```python
distutils.core.run_setup(script_name[, script_args=None, stop_after='run'])
```

Run a setup script in a somewhat controlled environment, and return the distutils.dist.Distribution instance that drives things. This is useful if you need to find out the distribution metadata (passed as keyword args from `script` to `setup()`), or the contents of the config files or command-line.

`script_name` is a file that will be read and run with `exec()`. `sys.argv[0]` will be replaced with `script` for the duration of the
call. *script_args* is a list of strings; if supplied, `sys.argv[1:]` will be replaced by *script_args* for the duration of the call.

*stop_after* tells *setup()* when to stop processing; possible values:

<table>
<thead>
<tr>
<th>value</th>
<th>description</th>
</tr>
</thead>
<tbody>
<tr>
<td><em>init</em></td>
<td>Stop after the <em>Distribution</em> instance has been created and populated with the keyword arguments to <em>setup()</em></td>
</tr>
<tr>
<td><em>config</em></td>
<td>Stop after config files have been parsed (and their data stored in the <em>Distribution</em> instance)</td>
</tr>
<tr>
<td><em>commandline</em></td>
<td>Stop after the command-line (<code>sys.argv[1:]</code> or <em>script_args</em>) have been parsed (and the data stored in the <em>Distribution</em> instance.)</td>
</tr>
<tr>
<td><em>run</em></td>
<td>Stop after all commands have been run (the same as if <em>setup()</em> had been called in the usual way). This is the default value.</td>
</tr>
</tbody>
</table>

In addition, the *distutils.core* module exposed a number of classes that live elsewhere.

- Extension from *distutils.extension*
- Command from *distutils.cmd*
- Distribution from *distutils.dist*

A short description of each of these follows, but see the relevant module for the full reference.

**class distutils.core.Extension**

The Extension class describes a single C or C++extension module in a setup script. It accepts the following keyword arguments in its constructor:
<table>
<thead>
<tr>
<th>argument name</th>
<th>value</th>
<th>type</th>
</tr>
</thead>
<tbody>
<tr>
<td>name</td>
<td>the full name of the extension, including any packages — i.e. <em>not</em> a filename or pathname, but Python dotted name</td>
<td>a string</td>
</tr>
<tr>
<td>sources</td>
<td>list of source filenames, relative to the distribution root (where the setup script lives), in Unix form (slash-separated) for portability. Source files may be C, C++, SWIG (.i), platform-specific resource files, or whatever else is recognized by the <code>build_ext</code> command as source for a Python extension.</td>
<td>a list of strings</td>
</tr>
<tr>
<td>include_dirs</td>
<td>list of directories to search for C/C++ header files (in Unix form for portability)</td>
<td>a list of strings</td>
</tr>
<tr>
<td>define_macros</td>
<td>list of macros to define; each macro is defined using a 2-tuple <code>(name, value)</code>, where <code>value</code> is either the string to define it to or None to define it without a particular value (equivalent of <code>#define FOO</code> in C/C++)</td>
<td>a list of tuples</td>
</tr>
<tr>
<td><strong>source or -DFOO on Unix C compiler command line</strong></td>
<td></td>
<td></td>
</tr>
<tr>
<td>---</td>
<td></td>
<td></td>
</tr>
<tr>
<td><strong>undefined_macros</strong></td>
<td>list of macros to undefine explicitly</td>
<td>a list of strings</td>
</tr>
<tr>
<td><strong>library_dirs</strong></td>
<td>list of directories to search for C/C++ libraries at link time</td>
<td>a list of strings</td>
</tr>
<tr>
<td><strong>libraries</strong></td>
<td>list of library names (not filenames or paths) to link against</td>
<td>a list of strings</td>
</tr>
<tr>
<td><strong>runtime_library_dirs</strong></td>
<td>list of directories to search for C/C++ libraries at run time (for shared extensions, this is when the extension is loaded)</td>
<td>a list of strings</td>
</tr>
<tr>
<td><strong>extra_objects</strong></td>
<td>list of extra files to link with (eg. object files not implied by ‘sources’, static library that must be explicitly specified, binary resource files, etc.)</td>
<td>a list of strings</td>
</tr>
<tr>
<td><strong>extra_compile_args</strong></td>
<td>any extra platform- and compiler-specific information to use when compiling the source files in ‘sources’. For platforms and compilers where a command line makes sense, this is typically a list of command-line</td>
<td>a list of strings</td>
</tr>
<tr>
<td><strong>extra_link_args</strong></td>
<td>arguments, but for other platforms it could be anything.</td>
<td>any extra platform- and compiler-specific information to use when linking object files together to create the extension (or to create a new static Python interpreter). Similar interpretation as for ‘extra_compile_args’.</td>
</tr>
<tr>
<td><strong>export_symbols</strong></td>
<td>list of symbols to be exported from a shared extension. Not used on all platforms, and not generally necessary for Python extensions, which typically export exactly one symbol: init + extension_name.</td>
<td>list of symbols to be exported from a shared extension. Not used on all platforms, and not generally necessary for Python extensions, which typically export exactly one symbol: init + extension_name.</td>
</tr>
<tr>
<td><strong>depends</strong></td>
<td>list of files that the extension depends on</td>
<td>list of files that the extension depends on</td>
</tr>
<tr>
<td><strong>language</strong></td>
<td>extension language (i.e. 'c', 'c++', 'objc'). Will be detected from the source extensions if not provided.</td>
<td>extension language (i.e. 'c', 'c++', 'objc'). Will be detected from the source extensions if not provided.</td>
</tr>
<tr>
<td><strong>optional</strong></td>
<td>specifies that a build failure in the extension should not abort the build process, but</td>
<td>specifies that a build failure in the extension should not abort the build process, but</td>
</tr>
</tbody>
</table>
A `Distribution` describes how to build, install and package up a Python software package.

See the `setup()` function for a list of keyword arguments accepted by the Distribution constructor. `setup()` creates a `Distribution` instance.

A `Command` class (or rather, an instance of one of its subclasses) implement a single distutils command.
10.2. **distutils.ccompiler** — CCompiler base class

This module provides the abstract base class for the CCompiler classes. A CCompiler instance can be used for all the compile and link steps needed to build a single project. Methods are provided to set options for the compiler — macro definitions, include directories, link path, libraries and the like.

This module provides the following functions.

```
import distutils.ccompiler

generate_options = distutils.ccompiler.

distutils.ccompiler.

distutils.ccompiler.

distutils.ccompiler.
```

```
gen_lib_options(compiler,

Generate linker options for searching library directories and linking with specific libraries. libraries and library_dirs are, respectively, lists of library names (not filenames!) and search directories. Returns a list of command-line options suitable for use with some compiler (depending on the two format strings passed in).

```

gen_preprocess_options(macros,

Generate C pre-processor options (-D, -U, -I) as used by at least two types of compilers: the typical Unix compiler and Visual C++. macros is the usual thing, a list of 1- or 2-tuples, where (name,) means undefine (-U) macro name, and (name, value) means define (-D) macro name to value. include_dirs is just a list of directory names to be added to the header file search path (-I). Returns a list of command-line options suitable for either Unix compilers or Visual C++.

```

get_default_compiler(osname,
```
Determine the default compiler to use for the given platform.

*osname* should be one of the standard Python OS names (i.e. the ones returned by `os.name`) and *platform* the common value returned by `sys.platform` for the platform in question.

The default values are `os.name` and `sys.platform` in case the parameters are not given.

```python
distutils.ccompiler.new_compiler(plat=None, compiler=None, verbose=0, dry_run=0, force=0)
```

Factory function to generate an instance of some CCompiler subclass for the supplied platform/compiler combination. *plat* defaults to `os.name` (eg. `'posix'`, `'nt'`), and *compiler* defaults to the default compiler for that platform. Currently only `'posix'` and `'nt'` are supported, and the default compilers are “traditional Unix interface” (UnixCCompiler class) and Visual C++ (MSVCCompiler class). Note that it’s perfectly possible to ask for a Unix compiler object under Windows, and a Microsoft compiler object under Unix—if you supply a value for *compiler*, *plat* is ignored.

```python
distutils.ccompiler.show_compilers()
```

Print list of available compilers (used by the *--help-compiler* options to `build`, `build_ext`, `build_clib`).

```python
class distutils.ccompiler.CCompiler([verbose=0, dry_run=0, force=0])
```

The abstract base class `CCompiler` defines the interface that must be implemented by real compiler classes. The class also has some utility methods used by several compiler classes.
The basic idea behind a compiler abstraction class is that each instance can be used for all the compile/link steps in building a single project. Thus, attributes common to all of those compile and link steps — include directories, macros to define, libraries to link against, etc. — are attributes of the compiler instance. To allow for variability in how individual files are treated, most of those attributes may be varied on a per-compilation or per-link basis.

The constructor for each subclass creates an instance of the Compiler object. Flags are `verbose` (show verbose output), `dry_run` (don’t actually execute the steps) and `force` (rebuild everything, regardless of dependencies). All of these flags default to 0 (off). Note that you probably don’t want to instantiate `CCompiler` or one of its subclasses directly - use the `distutils.CCompiler.new_compiler()` factory function instead.

The following methods allow you to manually alter compiler options for the instance of the Compiler class.

**add_include_dir(dir)**

Add `dir` to the list of directories that will be searched for header files. The compiler is instructed to search directories in the order in which they are supplied by successive calls to `add_include_dir()`.

**set_include_dirs(dirs)**

Set the list of directories that will be searched to `dirs` (a list of strings). Overrides any preceding calls to `add_include_dir()`; subsequent calls to `add_include_dir()` add to the list passed to `set_include_dirs()`. This does not affect any list of
standard include directories that the compiler may search by default.

**add_library**(libname)
Add libname to the list of libraries that will be included in all links driven by this compiler object. Note that libname should *not* be the name of a file containing a library, but the name of the library itself: the actual filename will be inferred by the linker, the compiler, or the compiler class (depending on the platform).

The linker will be instructed to link against libraries in the order they were supplied to add_library() and/or set_libraries(). It is perfectly valid to duplicate library names; the linker will be instructed to link against libraries as many times as they are mentioned.

**set_libraries**(libnames)
Set the list of libraries to be included in all links driven by this compiler object to libnames (a list of strings). This does not affect any standard system libraries that the linker may include by default.

**add_library_dir**(dir)
Add dir to the list of directories that will be searched for libraries specified to add_library() and set_libraries(). The linker will be instructed to search for libraries in the order they are supplied to add_library_dir() and/or set_library_dirs().

**set_library_dirs**(dirs)
Set the list of library search directories to dirs (a list of strings). This does not affect any standard library search path that the
linker may search by default.

**add_runtime_library_dir(dir)**
Add *dir* to the list of directories that will be searched for shared libraries at runtime.

**set_runtime_library_dirs(dirs)**
Set the list of directories to search for shared libraries at runtime to *dirs* (a list of strings). This does not affect any standard search path that the runtime linker may search by default.

**define_macro(name[, value=None])**
Define a preprocessor macro for all compilations driven by this compiler object. The optional parameter *value* should be a string; if it is not supplied, then the macro will be defined without an explicit value and the exact outcome depends on the compiler used.

**undefine_macro(name)**
Undefine a preprocessor macro for all compilations driven by this compiler object. If the same macro is defined by **define_macro()** and undefined by **undefine_macro()** the last call takes precedence (including multiple redefinitions or undefinitions). If the macro is redefined/undefined on a per-compilation basis (ie. in the call to **compile()**), then that takes precedence.

**add_link_object(object)**
Add *object* to the list of object files (or analogues, such as explicitly named library files or the output of “resource compilers”) to be included in every link driven by this compiler
set_link_objects(objects)
Set the list of object files (or analogues) to be included in every link to objects. This does not affect any standard object files that the linker may include by default (such as system libraries).

The following methods implement methods for autodetection of compiler options, providing some functionality similar to GNU autoconf.

detect_language(sources)
Detect the language of a given file, or list of files. Uses the instance attributes language_map (a dictionary), and language_order (a list) to do the job.

find_library_file(dirs, lib, debug=0)
Search the specified list of directories for a static or shared library file lib and return the full path to that file. If debug is true, look for a debugging version (if that makes sense on the current platform). Return None if lib wasn’t found in any of the specified directories.

has_function(funcname, includes=None, include_dirs=None, libraries=None, library_dirs=None)
Return a boolean indicating whether funcname is supported on the current platform. The optional arguments can be used to augment the compilation environment by providing additional include files and paths and libraries and paths.

library_dir_option(dir)
Return the compiler option to add dir to the list of directories
searched for libraries.

**library_option**(lib)

Return the compiler option to add *dir* to the list of libraries linked into the shared library or executable.

**runtime_library_dir_option**(dir)

Return the compiler option to add *dir* to the list of directories searched for runtime libraries.

**set_executables**(**args**)

Define the executables (and options for them) that will be run to perform the various stages of compilation. The exact set of executables that may be specified here depends on the compiler class (via the ‘executables’ class attribute), but most will have:

<table>
<thead>
<tr>
<th>attribute</th>
<th>description</th>
</tr>
</thead>
<tbody>
<tr>
<td>compiler</td>
<td>the C/C++ compiler</td>
</tr>
<tr>
<td>linker_so</td>
<td>linker used to create shared objects and libraries</td>
</tr>
<tr>
<td>linker_exe</td>
<td>linker used to create binary executables</td>
</tr>
<tr>
<td>archiver</td>
<td>static library creator</td>
</tr>
</tbody>
</table>

On platforms with a command-line (Unix, DOS/Windows), each of these is a string that will be split into executable name and (optional) list of arguments. (Splitting the string is done similarly to how Unix shells operate: words are delimited by spaces, but quotes and backslashes can override this. See `distutils.util.split_quoted()`.)

The following methods invoke stages in the build process.
`compile([sources[, output_dir=None, macros=None, include_dirs=None, debug=0, extra_preargs=None, extra_postargs=None, depends=None]])`

Compile one or more source files. Generates object files (e.g. transforms a `.c` file to a `.o` file.)

`sources` must be a list of filenames, most likely C/C++ files, but in reality anything that can be handled by a particular compiler and compiler class (eg. MSVCCompiler can handle resource files in `sources`). Return a list of object filenames, one per source filename in `sources`. Depending on the implementation, not all source files will necessarily be compiled, but all corresponding object filenames will be returned.

If `output_dir` is given, object files will be put under it, while retaining their original path component. That is, `foo/bar.c` normally compiles to `foo/bar.o` (for a Unix implementation); if `output_dir` is `build`, then it would compile to `build/foo/bar.o`.

`macros`, if given, must be a list of macro definitions. A macro definition is either a `(name, value)` 2-tuple or a `(name,)` 1-tuple. The former defines a macro; if the value is `None`, the macro is defined without an explicit value. The 1-tuple case undefines a macro. Later definitions/redefinitions/undefinitions take precedence.

`include_dirs`, if given, must be a list of strings, the directories to add to the default include file search path for this compilation only.

`debug` is a boolean; if true, the compiler will be instructed to
output debug symbols in (or alongside) the object file(s).

extra_preargs and extra_postargs are implementation-dependent. On platforms that have the notion of a command-line (e.g. Unix, DOS/Windows), they are most likely lists of strings: extra command-line arguments to prepend/append to the compiler command line. On other platforms, consult the implementation class documentation. In any event, they are intended as an escape hatch for those occasions when the abstract compiler framework doesn’t cut the mustard.

depends, if given, is a list of filenames that all targets depend on. If a source file is older than any file in depends, then the source file will be recompiled. This supports dependency tracking, but only at a coarse granularity.

Raises CompileError on failure.

create_static_lib(objects, output_libname[, output_dir=None, debug=0, target_lang=None])

Link a bunch of stuff together to create a static library file. The “bunch of stuff” consists of the list of object files supplied as objects, the extra object files supplied to add_link_object() and/or set_link_objects(), the libraries supplied to add_library() and/or set_libraries(), and the libraries supplied as libraries (if any).

output_libname should be a library name, not a filename; the filename will be inferred from the library name. output_dir is the directory where the library file will be put.

deploy is a boolean; if true, debugging information will be included in the library (note that on most platforms, it is the
compile step where this matters: the debug flag is included here just for consistency).

target_lang is the target language for which the given objects are being compiled. This allows specific linkage time treatment of certain languages.

Raises LibError on failure.

\texttt{link}(target_desc, objects, output_filename[, output_dir=None, libraries=None, library_dirs=None, runtime_library_dirs=None, export_symbols=None, debug=0, extra_preargs=None, extra_postargs=None, build_temp=None, target_lang=None])

Link a bunch of stuff together to create an executable or shared library file.

The “bunch of stuff” consists of the list of object files supplied as objects. output_filename should be a filename. If output_dir is supplied, output_filename is relative to it (i.e. output_filename can provide directory components if needed).

libraries is a list of libraries to link against. These are library names, not filenames, since they’re translated into filenames in a platform-specific way (eg. foo becomes \texttt{libfoo.a} on Unix and \texttt{foo.lib} on DOS/Windows). However, they can include a directory component, which means the linker will look in that specific directory rather than searching all the normal locations.

library_dirs, if supplied, should be a list of directories to search for libraries that were specified as bare library names (ie. no directory component). These are on top of the system default and those supplied to \texttt{add_library_dir()} and/or \texttt{set_library_dirs()}. runtime_library_dirs is a list of
directories that will be embedded into the shared library and used to search for other shared libraries that *it* depends on at run-time. (This may only be relevant on Unix.)

export_symbols is a list of symbols that the shared library will export. (This appears to be relevant only on Windows.)

dec2 is as for compile() and create_static_lib(), with the slight distinction that it actually matters on most platforms (as opposed to create_static_lib(), which includes a debug flag mostly for form's sake).

extra_preargs and extra_postargs are as for compile() (except of course that they supply command-line arguments for the particular linker being used).

target_lang is the target language for which the given objects are being compiled. This allows specific linkage time treatment of certain languages.

Raises LinkError on failure.

link_executable(objects, output_prog_name[, output_dir=None, libraries=None, library_dirs=None, runtime_library_dirs=None, debug=0, extra_preargs=None, extra_postargs=None, target_lang=None])

Link an executable. output_prog_name is the name of the file executable, while objects are a list of object filenames to link in. Other arguments are as for the link() method.

link_shared_lib(objects, output_lib_name[, output_dir=None, libraries=None, library_dirs=None, runtime_library_dirs=None, export_symbols=None, debug=0,
Link a shared library. `output_libname` is the name of the output library, while `objects` is a list of object filenames to link in. Other arguments are as for the `link()` method.

```python
link_shared_object(objects, output_filename[, output_dir=None, libraries=None, library_dirs=None, runtime_library_dirs=None, export_symbols=None, debug=0, extra_preargs=None, extra_postargs=None, build_temp=None, target_lang=None])
```

Link a shared object. `output_filename` is the name of the shared object that will be created, while `objects` is a list of object filenames to link in. Other arguments are as for the `link()` method.

```python
preprocess(source[, output_file=None, macros=None, include_dirs=None, extra_preargs=None, extra_postargs=None])
```

Preprocess a single C/C++ source file, named in `source`. Output will be written to file named `output_file`, or `stdout` if `output_file` not supplied. `macros` is a list of macro definitions as for `compile()`, which will augment the macros set with `define_macro()` and `undefine_macro()`. `include_dirs` is a list of directory names that will be added to the default list, in the same way as `add_include_dir()`.

Raises `PreprocessError` on failure.

The following utility methods are defined by the `CCompiler` class, for use by the various concrete subclasses.
**executable_filename** *(basename[, strip_dir=0, output_dir=’’]*)

Returns the filename of the executable for the given `basename`. Typically for non-Windows platforms this is the same as the basename, while Windows will get a `.exe` added.

**library_filename** *(libname[, lib_type=’static’, strip_dir=0, output_dir=’’]*)

Returns the filename for the given library name on the current platform. On Unix a library with `lib_type` of `'static'` will typically be of the form `liblibname.a`, while a `lib_type` of `'dynamic'` will be of the form `liblibname.so`.

**object_filenames** *(source_filenames[, strip_dir=0, output_dir=’’]*)

Returns the name of the object files for the given source files. `source_filenames` should be a list of filenames.

**shared_object_filename** *(basename[, strip_dir=0, output_dir=’’]*)

Returns the name of a shared object file for the given file name `basename`.

**execute** *(func, args[, msg=None, level=1]*)

Invokes `distutils.util.execute()` . This method invokes a Python function `func` with the given arguments `args`, after logging and taking into account the `dry_run` flag.

**spawn** *(cmd)*

Invokes `distutils.util.spawn()` . This invokes an
external process to run the given command.

**mkpath**(name[, mode=511])

Invokes distutils.dir_util.mkpath(). This creates a directory and any missing ancestor directories.

**move_file**(src, dst)

Invokes distutils.file_util.move_file(). Renames src to dst.

**announce**(msg[, level=1])

Write a message using distutils.log.debug().

**warn**(msg)

Write a warning message msg to standard error.

**debug_print**(msg)

If the debug flag is set on this CCompiler instance, print msg to standard output, otherwise do nothing.
10.3. `distutils.unixccompiler` — Unix C Compiler

This module provides the UnixCCompiler class, a subclass of CCompiler that handles the typical Unix-style command-line C compiler:

- macros defined with `-Dname[=value]`
- macros undefined with `-Uname`
- include search directories specified with `-Idir`
- libraries specified with `-l`<br>  `lib`
- library search directories specified with `-Ldir`
- compile handled by `cc` (or similar) executable with `-c` option: compiles `.c` to `.o`
- link static library handled by `ar` command (possibly with `ranlib`)
- link shared library handled by `cc -shared`
This module provides MSVCCompiler, an implementation of the abstract CCompiler class for Microsoft Visual Studio. Typically, extension modules need to be compiled with the same compiler that was used to compile Python. For Python 2.3 and earlier, the compiler was Visual Studio 6. For Python 2.4 and 2.5, the compiler is Visual Studio .NET 2003. The AMD64 and Itanium binaries are created using the Platform SDK.

MSVCCompiler will normally choose the right compiler, linker etc. on its own. To override this choice, the environment variables \texttt{DISTUTILS\_USE\_SDK} and \texttt{MSSdk} must be both set. \texttt{MSSdk} indicates that the current environment has been setup by the SDK’s \texttt{SetEnv.Cmd} script, or that the environment variables had been registered when the SDK was installed; \texttt{DISTUTILS\_USE\_SDK} indicates that the distutils user has made an explicit choice to override the compiler selection by MSVCCompiler.
10.5. distutils.bcppcompiler — Borland Compiler

This module provides BorlandCCompiler, an subclass of the abstract CCompiler class for the Borland C++ compiler.
10.6. distutils.cygwincompiler — Cygwin Compiler

This module provides the CygwinCCompiler class, a subclass of UnixCCompiler that handles the Cygwin port of the GNU C compiler to Windows. It also contains the Mingw32CCompiler class which handles the mingw32 port of GCC (same as cygwin in no-cygwin mode).
10.7. `distutils.emxccompiler` — OS/2 EMX Compiler

This module provides the EMXCCompiler class, a subclass of UnixCCompiler that handles the EMX port of the GNU C compiler to OS/2.
10.8. **distutils.archive_util** — Archiving utilities

This module provides a few functions for creating archive files, such as tarballs or zipfiles.

```python
distutils.archive_util.make_archive(base_name, format[, root_dir=None, base_dir=None, verbose=0, dry_run=0])
```

Create an archive file (eg. zip or tar). `base_name` is the name of the file to create, minus any format-specific extension; `format` is the archive format: one of zip, tar, ztar, or gztar. `root_dir` is a directory that will be the root directory of the archive; ie. we typically `chdir` into `root_dir` before creating the archive. `base_dir` is the directory where we start archiving from; ie. `base_dir` will be the common prefix of all files and directories in the archive. `root_dir` and `base_dir` both default to the current directory. Returns the name of the archive file.

```python
distutils.archive_util.make_tarball(base_name, base_dir[, compress='gzip', verbose=0, dry_run=0])
```

'Create an (optional compressed) archive as a tar file from all files in and under `base_dir`. `compress` must be 'gzip' (the default), 'compress', 'bzip2', or None. Both `tar` and the compression utility named by `compress` must be on the default program search path, so this is probably Unix-specific. The output tar file will be named `base_dir.tar`, possibly plus the appropriate compression extension (.gz, .bz2 or .Z). Return the output filename.

```python
distutils.archive_util.make_zipfile(base_name, base_dir[, verbose=0, dry_run=0])
```

Create a zipfile from all files in and under `base_dir`. Returns the name of the zipfile.
Create a zip file from all files in and under `base_dir`. The output zip file will be named `base_name + .zip`. Uses either the `zipfile` Python module (if available) or the InfoZIP `zip` utility (if installed and found on the default search path). If neither tool is available, raises `DistutilsExecError`. Returns the name of the output zip file.
10.9. **distutils.dep_util** — Dependency checking

This module provides functions for performing simple, timestamp-based dependency of files and groups of files; also, functions based entirely on such timestamp dependency analysis.

