtime() failure. It's common for this to be restricted to years from 1970 through 2038. Note that on non-POSIX systems that include leap seconds in their notion of a timestamp, leap seconds are ignored by fromtimestamp().

Changed in version 3.3: Raise OverflowError instead of ValueError if the timestamp is out of the range of values supported by the platform C localtime() function. Raise OSError instead of ValueError on localtime() failure.

classmethod date.fromordinal(ordinal)

Return the date corresponding to the proleptic Gregorian ordinal, where January 1 of year 1 has ordinal 1. ValueError is raised unless 1 <= ordinal <= date.max.toordinal(). For any date \( d \), \( \text{date.fromordinal(d.toordinal()) == d} \).

Class attributes:

date.min

The earliest representable date, date(MINYEAR, 1, 1).

date.max

The latest representable date, date(MAXYEAR, 12, 31).

date.resolution

The smallest possible difference between non-equal date objects, timedelta(days=1).

Instance attributes (read-only):

date.year
Between **MINYEAR** and **MAXYEAR** inclusive.

**date.month**

Between 1 and 12 inclusive.

**date.day**

Between 1 and the number of days in the given month of the given year.

Supported operations:

<table>
<thead>
<tr>
<th>Operation</th>
<th>Result</th>
</tr>
</thead>
<tbody>
<tr>
<td>date2 = date1 + timedelta</td>
<td><em>date2</em> is <em>timedelta.days</em> days removed from <em>date1</em>. (1)</td>
</tr>
<tr>
<td>date2 = date1 - timedelta</td>
<td>Computes <em>date2</em> such that <em>date2</em> + <em>timedelta</em> == <em>date1</em>. (2)</td>
</tr>
<tr>
<td>timedelta = date1 - date2</td>
<td>(3)</td>
</tr>
<tr>
<td>date1 &lt; date2</td>
<td><em>date1</em> is considered less than <em>date2</em> when <em>date1</em> precedes <em>date2</em> in time. (4)</td>
</tr>
</tbody>
</table>

Notes:

1. *date2* is moved forward in time if *timedelta.days* > 0, or backward if *timedelta.days* < 0. Afterward *date2 - date1* == *timedelta.days*. *timedelta.seconds* and *timedelta.microseconds* are ignored. **OverflowError** is raised if *date2.year* would be smaller than **MINYEAR** or larger than **MAXYEAR**.

2. This isn’t quite equivalent to *date1 + (-timedelta)*, because *timedelta* in isolation can overflow in cases where *date1 - timedelta* does not. *timedelta.seconds* and
3. This is exact, and cannot overflow. timedelta.seconds and timedelta.microseconds are 0, and date2 + timedelta == date1 after.

4. In other words, date1 < date2 if and only if date1.toordinal() < date2.toordinal(). In order to stop comparison from falling back to the default scheme of comparing object addresses, date comparison normally raises TypeError if the other comparand isn't also a date object. However, NotImplemented is returned instead if the other comparand has a timetuple() attribute. This hook gives other kinds of date objects a chance at implementing mixed-type comparison. If not, when a date object is compared to an object of a different type, TypeError is raised unless the comparison is == or !=. The latter cases return False or True, respectively.

Dates can be used as dictionary keys. In Boolean contexts, all date objects are considered to be true.

Instance methods:

date.replace(year, month, day)

Return a date with the same value, except for those parameters given new values by whichever keyword arguments are specified. For example, if d == date(2002, 12, 31), then d.replace(day=26) == date(2002, 12, 26).

date.timetuple()

Return a time.struct_time such as returned by time.localtime(). The hours, minutes and seconds are 0, and the DST flag is -1. d.timetuple() is equivalent to time.struct_time((d.year, d.month, d.day, 0, 0,
0, d.weekday(), yday, -1)), where yday =

d.toordinal() - date(d.year, 1, 1).toordinal() +

1 is the day number within the current year starting with 1 for January 1st.

date.toordinal()

Return the proleptic Gregorian ordinal of the date, where January 1
of year 1 has ordinal 1. For any date object d,
date.fromordinal(d.toordinal()) == d.

date.weekday()

Return the day of the week as an integer, where Monday is 0 and
Sunday is 6. For example, date(2002, 12, 4).weekday() == 2, a Wednesday. See also isoweekday().

date.isoweekday()

Return the day of the week as an integer, where Monday is 1 and
Sunday is 7. For example, date(2002, 12, 4).isoweekday() == 3, a Wednesday. See also weekday(),
isocalendar().

date.isocalendar()

Return a 3-tuple, (ISO year, ISO week number, ISO weekday).

The ISO calendar is a widely used variant of the Gregorian
calendar. See http://www.phys.uu.nl/~vgent/calendar/isocalendar.htm for a good explanation.

The ISO year consists of 52 or 53 full weeks, and where a week
starts on a Monday and ends on a Sunday. The first week of an
ISO year is the first (Gregorian) calendar week of a year containing
a Thursday. This is called week number 1, and the ISO year of that Thursday is the same as its Gregorian year.

For example, 2004 begins on a Thursday, so the first week of ISO year 2004 begins on Monday, 29 Dec 2003 and ends on Sunday, 4 Jan 2004, so that `date(2003, 12, 29).isocalendar() == (2004, 1, 1)` and `date(2004, 1, 4).isocalendar() == (2004, 1, 7)`.

**date.isoformat()**

Return a string representing the date in ISO 8601 format, ‘YYYY-MM-DD’. For example, `date(2002, 12, 4).isoformat() == '2002-12-04'`.