**`distutils.dep_util.newer(source, target)`**

Return true if `source` exists and is more recently modified than `target`, or if `source` exists and `target` doesn't. Return false if both exist and `target` is the same age or newer than `source`. Raise DistutilsFileError if `source` does not exist.

**`distutils.dep_util.newer_pairwise(sources, targets)`**

Walk two filename lists in parallel, testing if each source is newer than its corresponding target. Return a pair of lists (`sources`, `targets`) where source is newer than target, according to the semantics of `newer()`

**`distutils.dep_util.newer_group(sources, target[, missing='error'])`**

Return true if `target` is out-of-date with respect to any file listed in `sources` In other words, if `target` exists and is newer than every file in `sources`, return false; otherwise return true. `missing` controls what we do when a source file is missing; the default ('error') is to blow up with an OSErr from inside `os.stat()`; if it is 'ignore', we silently drop any missing source files; if it is 'newer', any missing source files make us assume that `target` is out-of-date (this is handy in “dry-run” mode: it’ll make you pretend to carry out commands that wouldn’t work because inputs are
missing, but that doesn't matter because you're not actually going to run the commands).
10.10. `distutils.dir_util` — Directory tree operations

This module provides functions for operating on directories and trees of directories.

```python
distutils.dir_util.mkpath(name[, mode=0o777, verbose=0, dry_run=0])
```

Create a directory and any missing ancestor directories. If the directory already exists (or if `name` is the empty string, which means the current directory, which of course exists), then do nothing. Raise DistutilsFileError if unable to create some directory along the way (eg. some sub-path exists, but is a file rather than a directory). If `verbose` is true, print a one-line summary of each mkdir to stdout. Return the list of directories actually created.

```python
distutils.dir_util.create_tree(base_dir, files[, mode=0o777, verbose=0, dry_run=0])
```

Create all the empty directories under `base_dir` needed to put `files` there. `base_dir` is just the a name of a directory which doesn’t necessarily exist yet; `files` is a list of filenames to be interpreted relative to `base_dir`. `base_dir` + the directory portion of every file in `files` will be created if it doesn’t already exist. `mode`, `verbose` and `dry_run` flags are as for `mkpath()`.

```python
distutils.dir_util.copy_tree(src, dst[, preserve_mode=1, preserve_times=1, preserve_symlinks=0, update=0, verbose=0, dry_run=0])
```

Copy an entire directory tree `src` to a new location `dst`. Both `src` and
dst must be directory names. If src is not a directory, raise DistutilsFileError. If dst does not exist, it is created with mkpath(). The end result of the copy is that every file in src is copied to dst, and directories under src are recursively copied to dst. Return the list of files that were copied or might have been copied, using their output name. The return value is unaffected by update or dry_run: it is simply the list of all files under src, with the names changed to be under dst.

preserve_mode and preserve_times are the same as for distutils.file_util.copy_file(); note that they only apply to regular files, not to directories. If preserve_symlinks is true, symlinks will be copied as symlinks (on platforms that support them!); otherwise (the default), the destination of the symlink will be copied. update and verbose are the same as for copy_file().

Files in src that begin with .nfs are skipped (more information on these files is available in answer D2 of the NFS FAQ page.

Changed in version 3.3.1: NFS files are ignored.

distutils.dir_util.remove_tree(directory[, verbose=0, dry_run=0])

Recursively remove directory and all files and directories underneath it. Any errors are ignored (apart from being reported to sys.stdout if verbose is true).
10.11. **distutils.file_util** — Single file operations

This module contains some utility functions for operating on individual files.

```python
distutils.file_util.copy_file(src, dst[, preserve_mode=1, preserve_times=1, update=0, link=None, verbose=0, dry_run=0])
```

Copy file `src` to `dst`. If `dst` is a directory, then `src` is copied there with the same name; otherwise, it must be a filename. (If the file exists, it will be ruthlessly clobbered.) If `preserve_mode` is true (the default), the file's mode (type and permission bits, or whatever is analogous on the current platform) is copied. If `preserve_times` is true (the default), the last-modified and last-access times are copied as well. If `update` is true, `src` will only be copied if `dst` does not exist, or if `dst` does exist but is older than `src`.

`link` allows you to make hard links (using `os.link()`) or symbolic links (using `os.symlink()`) instead of copying: set it to `'hard'` or `'sym'`; if it is `None` (the default), files are copied. Don't set `link` on systems that don't support it: `copy_file()` doesn't check if hard or symbolic linking is available. It uses `_copy_file_contents()` to copy file contents.

Return a tuple `(dest_name, copied):` `dest_name` is the actual name of the output file, and `copied` is true if the file was copied (or would have been copied, if `dry_run` true).

```python
distutils.file_util.move_file(src, dst[, verbose, dry_run])
```
Move file src to dst. If dst is a directory, the file will be moved into it with the same name; otherwise, src is just renamed to dst. Returns the new full name of the file.

**Warning:** Handles cross-device moves on Unix using `copy_file()`. What about other systems?

```
distutils.file_util.write_file(filename, contents)
```

Create a file called `filename` and write `contents` (a sequence of strings without line terminators) to it.
10.12. `distutils.util` — Miscellaneous other utility functions

This module contains other assorted bits and pieces that don’t fit into any other utility module.

`distutils.util.get_platform()`

Return a string that identifies the current platform. This is used mainly to distinguish platform-specific build directories and platform-specific built distributions. Typically includes the OS name and version and the architecture (as supplied by ‘os.uname()’), although the exact information included depends on the OS; eg. for IRIX the architecture isn’t particularly important (IRIX only runs on SGI hardware), but for Linux the kernel version isn't particularly important.

Examples of returned values:

- `linux-i586`
- `linux-alpha`
- `solaris-2.6-sun4u`
- `irix-5.3`
- `irix64-6.2`

For non-POSIX platforms, currently just returns `sys.platform`.

For Mac OS X systems the OS version reflects the minimal version on which binaries will run (that is, the value of `MACOSX_DEPLOYMENT_TARGET` during the build of Python), not the OS version of the current system.

For universal binary builds on Mac OS X the architecture value
reflects the universal binary status instead of the architecture of the current processor. For 32-bit universal binaries the architecture is **fat**, for 64-bit universal binaries the architecture is **fat64**, and for 4-way universal binaries the architecture is **universal**. Starting from Python 2.7 and Python 3.2 the architecture **fat3** is used for a 3-way universal build (ppc, i386, x86_64) and **intel** is used for a universal build with the i386 and x86_64 architectures.

Examples of returned values on Mac OS X:

- `macosx-10.3-ppc`
- `macosx-10.3-fat`
- `macosx-10.5-universal`
- `macosx-10.6-intel`

**distutils.util.convert_path(pathname)**

Return ‘pathname’ as a name that will work on the native filesystem, i.e. split it on ‘/’ and put it back together again using the current directory separator. Needed because filenames in the setup script are always supplied in Unix style, and have to be converted to the local convention before we can actually use them in the filesystem. Raises **ValueError** on non-Unix-ish systems if **pathname** either starts or ends with a slash.

**distutils.util.change_root(new_root, pathname)**

Return **pathname** with **new_root** prepended. If **pathname** is relative, this is equivalent to `os.path.join(new_root, pathname)` Otherwise, it requires making **pathname** relative and then joining the two, which is tricky on DOS/Windows.

**distutils.util.check_environ()**
Ensure that ‘os.environ’ has all the environment variables we guarantee that users can use in config files, command-line options, etc. Currently this includes:

- HOME - user's home directory (Unix only)
- PLAT - description of the current platform, including hardware and OS (see \texttt{get_platform()})

\texttt{distutils.util.subst\_vars(s, local\_vars)}

Perform shell/Perl-style variable substitution on \(s\). Every occurrence of \$ followed by a name is considered a variable, and variable is substituted by the value found in the \(\text{local\_vars}\) dictionary, or in \texttt{os.environ} if it's not in \(\text{local\_vars}\). \texttt{os.environ} is first checked/augmented to guarantee that it contains certain values: see \texttt{check\_environ()}. Raise \texttt{ValueError} for any variables not found in either \(\text{local\_vars}\) or \texttt{os.environ}.

Note that this is not a fully-fledged string interpolation function. A valid \$\text{variable} can consist only of upper and lower case letters, numbers and an underscore. No \{\} or ( ) style quoting is available.

\texttt{distutils.util.grok\_environment\_error(exc[, prefix='error: '])}

Generate a useful error message from an \texttt{OSError} exception object. Handles Python 1.5.1 and later styles, and does what it can to deal with exception objects that don't have a filename (which happens when the error is due to a two-file operation, such as \texttt{rename()} or \texttt{link()}). Returns the error message as a string prefixed with \texttt{prefix}.

\texttt{distutils.util.split\_quoted(s)}

Split a string up according to Unix shell-like rules for quotes and
backslashes. In short: words are delimited by spaces, as long as those spaces are not escaped by a backslash, or inside a quoted string. Single and double quotes are equivalent, and the quote characters can be backslash-escaped. The backslash is stripped from any two-character escape sequence, leaving only the escaped character. The quote characters are stripped from any quoted string. Returns a list of words.

distutils.util.execute(func, args[, msg=None, verbose=0, dry_run=0])
Perform some action that affects the outside world (for instance, writing to the filesystem). Such actions are special because they are disabled by the dry_run flag. This method takes care of all that bureaucracy for you; all you have to do is supply the function to call and an argument tuple for it (to embody the “external action” being performed), and an optional message to print.

distutils.util.strtobool(val)
Convert a string representation of truth to true (1) or false (0).

True values are y, yes, t, true, on and 1; false values are n, no, f, false, off and 0. Raises ValueError if val is anything else.

distutils.util.byte_compile(py_files[, optimize=0, force=0, prefix=None, base_dir=None, verbose=1, dry_run=0, direct=None])
Byte-compile a collection of Python source files to either .pyc or .pyo files in a __pycache__ subdirectory (see PEP 3147). py_files is a list of files to compile; any files that don’t end in .py are silently skipped. optimize must be one of the following:

- 0 - don’t optimize (generate .pyc)
• 1 - normal optimization (like python -O)
• 2 - extra optimization (like python -OO)

If force is true, all files are recompiled regardless of timestamps.

The source filename encoded in each bytecode file defaults to the filenames listed in py_files; you can modify these with prefix and basedir. prefix is a string that will be stripped off of each source filename, and base_dir is a directory name that will be prepended (after prefix is stripped). You can supply either or both (or neither) of prefix and base_dir, as you wish.

If dry_run is true, doesn’t actually do anything that would affect the filesystem.

Byte-compile is either done directly in this interpreter process with the standard py_compile module, or indirectly by writing a temporary script and executing it. Normally, you should let byte_compile() figure out to use direct compilation or not (see the source for details). The direct flag is used by the script generated in indirect mode; unless you know what you’re doing, leave it set to None.

Changed in version 3.2.3: Create .pyc or .pyo files with an import magic tag in their name, in a __pycache__ subdirectory instead of files without tag in the current directory.

distutils.util.rfc822_escape(header)

Return a version of header escaped for inclusion in an RFC 822 header, by ensuring there are 8 spaces space after each newline. Note that it does no other modification of the string.
10.13. distutils.dist — The Distribution class

This module provides the Distribution class, which represents the module distribution being built/installed/distributed.
10.14. *distutils.extension* — The Extension class

This module provides the Extension class, used to describe C/C++ extension modules in setup scripts.
10.15. `distutils.debug` — Distutils debug mode

This module provides the DEBUG flag.
10.16. distutils.errors — Distutils exceptions

Provides exceptions used by the Distutils modules. Note that Distutils modules may raise standard exceptions; in particular, SystemExit is usually raised for errors that are obviously the end-user’s fault (eg. bad command-line arguments).

This module is safe to use in from ... import * mode; it only exports symbols whose names start with Distutils and end with Error.
10.17. **distutils.fancy_getopt** —
Wrapper around the standard getopt module

This module provides a wrapper around the standard `getopt` module that provides the following additional features:

- short and long options are tied together
- options have help strings, so `fancy_getopt()` could potentially create a complete usage summary
- options set attributes of a passed-in object
- boolean options can have “negative aliases” — eg. if `--quiet` is the “negative alias” of `--verbose`, then `--quiet` on the command line sets `verbose` to false.

```python
distutils.fancy_getopt.fancy_getopt(options, negative_opt, object, args)
```

Wrapper function. `options` is a list of `(long_option, short_option, help_string)` 3-tuples as described in the constructor for `FancyGetopt`. `negative_opt` should be a dictionary mapping option names to option names, both the key and value should be in the `options` list. `object` is an object which will be used to store values (see the `getopt()` method of the `FancyGetopt` class). `args` is the argument list. Will use `sys.argv[1:]` if you pass None as `args`.

```python
distutils.fancy_getopt.wrap_text(text, width)
```

Wraps `text` to less than `width` wide.

```python
class
distutils.fancy_getopt.FancyGetopt([option_table=None],)
```
The `option_table` is a list of 3-tuples: `(long_option, short_option, help_string)`

If an option takes an argument, its `long_option` should have `'='` appended; `short_option` should just be a single character, no `':'` in any case. `short_option` should be None if a `long_option` doesn't have a corresponding `short_option`. All option tuples must have long options.

The `FancyGetopt` class provides the following methods:

FancyGetopt.`getopt`([`args=None, object=None`])

Parse command-line options in `args`. Store as attributes on `object`.

If `args` is None or not supplied, uses `sys.argv[1:]`. If `object` is None or not supplied, creates a new `OptionDummy` instance, stores option values there, and returns a tuple `(args, object)`. If `object` is supplied, it is modified in place and `getopt()` just returns `args`; in both cases, the returned `args` is a modified copy of the passed-in `args` list, which is left untouched.

FancyGetopt.`get_option_order`()

Returns the list of `(option, value)` tuples processed by the previous run of `getopt()` Raises `RuntimeError` if `getopt()` hasn't been called yet.

FancyGetopt.`generate_help`([`header=None`])

Generate help text (a list of strings, one per suggested line of output) from the option table for this `FancyGetopt` object.

If supplied, prints the supplied `header` at the top of the help.
This module provides the `FileList` class, used for poking about the filesystem and building lists of files.
10.19. *distutils.log* — Simple PEP 282-style logging
10.20. `distutils.spawn` — Spawn a sub-process

This module provides the `spawn()` function, a front-end to various platform-specific functions for launching another program in a subprocess. Also provides `find_executable()` to search the path for a given executable name.
10.21. *distutils.sysconfig* — System configuration information

The *distutils.sysconfig* module provides access to Python’s low-level configuration information. The specific configuration variables available depend heavily on the platform and configuration. The specific variables depend on the build process for the specific version of Python being run; the variables are those found in the `Makefile` and configuration header that are installed with Python on Unix systems. The configuration header is called `pyconfig.h` for Python versions starting with 2.2, and `config.h` for earlier versions of Python.

Some additional functions are provided which perform some useful manipulations for other parts of the *distutils* package.

*distutils.sysconfig.*`PREFIX`
   
   The result of `os.path.normpath(sys.prefix)`.

*distutils.sysconfig.*`EXEC_PREFIX`
   
   The result of `os.path.normpath(sys.exec_prefix)`.

*distutils.sysconfig.*`get_config_var(name)`
   
   Return the value of a single variable. This is equivalent to `get_config_vars().get(name)`.

*distutils.sysconfig.*`get_config_vars(...)`
   
   Return a set of variable definitions. If there are no arguments, this returns a dictionary mapping names of configuration variables to values. If arguments are provided, they should be strings, and the return value will be a sequence giving the associated values. If a
given name does not have a corresponding value, None will be included for that variable.

```
given
	does
	not
	have
	a

corresponding

t value,

None

will

be

included

for

that

variable.
```

distutils.sysconfig.get_config_h_filename()

Return the full path name of the configuration header. For Unix, this will be the header generated by the `configure` script; for other platforms the header will have been supplied directly by the Python source distribution. The file is a platform-specific text file.

distutils.sysconfig.get_makefile_filename()

Return the full path name of the `Makefile` used to build Python. For Unix, this will be a file generated by the `configure` script; the meaning for other platforms will vary. The file is a platform-specific text file, if it exists. This function is only useful on POSIX platforms.

distutils.sysconfig.get_python_inc([plat_specific[, prefix]])

Return the directory for either the general or platform-dependent C include files. If `plat_specific` is true, the platform-dependent include directory is returned; if false or omitted, the platform-independent directory is returned. If `prefix` is given, it is used as either the prefix instead of `PREFIX`, or as the exec-prefix instead of `EXEC_PREFIX` if `plat_specific` is true.

distutils.sysconfig.get_python_lib([plat_specific[, standard_lib[, prefix]]]

Return the directory for either the general or platform-dependent library installation. If `plat_specific` is true, the platform-dependent include directory is returned; if false or omitted, the platform-independent directory is returned. If `prefix` is given, it is used as either the prefix instead of `PREFIX`, or as the exec-prefix instead of `EXEC_PREFIX` if `plat_specific` is true.
**EXEC_PREFIX** if *plat_specific* is true. If *standard_lib* is true, the directory for the standard library is returned rather than the directory for the installation of third-party extensions.

The following function is only intended for use within the **distutils** package.

```
distutils.sysconfig.customize_compiler(compiler)
```

Do any platform-specific customization of a **distutils.ccompiler.CCompiler** instance.

This function is only needed on Unix at this time, but should be called consistently to support forward-compatibility. It inserts the information that varies across Unix flavors and is stored in Python's Makefile. This information includes the selected compiler, compiler and linker options, and the extension used by the linker for shared objects.

This function is even more special-purpose, and should only be used from Python's own build procedures.

```
distutils.sysconfig.set_python_build()
```

Inform the **distutils.sysconfig** module that it is being used as part of the build process for Python. This changes a lot of relative locations for files, allowing them to be located in the build area rather than in an installed Python.
10.22. `distutils.text_file` — The TextFile class

This module provides the `TextFile` class, which gives an interface to text files that (optionally) takes care of stripping comments, ignoring blank lines, and joining lines with backslashes.

```python
class distutils.text_file.TextFile([filename=None, file=None, **options])
```

This class provides a file-like object that takes care of all the things you commonly want to do when processing a text file that has some line-by-line syntax: strip comments (as long as `#` is your comment character), skip blank lines, join adjacent lines by escaping the newline (ie. backslash at end of line), strip leading and/or trailing whitespace. All of these are optional and independently controllable.

The class provides a `warn()` method so you can generate warning messages that report physical line number, even if the logical line in question spans multiple physical lines. Also provides `unreadline()` for implementing line-at-a-time lookahead.

`TextFile` instances are create with either `filename`, `file`, or both. `RuntimeError` is raised if both are None. `filename` should be a string, and `file` a file object (or something that provides `readline()` and `close()` methods). It is recommended that you supply at least `filename`, so that `TextFile` can include it in warning messages. If `file` is not supplied, `TextFile` creates its own using the `open()` built-in function.
The options are all boolean, and affect the values returned by `readline()`

<table>
<thead>
<tr>
<th>option name</th>
<th>description</th>
<th>default</th>
</tr>
</thead>
<tbody>
<tr>
<td><code>strip_comments</code></td>
<td>strip from '# ' to end-of-line, as well as any whitespace leading up to the '#'—unless it is escaped by a backslash.</td>
<td>true</td>
</tr>
<tr>
<td><code>lstrip_ws</code></td>
<td>strip leading whitespace from each line before returning it</td>
<td>false</td>
</tr>
<tr>
<td><code>rstrip_ws</code></td>
<td>strip trailing whitespace (including line terminator!) from each line before returning it.</td>
<td>true</td>
</tr>
<tr>
<td><code>skip_blanks</code></td>
<td>skip lines that are empty <em>after</em> stripping comments and whitespace. (If both <code>lstrip_ws</code> and <code>rstrip_ws</code> are false, then some lines may consist of solely whitespace: these will <em>not</em> be skipped, even if <code>skip_blanks</code> is true.)</td>
<td>true</td>
</tr>
<tr>
<td><code>join_lines</code></td>
<td>if a backslash is the last non-newline character on a line after stripping comments and whitespace, join the following line to it to form one logical line; if N consecutive lines end with a backslash, then N+1 physical lines will be joined to form one logical line.</td>
<td>false</td>
</tr>
<tr>
<td><code>collapse_join</code></td>
<td>strip leading whitespace from lines that are joined to their predecessor; only matters if <code>(join_lines and not lstrip_ws)</code></td>
<td>false</td>
</tr>
</tbody>
</table>
Note that since rstrip_ws can strip the trailing newline, the semantics of readline() must differ from those of the built-in file object’s readline() method! In particular, readline() returns None for end-of-file: an empty string might just be a blank line (or an all-whitespace line), if rstrip_ws is true but skip_blanks is not.

**open(filename)**

Open a new file filename. This overrides any file or filename constructor arguments.

**close()**

Close the current file and forget everything we know about it (including the filename and the current line number).

**warn(msg[, line=None])**

Print (to stderr) a warning message tied to the current logical line in the current file. If the current logical line in the file spans multiple physical lines, the warning refers to the whole range, such as "lines 3-5". If line is supplied, it overrides the current line number; it may be a list or tuple to indicate a range of physical lines, or an integer for a single physical line.

**readline()**

Read and return a single logical line from the current file (or from an internal buffer if lines have previously been “unread” with unreadline()). If the join_lines option is true, this may involve reading multiple physical lines concatenated into a single string. Updates the current line number, so calling warn() after readline() emits a warning about the physical line(s) just read. Returns None on end-of-file, since the empty string can occur if rstrip_ws is true but strip_blanks is not.
**readlines()**

Read and return the list of all logical lines remaining in the current file. This updates the current line number to the last line of the file.

**unreadline(line)**

Push *line* (a string) onto an internal buffer that will be checked by future `readline()` calls. Handy for implementing a parser with line-at-a-time lookahead. Note that lines that are “unread” with `unreadline()` are not subsequently re-cleansed (whitespace stripped, or whatever) when read with `readline()`. If multiple calls are made to `unreadline()` before a call to `readline()`, the lines will be returned most in most recent first order.
10.23. \texttt{distutils.version} — Version number classes
10.24. **distutils.cmd** — Abstract base class for Distutils commands

This module supplies the abstract base class **Command**.

```python
class distutils.cmd.Command(dist)
```

Abstract base class for defining command classes, the “worker bees” of the Distutils. A useful analogy for command classes is to think of them as subroutines with local variables called *options*. The options are declared in `initialize_options()` and defined (given their final values) in `finalize_options()`, both of which must be defined by every command class. The distinction between the two is necessary because option values might come from the outside world (command line, config file, ...), and any options dependent on other options must be computed after these outside influences have been processed — hence `finalize_options()`. The body of the subroutine, where it does all its work based on the values of its options, is the `run()` method, which must also be implemented by every command class.

The class constructor takes a single argument `dist`, a `Distribution` instance.
10.25. Creating a new Distutils command

This section outlines the steps to create a new Distutils command.

A new command lives in a module in the `distutils.command` package. There is a sample template in that directory called `command_template`. Copy this file to a new module with the same name as the new command you're implementing. This module should implement a class with the same name as the module (and the command). So, for instance, to create the command `peel_banana` (so that users can run `setup.py peel_banana`), you'd copy `command_template` to `distutils/command/peel_banana.py`, then edit it so that it's implementing the class `peel_banana`, a subclass of `distutils.cmd.Command`.

Subclasses of `Command` must define the following methods.

**Command. `initialize_options()`**

Set default values for all the options that this command supports. Note that these defaults may be overridden by other commands, by the setup script, by config files, or by the command-line. Thus, this is not the place to code dependencies between options; generally, `initialize_options()` implementations are just a bunch of `self.foo = None` assignments.

**Command. `finalize_options()`**

Set final values for all the options that this command supports. This is always called as late as possible, ie. after any option assignments from the command-line or from other commands have been done. Thus, this is the place to code option dependencies: if `foo` depends on `bar`, then it is safe to set `foo` from `bar` as long as
foo still has the same value it was assigned in initialize_options().

Command run()

A command’s raison d’etre: carry out the action it exists to perform, controlled by the options initialized in initialize_options(), customized by other commands, the setup script, the command-line, and config files, and finalized in finalize_options(). All terminal output and filesystem interaction should be done by run().

Command sub_commands

sub_commands formalizes the notion of a “family” of commands, e.g. install as the parent with sub-commands install_lib, install_headers, etc. The parent of a family of commands defines sub_commands as a class attribute; it’s a list of 2-tuples (command_name, predicate), with command_name a string and predicate a function, a string or None. predicate is a method of the parent command that determines whether the corresponding command is applicable in the current situation. (E.g. install_headers is only applicable if we have any C header files to install.) If predicate is None, that command is always applicable.

sub_commands is usually defined at the end of a class, because predicates can be methods of the class, so they must already have been defined. The canonical example is the install command.
10.26. distutils.command — Individual Distutils commands
10.27. `distutils.command.bdist` —
Build a binary installer
10.28.
distutils.command.bdist_packager
— Abstract base class for packagers
10.29.  
distutils.command.bdist_dumb —  
Build a “dumb” installer
10.30.  
**distutils.command.bdist_msi** —  
Build a Microsoft Installer binary package

```python
class distutils.command.bdist_msi.bdist_msi
```

Builds a *Windows Installer* (.msi) binary package.

In most cases, the `bdist_msi` installer is a better choice than the `bdist_wininst` installer, because it provides better support for Win64 platforms, allows administrators to perform non-interactive installations, and allows installation through group policies.
10.31. 
**distutils.command.bdist_rpm** —
Build a binary distribution as a Redhat RPM and SRPM
10.32.
distutils.command.bdist_wininst
— Build a Windows installer
10.33. `distutils.command.sdist` — Build a source distribution
10.34. `distutils.command.build` — Build all files of a package
10.35.
```
distutils.command.build_clib —
Build any C libraries in a package
```
10.36.
\texttt{distutils.command.build\_ext} —
Build any extensions in a package
10.37. distutils.command.build_py — Build the .py/.pyc files of a package

```python
class distutils.command.build_py.build_py

class distutils.command.build_py.build_py_2to3
    Alternative implementation of build_py which also runs the 2to3 conversion library on each .py file that is going to be installed. To use this in a setup.py file for a distribution that is designed to run with both Python 2.x and 3.x, add:

    try:
        from distutils.command.build_py import build_py
    except ImportError:
        from distutils.command.build_py import build_py

    to your setup.py, and later:

    cmdclass = {'build_py': build_py}
```

to the invocation of setup().
10.38. 
distutils.command.build_scripts
— Build the scripts of a package
10.39. `distutils.command.clean` —
Clean a package build area
10.40. `distutils.command.config` — Perform package configuration
10.41. `distutils.command.install` — Install a package
10.42. distutils.command.install_data
— Install data files from a package
10.43. distutils.command.install_header
— Install C/C++ header files from a package
10.44.

distutils.command.install_lib —
Install library files from a package
10.45.  
distutils.command.install_script  
— Install script files from a package
10.46. `distutils.command.register` — Register a module with the Python Package Index

The `register` command registers the package with the Python Package Index. This is described in more detail in PEP 301.
10.47. distutils.command.check — Check the meta-data of a package

The `check` command performs some tests on the meta-data of a package. For example, it verifies that all required meta-data are provided as the arguments passed to the `setup()` function.
Porting Python 2 Code to Python 3

author: Brett Cannon

Abstract

With Python 3 being the future of Python while Python 2 is still in active use, it is good to have your project available for both major releases of Python. This guide is meant to help you choose which strategy works best for your project to support both Python 2 & 3 along with how to execute that strategy.

If you are looking to port an extension module instead of pure Python code, please see *Porting Extension Modules to Python 3.*
Choosing a Strategy

When a project chooses to support both Python 2 & 3, a decision needs to be made as to how to go about accomplishing that goal. The chosen strategy will depend on how large the project's existing codebase is and how much divergence you want from your current Python 2 codebase (e.g., changing your code to work simultaneously with Python 2 and 3).

If you would prefer to maintain a codebase which is semantically and syntactically compatible with Python 2 & 3 simultaneously, you can write Python 2/3 Compatible Source. While this tends to lead to somewhat non-idiomatic code, it does mean you keep a rapid development process for you, the developer.

If your project is brand-new or does not have a large codebase, then you may want to consider writing/porting all of your code for Python 3 and use 3to2 to port your code for Python 2.

Finally, you do have the option of using 2to3 to translate Python 2 code into Python 3 code (with some manual help). This can take the form of branching your code and using 2to3 to start a Python 3 branch. You can also have users perform the translation at installation time automatically so that you only have to maintain a Python 2 codebase.

Regardless of which approach you choose, porting is not as hard or time-consuming as you might initially think. You can also tackle the problem piece-meal as a good portion of porting is simply updating your code to follow current best practices in a Python 2/3 compatible way.

Universal Bits of Advice
Regardless of what strategy you pick, there are a few things you should consider.

One is make sure you have a robust test suite. You need to make sure everything continues to work, just like when you support a new minor/feature release of Python. This means making sure your test suite is thorough and is ported properly between Python 2 & 3. You will also most likely want to use something like tox to automate testing between both a Python 2 and Python 3 interpreter.

Two, once your project has Python 3 support, make sure to add the proper classifier on the Cheeseshop (PyPI). To have your project listed as Python 3 compatible it must have the Python 3 classifier (from http://techspot.zzeek.org/2011/01/24/zzzeek-s-guide-to-python-3-porting/):

```python
def setup(
    name='Your Library',
    version='1.0',
    classifiers=[
        # make sure to use :: Python *and* :: Python :
        # that pypi can list the package on the python :
        'Programming Language :: Python',
        'Programming Language :: Python :: 3'
    ],
    packages=['yourlibrary'],
    # make sure to add custom_fixers to the MANIFEST.in
    include_package_data=True,
    # ... )
```

Doing so will cause your project to show up in the Python 3 packages list. You will know you set the classifier properly as visiting your project
page on the Cheeseshop will show a Python 3 logo in the upper-left corner of the page.

Three, the six project provides a library which helps iron out differences between Python 2 & 3. If you find there is a sticky point that is a continual point of contention in your translation or maintenance of code, consider using a source-compatible solution relying on six. If you have to create your own Python 2/3 compatible solution, you can use `sys.version_info[0] >= 3` as a guard.

Four, read all the approaches. Just because some bit of advice applies to one approach more than another doesn’t mean that some advice doesn’t apply to other strategies. This is especially true of whether you decide to use 2to3 or be source-compatible; tips for one approach almost always apply to the other.

Five, drop support for older Python versions if possible. Python 2.5 introduced a lot of useful syntax and libraries which have become idiomatic in Python 3. Python 2.6 introduced future statements which makes compatibility much easier if you are going from Python 2 to 3. Python 2.7 continues the trend in the stdlib. So choose the newest version of Python which you believe can be your minimum support version and work from there.

Six, target the newest version of Python 3 that you can. Beyond just the usual bugfixes, compatibility has continued to improve between Python 2 and 3 as time has passed. This is especially true for Python 3.3 where the `u` prefix for strings is allowed, making source-compatible Python code easier.

Seven, make sure to look at the Other Resources for tips from other people which may help you out.
Python 3 and 3to2

If you are starting a new project or your codebase is small enough, you may want to consider writing your code for Python 3 and backporting to Python 2 using 3to2. Thanks to Python 3 being more strict about things than Python 2 (e.g., bytes vs. strings), the source translation can be easier and more straightforward than from Python 2 to 3. Plus it gives you more direct experience developing in Python 3 which, since it is the future of Python, is a good thing long-term.

A drawback of this approach is that 3to2 is a third-party project. This means that the Python core developers (and thus this guide) can make no promises about how well 3to2 works at any time. There is nothing to suggest, though, that 3to2 is not a high-quality project.
Python 2 and 2to3

Included with Python since 2.6, the 2to3 tool (and lib2to3 module) helps with porting Python 2 to Python 3 by performing various source translations. This is a perfect solution for projects which wish to branch their Python 3 code from their Python 2 codebase and maintain them as independent codebases. You can even begin preparing to use this approach today by writing future-compatible Python code which works cleanly in Python 2 in conjunction with 2to3; all steps outlined below will work with Python 2 code up to the point when the actual use of 2to3 occurs.

Use of 2to3 as an on-demand translation step at install time is also possible, preventing the need to maintain a separate Python 3 codebase, but this approach does come with some drawbacks. While users will only have to pay the translation cost once at installation, you as a developer will need to pay the cost regularly during development. If your codebase is sufficiently large enough then the translation step ends up acting like a compilation step, robbing you of the rapid development process you are used to with Python. Obviously the time required to translate a project will vary, so do an experimental translation just to see how long it takes to evaluate whether you prefer this approach compared to using Python 2/3 Compatible Source or simply keeping a separate Python 3 codebase.

Below are the typical steps taken by a project which tries to support Python 2 & 3 while keeping the code directly executable by Python 2.

Support Python 2.7

As a first step, make sure that your project is compatible with Python
2.7. This is just good to do as Python 2.7 is the last release of Python 2 and thus will be used for a rather long time. It also allows for use of the `-3` flag to Python to help discover places in your code which 2to3 cannot handle but are known to cause issues.

**Try to Support Python 2.6 and Newer Only**

While not possible for all projects, if you can support Python 2.6 and newer only, your life will be much easier. Various future statements, stdlib additions, etc. exist only in Python 2.6 and later which greatly assist in porting to Python 3. But if you project must keep support for Python 2.5 (or even Python 2.4) then it is still possible to port to Python 3.

Below are the benefits you gain if you only have to support Python 2.6 and newer. Some of these options are personal choice while others are strongly recommended (the ones that are more for personal choice are labeled as such). If you continue to support older versions of Python then you at least need to watch out for situations that these solutions fix.

```python
from __future__ import print_function
```

This is a personal choice. 2to3 handles the translation from the print statement to the print function rather well so this is an optional step. This future statement does help, though, with getting used to typing `print('Hello, World')` instead of `print 'Hello, World'`.

```python
from __future__ import unicode_literals
```

Another personal choice. You can always mark what you want to be a (unicode) string with a `u` prefix to get the same effect. But regardless
of whether you use this future statement or not, you **must** make sure you know exactly which Python 2 strings you want to be bytes, and which are to be strings. This means you should, **at minimum** mark all strings that are meant to be text strings with a u prefix if you do not use this future statement. Python 3.3 allows strings to continue to have the u prefix (it's a no-op in that case) to make it easier for code to be source-compatible between Python 2 & 3.

**Bytes literals**

This is a **very** important one. The ability to prefix Python 2 strings that are meant to contain bytes with a b prefix help to very clearly delineate what is and is not a Python 3 string. When you run 2to3 on code, all Python 2 strings become Python 3 strings **unless** they are prefixed with b.

This point cannot be stressed enough: make sure you know what all of your string literals in Python 2 are meant to become in Python 3. Any string literal that should be treated as bytes should have the b prefix. Any string literal that should be Unicode/text in Python 2 should either have the u literal (supported, but ignored, in Python 3.3 and later) or you should have from __future__ import unicode_literals at the top of the file. But the key point is you should know how Python 3 will treat everyone one of your string literals and you should mark them as appropriate.

There are some differences between byte literals in Python 2 and those in Python 3 thanks to the bytes type just being an alias to str in Python 2. Probably the biggest “gotcha” is that indexing results in different values. In Python 2, the value of b'py'[1] is 'y', while in Python 3 it's 121. You can avoid this disparity by always slicing at the size of a single element: b'py'[1:2] is 'y' in Python 2 and b'y'
in Python 3 (i.e., close enough).

You cannot concatenate bytes and strings in Python 3. But since Python 2 has bytes aliased to str, it will succeed: b'a' + u'b' works in Python 2, but b'a' + 'b' in Python 3 is a TypeError. A similar issue also comes about when doing comparisons between bytes and strings.

Supporting Python 2.5 and Newer Only

If you are supporting Python 2.5 and newer there are still some features of Python that you can utilize.

from __future__ import absolute_import

Implicit relative imports (e.g., importing spam.bacon from within spam.eggs with the statement import bacon) does not work in Python 3. This future statement moves away from that and allows the use of explicit relative imports (e.g., from .. import bacon).

In Python 2.5 you must use the __future__ statement to get to use explicit relative imports and prevent implicit ones. In Python 2.6 explicit relative imports are available without the statement, but you still want the __future__ statement to prevent implicit relative imports. In Python 2.7 the __future__ statement is not needed. In other words, unless you are only supporting Python 2.7 or a version earlier than Python 2.5, use the __future__ statement.

Mark all Unicode strings with a u prefix

While Python 2.6 has a __future__ statement to automatically cause Python 2 to treat all string literals as Unicode, Python 2.5 does
not have that shortcut. This means you should go through and mark all string literals with a u prefix to turn them explicitly into Unicode strings where appropriate. That leaves all unmarked string literals to be considered byte literals in Python 3.

Handle Common “Gotchas”

There are a few things that just consistently come up as sticking points for people which 2to3 cannot handle automatically or can easily be done in Python 2 to help modernize your code.

```
from __future__ import division
```

While the exact same outcome can be had by using the -Qnew argument to Python, using this future statement lifts the requirement that your users use the flag to get the expected behavior of division in Python 3 (e.g., `1/2 == 0.5; 1//2 == 0`).

Specify when opening a file as binary

Unless you have been working on Windows, there is a chance you have not always bothered to add the b mode when opening a binary file (e.g., rb for binary reading). Under Python 3, binary files and text files are clearly distinct and mutually incompatible; see the io module for details. Therefore, you must make a decision of whether a file will be used for binary access (allowing to read and/or write bytes data) or text access (allowing to read and/or write unicode data).

Text files

Text files created using open() under Python 2 return byte strings,
while under Python 3 they return unicode strings. Depending on your porting strategy, this can be an issue.

If you want text files to return unicode strings in Python 2, you have two possibilities:

- Under Python 2.6 and higher, use `io.open()`. Since `io.open()` is essentially the same function in both Python 2 and Python 3, it will help iron out any issues that might arise.
- If pre-2.6 compatibility is needed, then you should use `codecs.open()` instead. This will make sure that you get back unicode strings in Python 2.

Subclass object

New-style classes have been around since Python 2.2. You need to make sure you are subclassing from `object` to avoid odd edge cases involving method resolution order, etc. This continues to be totally valid in Python 3 (although unneeded as all classes implicitly inherit from `object`).

Deal With the Bytes/String Dichotomy

One of the biggest issues people have when porting code to Python 3 is handling the bytes/string dichotomy. Because Python 2 allowed the `str` type to hold textual data, people have over the years been rather loose in their delineation of what `str` instances held text compared to bytes. In Python 3 you cannot be so care-free anymore and need to properly handle the difference. The key handling this issue is to make sure that every string literal in your Python 2 code is either syntactically or functionally marked as either bytes or text data. After this is done you then need to make sure your APIs are designed to
either handle a specific type or made to be properly polymorphic.

Mark Up Python 2 String Literals

First thing you must do is designate every single string literal in Python 2 as either textual or bytes data. If you are only supporting Python 2.6 or newer, this can be accomplished by marking bytes literals with a \texttt{b} prefix and then designating textual data with a \texttt{u} prefix or using the \texttt{unicode_literals} future statement.

If your project supports versions of Python predating 2.6, then you should use the \texttt{six} project and its \texttt{b()} function to denote bytes literals. For text literals you can either use six's \texttt{u()} function or use a \texttt{u} prefix.

Decide what APIs Will Accept

In Python 2 it was very easy to accidentally create an API that accepted both bytes and textual data. But in Python 3, thanks to the more strict handling of disparate types, this loose usage of bytes and text together tends to fail.

Take the dict \{\texttt{b'a'': 'bytes'}, \texttt{u'a'': 'text'}\} in Python 2.6. It creates the dict \{\texttt{u'a'': 'text'}\} since \texttt{b'a' == u'a'}. But in Python 3 the equivalent dict creates \{\texttt{b'a': 'bytes'}, \texttt{'a': 'text'}\}, i.e., no lost data. Similar issues can crop up when transitioning Python 2 code to Python 3.

This means you need to choose what an API is going to accept and create and consistently stick to that API in both Python 2 and 3.

Bytes / Unicode Comparison
In Python 3, mixing bytes and unicode is forbidden in most situations; it will raise a `TypeError` where Python 2 would have attempted an implicit coercion between types. However, there is one case where it doesn’t and it can be very misleading:

```python
>>> b"" == ""
False
```

This is because an equality comparison is required by the language to always succeed (and return `False` for incompatible types). However, this also means that code incorrectly ported to Python 3 can display buggy behaviour if such comparisons are silently executed. To detect such situations, Python 3 has a `-b` flag that will display a warning:

```bash
$ python3 -b
>>> b'' == ''
__main__:1: BytesWarning: Comparison between bytes and string
False
```

To turn the warning into an exception, use the `-bb` flag instead:

```bash
$ python3 -bb
>>> b'' == ''
Traceback (most recent call last):
  File "<stdin>", line 1, in <module>
BytesWarning: Comparison between bytes and string
```

**Indexing bytes objects**

Another potentially surprising change is the indexing behaviour of bytes objects in Python 3:

```python
>>> b"xyz"[0]
```
Indeed, Python 3 bytes objects (as well as `bytearray` objects) are sequences of integers. But code converted from Python 2 will often assume that indexing a bytestring produces another bytestring, not an integer. To reconcile both behaviours, use slicing:

```
>>> b"xyz"[0:1]
b'x'
>>> n = 1
>>> b"xyz"[n:n+1]
b'y'
```

The only remaining gotcha is that an out-of-bounds slice returns an empty bytes object instead of raising `IndexError`:

```
>>> b"xyz"[3]
Traceback (most recent call last):
  File "<stdin>", line 1, in <module>
IndexError: index out of range
>>> b"xyz"[3:4]
''
```

`__str__()`/__`unicode__()__

In Python 2, objects can specify both a string and unicode representation of themselves. In Python 3, though, there is only a string representation. This becomes an issue as people can inadvertently do things in their `__str__()` methods which have unpredictable results (e.g., infinite recursion if you happen to use the `unicode(self).encode('utf8')` idiom as the body of your `__str__()` method).
There are two ways to solve this issue. One is to use a custom 2to3 fixer. The blog post at http://lucumr.pocoo.org/2011/1/22/forwards-compatible-python/ specifies how to do this. That will allow 2to3 to change all instances of def __unicode__(self): ... to def __str__(self): .... This does require that you define your __str__() method in Python 2 before your __unicode__() method.

The other option is to use a mixin class. This allows you to only define a __unicode__() method for your class and let the mixin derive __str__() for you (code from http://lucumr.pocoo.org/2011/1/22/forwards-compatible-python/):

```python
import sys

class UnicodeMixin(object):
    """Mixin class to handle defining the proper __str__/__unicode__ methods in Python 2 or 3."""

    if sys.version_info[0] >= 3: # Python 3
        def __str__(self):
            return self.__unicode__()
    else: # Python 2
        def __str__(self):
            return self.__unicode__().encode('utf8')

class Spam(UnicodeMixin):
    def __unicode__(self):
        return u'spam-spam-bacon-spam' # 2to3 will remove the u'prefix

Don't Index on Exceptions
In Python 2, the following worked:

```python
>>> exc = Exception(1, 2, 3)
>>> exc.args[1]
2
>>> exc[1]  # Python 2 only!
2
```

But in Python 3, indexing directly on an exception is an error. You need to make sure to only index on the `BaseException.args` attribute which is a sequence containing all arguments passed to the `__init__()` method.

Even better is to use the documented attributes the exception provides.

Don't use `__getslice__` & Friends

Been deprecated for a while, but Python 3 finally drops support for `__getslice__()`, etc. Move completely over to `__getitem__()` and friends.

Updating doctests

`2to3` will attempt to generate fixes for doctests that it comes across. It's not perfect, though. If you wrote a monolithic set of doctests (e.g., a single docstring containing all of your doctests), you should at least consider breaking the doctests up into smaller pieces to make it more manageable to fix. Otherwise it might very well be worth your time and effort to port your tests to `unittest`.

Update `map` for imbalanced input sequences
With Python 2, `map` would pad input sequences of unequal length with `None` values, returning a sequence as long as the longest input sequence.

With Python 3, if the input sequences to `map` are of unequal length, `map` will stop at the termination of the shortest of the sequences. For full compatibility with `map` from Python 2.x, also wrap the sequences in `itertools.zip_longest()`, e.g. `map(func, *sequences)` becomes `list(map(func, itertools.zip_longest(*sequences))).`

**Eliminate -3 Warnings**

When you run your application's test suite, run it using the `-3` flag passed to Python. This will cause various warnings to be raised during execution about things that 2to3 cannot handle automatically (e.g., modules that have been removed). Try to eliminate those warnings to make your code even more portable to Python 3.

**Run 2to3**

Once you have made your Python 2 code future-compatible with Python 3, it's time to use 2to3 to actually port your code.

**Manually**

To manually convert source code using 2to3, you use the 2to3 script that is installed with Python 2.6 and later.:

```
2to3 <directory or file to convert>
```
This will cause 2to3 to write out a diff with all of the fixers applied for the converted source code. If you would like 2to3 to go ahead and apply the changes you can pass it the `-w` flag:

```
2to3 -w <stuff to convert>
```

There are other flags available to control exactly which fixers are applied, etc.

During Installation

When a user installs your project for Python 3, you can have either `distutils` or `Distribute` run 2to3 on your behalf. For distutils, use the following idiom:

```
try:  # Python 3
    from distutils.command.build_py import build_py_2to3
except ImportError:  # Python 2
    from distutils.command.build_py import build_py

setup(cmdclass = {'build_py': build_py_2to3},
      # ...
)
```

For Distribute:

```
setup(use_2to3=True,
       # ...
)
```

This will allow you to not have to distribute a separate Python 3 version of your project. It does require, though, that when you perform development that you at least build your project and use the built
Python 3 source for testing.

Verify & Test

At this point you should (hopefully) have your project converted in such a way that it works in Python 3. Verify it by running your unit tests and making sure nothing has gone awry. If you miss something then figure out how to fix it in Python 3, backport to your Python 2 code, and run your code through 2to3 again to verify the fix transforms properly.
Python 2/3 Compatible Source

While it may seem counter-intuitive, you can write Python code which is source-compatible between Python 2 & 3. It does lead to code that is not entirely idiomatic Python (e.g., having to extract the currently raised exception from `sys.exc_info()[1]`), but it can be run under Python 2 and Python 3 without using 2to3 as a translation step (although the tool should be used to help find potential portability problems). This allows you to continue to have a rapid development process regardless of whether you are developing under Python 2 or Python 3. Whether this approach or using Python 2 and 2to3 works best for you will be a per-project decision.

To get a complete idea of what issues you will need to deal with, see the What's New in Python 3.0. Others have reorganized the data in other formats such as http://docs.pythonsprints.com/python3_porting/py-porting.html.

The following are some steps to take to try to support both Python 2 & 3 from the same source code.

Follow The Steps for Using 2to3

All of the steps outlined in how to port Python 2 code with 2to3 apply to creating a Python 2/3 codebase. This includes trying only support Python 2.6 or newer (the __future__ statements work in Python 3 without issue), eliminating warnings that are triggered by -3, etc.

You should even consider running 2to3 over your code (without committing the changes). This will let you know where potential pain points are within your code so that you can fix them properly before
they become an issue.

**Use six**

The *six* project contains many things to help you write portable Python code. You should make sure to read its documentation from beginning to end and use any and all features it provides. That way you will minimize any mistakes you might make in writing cross-version code.

**Capturing the Currently Raised Exception**

One change between Python 2 and 3 that will require changing how you code (if you support Python 2.5 and earlier) is accessing the currently raised exception. In Python 2.5 and earlier the syntax to access the current exception is:

```python
try:
    raise Exception()
except Exception, exc:
    # Current exception is 'exc'
    pass
```

This syntax changed in Python 3 (and backported to Python 2.6 and later) to:

```python
try:
    raise Exception()
except Exception as exc:
    # Current exception is 'exc'
    # In Python 3, 'exc' is restricted to the block; Python 2.6 will "leak"
    pass
```

Because of this syntax change you must change to capturing the
current exception to:

```python
try:
    raise Exception()
except Exception:
    import sys
    exc = sys.exc_info()[1]
    # Current exception is 'exc'
    pass
```

You can get more information about the raised exception from `sys.exc_info()` than simply the current exception instance, but you most likely don’t need it.

**Note:** In Python 3, the traceback is attached to the exception instance through the `__traceback__` attribute. If the instance is saved in a local variable that persists outside of the `except` block, the traceback will create a reference cycle with the current frame and its dictionary of local variables. This will delay reclaiming dead resources until the next cyclic _garbage collection_ pass.

In Python 2, this problem only occurs if you save the traceback itself (e.g. the third element of the tuple returned by `sys.exc_info()`) in a variable.

Porting Extension Modules to Python 3

author: Benjamin Peterson

Abstract

Although changing the C-API was not one of Python 3's objectives, the many Python-level changes made leaving Python 2's API intact impossible. In fact, some changes such as int() and long() unification are more obvious on the C level. This document endeavors to document incompatibilities and how they can be worked around.
Conditional compilation

The easiest way to compile only some code for Python 3 is to check if `PY_MAJOR_VERSION` is greater than or equal to 3.