**date.__str__()**

For a date `d`, `str(d)` is equivalent to `d.isoformat()`.

**date.ctime()**

Return a string representing the date, for example `date(2002, 12, 4).ctime() == 'Wed Dec 4 00:00:00 2002'`. `d.ctime()` is equivalent to `time.ctime(time.mktime(d.timetuple()))` on platforms where the native C `ctime()` function (which `time.ctime()` invokes, but which `date.ctime()` does not invoke) conforms to the C standard.

**date.strftime(format)**

Return a string representing the date, controlled by an explicit format string. Format codes referring to hours, minutes or seconds will see 0 values. For a complete list of formatting directives, see `strftime() and strptime() Behavior.`
date.__format__(format)

Same as date.strftime(). This makes it possible to specify format string for a date object when using str.format(). For a complete list of formatting directives, see strftime() and strptime()

Behavior

Example of counting days to an event:

```python
>>> import time
>>> from datetime import date
>>> today = date.today()
>>> today
datetime.date(2007, 12, 5)
>>> today == date.fromtimestamp(time.time())
True
>>> my_birthday = date(today.year, 6, 24)
>>> if my_birthday < today:
...   my_birthday = my_birthday.replace(year=today.year)
>>> my_birthday
datetime.date(2008, 6, 24)
>>> time_to_birthday = abs(my_birthday - today)
>>> time_to_birthday.days
202
```

Example of working with date:

```python
>>> from datetime import date
>>> d = date.fromordinal(730920)  # 730920th day after 1.1.0001
>>> d
datetime.date(2002, 3, 11)
>>> t = d.timetuple()
>>> for i in t:
...   print(i)
2002  # year
3  # month
```
11     # day
0
0
0
0
0     # weekday (0 = Monday)
70     # 70th day in the year
-1

>>> ic = d.isocalendar()
>>> for i in ic:
...     print(i)
2002    # ISO year
11    # ISO week number
1     # ISO day number (1 = Monday)

>>> d.isoformat()
'2002-03-11'
>>> d.strftime("%d/%m/%y")
'11/03/02'
>>> d.strftime("%A %d. %B %Y")
'Monday 11. March 2002'
>>> 'The {1} is {0:%d}, the {2} is {0:%B}'.format(d, 1, 2)
'The day is 11, the month is March.'
8.1.4. **datetime** Objects

A **datetime** object is a single object containing all the information from a **date** object and a **time** object. Like a **date** object, **datetime** assumes the current Gregorian calendar extended in both directions; like a time object, **datetime** assumes there are exactly 3600*24 seconds in every day.

Constructor:

```python
class datetime.datetime(year, month, day, hour=0, minute=0, second=0, microsecond=0, tzinfo=None)
```

The year, month and day arguments are required. **tzinfo** may be None, or an instance of a **tzinfo** subclass. The remaining arguments may be integers, in the following ranges:

- \( \text{MINYEAR} \leq \text{year} \leq \text{MAXYEAR} \)
- \( 1 \leq \text{month} \leq 12 \)
- \( 1 \leq \text{day} \leq \text{number of days in the given month and year} \)
- \( 0 \leq \text{hour} < 24 \)
- \( 0 \leq \text{minute} < 60 \)
- \( 0 \leq \text{second} < 60 \)
- \( 0 \leq \text{microsecond} < 1000000 \)

If an argument outside those ranges is given, **ValueError** is raised.

Other constructors, all class methods:

```python
classmethod datetime.today()
```

Return the current local datetime, with **tzinfo** None. This is
equivalent to \texttt{datetime.fromtimestamp(time.time())}. See also \texttt{now()}, \texttt{fromtimestamp()}.

classmethod \texttt{datetime.now(tz=None)}

Return the current local date and time. If optional argument \texttt{tz} is None or not specified, this is like \texttt{today()}, but, if possible, supplies more precision than can be gotten from going through a \texttt{time.time()} timestamp (for example, this may be possible on platforms supplying the C \texttt{gettimeofday()} function).

Else \texttt{tz} must be an instance of a class \texttt{tzinfo} subclass, and the current date and time are converted to \texttt{tz}'s time zone. In this case the result is equivalent to \texttt{tz.fromutc(datetime.utcnow().replace(tzinfo=tz))}.

See also \texttt{today()}, \texttt{utcnow()}.

classmethod \texttt{datetime.utcnow()}

Return the current UTC date and time, with \texttt{tzinfo} None. This is like \texttt{now()}, but returns the current UTC date and time, as a naive \texttt{datetime} object. An aware current UTC datetime can be obtained by calling \texttt{datetime.now(timezone.utc)}. See also \texttt{now()}.

classmethod \texttt{datetime.fromtimestamp(timestamp, tz=None)}

Return the local date and time corresponding to the POSIX timestamp, such as is returned by \texttt{time.time()}. If optional argument \texttt{tz} is None or not specified, the timestamp is converted to the platform's local date and time, and the returned \texttt{datetime} object is naive.

Else \texttt{tz} must be an instance of a class \texttt{tzinfo} subclass, and the
timestamp is converted to tz's time zone. In this case the result is equivalent to
tz.fromutc(datetime.utcfromtimestamp(timestamp).replace(tzinfo=tz))

fromtimestamp() may raise OverflowError, if the timestamp is out of the range of values supported by the platform C localtime() or gmtime() functions, and OSError on localtime() or gmtime() failure. It's common for this to be restricted to years in 1970 through 2038. Note that on non-POSIX systems that include leap seconds in their notion of a timestamp, leap seconds are ignored by fromtimestamp(), and then it's possible to have two timestamps differing by a second that yield identical datetime objects. See also utcfromtimestamp().