```c
#if PY_MAJOR_VERSION >= 3
#define IS_PY3K
#endif
```

API functions that are not present can be aliased to their equivalents within conditional blocks.
Changes to Object APIs

Python 3 merged together some types with similar functions while cleanly separating others.

str/unicode Unification

Python 3's `str()` (PyString_* functions in C) type is equivalent to Python 2's `unicode()` (PyUnicode_*). The old 8-bit string type has become `bytes()`. Python 2.6 and later provide a compatibility header, `bytesobject.h`, mapping `PyBytes` names to `PyString` ones. For best compatibility with Python 3, `PyUnicode` should be used for textual data and `PyBytes` for binary data. It's also important to remember that `PyBytes` and `PyUnicode` in Python 3 are not interchangeable like `PyString` and `PyUnicode` are in Python 2. The following example shows best practices with regards to `PyUnicode`, `PyString`, and `PyBytes`.

```c
#include "stdlib.h"
#include "Python.h"
#include "bytesobject.h"

/* text example */
static PyObject *
say_hello(PyObject *self, PyObject *args) {
    PyObject *name, *result;

    if (!PyArg_ParseTuple(args, "U:say_hello", &name))
        return NULL;

    result = PyUnicode_FromFormat("Hello, %S!", name);
    return result;
```
long/int Unification

Python 3 has only one integer type, `int()`. But it actually corresponds to Python 2's `long()` type—the `int()` type used in Python 2 was removed. In the C-API, `PyInt_*` functions are replaced by their `PyLong_*` equivalents.
Module initialization and state

Python 3 has a revamped extension module initialization system. (See PEP 3121.) Instead of storing module state in globals, they should be stored in an interpreter specific structure. Creating modules that act correctly in both Python 2 and Python 3 is tricky. The following simple example demonstrates how.

```c
#include "Python.h"

struct module_state {
    PyObject *error;
};

#if PY_MAJOR_VERSION >= 3
#define GETSTATE(m) ((struct module_state*)PyModule_GetState(m))
#else
#define GETSTATE(m) (&_state)
#endif

static struct module_state _state;

static PyObject *
error_out(PyObject *m) {
    struct module_state *st = GETSTATE(m);
    PyErr_SetString(st->error, "something bad happened"
    return NULL;
}

static PyMethodDef myextension_methods[] = {
    {"error_out", (PyCFunction)error_out, METH_NOARGS
        {NULL, NULL}
};

#if PY_MAJOR_VERSION >= 3
```
static int myextension_traverse(PyObject *m, visitproc visitp, void *arg)
{
    Py_VISIT(GETSTATE(m)->error);
    return 0;
}

static int myextension_clear(PyObject *m) {
    Py_CLEAR(GETSTATE(m)->error);
    return 0;
}

static struct PyModuleDef moduledef = {
    PyModuleDef_HEAD_INIT,
    "myextension",
    NULL,
    sizeof(struct module_state),
    myextension_methods,
    NULL,
    myextension_traverse,
    myextension_clear,
    NULL
};

#define INITERROR return NULL

PyObject *
PyInit_myextension(void)

#else
#define INITERROR return

void
initmyextension(void)
#endif

{    #if PY_MAJOR_VERSION >= 3
    PyObject *module = PyModule_Create(&moduledef);

PyObject *module = Py_InitModule("myextension",
#else

if (module == NULL)
    INITERROR;
struct module_state *st = GETSTATE(module);

st->error = PyErr_NewException("myextension.Error",
if (st->error == NULL) {
    Py_DECREF(module);
    INITERROR;
}

#endif

#if PY_MAJOR_VERSION >= 3
    return module;
#endif
}
CObject replaced with Capsule

The Capsule object was introduced in Python 3.1 and 2.7 to replace CObject. CObjects were useful, but the CObject API was problematic: it didn’t permit distinguishing between valid CObjects, which allowed mismatched CObjects to crash the interpreter, and some of its APIs relied on undefined behavior in C. (For further reading on the rationale behind Capsules, please see issue 5630.)

If you’re currently using CObjects, and you want to migrate to 3.1 or newer, you’ll need to switch to Capsules. CObject was deprecated in 3.1 and 2.7 and completely removed in Python 3.2. If you only support 2.7, or 3.1 and above, you can simply switch to Capsule. If you need to support Python 3.0, or versions of Python earlier than 2.7, you’ll have to support both CObjects and Capsules. (Note that Python 3.0 is no longer supported, and it is not recommended for production use.)

The following example header file capsulethunk.h may solve the problem for you. Simply write your code against the Capsule API and include this header file after Python.h. Your code will automatically use Capsules in versions of Python with Capsules, and switch to CObjects when Capsules are unavailable.

capsulethunk.h simulates Capsules using CObjects. However, CObject provides no place to store the capsule’s “name”. As a result the simulated Capsule objects created by capsulethunk.h behave slightly differently from real Capsules. Specifically:

- The name parameter passed in to PyCapsule_New() is ignored.
- The name parameter passed in to PyCapsule_IsValid()
and `PyCapsule_GetPointer()` is ignored, and no error checking of the name is performed.

- `PyCapsule_GetName()` always returns NULL.
- `PyCapsule_SetName()` always raises an exception and returns failure. (Since there’s no way to store a name in a CObject, noisy failure of `PyCapsule_SetName()` was deemed preferable to silent failure here. If this is inconvenient, feel free to modify your local copy as you see fit.)

You can find `capsulethunk.h` in the Python source distribution as `Doc/includes/capsulethunk.h`. We also include it here for your convenience:

```c
#ifndef __CAPSULETHUNK_H
#define __CAPSULETHUNK_H

#if (       (PY_VERSION_HEX < 0x02070000) \n    || ((PY_VERSION_HEX >= 0x03000000) \n        && (PY_VERSION_HEX < 0x03010000)) )

#define __PyCapsule_GetField(capsule, field, default_value) ( 
    PyCapsule_CheckExact(capsule) \n    ? (((PyObject *)capsule)->field) \n    : (default_value) \n  )

#define __PyCapsule_SetField(capsule, field, value) ( 
    PyCapsule_CheckExact(capsule) \n    ? (((PyObject *)capsule)->field = value), 1 \n    : 0 \n  )

#define PyCapsule_Type PyObject_Type
```

#define PyCapsule_CheckExact(capsule) (PyCObject_Check(capsule))
#define PyCapsule_IsValid(capsule, name) (PyCObject_Check(capsule))
#define PyCapsule_New(pointer, name, destructor)  
  (PyCObject_FromVoidPtr(pointer, destructor))
#define PyCapsule_GetPointer(capsule, name)  
  (PyCObject_AsVoidPtr(capsule))
/* Don't call PyObject_SetPointer here, it fails if */
#define PyCapsule_SetPointer(capsule, pointer)

    return_value = cobject->cobject;
} else {
    PyErr_Format(PyExc_AttributeError,
                 "PyCapsule_Import \"%s\" is not valid", name);
}

EXIT:
Py_XDECREF(object);
if (name_dup) {
    PyMem_FREE(name_dup);
}
return return_value;

#endif /* #if PY_VERSION_HEX < 0x02070000 */
#endif /* __CAPSULETHUNK_H */
Other options

If you are writing a new extension module, you might consider Cython. It translates a Python-like language to C. The extension modules it creates are compatible with Python 3 and Python 2.
Curses Programming with Python

**Abstract**

This document describes how to use the [curses](https://docs.python.org/3/library/curses.html) extension module to control text-mode displays.
What is curses?

The curses library supplies a terminal-independent screen-painting and keyboard-handling facility for text-based terminals; such terminals include VT100s, the Linux console, and the simulated terminal provided by various programs. Display terminals support various control codes to perform common operations such as moving the cursor, scrolling the screen, and erasing areas. Different terminals use widely differing codes, and often have their own minor quirks.

In a world of graphical displays, one might ask “why bother”? It’s true that character-cell display terminals are an obsolete technology, but there are niches in which being able to do fancy things with them are still valuable. One niche is on small-footprint or embedded Unixes that don’t run an X server. Another is tools such as OS installers and kernel configurators that may have to run before any graphical support is available.

The curses library provides fairly basic functionality, providing the programmer with an abstraction of a display containing multiple non-overlapping windows of text. The contents of a window can be changed in various ways—adding text, erasing it, changing its appearance—and the curses library will figure out what control codes need to be sent to the terminal to produce the right output. Curses doesn’t provide many user-interface concepts such as buttons, checkboxes, or dialogs; if you need such features, consider a user interface library such as Urwid.

The curses library was originally written for BSD Unix; the later System V versions of Unix from AT&T added many enhancements and new functions. BSD curses is no longer maintained, having been replaced by ncurse, which is an open-source implementation of the AT&T
interface. If you’re using an open-source Unix such as Linux or FreeBSD, your system almost certainly uses ncurses. Since most current commercial Unix versions are based on System V code, all the functions described here will probably be available. The older versions of curses carried by some proprietary Unixes may not support everything, though.

The Windows version of Python doesn’t include the curses module. A ported version called UniCurses is available. You could also try the Console module written by Fredrik Lundh, which doesn’t use the same API as curses but provides cursor-addressable text output and full support for mouse and keyboard input.

The Python curses module

The Python module is a fairly simple wrapper over the C functions provided by curses; if you’re already familiar with curses programming in C, it’s really easy to transfer that knowledge to Python. The biggest difference is that the Python interface makes things simpler by merging different C functions such as addstr(), mvaddstr(), and mvwaddstr() into a single addstr() method. You’ll see this covered in more detail later.

This HOWTO is an introduction to writing text-mode programs with curses and Python. It doesn’t attempt to be a complete guide to the curses API; for that, see the Python library guide’s section on ncurses, and the C manual pages for ncurses. It will, however, give you the basic ideas.
Starting and ending a curses application

Before doing anything, curses must be initialized. This is done by calling the `initscr()` function, which will determine the terminal type, send any required setup codes to the terminal, and create various internal data structures. If successful, `initscr()` returns a window object representing the entire screen; this is usually called `stdscr` after the name of the corresponding C variable.

```python
import curses
stdscr = curses.initscr()
```

Usually curses applications turn off automatic echoing of keys to the screen, in order to be able to read keys and only display them under certain circumstances. This requires calling the `noecho()` function.

```python
curses.noecho()
```

Applications will also commonly need to react to keys instantly, without requiring the Enter key to be pressed; this is called cbreak mode, as opposed to the usual buffered input mode.

```python
curses.cbreak()
```

Terminals usually return special keys, such as the cursor keys or navigation keys such as Page Up and Home, as a multibyte escape sequence. While you could write your application to expect such sequences and process them accordingly, curses can do it for you, returning a special value such as `curses.KEY_LEFT`. To get curses to do the job, you’ll have to enable keypad mode.

```python
stdscr.keypad(True)
```
Terminating a curses application is much easier than starting one. You'll need to call:

```python
curses.nocbreak()
stdscr.keypad(False)
curses.echo()
```

to reverse the curses-friendly terminal settings. Then call the `endwin()` function to restore the terminal to its original operating mode.

```python
curses.endwin()
```

A common problem when debugging a curses application is to get your terminal messed up when the application dies without restoring the terminal to its previous state. In Python this commonly happens when your code is buggy and raises an uncaught exception. Keys are no longer echoed to the screen when you type them, for example, which makes using the shell difficult.

In Python you can avoid these complications and make debugging much easier by importing the `curses.wrapper()` function and using it like this:

```python
from curses import wrapper

def main(stdscr):
    # Clear screen
    stdscr.clear()

    # This raises ZeroDivisionError when i == 10.
    for i in range(0, 11):
        v = i-10
```
The wrapper() function takes a callable object and does the initializations described above, also initializing colors if color support is present. wrapper() then runs your provided callable. Once the callable returns, wrapper() will restore the original state of the terminal. The callable is called inside a try...except that catches exceptions, restores the state of the terminal, and then re-raises the exception. Therefore your terminal won't be left in a funny state on exception and you'll be able to read the exception's message and traceback.
Windows and Pads

Windows are the basic abstraction in curses. A window object represents a rectangular area of the screen, and supports methods to display text, erase it, allow the user to input strings, and so forth.

The `stdscr` object returned by the `initscr()` function is a window object that covers the entire screen. Many programs may need only this single window, but you might wish to divide the screen into smaller windows, in order to redraw or clear them separately. The `newwin()` function creates a new window of a given size, returning the new window object.

```
begin_x = 20; begin_y = 7
height = 5; width = 40
win = curses.newwin(height, width, begin_y, begin_x)
```

Note that the coordinate system used in curses is unusual. Coordinates are always passed in the order y,x, and the top-left corner of a window is coordinate (0,0). This breaks the normal convention for handling coordinates where the x coordinate comes first. This is an unfortunate difference from most other computer applications, but it's been part of curses since it was first written, and it's too late to change things now.

Your application can determine the size of the screen by using the `curses.LINES` and `curses.COLS` variables to obtain the y and x sizes. Legal coordinates will then extend from `(0,0)` to `(curses.LINES - 1, curses.COLS - 1).

When you call a method to display or erase text, the effect doesn't
immediately show up on the display. Instead you must call the `refresh()` method of window objects to update the screen.

This is because curses was originally written with slow 300-baud terminal connections in mind; with these terminals, minimizing the time required to redraw the screen was very important. Instead curses accumulates changes to the screen and displays them in the most efficient manner when you call `refresh()`. For example, if your program displays some text in a window and then clears the window, there’s no need to send the original text because they’re never visible.

In practice, explicitly telling curses to redraw a window doesn’t really complicate programming with curses much. Most programs go into a flurry of activity, and then pause waiting for a keypress or some other action on the part of the user. All you have to do is to be sure that the screen has been redrawn before pausing to wait for user input, by first calling `stdscr.refresh()` or the `refresh()` method of some other relevant window.

A pad is a special case of a window; it can be larger than the actual display screen, and only a portion of the pad displayed at a time. Creating a pad requires the pad’s height and width, while refreshing a pad requires giving the coordinates of the on-screen area where a subsection of the pad will be displayed.

```python
pad = curses.newpad(100, 100)  
# These loops fill the pad with letters; addch() is explained in the next section
for y in range(0, 99):
    for x in range(0, 99):
        pad.addch(y, x, ord('a') + (x*x+y*y) % 26)

# Displays a section of the pad in the middle of the
# (0,0) : coordinate of upper-left corner of pad area
```
The `refresh()` call displays a section of the pad in the rectangle extending from coordinate (5,5) to coordinate (20,75) on the screen; the upper left corner of the displayed section is coordinate (0,0) on the pad. Beyond that difference, pads are exactly like ordinary windows and support the same methods.

If you have multiple windows and pads on screen there is a more efficient way to update the screen and prevent annoying screen flicker as each part of the screen gets updated. `refresh()` actually does two things:

1. Calls the `noutrefresh()` method of each window to update an underlying data structure representing the desired state of the screen.
2. Calls the function `doupdate()` function to change the physical screen to match the desired state recorded in the data structure.

Instead you can call `noutrefresh()` on a number of windows to update the data structure, and then call `doupdate()` to update the screen.
Displaying Text

From a C programmer’s point of view, curses may sometimes look like a twisty maze of functions, all subtly different. For example, `addstr()` displays a string at the current cursor location in the `stdscr` window, while `mvaddstr()` moves to a given y,x coordinate first before displaying the string. `waddstr()` is just like `addstr()`, but allows specifying a window to use instead of using `stdscr` by default. `mvwaddstr()` allows specifying both a window and a coordinate.

Fortunately the Python interface hides all these details. `stdscr` is a window object like any other, and methods such as `addstr()` accept multiple argument forms. Usually there are four different forms.

<table>
<thead>
<tr>
<th>Form</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td><code>str</code> or <code>ch</code></td>
<td>Display the string <code>str</code> or character <code>ch</code> at the current position</td>
</tr>
<tr>
<td><code>str</code> or <code>ch</code>, <code>attr</code></td>
<td>Display the string <code>str</code> or character <code>ch</code>, using attribute <code>attr</code> at the current position</td>
</tr>
<tr>
<td><code>y</code>, <code>x</code>, <code>str</code> or <code>ch</code></td>
<td>Move to position <code>y</code>,<code>x</code> within the window, and display <code>str</code> or <code>ch</code></td>
</tr>
<tr>
<td><code>y</code>, <code>x</code>, <code>str</code> or <code>ch</code>, <code>attr</code></td>
<td>Move to position <code>y</code>,<code>x</code> within the window, and display <code>str</code> or <code>ch</code>, using attribute <code>attr</code></td>
</tr>
</tbody>
</table>

Attributes allow displaying text in highlighted forms such as boldface, underline, reverse code, or in color. They’ll be explained in more detail in the next subsection.
The `addstr()` method takes a Python string or bytestring as the value to be displayed. The contents of bytestings are sent to the terminal as-is. Strings are encoded to bytes using the value of the window's encoding attribute; this defaults to the default system encoding as returned by `locale.getpreferredencoding()`.

The `addch()` methods take a character, which can be either a string of length 1, a bytestring of length 1, or an integer.

Constants are provided for extension characters; these constants are integers greater than 255. For example, ACS_PLMINUS is a +/- symbol, and ACS_ULCORNER is the upper left corner of a box (handy for drawing borders). You can also use the appropriate Unicode character.

Windows remember where the cursor was left after the last operation, so if you leave out the y,x coordinates, the string or character will be displayed wherever the last operation left off. You can also move the cursor with the `move(y,x)` method. Because some terminals always display a flashing cursor, you may want to ensure that the cursor is positioned in some location where it won’t be distracting; it can be confusing to have the cursor blinking at some apparently random location.

If your application doesn’t need a blinking cursor at all, you can call `curs_set(False)` to make it invisible. For compatibility with older curses versions, there’s a `leaveok(bool)` function that’s a synonym for `curs_set()`. When `bool` is true, the curses library will attempt to suppress the flashing cursor, and you won’t need to worry about leaving it in odd locations.

Attributes and Color
Characters can be displayed in different ways. Status lines in a text-based application are commonly shown in reverse video, or a text viewer may need to highlight certain words. curses supports this by allowing you to specify an attribute for each cell on the screen.

An attribute is an integer, each bit representing a different attribute. You can try to display text with multiple attribute bits set, but curses doesn’t guarantee that all the possible combinations are available, or that they’re all visually distinct. That depends on the ability of the terminal being used, so it’s safest to stick to the most commonly available attributes, listed here.

<table>
<thead>
<tr>
<th>Attribute</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>A_BLINK</td>
<td>Blinking text</td>
</tr>
<tr>
<td>A_BOLD</td>
<td>Extra bright or bold text</td>
</tr>
<tr>
<td>A_DIM</td>
<td>Half bright text</td>
</tr>
<tr>
<td>A_REVERSE</td>
<td>Reverse-video text</td>
</tr>
<tr>
<td>A_STANDOUT</td>
<td>The best highlighting mode available</td>
</tr>
<tr>
<td>A_UNDERLINE</td>
<td>Underlined text</td>
</tr>
</tbody>
</table>

So, to display a reverse-video status line on the top line of the screen, you could code:

```python
stdscr.addstr(0, 0, "Current mode: Typing mode", curses.A_REVERSE)
stdscr.refresh()
```

The curses library also supports color on those terminals that provide it. The most common such terminal is probably the Linux console, followed by color xterms.
To use color, you must call the `start_color()` function soon after calling `initscr()`, to initialize the default color set (the `curses.wrapper()` function does this automatically). Once that’s done, the `has_colors()` function returns TRUE if the terminal in use can actually display color. (Note: `curses` uses the American spelling ‘color’, instead of the Canadian/British spelling ‘colour’. If you’re used to the British spelling, you’ll have to resign yourself to misspelling it for the sake of these functions.)

The `curses` library maintains a finite number of color pairs, containing a foreground (or text) color and a background color. You can get the attribute value corresponding to a color pair with the `color_pair()` function; this can be bitwise-OR’ed with other attributes such as `A_REVERSE`, but again, such combinations are not guaranteed to work on all terminals.

An example, which displays a line of text using color pair 1:

```python
stdscr.addstr("Pretty text", curses.color_pair(1))
stdscr.refresh()
```

As I said before, a color pair consists of a foreground and background color. The `init_pair(n, f, b)` function changes the definition of color pair `n`, to foreground color `f` and background color `b`. Color pair 0 is hard-wired to white on black, and cannot be changed.

Colors are numbered, and `start_color()` initializes 8 basic colors when it activates color mode. They are: 0:black, 1:red, 2:green, 3:yellow, 4:blue, 5:magenta, 6:cyan, and 7:white. The `curses` module defines named constants for each of these colors: `curses.COLOR_BLACK`, `curses.COLOR_RED`, and so forth.

Let’s put all this together. To change color 1 to red text on a white
background, you would call:

```python
curses.init_pair(1, curses.COLOR_RED, curses.COLOR_WHITE)
```

When you change a color pair, any text already displayed using that color pair will change to the new colors. You can also display new text in this color with:

```python
stdscr.addstr(0, 0, "RED ALERT!", curses.color_pair(1))
```

Very fancy terminals can change the definitions of the actual colors to a given RGB value. This lets you change color 1, which is usually red, to purple or blue or any other color you like. Unfortunately, the Linux console doesn’t support this, so I’m unable to try it out, and can’t provide any examples. You can check if your terminal can do this by calling `can_change_color()`, which returns True if the capability is there. If you’re lucky enough to have such a talented terminal, consult your system’s man pages for more information.
User Input

The C curses library offers only very simple input mechanisms. Python’s `curses` module adds a basic text-input widget. (Other libraries such as Urwid have more extensive collections of widgets.)

There are two methods for getting input from a window:

- `getch()` refreshes the screen and then waits for the user to hit a key, displaying the key if `echo()` has been called earlier. You can optionally specify a coordinate to which the cursor should be moved before pausing.
- `getkey()` does the same thing but converts the integer to a string. Individual characters are returned as 1-character strings, and special keys such as function keys return longer strings containing a key name such as `KEY_UP` or `^G`.

It's possible to not wait for the user using the `nodelay()` window method. After `nodelay(True)`, `getch()` and `getkey()` for the window become non-blocking. To signal that no input is ready, `getch()` returns `curses.ERR` (a value of -1) and `getkey()` raises an exception. There's also a `halfdelay()` function, which can be used to (in effect) set a timer on each `getch()`; if no input becomes available within a specified delay (measured in tenths of a second), `curses` raises an exception.

The `getch()` method returns an integer; if it's between 0 and 255, it represents the ASCII code of the key pressed. Values greater than 255 are special keys such as Page Up, Home, or the cursor keys. You can compare the value returned to constants such as `curses.KEY_PPAGE`, `curses.KEY_HOME`, or `curses.KEY_LEFT`. The main loop of your program may look something like this:
while True:
    c = stdscr.getch()
    if c == ord('p'):
        PrintDocument()
    elif c == ord('q'):
        break  # Exit the while loop
    elif c == curses.KEY_HOME:
        x = y = 0

The `curses.ascii` module supplies ASCII class membership functions that take either integer or 1-character string arguments; these may be useful in writing more readable tests for such loops. It also supplies conversion functions that take either integer or 1-character-string arguments and return the same type. For example, `curses.ascii.ctrl()` returns the control character corresponding to its argument.

There's also a method to retrieve an entire string, `getstr()`. It isn't used very often, because its functionality is quite limited; the only editing keys available are the backspace key and the Enter key, which terminates the string. It can optionally be limited to a fixed number of characters.

curses.echo()  # Enable echoing of character

# Get a 15-character string, with the cursor on the top line
s = stdscr.getstr(0, 0, 15)

The `curses.textpad` module supplies a text box that supports an Emacs-like set of keybindings. Various methods of the `Textbox` class support editing with input validation and gathering the edit results either with or without trailing spaces. Here's an example:
import curses
from curses.textpad import Textbox, rectangle

def main(stdscr):
    stdscr.addstr(0, 0, "Enter IM message: (hit Ctrl-G to send)"

    editwin = curses.newwin(5, 30, 2, 1)
    rectangle(stdscr, 1, 0, 1+5+1, 1+30+1)
    stdscr.refresh()

    box = Textbox(editwin)

    # Let the user edit until Ctrl-G is struck.
    box.edit()

    # Get resulting contents
    message = box.gather()

See the library documentation on curses.textpad for more details.
For More Information

This HOWTO doesn’t cover some advanced topics, such as reading the contents of the screen or capturing mouse events from an xterm instance, but the Python library page for the curses module is now reasonably complete. You should browse it next.

If you’re in doubt about the detailed behavior of the curses functions, consult the manual pages for your curses implementation, whether it’s ncurses or a proprietary Unix vendor’s. The manual pages will document any quirks, and provide complete lists of all the functions, attributes, and ACS_* characters available to you.

Because the curses API is so large, some functions aren’t supported in the Python interface. Often this isn’t because they’re difficult to implement, but because no one has needed them yet. Also, Python doesn’t yet support the menu library associated with ncurses. Patches adding support for these would be welcome; see the Python Developer’s Guide to learn more about submitting patches to Python.

  - Static Methods and Class Methods
Abstract

Defines descriptors, summarizes the protocol, and shows how descriptors are called. Examines a custom descriptor and several built-in python descriptors including functions, properties, static methods, and class methods. Shows how each works by giving a pure Python equivalent and a sample application.

Learning about descriptors not only provides access to a larger toolset, it creates a deeper understanding of how Python works and an appreciation for the elegance of its design.
Definition and Introduction

In general, a descriptor is an object attribute with “binding behavior”, one whose attribute access has been overridden by methods in the descriptor protocol. Those methods are __get__(), __set__(), and __delete__(). If any of those methods are defined for an object, it is said to be a descriptor.

The default behavior for attribute access is to get, set, or delete the attribute from an object’s dictionary. For instance, a.x has a lookup chain starting with a.__dict__['x'], then type(a).__dict__['x'], and continuing through the base classes of type(a) excluding metaclasses. If the looked-up value is an object defining one of the descriptor methods, then Python may override the default behavior and invoke the descriptor method instead. Where this occurs in the precedence chain depends on which descriptor methods were defined.

Descriptors are a powerful, general purpose protocol. They are the mechanism behind properties, methods, static methods, class methods, and super(). They are used throughout Python itself to implement the new style classes introduced in version 2.2. Descriptors simplify the underlying C-code and offer a flexible set of new tools for everyday Python programs.
Descriptor Protocol

descr.__get__(self, obj, type=None) --> value
descr.__set__(self, obj, value) --> None
descr.__delete__(self, obj) --> None

That is all there is to it. Define any of these methods and an object is considered a descriptor and can override default behavior upon being looked up as an attribute.

If an object defines both __get__() and __set__(), it is considered a data descriptor. Descriptors that only define __get__() are called non-data descriptors (they are typically used for methods but other uses are possible).

Data and non-data descriptors differ in how overrides are calculated with respect to entries in an instance’s dictionary. If an instance’s dictionary has an entry with the same name as a data descriptor, the data descriptor takes precedence. If an instance’s dictionary has an entry with the same name as a non-data descriptor, the dictionary entry takes precedence.

To make a read-only data descriptor, define both __get__() and __set__() with the __set__() raising an AttributeError when called. Defining the __set__() method with an exception raising placeholder is enough to make it a data descriptor.
Invoking Descriptors

A descriptor can be called directly by its method name. For example, `d.__get__(obj)`.

Alternatively, it is more common for a descriptor to be invoked automatically upon attribute access. For example, `obj.d` looks up `d` in the dictionary of `obj`. If `d` defines the method `__get__()`, then `d.__get__(obj)` is invoked according to the precedence rules listed below.

The details of invocation depend on whether `obj` is an object or a class.

For objects, the machinery is in `object.__getattribute__()`, which transforms `b.x` into `type(b).__dict__['x'].__get__(b, type(b))`. The implementation works through a precedence chain that gives data descriptors priority over instance variables, instance variables priority over non-data descriptors, and assigns lowest priority to `__getattr__()` if provided. The full C implementation can be found in `PyObject_GenericGetAttr()` in `Objects/object.c`.

For classes, the machinery is in `type.__getattribute__()`, which transforms `B.x` into `B.__dict__['x'].__get__(None, B)`. In pure Python, it looks like:

```python
def __getattribute__(self, key):
    "Emulate type_getattro() in Objects/typeobject.c"
    v = object.__getattribute__(self, key)
    if hasattr(v, '__get__'):
        return v.__get__(None, self)
    return v
```
The important points to remember are:

- descriptors are invoked by the `__getattribute__()` method
- overriding `__getattribute__()` prevents automatic descriptor calls
- `object.__getattribute__()`, `type.__getattribute__()`, and `__get__()` make different calls to `__get__()`. data descriptors always override instance dictionaries.
- non-data descriptors may be overridden by instance dictionaries.

The object returned by `super()` also has a custom `__getattribute__()` method for invoking descriptors. The call `super(B, obj).m()` searches `obj.__class__.__mro__` for the base class A immediately following B and then returns `A.__dict__['m'].__get__(obj, B)`. If not a descriptor, m is returned unchanged. If not in the dictionary, m reverts to a search using `object.__getattribute__()`. The implementation details are in `super_getattro()` in `Objects/typeobject.c` and a pure Python equivalent can be found in Guido's Tutorial.

The details above show that the mechanism for descriptors is embedded in the `__getattribute__()` methods for `object`, `type`, and `super()`. Classes inherit this machinery when they derive from `object` or if they have a meta-class providing similar functionality. Likewise, classes can turn-off descriptor invocation by overriding `__getattribute__()`. 
Descriptor Example

The following code creates a class whose objects are data descriptors which print a message for each get or set. Overriding __getattribute__() is alternate approach that could do this for every attribute. However, this descriptor is useful for monitoring just a few chosen attributes:

```python
class RevealAccess(object):
    """A data descriptor that sets and returns values normally and prints a message logging their access."
    """
    def __init__(self, initval=None, name='var'):
        self.val = initval
        self.name = name

    def __get__(self, obj, objtype):
        print('Retrieving', self.name)
        return self.val

    def __set__(self, obj, val):
        print('Updating', self.name)
        self.val = val

>>> class MyClass(object):
    x = RevealAccess(10, 'var "x"')
    y = 5

>>> m = MyClass()
>>> m.x
Retrieving var "x"
10
>>> m.x = 20
Updating var "x"
```
The protocol is simple and offers exciting possibilities. Several use cases are so common that they have been packaged into individual function calls. Properties, bound and unbound methods, static methods, and class methods are all based on the descriptor protocol.
Properties

Calling \texttt{property()} is a succinct way of building a data descriptor that triggers function calls upon access to an attribute. Its signature is:

\begin{verbatim}
property(fget=\texttt{None}, fset=\texttt{None}, fdel=\texttt{None}, doc=\texttt{None})
\end{verbatim}

The documentation shows a typical use to define a managed attribute \texttt{x}:

\begin{verbatim}
class C(object):
    def getx(self): return self.__x
    def setx(self, value): self.__x = value
    def delx(self): del self.__x
    x = property(getx, setx, delx, "I'm the 'x' prop")
\end{verbatim}

To see how \texttt{property()} is implemented in terms of the descriptor protocol, here is a pure Python equivalent:

\begin{verbatim}
class Property(object):
    "Emulate PyProperty_Type() in Objects/descrobject.c"
    def __init__(self, fget=\texttt{None}, fset=\texttt{None}, fdel=\texttt{None},
                 self.fget = fget
                self.fset = fset
                self.fdel = fdel
                if doc is \texttt{None} and fget is not \texttt{None}:
                    doc = fget.__doc__
                self.__doc__ = doc

    def __get__(self, obj, objtype=\texttt{None}):
        if obj is \texttt{None}:
            return self
\end{verbatim}
The `property()` builtin helps whenever a user interface has granted attribute access and then subsequent changes require the intervention of a method.

For instance, a spreadsheet class may grant access to a cell value through `Cell('b10').value`. Subsequent improvements to the program require the cell to be recalculated on every access; however, the programmer does not want to affect existing client code accessing the attribute directly. The solution is to wrap access to the value attribute in a property data descriptor:

```python
class Cell(object):
    ...
def getvalue(self, obj):
    "Recalculate cell before returning value"
    self.recalc()
    return obj._value
value = property(getvalue)
Functions and Methods

Python’s object oriented features are built upon a function based environment. Using non-data descriptors, the two are merged seamlessly.

Class dictionaries store methods as functions. In a class definition, methods are written using `def` and `lambda`, the usual tools for creating functions. The only difference from regular functions is that the first argument is reserved for the object instance. By Python convention, the instance reference is called `self` but may be called `this` or any other variable name.

To support method calls, functions include the `__get__()` method for binding methods during attribute access. This means that all functions are non-data descriptors which return bound or unbound methods depending whether they are invoked from an object or a class. In pure python, it works like this:

```python
class Function(object):
    ...
    def __get__(self, obj, objtype=None):
        "Simulate func_descr_get() in Objects/funcobject.c"
        return types.MethodType(self, obj, objtype)
```

Running the interpreter shows how the function descriptor works in practice:

```python
>>> class D(object):
    def f(self, x):
        return x
```
```python
>>> d = D()
>>> D.__dict__['f']  # Stored internally as a function
<function f at 0x00C45070>
>>> D.f  # Get from a class becomes an unbound method
<unbound method D.f>
>>> d.f  # Get from an instance becomes a bound method
<bound method D.f of <__main__.D object at 0x00B18C90>>
```

The output suggests that bound and unbound methods are two different types. While they could have been implemented that way, the actual C implementation of `PyMethod_Type` in `Objects/classobject.c` is a single object with two different representations depending on whether the `im_self` field is set or is `NULL` (the C equivalent of `None`).

Likewise, the effects of calling a method object depend on the `im_self` field. If set (meaning bound), the original function (stored in the `im_func` field) is called as expected with the first argument set to the instance. If unbound, all of the arguments are passed unchanged to the original function. The actual C implementation of `instancemethod_call()` is only slightly more complex in that it includes some type checking.
Static Methods and Class Methods

Non-data descriptors provide a simple mechanism for variations on the usual patterns of binding functions into methods.

To recap, functions have a `__get__()` method so that they can be converted to a method when accessed as attributes. The non-data descriptor transforms a `obj.f(*args)` call into `f(obj, *args)`. Calling `klass.f(*args)` becomes `f(*args)`.

This chart summarizes the binding and its two most useful variants:

<table>
<thead>
<tr>
<th>Transformation</th>
<th>Called from an Object</th>
<th>Called from a Class</th>
</tr>
</thead>
<tbody>
<tr>
<td>function</td>
<td><code>f(obj, *args)</code></td>
<td><code>f(*args)</code></td>
</tr>
<tr>
<td>staticmethod</td>
<td><code>f(*args)</code></td>
<td><code>f(*args)</code></td>
</tr>
<tr>
<td>classmethod</td>
<td><code>f(type(obj), *args)</code></td>
<td><code>f(klass, *args)</code></td>
</tr>
</tbody>
</table>

Static methods return the underlying function without changes. Calling either `c.f` or `C.f` is the equivalent of a direct lookup into `object.__getattribute__(c, "f")` or `object.__getattribute__(C, "f")`. As a result, the function becomes identically accessible from either an object or a class.

Good candidates for static methods are methods that do not reference the `self` variable.

For instance, a statistics package may include a container class for experimental data. The class provides normal methods for computing the average, mean, median, and other descriptive statistics that depend on the data. However, there may be useful functions which are...
conceptually related but do not depend on the data. For instance, \( \text{erf}(x) \) is handy conversion routine that comes up in statistical work but does not directly depend on a particular dataset. It can be called either from an object or the class: \( \text{s.erf}(1.5) \rightarrow .9332 \) or \( \text{Sample.erf}(1.5) \rightarrow .9332 \).

Since staticmethods return the underlying function with no changes, the example calls are unexciting:

```python
>>> class E(object):
    def f(x):
        print(x)
    f = staticmethod(f)

>>> print(E.f(3))
3
>>> print(E().f(3))
3
```

Using the non-data descriptor protocol, a pure Python version of \texttt{staticmethod()} would look like this:

```python
class StaticMethod(object):
    "Emulate PyStaticMethod_Type() in Objects/funcobject"
    def __init__(self, f):
        self.f = f
    def __get__(self, obj, objtype=None):
        return self.f
```

Unlike static methods, class methods prepend the class reference to the argument list before calling the function. This format is the same for whether the caller is an object or a class:
```python
class E(object):
    def f(klass, x):
        return klass.__name__, x
    f = classmethod(f)

>>> print(E.f(3))
('E', 3)
>>> print(E().f(3))
('E', 3)
```

This behavior is useful whenever the function only needs to have a class reference and does not care about any underlying data. One use for classmethods is to create alternate class constructors. In Python 2.3, the classmethod `dict.fromkeys()` creates a new dictionary from a list of keys. The pure Python equivalent is:

```python
class Dict(object):
    ...
    def fromkeys(klass, iterable, value=None):
        """Emulate dict_fromkeys() in Objects/dictobject.c"
        d = klass()
        for key in iterable:
            d[key] = value
        return d
    fromkeys = classmethod(fromkeys)
```

Now a new dictionary of unique keys can be constructed like this:

```python
>>> Dict.fromkeys('abracadabra')
{'a': None, 'r': None, 'b': None, 'c': None, 'd': None}
```

Using the non-data descriptor protocol, a pure Python version of `classmethod()` would look like this:
```python
class ClassMethod(object):
    "Emulate PyClassMethod_Type() in Objects/funcobject.c"

    def __init__(self, f):
        self.f = f

    def __get__(self, obj, klass=None):
        if klass is None:
            klass = type(obj)
        def newfunc(*args):
            return self.f(klass, *args)
        return newfunc
```

Functional Programming HOWTO

<table>

In this document, we'll take a tour of Python’s features suitable for implementing programs in a functional style. After an introduction to the concepts of functional programming, we'll look at language features such as *iterators* and *generators* and relevant library modules such as *itertools* and *functools*.
Introduction

This section explains the basic concept of functional programming; if you’re just interested in learning about Python language features, skip to the next section.

Programming languages support decomposing problems in several different ways:

- Most programming languages are **procedural**: programs are lists of instructions that tell the computer what to do with the program’s input. C, Pascal, and even Unix shells are procedural languages.
- In **declarative** languages, you write a specification that describes the problem to be solved, and the language implementation figures out how to perform the computation efficiently. SQL is the declarative language you’re most likely to be familiar with; a SQL query describes the data set you want to retrieve, and the SQL engine decides whether to scan tables or use indexes, which subclauses should be performed first, etc.
- **Object-oriented** programs manipulate collections of objects. Objects have internal state and support methods that query or modify this internal state in some way. Smalltalk and Java are object-oriented languages. C++ and Python are languages that support object-oriented programming, but don’t force the use of object-oriented features.
- **Functional** programming decomposes a problem into a set of functions. Ideally, functions only take inputs and produce outputs, and don’t have any internal state that affects the output produced for a given input. Well-known functional languages include the ML family (Standard ML, OCaml, and other variants) and Haskell.

The designers of some computer languages choose to emphasize one particular approach to programming. This often makes it difficult to
write programs that use a different approach. Other languages are multi-paradigm languages that support several different approaches. Lisp, C++, and Python are multi-paradigm; you can write programs or libraries that are largely procedural, object-oriented, or functional in all of these languages. In a large program, different sections might be written using different approaches; the GUI might be object-oriented while the processing logic is procedural or functional, for example.

In a functional program, input flows through a set of functions. Each function operates on its input and produces some output. Functional style discourages functions with side effects that modify internal state or make other changes that aren’t visible in the function’s return value. Functions that have no side effects at all are called purely functional. Avoiding side effects means not using data structures that get updated as a program runs; every function’s output must only depend on its input.

Some languages are very strict about purity and don’t even have assignment statements such as \texttt{a=3} or \texttt{c = a + b}, but it’s difficult to avoid all side effects. Printing to the screen or writing to a disk file are side effects, for example. For example, in Python a call to the \texttt{print()} or \texttt{time.sleep()} function both return no useful value; they’re only called for their side effects of sending some text to the screen or pausing execution for a second.

Python programs written in functional style usually won’t go to the extreme of avoiding all I/O or all assignments; instead, they’ll provide a functional-appearing interface but will use non-functional features internally. For example, the implementation of a function will still use assignments to local variables, but won’t modify global variables or have other side effects.

Functional programming can be considered the opposite of object-
oriented programming. Objects are little capsules containing some internal state along with a collection of method calls that let you modify this state, and programs consist of making the right set of state changes. Functional programming wants to avoid state changes as much as possible and works with data flowing between functions. In Python you might combine the two approaches by writing functions that take and return instances representing objects in your application (e-mail messages, transactions, etc.).

Functional design may seem like an odd constraint to work under. Why should you avoid objects and side effects? There are theoretical and practical advantages to the functional style:

- Formal provability.
- Modularity.
- Composability.
- Ease of debugging and testing.

**Formal provability**

A theoretical benefit is that it's easier to construct a mathematical proof that a functional program is correct.

For a long time researchers have been interested in finding ways to mathematically prove programs correct. This is different from testing a program on numerous inputs and concluding that its output is usually correct, or reading a program’s source code and concluding that the code looks right; the goal is instead a rigorous proof that a program produces the right result for all possible inputs.

The technique used to prove programs correct is to write down **invariants**, properties of the input data and of the program’s variables that are always true. For each line of code, you then show that if
invariants X and Y are true **before** the line is executed, the slightly different invariants X' and Y' are true **after** the line is executed. This continues until you reach the end of the program, at which point the invariants should match the desired conditions on the program’s output.

Functional programming’s avoidance of assignments arose because assignments are difficult to handle with this technique; assignments can break invariants that were true before the assignment without producing any new invariants that can be propagated onward.

Unfortunately, proving programs correct is largely impractical and not relevant to Python software. Even trivial programs require proofs that are several pages long; the proof of correctness for a moderately complicated program would be enormous, and few or none of the programs you use daily (the Python interpreter, your XML parser, your web browser) could be proven correct. Even if you wrote down or generated a proof, there would then be the question of verifying the proof; maybe there’s an error in it, and you wrongly believe you’ve proved the program correct.

**Modularity**

A more practical benefit of functional programming is that it forces you to break apart your problem into small pieces. Programs are more modular as a result. It’s easier to specify and write a small function that does one thing than a large function that performs a complicated transformation. Small functions are also easier to read and to check for errors.

**Ease of debugging and testing**
Testing and debugging a functional-style program is easier.

Debugging is simplified because functions are generally small and clearly specified. When a program doesn’t work, each function is an interface point where you can check that the data are correct. You can look at the intermediate inputs and outputs to quickly isolate the function that’s responsible for a bug.

Testing is easier because each function is a potential subject for a unit test. Functions don’t depend on system state that needs to be replicated before running a test; instead you only have to synthesize the right input and then check that the output matches expectations.

Composability

As you work on a functional-style program, you’ll write a number of functions with varying inputs and outputs. Some of these functions will be unavoidably specialized to a particular application, but others will be useful in a wide variety of programs. For example, a function that takes a directory path and returns all the XML files in the directory, or a function that takes a filename and returns its contents, can be applied to many different situations.

Over time you’ll form a personal library of utilities. Often you’ll assemble new programs by arranging existing functions in a new configuration and writing a few functions specialized for the current task.
Iterators

I'll start by looking at a Python language feature that's an important foundation for writing functional-style programs: iterators.

An iterator is an object representing a stream of data; this object returns the data one element at a time. A Python iterator must support a method called `__next__()` that takes no arguments and always returns the next element of the stream. If there are no more elements in the stream, `__next__()` must raise the `StopIteration` exception. Iterators don't have to be finite, though; it's perfectly reasonable to write an iterator that produces an infinite stream of data.

The built-in `iter()` function takes an arbitrary object and tries to return an iterator that will return the object's contents or elements, raising `TypeError` if the object doesn't support iteration. Several of Python's built-in data types support iteration, the most common being lists and dictionaries. An object is called `iterable` if you can get an iterator for it.

You can experiment with the iteration interface manually:

```python
>>> L = [1, 2, 3]
>>> it = iter(L)
>>> it
<...iterator object at ...>
>>> it.__next__()  # same as next(it)
1
>>> next(it)
2
>>> next(it)
3
>>> next(it)
```

`StopIteration`
Python expects iterable objects in several different contexts, the most important being the `for` statement. In the statement `for X in Y`, `Y` must be an iterator or some object for which `iter()` can create an iterator. These two statements are equivalent:

```python
for i in iter(obj):
    print(i)

for i in obj:
    print(i)
```

Iterators can be materialized as lists or tuples by using the `list()` or `tuple()` constructor functions:

```python
>>> L = [1, 2, 3]
>>> iterator = iter(L)
>>> t = tuple(iterator)
>>> t
(1, 2, 3)
```

Sequence unpacking also supports iterators: if you know an iterator will return N elements, you can unpack them into an N-tuple:

```python
>>> L = [1, 2, 3]
>>> iterator = iter(L)
>>> a, b, c = iterator
>>> a, b, c
(1, 2, 3)
```

Built-in functions such as `max()` and `min()` can take a single iterator
argument and will return the largest or smallest element. The "in" and "not in" operators also support iterators: \texttt{X in iterator} is true if \( X \) is found in the stream returned by the iterator. You'll run into obvious problems if the iterator is infinite; \texttt{max()}, \texttt{min()} will never return, and if the element \( X \) never appears in the stream, the "in" and "not in" operators won't return either.

Note that you can only go forward in an iterator; there's no way to get the previous element, reset the iterator, or make a copy of it. Iterator objects can optionally provide these additional capabilities, but the iterator protocol only specifies the \texttt{__next__()} method. Functions may therefore consume all of the iterator's output, and if you need to do something different with the same stream, you'll have to create a new iterator.

**Data Types That Support Iterators**

We've already seen how lists and tuples support iterators. In fact, any Python sequence type, such as strings, will automatically support creation of an iterator.

Calling \texttt{iter()} on a dictionary returns an iterator that will loop over the dictionary's keys:

```
>>> m = {'Jan': 1, 'Feb': 2, 'Mar': 3, 'Apr': 4, 'May': ...
       'Jul': 7, 'Aug': 8, 'Sep': 9, 'Oct': 10, 'Nov': ...

>>> for key in m:
...    print(key, m[key])
Mar 3
Feb 2
Aug 8
Sep 9
Apr 4
```
Note that the order is essentially random, because it’s based on the hash ordering of the objects in the dictionary.

Applying `iter()` to a dictionary always loops over the keys, but dictionaries have methods that return other iterators. If you want to iterate over values or key/value pairs, you can explicitly call the `values()` or `items()` methods to get an appropriate iterator.

The `dict()` constructor can accept an iterator that returns a finite stream of (key, value) tuples:

```python
>>> L = [('Italy', 'Rome'), ('France', 'Paris'), ('US', 'Washington DC')
>>> dict(iter(L))
{'Italy': 'Rome', 'US': 'Washington DC', 'France': 'Paris'}
```

Files also support iteration by calling the `readline()` method until there are no more lines in the file. This means you can read each line of a file like this:

```python
for line in file:
    # do something for each line
...
```

Sets can take their contents from an iterable and let you iterate over the set’s elements:
S = {2, 3, 5, 7, 11, 13}
for i in S:
    print(i)
Generator expressions and list comprehensions

Two common operations on an iterator’s output are 1) performing some operation for every element, 2) selecting a subset of elements that meet some condition. For example, given a list of strings, you might want to strip off trailing whitespace from each line or extract all the strings containing a given substring.

List comprehensions and generator expressions (short form: “listcomps” and “genexps”) are a concise notation for such operations, borrowed from the functional programming language Haskell (http://www.haskell.org/). You can strip all the whitespace from a stream of strings with the following code:

```python
line_list = ['  line 1
', '  line 2  
', '  ...
#	Generator expression -- returns iterator
stripped_iter = (line.strip() for line in line_list)
#	List comprehension -- returns list
stripped_list = [line.strip() for line in line_list]
```

You can select only certain elements by adding an "if" condition:

```python
stripped_list = [line.strip() for line in line_list
  if line != '']
```

With a list comprehension, you get back a Python list; stripped_list is a list containing the resulting lines, not an iterator. Generator expressions return an iterator that computes the values as necessary, not needing to materialize all the values at once. This
means that list comprehensions aren’t useful if you’re working with iterators that return an infinite stream or a very large amount of data. Generator expressions are preferable in these situations.

Generator expressions are surrounded by parentheses (“()”) and list comprehensions are surrounded by square brackets (“[]”). Generator expressions have the form:

```
( expression for expr in sequence1
  if condition1
  for expr2 in sequence2
  if condition2
  for expr3 in sequence3 ...
  if condition3
  for exprN in sequenceN
  if conditionN )
```

Again, for a list comprehension only the outside brackets are different (square brackets instead of parentheses).