Changed in version 3.3: Raise OverflowError instead of ValueError if the timestamp is out of the range of values supported by the platform C localtime() or gmtime() functions. Raise OSError instead of ValueError on localtime() or gmtime() failure.

classmethod datetime.utcfromtimestamp(timestamp)
Return the UTC datetime corresponding to the POSIX timestamp, with tzinfo None. This may raise OverflowError, if the timestamp is out of the range of values supported by the platform C gmtime() function, and OSError on gmtime() failure. It's common for this to be restricted to years in 1970 through 2038. See also fromtimestamp().

On the POSIX compliant platforms, utcfromtimestamp(timestamp) is equivalent to the following expression:
`datetime(1970, 1, 1) + timedelta(seconds=timestamp)`

*Changed in version 3.3:* Raise `OverflowError` instead of `ValueError` if the timestamp is out of the range of values supported by the platform C `gmtime()` function. Raise `OSError` instead of `ValueError` on `gmtime()` failure.

**classmethod `datetime.fromordinal(ordinal)`**

- Return the `datetime` corresponding to the proleptic Gregorian ordinal, where January 1 of year 1 has ordinal 1. `ValueError` is raised unless `1 <= ordinal <= datetime.max.toordinal()`. The hour, minute, second and microsecond of the result are all 0, and `tzinfo` is None.

**classmethod `datetime.combine(date, time)`**

- Return a new `datetime` object whose date components are equal to the given `date` object's, and whose time components and `tzinfo` attributes are equal to the given `time` object's. For any `datetime` object `d`, `d == datetime.combine(d.date(), d.timetz())`. If `date` is a `datetime` object, its time components and `tzinfo` attributes are ignored.

**classmethod `datetime.strptime(date_string, format)`**

- Return a `datetime` corresponding to `date_string`, parsed according to `format`. This is equivalent to `datetime(*time.strptime(date_string, format)[0:6])`. `ValueError` is raised if the `date_string` and `format` can't be parsed by `time.strptime()` or if it returns a value which isn't a time tuple. For a complete list of formatting directives, see `strftime()` and `strptime()` Behavior.
Class attributes:

datetime. **min**
   The earliest representable datetime, datetime(MINYEAR, 1, 1, tzinfo=None).

datetime. **max**
   The latest representable datetime, datetime(MAXYEAR, 12, 31, 23, 59, 59, 999999, tzinfo=None).

datetime. **resolution**
   The smallest possible difference between non-equal datetime objects, timedelta(microseconds=1).

Instance attributes (read-only):

datetime. **year**
   Between MINYEAR and MAXYEAR inclusive.

datetime. **month**
   Between 1 and 12 inclusive.

datetime. **day**
   Between 1 and the number of days in the given month of the given year.

datetime. **hour**
   In range(24).

datetime. **minute**
   In range(60).

datetime. **second**
In `range(60)`.

`datetime.microsecond`

In `range(1000000)`.

`datetime.tzinfo`

The object passed as the `tzinfo` argument to the `datetime` constructor, or None if none was passed.

Supported operations:

<table>
<thead>
<tr>
<th>Operation</th>
<th>Result</th>
</tr>
</thead>
<tbody>
<tr>
<td><code>datetime2 = datetime1 + timedelta</code></td>
<td>(1)</td>
</tr>
<tr>
<td><code>datetime2 = datetime1 - timedelta</code></td>
<td>(2)</td>
</tr>
<tr>
<td><code>timedelta = datetime1 - datetime2</code></td>
<td>(3)</td>
</tr>
<tr>
<td><code>datetime1 &lt; datetime2</code></td>
<td>Compares <code>datetime</code> to <code>datetime</code>. (4)</td>
</tr>
</tbody>
</table>

1. `datetime2` is a duration of timedelta removed from `datetime1`, moving forward in time if `timedelta.days > 0`, or backward if `timedelta.days < 0`. The result has the same `tzinfo` attribute as the input `datetime`, and `datetime2 - datetime1 == timedelta` after. `OverflowError` is raised if `datetime2.year` would be smaller than `MINYEAR` or larger than `MAXYEAR`. Note that no time zone adjustments are done even if the input is an aware object.

2. Computes the `datetime2` such that `datetime2 + timedelta == datetime1`. As for addition, the result has the same `tzinfo`
attribute as the input datetime, and no time zone adjustments are done even if the input is aware. This isn't quite equivalent to \( \text{datetime1} + (-\text{timedelta}) \), because \(-\text{timedelta}\) in isolation can overflow in cases where \( \text{datetime1} - \text{timedelta} \) does not.

3. Subtraction of a `datetime` from a `datetime` is defined only if both operands are naive, or if both are aware. If one is aware and the other is naive, `TypeError` is raised.

If both are naive, or both are aware and have the same `tzinfo` attribute, the `tzinfo` attributes are ignored, and the result is a `timedelta` object \( t \) such that \( \text{datetime2} + t = \text{datetime1} \). No time zone adjustments are done in this case.