The elements of the generated output will be the successive values of expression. The if clauses are all optional; if present, expression is only evaluated and added to the result when condition is true.

Generator expressions always have to be written inside parentheses, but the parentheses signalling a function call also count. If you want to create an iterator that will be immediately passed to a function you can write:

```
obj_total = sum(obj.count for obj in list_all_objects)
```

The for...in clauses contain the sequences to be iterated over.
The sequences do not have to be the same length, because they are iterated over from left to right, **not** in parallel. For each element in `sequence1`, `sequence2` is looped over from the beginning. `sequence3` is then looped over for each resulting pair of elements from `sequence1` and `sequence2`.

To put it another way, a list comprehension or generator expression is equivalent to the following Python code:

```python
for expr1 in sequence1:
    if not (condition1):
        continue  # Skip this element
for expr2 in sequence2:
    if not (condition2):
        continue  # Skip this element
...  
for exprN in sequenceN:
    if not (conditionN):
        continue  # Skip this element

# Output the value of
# the expression.
```

This means that when there are multiple `for...in` clauses but no `if` clauses, the length of the resulting output will be equal to the product of the lengths of all the sequences. If you have two lists of length 3, the output list is 9 elements long:

```python
>>> seq1 = 'abc'
>>> seq2 = (1,2,3)
>>> [(x, y) for x in seq1 for y in seq2]
[('a', 1), ('a', 2), ('a', 3), ('b', 1), ('b', 2), ('b', 3), ('c', 1), ('c', 2), ('c', 3)]
```
To avoid introducing an ambiguity into Python’s grammar, if expression is creating a tuple, it must be surrounded with parentheses. The first list comprehension below is a syntax error, while the second one is correct:

```python
# Syntax error
[x, y for x in seq1 for y in seq2]
# Correct
[(x, y) for x in seq1 for y in seq2]
```
Generators

Generators are a special class of functions that simplify the task of writing iterators. Regular functions compute a value and return it, but generators return an iterator that returns a stream of values.

You’re doubtless familiar with how regular function calls work in Python or C. When you call a function, it gets a private namespace where its local variables are created. When the function reaches a `return` statement, the local variables are destroyed and the value is returned to the caller. A later call to the same function creates a new private namespace and a fresh set of local variables. But, what if the local variables weren’t thrown away on exiting a function? What if you could later resume the function where it left off? This is what generators provide; they can be thought of as resumable functions.

Here’s the simplest example of a generator function:

```python
>>> def generate_ints(N):
...     for i in range(N):
...         yield i
```

Any function containing a `yield` keyword is a generator function; this is detected by Python’s `bytecode` compiler which compiles the function specially as a result.

When you call a generator function, it doesn’t return a single value; instead it returns a generator object that supports the iterator protocol. On executing the `yield` expression, the generator outputs the value of `i`, similar to a `return` statement. The big difference between `yield` and a `return` statement is that on reaching a `yield` the generator’s state of execution is suspended and local variables are
preserved. On the next call to the generator’s `__next__()` method, the function will resume executing.

Here’s a sample usage of the `generate_ints()` generator:

```python
>>> gen = generate_ints(3)
>>> gen
<generator object generate_ints at ...>
>>> next(gen)
0
>>> next(gen)
1
>>> next(gen)
2
>>> next(gen)
Traceback (most recent call last):
  File "stdin", line 1, in ?
  File "stdin", line 2, in generate_ints
StopIteration
```

You could equally write `for i in generate_ints(5)`, or `a, b, c = generate_ints(3)`.

Inside a generator function, `return value` is semantically equivalent to `raise StopIteration(value)`. If no value is returned or the bottom of the function is reached, the procession of values ends and the generator cannot return any further values.

You could achieve the effect of generators manually by writing your own class and storing all the local variables of the generator as instance variables. For example, returning a list of integers could be done by setting `self.count` to 0, and having the `__next__()` method increment `self.count` and return it. However, for a moderately complicated generator, writing a corresponding class can
be much messier.

The test suite included with Python’s library, `Lib/test/test_generators.py`, contains a number of more interesting examples. Here’s one generator that implements an in-order traversal of a tree using generators recursively.

```python
# A recursive generator that generates Tree leaves in in-order.
def inorder(t):
    if t:
        for x in inorder(t.left):
            yield x

        yield t.label

        for x in inorder(t.right):
            yield x
```

Two other examples in `test_generators.py` produce solutions for the N-Queens problem (placing N queens on an NxN chess board so that no queen threatens another) and the Knight’s Tour (finding a route that takes a knight to every square of an NxN chessboard without visiting any square twice).

**Passing values into a generator**

In Python 2.4 and earlier, generators only produced output. Once a generator’s code was invoked to create an iterator, there was no way to pass any new information into the function when its execution is resumed. You could hack together this ability by making the generator look at a global variable or by passing in some mutable object that callers then modify, but these approaches are messy.
In Python 2.5 there's a simple way to pass values into a generator. `yield` became an expression, returning a value that can be assigned to a variable or otherwise operated on:

```python
val = (yield i)
```

I recommend that you **always** put parentheses around a `yield` expression when you're doing something with the returned value, as in the above example. The parentheses aren't always necessary, but it's easier to always add them instead of having to remember when they're needed.

(PEP 342 explains the exact rules, which are that a `yield`-expression must always be parenthesized except when it occurs at the top-level expression on the right-hand side of an assignment. This means you can write `val = yield i` but have to use parentheses when there's an operation, as in `val = (yield i) + 12`.)

Values are sent into a generator by calling its `send(value)` method. This method resumes the generator's code and the `yield` expression returns the specified value. If the regular `__next__()` method is called, the `yield` returns None.

Here's a simple counter that increments by 1 and allows changing the value of the internal counter.

```python
def counter(maximum):
    i = 0
    while i < maximum:
        val = (yield i)
        # If value provided, change counter
        if val is not None:
            i = val
```
else:
    i += 1

And here's an example of changing the counter:

```python
>>> it = counter(10)
>>> next(it)
0
>>> next(it)
1
>>> it.send(8)
8
>>> next(it)
9
>>> next(it)
Traceback (most recent call last):
  File "t.py", line 15, in ?
    it.next()
StopIteration
```

Because `yield` will often be returning `None`, you should always check for this case. Don’t just use its value in expressions unless you’re sure that the `send()` method will be the only method used resume your generator function.

In addition to `send()`, there are two other methods on generators:

- `throw(type, value=None, traceback=None)` is used to raise an exception inside the generator; the exception is raised by the `yield` expression where the generator’s execution is paused.

- `close()` raises a `GeneratorExit` exception inside the generator to terminate the iteration. On receiving this exception, the generator’s code must either raise `GeneratorExit` or
StopIteration; catching the exception and doing anything else is illegal and will trigger a RuntimeError. close() will also be called by Python’s garbage collector when the generator is garbage-collected.

If you need to run cleanup code when a GeneratorExit occurs, I suggest using a try: ... finally: suite instead of catching GeneratorExit.

The cumulative effect of these changes is to turn generators from one-way producers of information into both producers and consumers.

Generators also become coroutines, a more generalized form of subroutines. Subroutines are entered at one point and exited at another point (the top of the function, and a return statement), but coroutines can be entered, exited, and resumed at many different points (the yield statements).
Built-in functions

Let's look in more detail at built-in functions often used with iterators.

Two of Python's built-in functions, `map()` and `filter()` duplicate the features of generator expressions:

`map(f, iterA, iterB, ...)` returns an iterator over the sequence

\[
f(\text{iterA}[0], \text{iterB}[0]), f(\text{iterA}[1], \text{iterB}[1]), f(\text{iterA}[2], \text{iterB}[2]), \ldots
\]

```python
>>> def upper(s):
...       return s.upper()

>>> list(map(upper, ['sentence', 'fragment']))
['SENTENCE', 'FRAGMENT']

>>> [upper(s) for s in ['sentence', 'fragment']]
['SENTENCE', 'FRAGMENT']
```

You can of course achieve the same effect with a list comprehension.

`filter(predicate, iter)` returns an iterator over all the sequence elements that meet a certain condition, and is similarly duplicated by list comprehensions. A `predicate` is a function that returns the truth value of some condition; for use with `filter()`, the predicate must take a single value.

```python
>>> def is_even(x):
...       return (x % 2) == 0

>>> list(filter(is_even, range(10)))
[0, 2, 4, 6, 8]
```
This can also be written as a list comprehension:

```python
>>> list(x for x in range(10) if is_even(x))
[0, 2, 4, 6, 8]
```

`enumerate(iter)` counts off the elements in the iterable, returning 2-tuples containing the count and each element.

```python
>>> for item in enumerate(['subject', 'verb', 'object', ...
   ...      print(item)
(0, 'subject')
(1, 'verb')
(2, 'object')
```

`enumerate()` is often used when looping through a list and recording the indexes at which certain conditions are met:

```python
f = open('data.txt', 'r')
for i, line in enumerate(f):
    if line.strip() == '':
        print('Blank line at line #%i' % i)
```

`sorted(iterable, key=None, reverse=False)` collects all the elements of the iterable into a list, sorts the list, and returns the sorted result. The `key`, and `reverse` arguments are passed through to the constructed list's `sort()` method.

```python
>>> import random
>>> # Generate 8 random numbers between [0, 10000)
>>> rand_list = random.sample(range(10000), 8)
>>> rand_list
[769, 7953, 9828, 6431, 8442, 9878, 6213, 2207]
>>> sorted(rand_list)
[769, 2207, 6213, 6431, 7953, 8442, 9828, 9878]
```
sorted(rand_list, reverse=True)
[9878, 9828, 8442, 7953, 6431, 6213, 2207, 769]

(For a more detailed discussion of sorting, see the Sorting HOW TO.)

The any(iter) and all(iter) built-ins look at the truth values of an iterable's contents. any() returns True if any element in the iterable is a true value, and all() returns True if all of the elements are true values:

```python
>>> any([0,1,0])
True
>>> any([0,0,0])
False
>>> any([1,1,1])
True
>>> all([0,1,0])
False
>>> all([0,0,0])
False
>>> all([1,1,1])
True
```

zip(iterA, iterB, ...) takes one element from each iterable and returns them in a tuple:

```python
zip(['a', 'b', 'c'], (1, 2, 3)) =>
('a', 1), ('b', 2), ('c', 3)
```

It doesn't construct an in-memory list and exhaust all the input iterators before returning; instead tuples are constructed and returned only if they're requested. (The technical term for this behaviour is lazy evaluation.)

This iterator is intended to be used with iterables that are all of the
same length. If the iterables are of different lengths, the resulting stream will be the same length as the shortest iterable.

\[
\text{zip(['a', 'b'], (1, 2, 3)) => ('a', 1), ('b', 2)}
\]

You should avoid doing this, though, because an element may be taken from the longer iterators and discarded. This means you can’t go on to use the iterators further because you risk skipping a discarded element.
The `itertools` module

The `itertools` module contains a number of commonly-used iterators as well as functions for combining several iterators. This section will introduce the module's contents by showing small examples.

The module's functions fall into a few broad classes:

- Functions that create a new iterator based on an existing iterator.
- Functions for treating an iterator's elements as function arguments.
- Functions for selecting portions of an iterator's output.
- A function for grouping an iterator's output.

Creating new iterators

`itertools.count(n)` returns an infinite stream of integers, increasing by 1 each time. You can optionally supply the starting number, which defaults to 0:

```python
itertools.count() =>
0, 1, 2, 3, 4, 5, 6, 7, 8, 9, ...
```

```python
itertools.count(10) =>
10, 11, 12, 13, 14, 15, 16, 17, 18, 19, ...
```

`itertools.cycle(iter)` saves a copy of the contents of a provided iterable and returns a new iterator that returns its elements from first to last. The new iterator will repeat these elements infinitely.

```python
itertools.cycle([1,2,3,4,5]) =>
1, 2, 3, 4, 5, 1, 2, 3, 4, 5, ...
```
itertools.repeat(elem, [n]) returns the provided element \( n \) times, or returns the element endlessly if \( n \) is not provided.

```python
itertools.repeat('abc') => abc, abc, abc, abc, abc, abc, abc, abc, abc, abc
itertools.repeat('abc', 5) => abc, abc, abc, abc, abc
```

itertools.chain(iterA, iterB, ...) takes an arbitrary number of iterables as input, and returns all the elements of the first iterator, then all the elements of the second, and so on, until all of the iterables have been exhausted.

```python
itertools.chain(["a", "b", "c"], (1, 2, 3)) => a, b, c, 1, 2, 3
```

itertools.islice(iter, [start], stop, [step]) returns a stream that's a slice of the iterator. With a single stop argument, it will return the first stop elements. If you supply a starting index, you'll get stop-start elements, and if you supply a value for step, elements will be skipped accordingly. Unlike Python's string and list slicing, you can't use negative values for start, stop, or step.

```python
itertools.islice(range(10), 8) => 0, 1, 2, 3, 4, 5, 6, 7
itertools.islice(range(10), 2, 8) => 2, 3, 4, 5, 6, 7
itertools.islice(range(10), 2, 8, 2) => 2, 4, 6
```

itertools.tee(iter, [n]) replicates an iterator; it returns \( n \) independent iterators that will all return the contents of the source iterator. If you don't supply a value for \( n \), the default is 2. Replicating
iterators requires saving some of the contents of the source iterator, so this can consume significant memory if the iterator is large and one of the new iterators is consumed more than the others.

```
iterators.tee( itertools.count() ) => iterA, iterB
```

```
where iterA =>
  0, 1, 2, 3, 4, 5, 6, 7, 8, 9, ...

and iterB =>
  0, 1, 2, 3, 4, 5, 6, 7, 8, 9, ...
```

**Calling functions on elements**

The `operator` module contains a set of functions corresponding to Python's operators. Some examples are `operator.add(a, b)` (adds two values), `operator.ne(a, b)` (same as `a != b`), and `operator.attrgetter('id')` (returns a callable that fetches the `id` attribute).

`itertools.starmap(func, iter)` assumes that the iterable will return a stream of tuples, and calls `func` using these tuples as the arguments:

```
itertools.starmap(os.path.join,
  [('bin', 'python'), ('usr', 'bin', 'java'), ('usr', 'bin', 'perl'), ('usr', 'bin', 'perl'),], =>
  /bin/python, /usr/bin/java, /usr/bin/perl, /usr/bin/perl
```

**Selecting elements**
Another group of functions chooses a subset of an iterator’s elements based on a predicate.

`itertools.filterfalse(predicate, iter)` is the opposite, returning all elements for which the predicate returns false:

```
itertools.filterfalse(is_even, itertools.count()) => 1, 3, 5, 7, 9, 11, 13, 15, ...
```

`itertools.takewhile(predicate, iter)` returns elements for as long as the predicate returns true. Once the predicate returns false, the iterator will signal the end of its results.

```
def less_than_10(x):
    return x < 10

itertools.takewhile(less_than_10, itertools.count())  
0, 1, 2, 3, 4, 5, 6, 7, 8, 9

itertools.takewhile(is_even, itertools.count()) =>  
0
```

`itertools.dropwhile(predicate, iter)` discards elements while the predicate returns true, and then returns the rest of the iterable's results.

```
itertools.dropwhile(less_than_10, itertools.count())  
10, 11, 12, 13, 14, 15, 16, 17, 18, 19, ...

itertools.dropwhile(is_even, itertools.count()) =>  
1, 2, 3, 4, 5, 6, 7, 8, 9, 10, ...
```
Grouping elements

The last function I’ll discuss, `itertools.groupby(iter, key_func=None)`, is the most complicated. `key_func(elem)` is a function that can compute a key value for each element returned by the iterable. If you don’t supply a key function, the key is simply each element itself.

`groupby()` collects all the consecutive elements from the underlying iterable that have the same key value, and returns a stream of 2-tuples containing a key value and an iterator for the elements with that key.

city_list = [('Decatur', 'AL'), ('Huntsville', 'AL'),
             ('Anchorage', 'AK'), ('Nome', 'AK'),
             ('Flagstaff', 'AZ'), ('Phoenix', 'AZ'),
             ...
]

def get_state(city_state):
    return city_state[1]

itertools.groupby(city_list, get_state) =>
    ('AL', iterator-1),
    ('AK', iterator-2),
    ('AZ', iterator-3), ...

where
iterator-1 =>
    ('Decatur', 'AL'), ('Huntsville', 'AL'), ('Selma',
iterator-2 =>
    ('Anchorage', 'AK'), ('Nome', 'AK')
iterator-3 =>
    ('Flagstaff', 'AZ'), ('Phoenix', 'AZ'), ('Tucson',

groupby() assumes that the underlying iterable’s contents will already be sorted based on the key. Note that the returned iterators also use the underlying iterable, so you have to consume the results of iterator-1 before requesting iterator-2 and its corresponding key.
The **functools** module

The **functools** module in Python 2.5 contains some higher-order functions. A **higher-order function** takes one or more functions as input and returns a new function. The most useful tool in this module is the **functools.partial()** function.

For programs written in a functional style, you'll sometimes want to construct variants of existing functions that have some of the parameters filled in. Consider a Python function \( f(a, b, c) \); you may wish to create a new function \( g(b, c) \) that's equivalent to \( f(1, b, c) \); you're filling in a value for one of \( f() \)'s parameters. This is called “partial function application”.

The constructor for **partial()** takes the arguments (**function**, **arg1**, **arg2**, ..., **kwarg1=value1**, **kwarg2=value2**). The resulting object is callable, so you can just call it to invoke **function** with the filled-in arguments.

Here's a small but realistic example:

```python
import functools

def log(message, subsystem):
    """Write the contents of 'message' to the specified subsystem."
    print('%s: %s' % (subsystem, message))
...

server_log = functools.partial(log, subsystem='server')
server_log('Unable to open socket')

functools.reduce(func, iter, [initial_value])
```
cumulatively performs an operation on all the iterable's elements and, therefore, can't be applied to infinite iterables. `func` must be a function that takes two elements and returns a single value. `functools.reduce()` takes the first two elements A and B returned by the iterator and calculates `func(A, B)`. It then requests the third element, C, calculates `func(func(A, B), C)`, combines this result with the fourth element returned, and continues until the iterable is exhausted. If the iterable returns no values at all, a `TypeError` exception is raised. If the initial value is supplied, it's used as a starting point and `func(initial_value, A)` is the first calculation.

```python
>>> import operator, functools
>>> functools.reduce(operator.concat, ['A', 'BB', 'C', 'ABBC'])
Traceback (most recent call last):
 ...
TypeError: reduce() of empty sequence with no initial value
>>> functools.reduce(operator.concat, [])
>>> functools.reduce(operator.mul, [1,2,3], 1)
6
>>> functools.reduce(operator.mul, [], 1)
1
```

If you use `operator.add()` with `functools.reduce()`, you'll add up all the elements of the iterable. This case is so common that there's a special built-in called `sum()` to compute it:

```python
>>> import functools
>>> functools.reduce(operator.add, [1,2,3,4], 0)
10
>>> sum([1,2,3,4])
10
>>> sum([])
```

For many uses of `functools.reduce()`, though, it can be clearer to just write the obvious `for` loop:

```python
import functools

# Instead of:
product = functools.reduce(operator.mul, [1,2,3], 1)

# You can write:
product = 1
for i in [1,2,3]:
    product *= i
```

### The operator module

The `operator` module was mentioned earlier. It contains a set of functions corresponding to Python’s operators. These functions are often useful in functional-style code because they save you from writing trivial functions that perform a single operation.

Some of the functions in this module are:

- Math operations: `add()`, `sub()`, `mul()`, `floordiv()`, `abs()`, ...
- Logical operations: `not_()`, `truth()`.
- Bitwise operations: `and_()`, `or_()`, `invert()`.
- Comparisons: `eq()`, `ne()`, `lt()`, `le()`, `gt()`, and `ge()`.
- Object identity: `is_()`, `is_not()`.

Consult the operator module’s documentation for a complete list.
Small functions and the lambda expression

When writing functional-style programs, you'll often need little functions that act as predicates or that combine elements in some way.

If there's a Python built-in or a module function that's suitable, you don't need to define a new function at all:

```python
stripped_lines = [line.strip() for line in lines]
existing_files = filter(os.path.exists, file_list)
```

If the function you need doesn't exist, you need to write it. One way to write small functions is to use the `lambda` statement. `lambda` takes a number of parameters and an expression combining these parameters, and creates an anonymous function that returns the value of the expression:

```python
adder = lambda x, y: x+y
print_assign = lambda name, value: name + '=' + str(value)
```

An alternative is to just use the `def` statement and define a function in the usual way:

```python
def adder(x, y):
    return x + y

def print_assign(name, value):
    return name + '=' + str(value)
```

Which alternative is preferable? That's a style question; my usual
course is to avoid using \texttt{lambda}.

One reason for my preference is that \texttt{lambda} is quite limited in the functions it can define. The result has to be computable as a single expression, which means you can't have multiway \texttt{if... elif... else} comparisons or \texttt{try... except} statements. If you try to do too much in a \texttt{lambda} statement, you'll end up with an overly complicated expression that's hard to read. Quick, what’s the following code doing?

\begin{verbatim}
import functools
total = functools.reduce(lamba a, b: (0, a[1] + b[1]),
                        items[1])
\end{verbatim}

You can figure it out, but it takes time to disentangle the expression to figure out what's going on. Using a short nested \texttt{def} statements makes things a little bit better:

\begin{verbatim}
import functools
def combine(a, b):
    return 0, a[1] + b[1]
total = functools.reduce(combine, items)[1]
\end{verbatim}

But it would be best of all if I had simply used a \texttt{for} loop:

\begin{verbatim}
total = 0
for a, b in items:
    total += b
\end{verbatim}

Or the \texttt{sum()} built-in and a generator expression:

\begin{verbatim}
total = sum(b for a,b in items)
\end{verbatim}
Many uses of `functools.reduce()` are clearer when written as `for` loops.

Fredrik Lundh once suggested the following set of rules for refactoring uses of lambda:

1. Write a lambda function.
2. Write a comment explaining what the heck that lambda does.
3. Study the comment for a while, and think of a name that captures the essence of the comment.
4. Convert the lambda to a `def` statement, using that name.
5. Remove the comment.

I really like these rules, but you’re free to disagree about whether this lambda-free style is better.
Revision History and Acknowledgements

The author would like to thank the following people for offering suggestions, corrections and assistance with various drafts of this article: Ian Bicking, Nick Coghlan, Nick Efford, Raymond Hettinger, Jim Jewett, Mike Krell, Leandro Lameiro, Jussi Salmela, Collin Winter, Blake Winton.

Version 0.1: posted June 30 2006.

Version 0.11: posted July 1 2006. Typo fixes.

Version 0.2: posted July 10 2006. Merged genexp and listcomp sections into one. Typo fixes.

Version 0.21: Added more references suggested on the tutor mailing list.

Version 0.30: Adds a section on the functional module written by Collin Winter; adds short section on the operator module; a few other edits.

Logging HOWTO

**Author:** Vinay Sajip <vinay_sajip at red-dove dot com>
Basic Logging Tutorial

Logging is a means of tracking events that happen when some software runs. The software’s developer adds logging calls to their code to indicate that certain events have occurred. An event is described by a descriptive message which can optionally contain variable data (i.e. data that is potentially different for each occurrence of the event). Events also have an importance which the developer ascribes to the event; the importance can also be called the level or severity.

When to use logging

Logging provides a set of convenience functions for simple logging usage. These are `debug()`, `info()`, `warning()`, `error()` and `critical()`. To determine when to use logging, see the table below, which states, for each of a set of common tasks, the best tool to use for it.

<table>
<thead>
<tr>
<th>Task you want to perform</th>
<th>The best tool for the task</th>
</tr>
</thead>
<tbody>
<tr>
<td>Display console output for ordinary usage of a command line script or program</td>
<td><code>print()</code></td>
</tr>
<tr>
<td>Report events that occur during normal operation of a program (e.g. for status monitoring or fault investigation)</td>
<td><code>logging.info()</code> (or <code>logging.debug()</code> for very detailed output for diagnostic purposes)</td>
</tr>
<tr>
<td></td>
<td><code>warnings.warn()</code> in library code if the issue is avoidable and the client application should be</td>
</tr>
</tbody>
</table>
Issue a warning regarding a particular runtime event modified to eliminate the warning logging.warning() if there is nothing the client application can do about the situation, but the event should still be noted

Report an error regarding a particular runtime event Raise an exception

Report suppression of an error without raising an exception (e.g. error handler in a long-running server process) logging.error(), logging.exception() or logging.critical() as appropriate for the specific error and application domain

The logging functions are named after the level or severity of the events they are used to track. The standard levels and their applicability are described below (in increasing order of severity):

<table>
<thead>
<tr>
<th>Level</th>
<th>When it’s used</th>
</tr>
</thead>
<tbody>
<tr>
<td>DEBUG</td>
<td>Detailed information, typically of interest only when diagnosing problems.</td>
</tr>
<tr>
<td>INFO</td>
<td>Confirmation that things are working as expected.</td>
</tr>
<tr>
<td>WARNING</td>
<td>An indication that something unexpected happened, or indicative of some problem in the near future (e.g. ‘disk space low’). The software is still working as expected.</td>
</tr>
<tr>
<td>ERROR</td>
<td>Due to a more serious problem, the software has not been able to perform some function.</td>
</tr>
<tr>
<td>CRITICAL</td>
<td>A serious error, indicating that the program itself may be unable to continue running.</td>
</tr>
</tbody>
</table>

The default level is WARNING, which means that only events of this
level and above will be tracked, unless the logging package is configured to do otherwise.

Events that are tracked can be handled in different ways. The simplest way of handling tracked events is to print them to the console. Another common way is to write them to a disk file.

A simple example

A very simple example is:

```python
import logging
logging.warning('Watch out!')  # will print a message
logging.info('I told you so')  # will not print anything
```

If you type these lines into a script and run it, you’ll see:

```
WARNING:root:Watch out!
```

printed out on the console. The `INFO` message doesn’t appear because the default level is `WARNING`. The printed message includes the indication of the level and the description of the event provided in the logging call, i.e. ‘Watch out!’. Don’t worry about the ‘root’ part for now: it will be explained later. The actual output can be formatted quite flexibly if you need that; formatting options will also be explained later.

Logging to a file

A very common situation is that of recording logging events in a file, so let’s look at that next:

```python
import logging
```
logging.basicConfig(filename='example.log', level=logging.DEBUG)
logging.debug('This message should go to the log file')
logging.info('So should this')
logging.warning('And this, too')

And now if we open the file and look at what we have, we should find the log messages:

DEBUG:root:This message should go to the log file
INFO:root:So should this
WARNING:root:And this, too

This example also shows how you can set the logging level which acts as the threshold for tracking. In this case, because we set the threshold to DEBUG, all of the messages were printed.

If you want to set the logging level from a command-line option such as:

```
--log=INFO
```

and you have the value of the parameter passed for --log in some variable `loglevel`, you can use:

```
getattr(logging, loglevel.upper())
```

to get the value which you'll pass to `basicConfig()` via the `level` argument. You may want to error check any user input value, perhaps as in the following example:

```
# assuming loglevel is bound to the string value obtained from the command line argument. Convert to upper case to allow for any user input.
# specify --log=DEBUG or --log=debug
numeric_level = getattr(logging, loglevel.upper(), None)
```
if not isinstance(numeric_level, int):
    raise ValueError('Invalid log level: %s' % loglevel)
logging.basicConfig(level=numeric_level, ...)

The call to basicConfig() should come before any calls to debug(), info() etc. As it's intended as a one-off simple configuration facility, only the first call will actually do anything: subsequent calls are effectively no-ops.

If you run the above script several times, the messages from successive runs are appended to the file example.log. If you want each run to start afresh, not remembering the messages from earlier runs, you can specify the filemode argument, by changing the call in the above example to:

logging.basicConfig(filename='example.log', filemode=...)

The output will be the same as before, but the log file is no longer appended to, so the messages from earlier runs are lost.

Logging from multiple modules

If your program consists of multiple modules, here's an example of how you could organize logging in it:

# myapp.py
import logging
import mylib

def main():
    logging.basicConfig(filename='myapp.log', level=logging.INFO('Started'))
mylib.do_something()
logging.info('Finished')

if __name__ == '__main__':
    main()

# mylib.py
import logging
def do_something():
    logging.info('Doing something')

If you run myapp.py, you should see this in myapp.log:

INFO:root:Started
INFO:root:Doing something
INFO:root:Finished

which is hopefully what you were expecting to see. You can generalize this to multiple modules, using the pattern in mylib.py. Note that for this simple usage pattern, you won’t know, by looking in the log file, where in your application your messages came from, apart from looking at the event description. If you want to track the location of your messages, you’ll need to refer to the documentation beyond the tutorial level – see Advanced Logging Tutorial.

Logging variable data

To log variable data, use a format string for the event description message and append the variable data as arguments. For example:

import logging
logging.warning('%%s before you %%s', 'Look', 'leap!')
will display:

```
WARNING:root:Look before you leap!
```

As you can see, merging of variable data into the event description message uses the old, %-style of string formatting. This is for backwards compatibility: the logging package pre-dates newer formatting options such as `str.format()` and `string.Template`. These newer formatting options are supported, but exploring them is outside the scope of this tutorial.

### Changing the format of displayed messages

To change the format which is used to display messages, you need to specify the format you want to use:

```python
import logging
logging.basicConfig(format='%(levelname)s:%(message)s')
logging.debug('This message should appear on the console')
logging.info('So should this')
logging.warning('And this, too')
```

which would print:

```
DEBUG:This message should appear on the console
INFO:So should this
WARNING:And this, too
```

Notice that the ‘root’ which appeared in earlier examples has disappeared. For a full set of things that can appear in format strings, you can refer to the documentation for `LogRecord attributes`, but for simple usage, you just need the `levelname` (severity), `message` (event
description, including variable data) and perhaps to display when the event occurred. This is described in the next section.

Displaying the date/time in messages

To display the date and time of an event, you would place '%(asctime)s' in your format string:

```python
import logging
logging.basicConfig(format='%s %s
logging.warning('is when this event was logged."
```

which should print something like this:

```
2010-12-12 11:41:42,612 is when this event was logged.
```

The default format for date/time display (shown above) is ISO8601. If you need more control over the formatting of the date/time, provide a `datefmt` argument to `basicConfig`, as in this example:

```python
import logging
logging.basicConfig(format='%s %s
logging.warning('is when this event was logged."
```

which would display something like this:

```
12/12/2010 11:46:36 AM is when this event was logged.
```

The format of the `datefmt` argument is the same as supported by `time.strftime()`.
Next Steps

That concludes the basic tutorial. It should be enough to get you up and running with logging. There's a lot more that the logging package offers, but to get the best out of it, you'll need to invest a little more of your time in reading the following sections. If you're ready for that, grab some of your favourite beverage and carry on.

If your logging needs are simple, then use the above examples to incorporate logging into your own scripts, and if you run into problems or don't understand something, please post a question on the comp.lang.python Usenet group (available at http://groups.google.com/group/comp.lang.python) and you should receive help before too long.

Still here? You can carry on reading the next few sections, which provide a slightly more advanced/in-depth tutorial than the basic one above. After that, you can take a look at the *Logging Cookbook*. 
Advanced Logging Tutorial

The logging library takes a modular approach and offers several categories of components: loggers, handlers, filters, and formatters.

- Loggers expose the interface that application code directly uses.
- Handlers send the log records (created by loggers) to the appropriate destination.
- Filters provide a finer grained facility for determining which log records to output.
- Formatters specify the layout of log records in the final output.

Log event information is passed between loggers, handlers, filters and formatters in a `LogRecord` instance.

Logging is performed by calling methods on instances of the `Logger` class (hereafter called `loggers`). Each instance has a name, and they are conceptually arranged in a namespace hierarchy using dots (periods) as separators. For example, a logger named ‘scan’ is the parent of loggers ‘scan.text’, ‘scan.html’ and ‘scan.pdf’. Logger names can be anything you want, and indicate the area of an application in which a logged message originates.

A good convention to use when naming loggers is to use a module-level logger, in each module which uses logging, named as follows:

```
logger = logging.getLogger(__name__)
```

This means that logger names track the package/module hierarchy, and it’s intuitively obvious where events are logged just from the logger name.

The root of the hierarchy of loggers is called the root logger. That’s the
logger used by the functions `debug()`, `info()`, `warning()`, `error()` and `critical()`, which just call the same-named method of the root logger. The functions and the methods have the same signatures. The root logger’s name is printed as ‘root’ in the logged output.

It is, of course, possible to log messages to different destinations. Support is included in the package for writing log messages to files, HTTP GET/POST locations, email via SMTP, generic sockets, queues, or OS-specific logging mechanisms such as syslog or the Windows NT event log. Destinations are served by `handler` classes. You can create your own log destination class if you have special requirements not met by any of the built-in handler classes.

By default, no destination is set for any logging messages. You can specify a destination (such as console or file) by using `basicConfig()` as in the tutorial examples. If you call the functions `debug()`, `info()`, `warning()`, `error()` and `critical()`, they will check to see if no destination is set; and if one is not set, they will set a destination of the console (`sys.stderr`) and a default format for the displayed message before delegating to the root logger to do the actual message output.

The default format set by `basicConfig()` for messages is:

```
severity:logger name:message
```

You can change this by passing a format string to `basicConfig()` with the `format` keyword argument. For all options regarding how a format string is constructed, see `Formatter Objects`.

Logging Flow
The flow of log event information in loggers and handlers is illustrated in the following diagram.

**Loggers**

**Logger** objects have a threefold job. First, they expose several methods to application code so that applications can log messages at runtime. Second, logger objects determine which log messages to act upon based upon severity (the default filtering facility) or filter objects. Third, logger objects pass along relevant log messages to all interested log handlers.

The most widely used methods on logger objects fall into two categories: configuration and message sending.
These are the most common configuration methods:

- `Logger.setLevel()` specifies the lowest-severity log message a logger will handle, where debug is the lowest built-in severity level and critical is the highest built-in severity. For example, if the severity level is INFO, the logger will handle only INFO, WARNING, ERROR, and CRITICAL messages and will ignore DEBUG messages.
- `Logger.addHandler()` and `Logger.removeHandler()` add and remove handler objects from the logger object. Handlers are covered in more detail in *Handlers*.
- `Logger.addFilter()` and `Logger.removeFilter()` add and remove filter objects from the logger object. Filters are covered in more detail in *Filter Objects*.

You don’t need to always call these methods on every logger you create. See the last two paragraphs in this section.

With the logger object configured, the following methods create log messages:

- `Logger.debug()`, `Logger.info()`, `Logger.warning()`, `Logger.error()`, and `Logger.critical()` all create log records with a message and a level that corresponds to their respective method names. The message is actually a format string, which may contain the standard string substitution syntax of `%s`, `%d`, `%f`, and so on. The rest of their arguments is a list of objects that correspond with the substitution fields in the message. With regard to **kwargs, the logging methods care only about a keyword of `exc_info` and use it to determine whether to log exception information.
- `Logger.exception()` creates a log message similar to `Logger.error()`. The difference is that `Logger.exception()` dumps a stack trace along with it. Call
this method only from an exception handler.

- **Logger.log()** takes a log level as an explicit argument. This is a little more verbose for logging messages than using the log level convenience methods listed above, but this is how to log at custom log levels.

`getLogger()` returns a reference to a logger instance with the specified name if it is provided, or `root` if not. The names are period-separated hierarchical structures. Multiple calls to `getLogger()` with the same name will return a reference to the same logger object. Loggers that are further down in the hierarchical list are children of loggers higher up in the list. For example, given a logger with a name of `foo`, loggers with names of `foo.bar`, `foo.bar.baz`, and `foo.bam` are all descendants of `foo`.

Loggers have a concept of **effective level**. If a level is not explicitly set on a logger, the level of its parent is used instead as its effective level. If the parent has no explicit level set, its parent is examined, and so on - all ancestors are searched until an explicitly set level is found. The root logger always has an explicit level set (```WARNING```) by default. When deciding whether to process an event, the effective level of the logger is used to determine whether the event is passed to the logger’s handlers.

Child loggers propagate messages up to the handlers associated with their ancestor loggers. Because of this, it is unnecessary to define and configure handlers for all the loggers an application uses. It is sufficient to configure handlers for a top-level logger and create child loggers as needed. (You can, however, turn off propagation by setting the `propagate` attribute of a logger to `False`.)

**Handlers**
Handler objects are responsible for dispatching the appropriate log messages (based on the log messages' severity) to the handler's specified destination. Logger objects can add zero or more handler objects to themselves with an addHandler() method. As an example scenario, an application may want to send all log messages to a log file, all log messages of error or higher to stdout, and all messages of critical to an email address. This scenario requires three individual handlers where each handler is responsible for sending messages of a specific severity to a specific location.

The standard library includes quite a few handler types (see Useful Handlers); the tutorials use mainly StreamHandler and FileHandler in its examples.

There are very few methods in a handler for application developers to concern themselves with. The only handler methods that seem relevant for application developers who are using the built-in handler objects (that is, not creating custom handlers) are the following configuration methods:

- The setLevel() method, just as in logger objects, specifies the lowest severity that will be dispatched to the appropriate destination. Why are there two setLevel() methods? The level set in the logger determines which severity of messages it will pass to its handlers. The level set in each handler determines which messages that handler will send on.
- setFormatter() selects a Formatter object for this handler to use.
- addFilter() and removeFilter() respectively configure and deconfigure filter objects on handlers.

Application code should not directly instantiate and use instances of Handler. Instead, the Handler class is a base class that defines the
interface that all handlers should have and establishes some default behavior that child classes can use (or override).

**Formatters**

Formatter objects configure the final order, structure, and contents of the log message. Unlike the base `logging.Handler` class, application code may instantiate formatter classes, although you could likely subclass the formatter if your application needs special behavior. The constructor takes three optional arguments – a message format string, a date format string and a style indicator.

```python
logging.Formatter.__init__(fmt=None, datefmt=None, style='%')
```

If there is no message format string, the default is to use the raw message. If there is no date format string, the default date format is:

```
%Y-%m-%d %H:%M:%S
```

with the milliseconds tacked on at the end. The `style` is one of `%`, `{` or `$`. If one of these is not specified, then `%` will be used.

If the `style` is `{`, the message format string uses `%(<dictionary key>)s` styled string substitution; the possible keys are documented in `LogRecord attributes`. If the style is `{`, the message format string is assumed to be compatible with `str.format()` (using keyword arguments), while if the style is `$` then the message format string should conform to what is expected by `string.Template.substitute()`.

*Changed in version 3.2:* Added the `style` parameter.
The following message format string will log the time in a human-readable format, the severity of the message, and the contents of the message, in that order:

%(asctime)s - %(levelname)s - %(message)s

Formatters use a user-configurable function to convert the creation time of a record to a tuple. By default, time.localtime() is used; to change this for a particular formatter instance, set the converter attribute of the instance to a function with the same signature as time.localtime() or time.gmtime(). To change it for all formatters, for example if you want all logging times to be shown in GMT, set the converter attribute in the Formatter class (to time.gmtime for GMT display).

Configuring Logging

Programmers can configure logging in three ways:

1. Creating loggers, handlers, and formatters explicitly using Python code that calls the configuration methods listed above.
2. Creating a logging config file and reading it using the fileConfig() function.
3. Creating a dictionary of configuration information and passing it to the dictConfig() function.

For the reference documentation on the last two options, see Configuration functions. The following example configures a very simple logger, a console handler, and a simple formatter using Python code:

import logging
# create logger
logger = logging.getLogger('simple_example')
logger.setLevel(logging.DEBUG)

# create console handler and set level to debug
ch = logging.StreamHandler()
ch.setLevel(logging.DEBUG)

# create formatter
formatter = logging.Formatter('%(asctime)s - %(name)s - %(levelname)s - %(message)s')

# add formatter to ch
ch.setFormatter(formatter)

# add ch to logger
logger.addHandler(ch)

# 'application' code
logger.debug('debug message')
logger.info('info message')
logger.warn('warn message')
logger.error('error message')
logger.critical('critical message')

Running this module from the command line produces the following output:

```
$ python simple_logging_module.py
2005-03-19 15:10:26,618 - simple_example - DEBUG - debug message
2005-03-19 15:10:26,620 - simple_example - INFO - info message
2005-03-19 15:10:26,695 - simple_example - WARNING - warn message
2005-03-19 15:10:26,697 - simple_example - ERROR - error message
2005-03-19 15:10:26,773 - simple_example - CRITICAL - critical message
```

The following Python module creates a logger, handler, and formatter.
nearly identical to those in the example listed above, with the only
difference being the names of the objects:

```python
import logging
import logging.config

logging.config.fileConfig('logging.conf')

# create logger
logger = logging.getLogger('simpleExample')

# 'application' code
logger.debug('debug message')
logger.info('info message')
logger.warn('warn message')
logger.error('error message')
logger.critical('critical message')
```

Here is the logging.conf file:

```conf
[loggers]
keys=root,simpleExample

[handlers]
keys=consoleHandler

[formatters]
keys=simpleFormatter

[logger_root]
level=DEBUG
handlers=consoleHandler

[logger_simpleExample]
level=DEBUG
handlers=consoleHandler
```
The output is nearly identical to that of the non-config-file-based example:

```
$ python simple_logging_config.py
2005-03-19 15:38:55,977 - simpleExample - DEBUG - debug message
2005-03-19 15:38:55,979 - simpleExample - INFO - info message
2005-03-19 15:38:56,054 - simpleExample - WARNING - warn message
2005-03-19 15:38:56,055 - simpleExample - ERROR - error message
2005-03-19 15:38:56,130 - simpleExample - CRITICAL - critical message
```

You can see that the config file approach has a few advantages over the Python code approach, mainly separation of configuration and code and the ability of noncoders to easily modify the logging properties.

**Warning:** The `fileConfig()` function takes a default parameter, `disable_existing_loggers`, which defaults to `True` for reasons of backward compatibility. This may or may not be what you want, since it will cause any loggers existing before the `fileConfig()` call to be disabled unless they (or an ancestor) are
explicitly named in the configuration. Please refer to the reference
documentation for more information, and specify False for this parameter if you wish.

The dictionary passed to `dictConfig()` can also specify a Boolean value with key `disable_existing_loggers`, which if not specified explicitly in the dictionary also defaults to being interpreted as True. This leads to the logger-disabling behaviour described above, which may not be what you want - in which case, provide the key explicitly with a value of False.

Note that the class names referenced in config files need to be either relative to the logging module, or absolute values which can be resolved using normal import mechanisms. Thus, you could use either `WatchedFileHandler` (relative to the logging module) or `mypackage.mymodule.MyHandler` (for a class defined in package `mypackage` and module `mymodule`, where `mypackage` is available on the Python import path).

In Python 3.2, a new means of configuring logging has been introduced, using dictionaries to hold configuration information. This provides a superset of the functionality of the config-file-based approach outlined above, and is the recommended configuration method for new applications and deployments. Because a Python dictionary is used to hold configuration information, and since you can populate that dictionary using different means, you have more options for configuration. For example, you can use a configuration file in JSON format, or, if you have access to YAML processing functionality, a file in YAML format, to populate the configuration dictionary. Or, of course, you can construct the dictionary in Python code, receive it in pickled form over a socket, or use whatever approach makes sense
for your application.

Here's an example of the same configuration as above, in YAML format for the new dictionary-based approach:

```yaml
version: 1
formatters:
  simple:
    format: '%(asctime)s - %(name)s - %(levelname)s
handlers:
  console:
    class: logging.StreamHandler
    level: DEBUG
    formatter: simple
    stream: ext://sys.stdout
loggers:
  simpleExample:
    level: DEBUG
    handlers: [console]
    propagate: no
root:
  level: DEBUG
  handlers: [console]
```

For more information about logging using a dictionary, see *Configuration functions*.

What happens if no configuration is provided

If no logging configuration is provided, it is possible to have a situation where a logging event needs to be output, but no handlers can be found to output the event. The behaviour of the logging package in these circumstances is dependent on the Python version.
For versions of Python prior to 3.2, the behaviour is as follows:

- If `logging.raiseExceptions` is `False` (production mode), the event is silently dropped.
- If `logging.raiseExceptions` is `True` (development mode), a message ‘No handlers could be found for logger X.Y.Z’ is printed once.

In Python 3.2 and later, the behaviour is as follows:

- The event is output using a ‘handler of last resort’, stored in `logging.lastResort`. This internal handler is not associated with any logger, and acts like a `StreamHandler` which writes the event description message to the current value of `sys.stderr` (therefore respecting any redirections which may be in effect). No formatting is done on the message - just the bare event description message is printed. The handler’s level is set to `WARNING`, so all events at this and greater severities will be output.

To obtain the pre-3.2 behaviour, `logging.lastResort` can be set to `None`.

**Configuring Logging for a Library**

When developing a library which uses logging, you should take care to document how the library uses logging - for example, the names of loggers used. Some consideration also needs to be given to its logging configuration. If the using application does not use logging, and library code makes logging calls, then (as described in the previous section) events of severity `WARNING` and greater will be printed to `sys.stderr`. This is regarded as the best default behaviour.
If for some reason you don’t want these messages printed in the absence of any logging configuration, you can attach a do-nothing handler to the top-level logger for your library. This avoids the message being printed, since a handler will be always be found for the library’s events: it just doesn’t produce any output. If the library user configures logging for application use, presumably that configuration will add some handlers, and if levels are suitably configured then logging calls made in library code will send output to those handlers, as normal.

A do-nothing handler is included in the logging package: **NullHandler** (since Python 3.1). An instance of this handler could be added to the top-level logger of the logging namespace used by the library (if you want to prevent your library’s logged events being output to **sys.stderr** in the absence of logging configuration). If all logging by a library *foo* is done using loggers with names matching ‘foo.x’, ‘foo.x.y’, etc. then the code:

```python
import logging
logging.getLogger('foo').addHandler(logging.NullHandler())
```

should have the desired effect. If an organisation produces a number of libraries, then the logger name specified can be ‘orgname.foo’ rather than just ‘foo’.

**Note:** It is strongly advised that you do not add any handlers other than **NullHandler** to your library’s loggers. This is because the configuration of handlers is the prerogative of the application developer who uses your library. The application developer knows their target audience and what handlers are most appropriate for their application: if you add handlers ‘under the hood’, you might well interfere with their ability to carry out unit tests and deliver logs which
suit their requirements.
Logging Levels

The numeric values of logging levels are given in the following table. These are primarily of interest if you want to define your own levels, and need them to have specific values relative to the predefined levels. If you define a level with the same numeric value, it overwrites the predefined value; the predefined name is lost.

<table>

Levels can also be associated with loggers, being set either by the developer or through loading a saved logging configuration. When a logging method is called on a logger, the logger compares its own level with the level associated with the method call. If the logger’s level is higher than the method call's, no logging message is actually generated. This is the basic mechanism controlling the verbosity of logging output.

Logging messages are encoded as instances of the `LogRecord` class. When a logger decides to actually log an event, a `LogRecord` instance is created from the logging message.

Logging messages are subjected to a dispatch mechanism through
the use of handlers, which are instances of subclasses of the Handler class. Handlers are responsible for ensuring that a logged message (in the form of a LogRecord) ends up in a particular location (or set of locations) which is useful for the target audience for that message (such as end users, support desk staff, system administrators, developers). Handlers are passed LogRecord instances intended for particular destinations. Each logger can have zero, one or more handlers associated with it (via the addHandler() method of Logger). In addition to any handlers directly associated with a logger, all handlers associated with all ancestors of the logger are called to dispatch the message (unless the propagate flag for a logger is set to a false value, at which point the passing to ancestor handlers stops).

Just as for loggers, handlers can have levels associated with them. A handler’s level acts as a filter in the same way as a logger’s level does. If a handler decides to actually dispatch an event, the emit() method is used to send the message to its destination. Most user-defined subclasses of Handler will need to override this emit().

Custom Levels

Defining your own levels is possible, but should not be necessary, as the existing levels have been chosen on the basis of practical experience. However, if you are convinced that you need custom levels, great care should be exercised when doing this, and it is possibly a very bad idea to define custom levels if you are developing a library. That’s because if multiple library authors all define their own custom levels, there is a chance that the logging output from such multiple libraries used together will be difficult for the using developer to control and/or interpret, because a given numeric value might mean
different things for different libraries.
Useful Handlers

In addition to the base Handler class, many useful subclasses are provided:

1. **StreamHandler** instances send messages to streams (file-like objects).
2. **FileHandler** instances send messages to disk files.
3. **BaseRotatingHandler** is the base class for handlers that rotate log files at a certain point. It is not meant to be instantiated directly. Instead, use **RotatingFileHandler** or **TimedRotatingFileHandler**.
4. **RotatingFileHandler** instances send messages to disk files, with support for maximum log file sizes and log file rotation.
5. **TimedRotatingFileHandler** instances send messages to disk files, rotating the log file at certain timed intervals.
6. **SocketHandler** instances send messages to TCP/IP sockets.
7. **DatagramHandler** instances send messages to UDP sockets.
8. **SMTPHandler** instances send messages to a designated email address.
9. **SysLogHandler** instances send messages to a Unix syslog daemon, possibly on a remote machine.
10. **NTEventLogHandler** instances send messages to a Windows NT/2000/XP event log.
11. **MemoryHandler** instances send messages to a buffer in memory, which is flushed whenever specific criteria are met.
12. **HTTPHandler** instances send messages to an HTTP server using either GET or POST semantics.
13. **WatchedFileHandler** instances watch the file they are logging to. If the file changes, it is closed and reopened using the file name. This handler is only useful on Unix-like systems; Windows does not support the underlying mechanism used.
14. **QueueHandler** instances send messages to a queue, such as those implemented in the `queue` or `multiprocessing` modules.