If both are aware and have different `tzinfo` attributes, \( a - b \) acts as if \( a \) and \( b \) were first converted to naive UTC datetimes first. The result is \( (a.\text{replace}(\text{tzinfo}=\text{None}) - a.\text{utcoffset}()) - (b.\text{replace}(\text{tzinfo}=\text{None}) - b.\text{utcoffset}()) \) except that the implementation never overflows.

4. `datetime1` is considered less than `datetime2` when `datetime1` precedes `datetime2` in time.

If one comparand is naive and the other is aware, `TypeError` is raised if an order comparison is attempted. For equality comparisons, naive instances are never equal to aware instances.

If both comparands are aware, and have the same `tzinfo` attribute, the common `tzinfo` attribute is ignored and the base datetimes are compared. If both comparands are aware and have different `tzinfo` attributes, the comparands are first adjusted by
subtracting their UTC offsets (obtained from `self.utcoffset()`).

*Changed in version 3.3:* Equality comparisons between naive and aware `datetime` instances don’t raise `TypeError`.

**Note:** In order to stop comparison from falling back to the default scheme of comparing object addresses, `datetime` comparison normally raises `TypeError` if the other comparand isn’t also a `datetime` object. However, `NotImplemented` is returned instead if the other comparand has a `timetuple()` attribute. This hook gives other kinds of date objects a chance at implementing mixed-type comparison. If not, when a `datetime` object is compared to an object of a different type, `TypeError` is raised unless the comparison is `==` or `!`=. The latter cases return `False` or `True`, respectively.

`datetime` objects can be used as dictionary keys. In Boolean contexts, all `datetime` objects are considered to be true.

Instance methods:

`datetime.date()`

Return `date` object with same year, month and day.

`datetime.time()`

Return `time` object with same hour, minute, second and microsecond. `tzinfo` is None. See also method `timetz()`.

`datetime.timetz()`

Return `time` object with same hour, minute, second, microsecond, and `tzinfo` attributes. See also method `time()`.
datetime.replace(year[, month[, day[, hour[, minute[, second[, microsecond[, tzinfo]]]]]]])

Return a datetime with the same attributes, except for those attributes given new values by whichever keyword arguments are specified. Note that tzinfo=None can be specified to create a naive datetime from an aware datetime with no conversion of date and time data.

datetime.astimezone(tz=None)

Return a datetime object with new tzinfo attribute tz, adjusting the date and time data so the result is the same UTC time as self, but in tz's local time.

If provided, tz must be an instance of a tzinfo subclass, and its utcoffset() and dst() methods must not return None. self must be aware (self.tzinfo must not be None, and self.utcoffset() must not return None).

If called without arguments (or with tz=None) the system local timezone is assumed. The tzinfo attribute of the converted datetime instance will be set to an instance of timezone with the zone name and offset obtained from the OS.

If self.tzinfo is tz, self.astimezone(tz) is equal to self: no adjustment of date or time data is performed. Else the result is local time in time zone tz, representing the same UTC time as self: after astz = dt.astimezone(tz), astz - astz.utcoffset() will usually have the same date and time data as dt - dt.utcoffset(). The discussion of class tzinfo explains the cases at Daylight Saving Time transition
boundaries where this cannot be achieved (an issue only if tz models both standard and daylight time).

If you merely want to attach a time zone object tz to a datetime dt without adjustment of date and time data, use dt.replace(tzinfo=tz). If you merely want to remove the time zone object from an aware datetime dt without conversion of date and time data, use dt.replace(tzinfo=None).

Note that the default tzinfo.fromutc() method can be overridden in a tzinfo subclass to affect the result returned by astimezone(). Ignoring error cases, astimezone() acts like:

```python
def astimezone(self, tz):
    if self.tzinfo is tz:
        return self
    utc = (self - self.utcoffset()).replace(tzinfo)
    return tz.fromutc(utc)
```

*Changed in version 3.3*: tz now can be omitted.

**datetime.utcoffset()**

If tzinfo is None, returns None, else returns self.tzinfo.utcoffset(self), and raises an exception if the latter doesn't return None, or a timedelta object representing a whole number of minutes with magnitude less than one day.

**datetime.dst()**

If tzinfo is None, returns None, else returns
self.tzinfo.dst(self), and raises an exception if the latter doesn't return None, or a *timedelta* object representing a whole number of minutes with magnitude less than one day.

**datetime.tzname()**

If tzinfo is None, returns None, else returns self.tzinfo.tzname(self), raises an exception if the latter doesn't return None or a string object,

**datetime.timetuple()**

Return a *time.struct_time* such as returned by *time.localtime()*.

d.timetuple() is equivalent to

time.struct_time((d.year, d.month, d.day, d.hour, d.minute, d.second, d.weekday(), yday, dst)), where

\[
yday = d.toordinal() - date(d.year, 1, 1).toordinal() + 1
\]

is the day number within the current year starting with 1 for January 1st. The tm_isdst flag of the result is set according to the dst() method: tzinfo is None or dst() returns None, tm_isdst is set to -1; else if dst() returns a non-zero value, tm_isdst is set to 1; else tm_isdst is set to 0.

**datetime.utctimetuple()**

If *datetime* instance d is naive, this is the same as d.timetuple() except that tm_isdst is forced to 0 regardless of what d.dst() returns. DST is never in effect for a UTC time.

If d is aware, d is normalized to UTC time, by subtracting d.utcoffset(), and a *time.struct_time* for the normalized time is returned. tm_isdst is forced to 0. Note that an *OverflowError* may be raised if d.year was MINYEAR or MAXYEAR and UTC adjustment spills over a year boundary.
datetime.\texttt{toordinal()} 

Return the proleptic Gregorian ordinal of the date. The same as \texttt{self.date().toordinal()}. 

datetime.\texttt{timestamp()} 

Return POSIX timestamp corresponding to the \texttt{datetime} instance. The return value is a \texttt{float} similar to that returned by \texttt{time.time()}. 

Naive \texttt{datetime} instances are assumed to represent local time and this method relies on the platform C \texttt{mktime()} function to perform the conversion. Since \texttt{datetime} supports wider range of values than \texttt{mktime()} on many platforms, this method may raise \texttt{OverflowError} for times far in the past or far in the future. 

For aware \texttt{datetime} instances, the return value is computed as: 

\begin{verbatim}
(dt - datetime(1970, 1, 1, tzinfo=timezone.utc)).total_seconds()
\end{verbatim}

\textit{New in version 3.3.}

\textbf{Note:} There is no method to obtain the POSIX timestamp directly from a naive \texttt{datetime} instance representing UTC time. If your application uses this convention and your system timezone is not set to UTC, you can obtain the POSIX timestamp by supplying \texttt{tzinfo=timezone.utc}:

\begin{verbatim}
timestamp = dt.replace(tzinfo=timezone.utc).timestamp()
\end{verbatim}

or by calculating the timestamp directly:

\begin{verbatim}
timestamp = (dt - datetime(1970, 1, 1)) / timedelta
\end{verbatim}
datetime. **weekday()**

Return the day of the week as an integer, where Monday is 0 and Sunday is 6. The same as `self.date().weekday()`. See also `isoweekday()`.

datetime. **isoweekday()**

Return the day of the week as an integer, where Monday is 1 and Sunday is 7. The same as `self.date().isoweekday()`. See also `weekday()`, `isocalendar()`.

datetime. **isocalendar()**

Return a 3-tuple, (ISO year, ISO week number, ISO weekday). The same as `self.date().isocalendar()`.

datetime. **isoformat**(sep='T')

Return a string representing the date and time in ISO 8601 format, `YYYY-MM-DDTHH:MM:SS.mmmmmm` or, if `microsecond` is 0, `YYYY-MM-DDTHH:MM:SS`

If `utcoffset()` does not return None, a 6-character string is appended, giving the UTC offset in (signed) hours and minutes: `YYYY-MM-DDTHH:MM:SS.mmmmmm+HH:MM` or, if `microsecond` is 0 `YYYY-MM-DDTHH:MM:SS+HH:MM`

The optional argument `sep` (default `'T'`) is a one-character separator, placed between the date and time portions of the result. For example,

```python
>>> from datetime import tzinfo, timedelta, datetime
>>> class TZ(tzinfo):
```
... def utcoffset(self, dt): return timedelta
...

>>> datetime(2002, 12, 25, tzinfo=TZ()).isoformat
'2002-12-25 00:00:00-06:39'

datetime.__str__()
For a datetime instance d, str(d) is equivalent to d.isoformat(' ').

datetime.ctime()  
Return a string representing the date and time, for example
datetime(2002, 12, 4, 20, 30, 40).ctime() == 'Wed Dec 4 20:30:40 2002'. d.ctime() is equivalent to
time.ctime(time.mktime(d.timetuple())) on platforms
where the native C ctime() function (which time.ctime() invokes, but which datetime.ctime() does not invoke)
conforms to the C standard.

datetime.strftime(format)
Return a string representing the date and time, controlled by an
explicit format string. For a complete list of formatting directives,
see strftime() and strptime() Behavior.

datetime.__format__(format)
Same as datetime.strftime(). This makes it possible to
specify format string for a datetime object when using
str.format(). For a complete list of formatting directives, see
strftime() and strptime() Behavior.

Examples of working with datetime objects:

>>> from datetime import datetime, date, time
>>> # Using datetime.combine()
>>> d = date(2005, 7, 14)
>>> t = time(12, 30)
>>> datetime.combine(d, t)
datetime.datetime(2005, 7, 14, 12, 30)

>>> # Using datetime.now() or datetime.utcnow()
>>> datetime.now()
datetime.datetime(2007, 12, 6, 16, 29, 43, 79043)
>>> datetime.utcnow()
datetime.datetime(2007, 12, 6, 15, 29, 43, 79060)

>>> # Using datetime.strptime()
>>> dt = datetime.strptime("21/11/06 16:30", "%d/%m/%y %H:%M")
>>> dt
datetime.datetime(2006, 11, 21, 16, 30)

>>> # Using datetime.timetuple() to get tuple of all attributes
>>> tt = dt.timetuple()

>>> for it in tt:
...    print(it)
...
2006  # year
11   # month
21   # day
16   # hour
30   # minute
0    # second
1    # weekday (0 = Monday)
325  # number of days since 1st January
-1   # dst - method tzinfo.dst() returned None

>>> # Date in ISO format
>>> ic = dt.isocalendar()

>>> for it in ic:
...    print(it)
...
2006  # ISO year
47   # ISO week
2    # ISO weekday

>>> # Formatting datetime
Using datetime with tzinfo:

```python
>>> from datetime import timedelta, datetime, tzinfo

>>> class GMT1(tzinfo):
...     def utcoffset(self, dt):
...         return timedelta(hours=1) + self.dst(dt)
...     def dst(self, dt):
...         # DST starts last Sunday in March
...         d = datetime(dt.year, 4, 1)  # ends last Sun in October
...         self.dston = d - timedelta(days=d.weekday())
...         d = datetime(dt.year, 11, 1)
...         self.dstoff = d - timedelta(days=d.weekday())
...         if self.dston <= dt.replace(tzinfo=None):
...             return timedelta(hours=1)
...         else:
...             return timedelta(0)

>>> class GMT2(tzinfo):
...     def utcoffset(self, dt):
...         return timedelta(hours=2) + self.dst(dt)
...     def dst(self, dt):
...         d = datetime(dt.year, 4, 1)
...         self.dston = d - timedelta(days=d.weekday())
...         d = datetime(dt.year, 11, 1)
...         self.dstoff = d - timedelta(days=d.weekday())
...         if self.dston <= dt.replace(tzinfo=None):
...             return timedelta(hours=1)
...         else:
...             return timedelta(0)
```
def tzname(self, dt):
    return "GMT +2"

>>> gmt1 = GMT1()
>>> # Daylight Saving Time
>>> dt1 = datetime(2006, 11, 21, 16, 30, tzinfo=gmt1)
>>> dt1.dst()
datetime.timedelta(0)
>>> dt1.utcoffset()
datetime.timedelta(0, 3600)
>>> dt2 = datetime(2006, 6, 14, 13, 0, tzinfo=gmt1)
>>> dt2.dst()
datetime.timedelta(0, 3600)
>>> dt2.utcoffset()
datetime.timedelta(0, 7200)
>>> # Convert datetime to another time zone
>>> dt3 = dt2.astimezone(GMT2())
>>> dt3
datetime.datetime(2006, 6, 14, 14, 0, tzinfo=<GMT2 object at 0x...>)
>>> dt2
datetime.datetime(2006, 6, 14, 13, 0, tzinfo=<GMT1 object at 0x...>)
>>> dt2.utctimetuple() == dt3.utctimetuple()
True
8.1.5. **time** Objects

A time object represents a (local) time of day, independent of any particular day, and subject to adjustment via a `tzinfo` object.

```python
class datetime.time(hour=0, minute=0, second=0, microsecond=0, tzinfo=None)
```

All arguments are optional. `tzinfo` may be `None`, or an instance of a `tzinfo` subclass. The remaining arguments may be integers, in the following ranges:

- 0 <= hour < 24
- 0 <= minute < 60
- 0 <= second < 60
- 0 <= microsecond < 1000000.

If an argument outside those ranges is given, `ValueError` is raised. All default to 0 except `tzinfo`, which defaults to `None`.

Class attributes:

**time.min**

The earliest representable `time`, `time(0, 0, 0, 0)`.

**time.max**

The latest representable `time`, `time(23, 59, 59, 999999)`.

**time.resolution**

The smallest possible difference between non-equal `time` objects, `timedelta(microseconds=1)`, although note that arithmetic on `time` objects is not supported.
Instance attributes (read-only):

```python
time.hour
    In range(24).
```

```python
time.minute
    In range(60).
```

```python
time.second
    In range(60).
```

```python
time.microsecond
    In range(1000000).
```

```python
time.tzinfo
    The object passed as the tzinfo argument to the time constructor, or None if none was passed.
```

Supported operations:

- comparison of `time` to `time`, where `a` is considered less than `b` when `a` precedes `b` in time. If one comparand is naive and the other is aware, `TypeError` is raised if an order comparison is attempted. For equality comparisons, naive instances are never equal to aware instances.

  If both comparands are aware, and have the same `tzinfo` attribute, the common `tzinfo` attribute is ignored and the base times are compared. If both comparands are aware and have different `tzinfo` attributes, the comparands are first adjusted by subtracting their UTC offsets (obtained from `self.utcoffset()`). In order to stop mixed-type comparisons from falling back to the default comparison by object address,
when a \texttt{time} object is compared to an object of a different type, \texttt{TypeError} is raised unless the comparison is \texttt{==} or \texttt{!=}. The latter cases return \texttt{False} or \texttt{True}, respectively.

\textit{Changed in version 3.3}: Equality comparisons between naive and aware \texttt{time} instances don't raise \texttt{TypeError}.

- hash, use as dict key
- efficient pickling

- in Boolean contexts, a \texttt{time} object is considered to be true if and only if, after converting it to minutes and subtracting utcoffset() (or 0 if that's None), the result is non-zero.

Instance methods:

\texttt{time.replace([\texttt{hour[, minute[, second[, microsecond[, tzinfo]]]]]])}

Return a \texttt{time} with the same value, except for those attributes given new values by whichever keyword arguments are specified. Note that \texttt{tzinfo=None} can be specified to create a naive \texttt{time} from an aware \texttt{time}, without conversion of the time data.

\texttt{time.isoformat()}

Return a string representing the time in ISO 8601 format, HH:MM:SS.mmmmmm or, if self.microsecond is 0, HH:MM:SS If \texttt{utcoffset()} does not return None, a 6-character string is appended, giving the UTC offset in (signed) hours and minutes: HH:MM:SS.mmmmmm+HH:MM or, if self.microsecond is 0, HH:MM:SS+HH:MM

\texttt{time.__str__()}

For a time \( t \), \texttt{str}(t) is equivalent to \texttt{t.isoformat()}. 
time.**strftime**(format)

Return a string representing the time, controlled by an explicit format string. For a complete list of formatting directives, see `strftime()` and `strptime()` Behavior.

time.**__format__**(format)

Same as `time.strftime()`. This makes it possible to specify format string for a `time` object when using `str.format()`. For a complete list of formatting directives, see `strftime()` and `strptime()` Behavior.

time.**utcoffset**()

If `tzinfo` is `None`, returns `None`, else returns `self.tzinfo.utcoffset(None)`, and raises an exception if the latter doesn't return `None` or a `timedelta` object representing a whole number of minutes with magnitude less than one day.

time.**dst**()

If `tzinfo` is `None`, returns `None`, else returns `self.tzinfo.dst(None)`, and raises an exception if the latter doesn't return `None`, or a `timedelta` object representing a whole number of minutes with magnitude less than one day.

time.**tzname**()

If `tzinfo` is `None`, returns `None`, else returns `self.tzinfo.tzname(None)`, or raises an exception if the latter doesn't return `None` or a string object.

Example:

```python
>>> from datetime import time, tzinfo
class GMT1(tzinfo):
```
def utcoffset(self, dt):
    return timedelta(hours=1)

def dst(self, dt):
    return timedelta(0)

def tzname(self, dt):
    return "Europe/Prague"

>>> t = time(12, 10, 30, tzinfo=GMT1())
>>> t
datetime.time(12, 10, 30, tzinfo=<GMT1 object at 0x...
>>> gmt = GMT1()
>>> t.isoformat()
'12:10:30+01:00'
>>> t.dst()
datetime.timedelta(0)
>>> t.tzname()
'Europe/Prague'
>>> t.strftime("%H:%M:%S %Z")
'12:10:30 Europe/Prague'
>>> 'The {} is {:%H:%M}'.format("time", t)
'The time is 12:10.'
8.1.6. **tzinfo** Objects

**tzinfo** is an abstract base class, meaning that this class should not be instantiated directly. You need to derive a concrete subclass, and (at least) supply implementations of the standard **tzinfo** methods needed by the **datetime** methods you use. The **datetime** module supplies a simple concrete subclass of **tzinfo timezone** which can represent timezones with fixed offset from UTC such as UTC itself or North American EST and EDT.

An instance of (a concrete subclass of) **tzinfo** can be passed to the constructors for **datetime** and **time** objects. The latter objects view their attributes as being in local time, and the **tzinfo** object supports methods revealing offset of local time from UTC, the name of the timezone, and DST offset, all relative to a date or time object passed to them.

Special requirement for pickling: A **tzinfo** subclass must have an **__init__()** method that can be called with no arguments, else it can be pickled but possibly not unpickled again. This is a technical requirement that may be relaxed in the future.

A concrete subclass of **tzinfo** may need to implement the following methods. Exactly which methods are needed depends on the uses made of aware **datetime** objects. If in doubt, simply implement all of them.

**tzinfo. utcoffset**(dt)

Return offset of local time from UTC, in minutes east of UTC. If local time is west of UTC, this should be negative. Note that this is intended to be the total offset from UTC; for example, if a **tzinfo**
object represents both time zone and DST adjustments, \texttt{utcoffset()} should return their sum. If the UTC offset isn't known, return None. Else the value returned must be a \texttt{timedelta} object specifying a whole number of minutes in the range -1439 to 1439 inclusive (1440 = 24*60; the magnitude of the offset must be less than one day). Most implementations of \texttt{utcoffset()} will probably look like one of these two:

\begin{verbatim}
return CONSTANT  # fixed-offset class
return CONSTANT + self.dst(dt)  # daylight-aware
\end{verbatim}

If \texttt{utcoffset()} does not return None, \texttt{dst()} should not return None either.

The default implementation of \texttt{utcoffset()} raises \texttt{NotImplementedError}.

\texttt{tzinfo.dst}(\texttt{dt})

Return the daylight saving time (DST) adjustment, in minutes east of UTC, or None if DST information isn’t known. Return \texttt{timedelta(0)} if DST is not in effect. If DST is in effect, return the offset as a \texttt{timedelta} object (see \texttt{utcoffset()} for details). Note that DST offset, if applicable, has already been added to the UTC offset returned by \texttt{utcoffset()}, so there’s no need to consult \texttt{dst()} unless you’re interested in obtaining DST info separately. For example, \texttt{datetime.timetuple()} calls its \texttt{tzinfo} attribute’s \texttt{dst()} method to determine how the \texttt{tm_isdst} flag should be set, and \texttt{tzinfo.fromutc()} calls \texttt{dst()} to account for DST changes when crossing time zones.

An instance \texttt{tz} of a \texttt{tzinfo} subclass that models both standard
and daylight times must be consistent in this sense:

```
tz.utcoffset(dt) - tz.dst(dt)
```

must return the same result for every `datetime dt` with `dt.tzinfo == tz` For sane `tzinfo` subclasses, this expression yields the time zone’s “standard offset”, which should not depend on the date or the time, but only on geographic location. The implementation of `datetime.astimezone()` relies on this, but cannot detect violations; it’s the programmer’s responsibility to ensure it. If a `tzinfo` subclass cannot guarantee this, it may be able to override the default implementation of `tzinfo.fromutc()` to work correctly with `astimezone()` regardless.

Most implementations of `dst()` will probably look like one of these two:

```python
def dst(self, dt):
    # a fixed-offset class: doesn't account for DST
    return timedelta(0)
```

or

```python
def dst(self, dt):
    # Code to set dston and dstoff to the time zone's DST transition times based on the input dt.year and in standard local time. Then
    if dston <= dt.replace(tzinfo=None) < dstoff:
        return timedelta(hours=1)
    else:
        return timedelta(0)
```
The default implementation of \texttt{dst()} raises \texttt{NotImplementedError}.

\texttt{tzinfo.tzname(dt)}

Return the time zone name corresponding to the \texttt{datetime} object \texttt{dt}, as a string. Nothing about string names is defined by the \texttt{datetime} module, and there's no requirement that it mean anything in particular. For example, “GMT”, “UTC”, “-500”, “-5:00”, “EDT”, “US/Eastern”, “America/New York” are all valid replies. Return \texttt{None} if a string name isn't known. Note that this is a method rather than a fixed string primarily because some \texttt{tzinfo} subclasses will wish to return different names depending on the specific value of \texttt{dt} passed, especially if the \texttt{tzinfo} class is accounting for daylight time.

The default implementation of \texttt{tzname()} raises \texttt{NotImplementedError}.

These methods are called by a \texttt{datetime} or \texttt{time} object, in response to their methods of the same names. A \texttt{datetime} object passes itself as the argument, and a \texttt{time} object passes \texttt{None} as the argument. A \texttt{tzinfo} subclass's methods should therefore be prepared to accept a \texttt{dt} argument of \texttt{None}, or of class \texttt{datetime}.

When \texttt{None} is passed, it's up to the class designer to decide the best response. For example, returning \texttt{None} is appropriate if the class wishes to say that time objects don't participate in the \texttt{tzinfo} protocols. It may be more useful for \texttt{utcoffset(None)} to return the standard UTC offset, as there is no other convention for discovering the standard offset.

When a \texttt{datetime} object is passed in response to a \texttt{datetime}
method, `dt.tzinfo` is the same object as `self`. `tzinfo` methods can rely on this, unless user code calls `tzinfo` methods directly. The intent is that the `tzinfo` methods interpret `dt` as being in local time, and not need worry about objects in other timezones.

There is one more `tzinfo` method that a subclass may wish to override:

`tzinfo.fromutc(dt)`

This is called from the default `datetime.astimezone()` implementation. When called from that, `dt.tzinfo` is `self`, and `dt`'s date and time data are to be viewed as expressing a UTC time. The purpose of `fromutc()` is to adjust the date and time data, returning an equivalent datetime in `self`'s local time.

Most `tzinfo` subclasses should be able to inherit the default `fromutc()` implementation without problems. It’s strong enough to handle fixed-offset time zones, and time zones accounting for both standard and daylight time, and the latter even if the DST transition times differ in different years. An example of a time zone the default `fromutc()` implementation may not handle correctly in all cases is one where the standard offset (from UTC) depends on the specific date and time passed, which can happen for political reasons. The default implementations of `astimezone()` and `fromutc()` may not produce the result you want if the result is one of the hours straddling the moment the standard offset changes.

Skipping code for error cases, the default `fromutc()` implementation acts like:

```python
def fromutc(self, dt):
```
# raise ValueError error if dt.tzinfo is not None
dtoff = dt.utcoffset()
dtdst = dt.dst()
# raise ValueError if dtoff is None or dtdst is None
delta = dtoff - dtdst  # this is self's standard offset
if delta:
    if delta:
        # convert to standard local time
        dt off = dt.utcoffset()
dtdst = dt.dst()
        # raise ValueError if dtdst is None
        if dtdst:
            return dt + dtdst
        else:
            return dt

Example tzinfo classes:

from datetime import tzinfo, timedelta, datetime

ZERO = timedelta(0)

HOUR = timedelta(hours=1)

# A UTC class.

class UTC(tzinfo):
    """UTC"""

    def utcoffset(self, dt):
        return ZERO

    def tzname(self, dt):
        return "UTC"

    def dst(self, dt):
        return ZERO

utc = UTC()
# A class building tzinfo objects for fixed-offset time zones.
# Note that FixedOffset(0, "UTC") is a different way to build a UTC tzinfo object.

class FixedOffset(tzinfo):
    """Fixed offset in minutes east from UTC."""
    def __init__(self, offset, name):
        self.__offset = timedelta(minutes=offset)
        self.__name = name

    def utcoffset(self, dt):
        return self.__offset

    def tzname(self, dt):
        return self.__name

    def dst(self, dt):
        return ZERO

# A class capturing the platform's idea of local time.

import time as _time

STDOFFSET = timedelta(seconds = -_time.timezone)
if _time.daylight:
    DSTOFFSET = timedelta(seconds = -_time.altzone)
else:
    DSTOFFSET = STDOFFSET

DSTDIFF = DSTOFFSET - STDOFFSET

class LocalTimezone(tzinfo):
    def utcoffset(self, dt):
        if self._isdst(dt):
def dst(self, dt):
    if self._isdst(dt):
        return DSTDIFF
    else:
        return ZERO

def tzname(self, dt):
    return _time.tzname[self._isdst(dt)]

def _isdst(self, dt):
    tt = (dt.year, dt.month, dt.day,
          dt.hour, dt.minute, dt.second,
          dt.weekday(), 0, 0)
    stamp = _time.mktime(tt)
    tt = _time.localtime(stamp)
    return tt.tm_isdst > 0

Local = LocalTimezone()

# A complete implementation of current DST rules for

def first_sunday_on_or_after(dt):
    days_to_go = 6 - dt.weekday()
    if days_to_go:
        dt += timedelta(days_to_go)
    return dt

# US DST Rules