15. **NullHandler** instances do nothing with error messages. They are used by library developers who want to use logging, but want to avoid the ‘No handlers could be found for logger XXX’ message which can be displayed if the library user has not configured logging. See [Configuring Logging for a Library](#) for more information.

*New in version 3.1:* The **NullHandler** class.

*New in version 3.2:* The **QueueHandler** class.

The NullHandler, StreamHandler and FileHandler classes are defined in the core logging package. The other handlers are defined in a sub-module, `logging.handlers`. (There is also another sub-module, `logging.config`, for configuration functionality.)

Logged messages are formatted for presentation through instances of the **Formatter** class. They are initialized with a format string suitable for use with the % operator and a dictionary.

For formatting multiple messages in a batch, instances of BufferingFormatter can be used. In addition to the format string (which is applied to each message in the batch), there is provision for header and trailer format strings.

When filtering based on logger level and/or handler level is not enough, instances of **Filter** can be added to both **Logger** and Handler instances (through their `addFilter()` method). Before deciding to process a message further, both loggers and handlers
consult all their filters for permission. If any filter returns a false value, the message is not processed further.

The basic **Filter** functionality allows filtering by specific logger name. If this feature is used, messages sent to the named logger and its children are allowed through the filter, and all others dropped.
Exceptions raised during logging

The logging package is designed to swallow exceptions which occur while logging in production. This is so that errors which occur while handling logging events - such as logging misconfiguration, network or other similar errors - do not cause the application using logging to terminate prematurely.

`SystemExit` and `KeyboardInterrupt` exceptions are never swallowed. Other exceptions which occur during the `emit()` method of a Handler subclass are passed to its `handleError()` method.

The default implementation of `handleError()` in Handler checks to see if a module-level variable, `raiseExceptions`, is set. If set, a traceback is printed to `sys.stderr`. If not set, the exception is swallowed.

**Note:** The default value of `raiseExceptions` is True. This is because during development, you typically want to be notified of any exceptions that occur. It’s advised that you set `raiseExceptions` to False for production usage.
Using arbitrary objects as messages

In the preceding sections and examples, it has been assumed that the message passed when logging the event is a string. However, this is not the only possibility. You can pass an arbitrary object as a message, and its `__str__()` method will be called when the logging system needs to convert it to a string representation. In fact, if you want to, you can avoid computing a string representation altogether - for example, the `SocketHandler` emits an event by pickling it and sending it over the wire.
Optimization

Formatting of message arguments is deferred until it cannot be avoided. However, computing the arguments passed to the logging method can also be expensive, and you may want to avoid doing it if the logger will just throw away your event. To decide what to do, you can call the `isEnabledFor()` method which takes a level argument and returns true if the event would be created by the Logger for that level of call. You can write code like this:

```python
if logger.isEnabledFor(logging.DEBUG):
    logger.debug('Message with %s, %s', expensive_func1, expensive_func2)
```

so that if the logger's threshold is set above `DEBUG`, the calls to `expensive_func1()` and `expensive_func2()` are never made.

There are other optimizations which can be made for specific applications which need more precise control over what logging information is collected. Here's a list of things you can do to avoid processing during logging which you don't need:

<table>
<thead>
<tr>
<th>What you don’t want to collect</th>
<th>How to avoid collecting it</th>
</tr>
</thead>
<tbody>
<tr>
<td>Information about where calls were made from.</td>
<td>Set <code>logging._srcfile</code> to <code>None</code>.</td>
</tr>
<tr>
<td>Threading information.</td>
<td>Set <code>logging.logThreads</code> to <code>0</code>.</td>
</tr>
<tr>
<td>Process information.</td>
<td>Set <code>logging.logProcesses</code> to <code>0</code>.</td>
</tr>
</tbody>
</table>
Also note that the core logging module only includes the basic handlers. If you don’t import `logging.handlers` and `logging.config`, they won’t take up any memory.

*A logging cookbook*
Logging Cookbook

Author: Vinay Sajip <vinay_sajip at red-dove dot com>

This page contains a number of recipes related to logging, which have been found useful in the past.
Using logging in multiple modules

Multiple calls to `logging.getLogger('someLogger')` return a reference to the same logger object. This is true not only within the same module, but also across modules as long as it is in the same Python interpreter process. It is true for references to the same object; additionally, application code can define and configure a parent logger in one module and create (but not configure) a child logger in a separate module, and all logger calls to the child will pass up to the parent. Here is a main module:

```python
import logging
import auxiliary_module

# create logger with 'spam_application'
logger = logging.getLogger('spam_application')
logger.setLevel(logging.DEBUG)
# create file handler which logs even debug messages
fh = logging.FileHandler('spam.log')
hf.setLevel(logging.DEBUG)
# create console handler with a higher log level
ch = logging.StreamHandler()
ch.setLevel(logging.ERROR)
# create formatter and add it to the handlers
formatter = logging.Formatter('%(asctime)s - %(name)s - %(levelname)s - %(message)s')
hf.setFormatter(formatter)
ch.setFormatter(formatter)
# add the handlers to the logger
logger.addHandler(hf)
logger.addHandler(ch)

logger.info('creating an instance of auxiliary_module.Auxiliary')
a = auxiliary_module.Auxiliary()
logger.info('created an instance of auxiliary_module.Auxiliary')
```
logger.info('calling auxiliary_module.Auxiliary.do_something()')
logger.info('finished auxiliary_module.Auxiliary.do_something()')
logger.info('calling auxiliary_module.some_function()')
auxiliary_module.some_function()
logger.info('done with auxiliary_module.some_function()')

Here is the auxiliary module:

```python
import logging

# create logger
module_logger = logging.getLogger('spam_application.auxiliary')

class Auxiliary:
    def __init__(self):
        self.logger = logging.getLogger('spam_application.auxiliary.Auxiliary')
        self.logger.info('creating an instance of Auxiliary')
    def do_something(self):
        self.logger.info('doing something')
        a = 1 + 1
        self.logger.info('done doing something')

def some_function():
    module_logger.info('received a call to "some_function()"')
```

The output looks like this:

```
2005-03-23 23:47:11,668 - spam_application - INFO -
```
calling auxiliary_module.Auxiliary.do_something
2005-03-23 23:47:11,668 - spam_application.auxiliary
doing something
2005-03-23 23:47:11,669 - spam_application.auxiliary
done doing something
2005-03-23 23:47:11,670 - spam_application - INFO -
finished auxiliary_module.Auxiliary.do_something
2005-03-23 23:47:11,671 - spam_application - INFO -
calling auxiliary_module.some_function()
2005-03-23 23:47:11,672 - spam_application.auxiliary
received a call to 'some_function'
2005-03-23 23:47:11,673 - spam_application - INFO -
done with auxiliary_module.some_function()
Multiple handlers and formatters

Loggers are plain Python objects. The addHandler() method has no minimum or maximum quota for the number of handlers you may add. Sometimes it will be beneficial for an application to log all messages of all severities to a text file while simultaneously logging errors or above to the console. To set this up, simply configure the appropriate handlers. The logging calls in the application code will remain unchanged. Here is a slight modification to the previous simple module-based configuration example:

```python
import logging

logger = logging.getLogger('simple_example')
logger.setLevel(logging.DEBUG)

# create file handler which logs even debug messages
fh = logging.FileHandler('spam.log')
fh.setLevel(logging.DEBUG)

# create console handler with a higher log level
ch = logging.StreamHandler()
ch.setLevel(logging.ERROR)

# create formatter and add it to the handlers
formatter = logging.Formatter('%(asctime)s - %(name)s - %(levelname)s - %(message)s')
ch.setFormatter(formatter)
fh.setFormatter(formatter)

# add the handlers to logger
logger.addHandler(ch)
logger.addHandler(fh)

# 'application' code
logger.debug('debug message')
logger.info('info message')
logger.warn('warn message')
logger.error('error message')```
Notice that the ‘application’ code does not care about multiple handlers. All that changed was the addition and configuration of a new handler named `fh`.

The ability to create new handlers with higher- or lower-severity filters can be very helpful when writing and testing an application. Instead of using many `print` statements for debugging, use `logger.debug`:

Unlike the print statements, which you will have to delete or comment out later, the `logger.debug` statements can remain intact in the source code and remain dormant until you need them again. At that time, the only change that needs to happen is to modify the severity level of the `logger` and/or handler to debug.
Logging to multiple destinations

Let's say you want to log to console and file with different message formats and in differing circumstances. Say you want to log messages with levels of DEBUG and higher to file, and those messages at level INFO and higher to the console. Let's also assume that the file should contain timestamps, but the console messages should not. Here's how you can achieve this:

```python
import logging

# set up logging to file - see previous section for
logging.basicConfig(level=logging.DEBUG,
    format='%(asctime)s %%(name)-12s %%(levelname)-8s %%(message)s',
    datefmt='%m-%d %H:%M',
    filename='/temp/myapp.log',
    filemode='w')

# define a Handler which writes INFO messages or higher to stderr
console = logging.StreamHandler()
console.setLevel(logging.INFO)

# set a format which is simpler for console use
formatter = logging.Formatter('%%(name)-12s: %%(levelname)-8s %%(message)s')

# tell the handler to use this format
console.setFormatter(formatter)

# add the handler to the root logger
logging.getLogger('').addHandler(console)

# Now, we can log to the root logger, or any other logger.
logging.info('Jackdaws love my big sphinx of quartz.

# Now, define a couple of other loggers which might
# application:

logger1 = logging.getLogger('myapp.area1')
logger2 = logging.getLogger('myapp.area2')
```
logger1.debug('Quick zephyrs blow, vexing daft Jim.')
logger1.info('How quickly daft jumping zebras vex.')
logger2.warning('Jail zesty vixen who grabbed pay from quack.')
logger2.error('The five boxing wizards jump quickly.

When you run this, on the console you will see

root      : INFO   Jackdaws love my big sphinx of area1:
myapp.area1 : INFO   How quickly daft jumping zebras
myapp.area2 : WARNING Jail zesty vixen who grabbed
myapp.area2 : ERROR   The five boxing wizards jump

and in the file you will see something like

10-22 22:19 root      INFO   Jackdaws love my big sphinx of area1:
10-22 22:19 myapp.area1 DEBUG   Quick zephyrs blow
10-22 22:19 myapp.area1 INFO   How quickly daft jumping zebras
10-22 22:19 myapp.area2 WARNING Jail zesty vixen who grabbed
10-22 22:19 myapp.area2 ERROR   The five boxing wizards jump

As you can see, the DEBUG message only shows up in the file. The other messages are sent to both destinations.

This example uses console and file handlers, but you can use any number and combination of handlers you choose.
Configuration server example

Here is an example of a module using the logging configuration server:

```python
import logging
import logging.config
import time
import os

# read initial config file
logging.config.fileConfig('logging.conf')

# create and start listener on port 9999

t = logging.config.listen(9999)
t.start()

logger = logging.getLogger('simpleExample')

try:
    # loop through logging calls to see the difference
    # new configurations make, until Ctrl+C is pressed
    while True:
        logger.debug('debug message')
        logger.info('info message')
        logger.warn('warn message')
        logger.error('error message')
        logger.critical('critical message')
        time.sleep(5)

except KeyboardInterrupt:
    # cleanup
    logging.config.stopListening()
t.join()
```

And here is a script that takes a filename and sends that file to the
server, properly preceded with the binary-encoded length, as the new logging configuration:

```python
#!/usr/bin/env python
import socket, sys, struct

with open(sys.argv[1], 'rb') as f:
    data_to_send = f.read()

HOST = 'localhost'
PORT = 9999
s = socket.socket(socket.AF_INET, socket.SOCK_STREAM)
print('connecting...')
s.connect((HOST, PORT))
print('sending config...')
s.send(struct.pack('>L', len(data_to_send)))
s.send(data_to_send)
s.close()
print('complete')
```
Dealing with handlers that block

Sometimes you have to get your logging handlers to do their work without blocking the thread you're logging from. This is common in Web applications, though of course it also occurs in other scenarios.

A common culprit which demonstrates sluggish behaviour is the `SMTPHandler`: sending emails can take a long time, for a number of reasons outside the developer's control (for example, a poorly performing mail or network infrastructure). But almost any network-based handler can block: Even a `SocketHandler` operation may do a DNS query under the hood which is too slow (and this query can be deep in the socket library code, below the Python layer, and outside your control).

One solution is to use a two-part approach. For the first part, attach only a `QueueHandler` to those loggers which are accessed from performance-critical threads. They simply write to their queue, which can be sized to a large enough capacity or initialized with no upper bound to their size. The write to the queue will typically be accepted quickly, though you will probably need to catch the `queue.Full` exception as a precaution in your code. If you are a library developer who has performance-critical threads in their code, be sure to document this (together with a suggestion to attach only `QueueHandlers` to your loggers) for the benefit of other developers who will use your code.

The second part of the solution is `QueueListener`, which has been designed as the counterpart to `QueueHandler`. A `QueueListener` is very simple: it's passed a queue and some handlers, and it fires up an internal thread which listens to its queue for LogRecords sent from
QueueHandlers (or any other source of LogRecords, for that matter). The LogRecords are removed from the queue and passed to the handlers for processing.

The advantage of having a separate QueueListener class is that you can use the same instance to service multiple QueueHandlers. This is more resource-friendly than, say, having threaded versions of the existing handler classes, which would eat up one thread per handler for no particular benefit.

An example of using these two classes follows (imports omitted):

```python
que = queue.Queue(-1)  # no limit on size
queue_handler = QueueHandler(que)
handler = logging.StreamHandler()
listener = QueueListener(que, handler)
root = logging.getLogger()
root.addHandler(queue_handler)
formatter = logging.Formatter('%(threadName)s: %(message)s')
handler.setFormatter(formatter)
listener.start()
# The log output will display the thread which generated the event (the main thread) rather than the internal thread which monitors the internal queue. This is what you want to happen.
root.warning('Look out!')
listener.stop()
```

which, when run, will produce:

```
MainThread: Look out!
```
Sending and receiving logging events across a network

Let's say you want to send logging events across a network, and handle them at the receiving end. A simple way of doing this is attaching a `SocketHandler` instance to the root logger at the sending end:

```python
import logging, logging.handlers

rootLogger = logging.getLogger('')
rootLogger.setLevel(logging.DEBUG)
socketHandler = logging.handlers.SocketHandler('localhost',logging.handlers.DEFAULT_TCP_LOGGING_PORT)
# don't bother with a formatter, since a socket handler
# an unformatted pickle
rootLogger.addHandler(socketHandler)

# Now, we can log to the root logger, or any other logger:
logging.info('Jackdaws love my big sphinx of quartz.

# Now, define a couple of other loggers which might
# application:

logger1 = logging.getLogger('myapp.area1')
logger2 = logging.getLogger('myapp.area2')

logger1.debug('Quick zephyrs blow, vexing daft Jim.'
logger1.info('How quickly daft jumping zebras vex.')
logger2.warning('Jail zesty vixen who grabbed pay from quack.'
logger2.error('The five boxing wizards jump quickly.
```

At the receiving end, you can set up a receiver using the
socketserver module. Here is a basic working example:

```python
import pickle
import logging
import logging.handlers
import socketserver
import struct

class LogRecordStreamHandler(socketserver.StreamRequestHandler):
    # Handler for a streaming logging request.
    # This basically logs the record using whatever local policy is configured locally.

    def handle(self):
        # Handle multiple requests - each expected to be 4-byte length, followed by the LogRecord in pickle format. Logs the record according to whatever policy is configured locally.

        while True:
            chunk = self.connection.recv(4)
            if len(chunk) < 4:
                break
            slen = struct.unpack('>L', chunk)[0]
            chunk = self.connection.recv(slen)
            while len(chunk) < slen:
                chunk = chunk + self.connection.recv(slen - len(chunk))
            obj = self.unPickle(chunk)
            record = logging.makeLogRecord(obj)
            self.handleLogRecord(record)

    def unPickle(self, data):
        return pickle.loads(data)
```
def handleLogRecord(self, record):
    # if a name is specified, we use the named logger
    # implied by the record.
    if self.server.logname is not None:
        name = self.server.logname
    else:
        name = record.name
    logger = logging.getLogger(name)
    # N.B. EVERY record gets logged. This is because
    # is normally called AFTER logger-level filtering.
    # to do filtering, do it at the client end to
    # cycles and network bandwidth!
    logger.handle(record)

class LogRecordSocketReceiver(socketserver.ThreadingTCPServer):
    """Simple TCP socket-based logging receiver suitable for testing."
    """
    allow_reuse_address = 1

    def __init__(self, host='localhost',
                 port= logging.handlers.DEFAULT_TCP_LOGGING_PORT,
                 handler=LogRecordStreamHandler):
        socketserver.ThreadingTCPServer.__init__(self, host, port, handler)
        self.abort = 0
        self.timeout = 1
        self.logname = None

    def serve_until_stopped(self):
        import select
        abort = 0
        while not abort:
            rd, wr, ex = select.select([self.socket.
                                         [], [], [], self.timeout])
            if rd:
self.handle_request()
abort = self.abort

def main():
    logging.basicConfig(  
        format='%(relativeCreated)5d %(name)-15s %(levelname)-8s %(message)s'  
    )
tcpserver = LogRecordSocketReceiver()
print('About to start TCP server...')
tcpserver.serve_until_stopped()

if __name__ == '__main__':
    main()

First run the server, and then the client. On the client side, nothing is printed on the console; on the server side, you should see something like:

```
About to start TCP server...
59 root INFO  Jackdaws love my big
59 myapp.area1 DEBUG Quick zephyrs blow, we
69 myapp.area1 INFO  How quickly daft jump
69 myapp.area2 WARNING Jail zesty vixen who
69 myapp.area2 ERROR The five boxing wizards
```

Note that there are some security issues with pickle in some scenarios. If these affect you, you can use an alternative serialization scheme by overriding the makePickle() method and implementing your alternative there, as well as adapting the above script to use your alternative serialization.
Adding contextual information to your logging output

Sometimes you want logging output to contain contextual information in addition to the parameters passed to the logging call. For example, in a networked application, it may be desirable to log client-specific information in the log (e.g. remote client's username, or IP address). Although you could use the extra parameter to achieve this, it's not always convenient to pass the information in this way. While it might be tempting to create Logger instances on a per-connection basis, this is not a good idea because these instances are not garbage collected. While this is not a problem in practice, when the number of Logger instances is dependent on the level of granularity you want to use in logging an application, it could be hard to manage if the number of Logger instances becomes effectively unbounded.

Using LoggerAdapters to impart contextual information

An easy way in which you can pass contextual information to be output along with logging event information is to use the LoggerAdapter class. This class is designed to look like a Logger, so that you can call debug(), info(), warning(), error(), exception(), critical() and log(). These methods have the same signatures as their counterparts in Logger, so you can use the two types of instances interchangeably.

When you create an instance of LoggerAdapter, you pass it a Logger instance and a dict-like object which contains your contextual information. When you call one of the logging methods on an instance
of LoggerAdapter, it delegates the call to the underlying instance of Logger passed to its constructor, and arranges to pass the contextual information in the delegated call. Here's a snippet from the code of LoggerAdapter:

```python
def debug(self, msg, *args, **kwargs):
    """
    Delegate a debug call to the underlying logger, contextual information from this adapter instance
    """
    msg, kwargs = self.process(msg, kwargs)
    self.logger.debug(msg, *args, **kwargs)
```

The process() method of LoggerAdapter is where the contextual information is added to the logging output. It's passed the message and keyword arguments of the logging call, and it passes back (potentially) modified versions of these to use in the call to the underlying logger. The default implementation of this method leaves the message alone, but inserts an ‘extra’ key in the keyword argument whose value is the dict-like object passed to the constructor. Of course, if you had passed an ‘extra’ keyword argument in the call to the adapter, it will be silently overwritten.

The advantage of using ‘extra’ is that the values in the dict-like object are merged into the LogRecord instance's __dict__, allowing you to use customized strings with your Formatter instances which know about the keys of the dict-like object. If you need a different method, e.g. if you want to prepend or append the contextual information to the message string, you just need to subclass LoggerAdapter and override process() to do what you need. Here is a simple example:

```python
class CustomAdapter(logging.LoggerAdapter):
```

This example adapter expects the passed in dict-like object to have a `'connid'` key, whose value in brackets is prepended to the log message.

```python
def process(self, msg, kwargs):
    return ' [%s] %s' % (self.extra['connid'], msg)
```

which you can use like this:

```python
logger = logging.getLogger(__name__)
adapter = CustomAdapter(logger, {'connid': some_conn_id})
```

Then any events that you log to the adapter will have the value of `some_conn_id` prepended to the log messages.

Using objects other than dicts to pass contextual information

You don’t need to pass an actual dict to a LoggerAdapter - you could pass an instance of a class which implements `__getitem__` and `__iter__` so that it looks like a dict to logging. This would be useful if you want to generate values dynamically (whereas the values in a dict would be constant).

Using Filters to impart contextual information

You can also add contextual information to log output using a user-defined Filter. Filter instances are allowed to modify the `LogRecords` passed to them, including adding additional attributes which can then be output using a suitable format string, or if needed a custom Formatter.

For example in a web application, the request being processed (or at
least, the interesting parts of it) can be stored in a threadlocal
(threading.local) variable, and then accessed from a Filter
to add, say, information from the request - say, the remote IP address
and remote user's username - to the LogRecord, using the attribute
names 'ip' and 'user' as in the LoggerAdapter example above. In
that case, the same format string can be used to get similar output to
that shown above. Here's an example script:

```python
import logging
from random import choice

class ContextFilter(logging.Filter):
    """
    This is a filter which injects contextual information.
    Rather than use actual contextual information, we just use
    random data in this demo.
    """

    USERS = ['jim', 'fred', 'sheila']
    IPS = ['123.231.231.123', '127.0.0.1', '192.168.

    def filter(self, record):
        record.ip = choice(ContextFilter.IPS)
        record.user = choice(ContextFilter.USERS)
        return True

if __name__ == '__main__':
    levels = (logging.DEBUG, logging.INFO, logging.WA
    logging.basicConfig(level=logging.DEBUG,
                        format='%(asctime)-15s	%(name)-5s	%(levelname)-8s	IP:	%(ip)-15s	User:	%(user)-8s	%(message)s'
    a1 = logging.getLogger('a.b.c')
    a2 = logging.getLogger('d.e.f')

    f = ContextFilter()
```
```python
a1.addFilter(f)
a2.addFilter(f)
a1.debug('A debug message')
a1.info('An info message with %s', 'some parameter')
for x in range(10):
    lvl = choice(levels)
    lvlname = logging.getLevelName(lvl)
a2.log(lvl, 'A message at %s level with %d %s'
which, when run, produces something like:

```
```
Logging to a single file from multiple processes

Although logging is thread-safe, and logging to a single file from multiple threads in a single process is supported, logging to a single file from multiple processes is not supported, because there is no standard way to serialize access to a single file across multiple processes in Python. If you need to log to a single file from multiple processes, one way of doing this is to have all the processes log to a SocketHandler, and have a separate process which implements a socket server which reads from the socket and logs to file. (If you prefer, you can dedicate one thread in one of the existing processes to perform this function.) This section documents this approach in more detail and includes a working socket receiver which can be used as a starting point for you to adapt in your own applications.

If you are using a recent version of Python which includes the multiprocessing module, you could write your own handler which uses the Lock class from this module to serialize access to the file from your processes. The existing FileHandler and subclasses do not make use of multiprocessing at present, though they may do so in the future. Note that at present, the multiprocessing module does not provide working lock functionality on all platforms (see http://bugs.python.org/issue3770).

Alternatively, you can use a Queue and a QueueHandler to send all logging events to one of the processes in your multi-process application. The following example script demonstrates how you can do this; in the example a separate listener process listens for events sent by other processes and logs them according to its own logging configuration. Although the example only demonstrates one way of
doing it (for example, you may want to use a listener thread rather than a separate listener process – the implementation would be analogous) it does allow for completely different logging configurations for the listener and the other processes in your application, and can be used as the basis for code meeting your own specific requirements:

```python
# You'll need these imports in your own code
import logging
import logging.handlers
import multiprocessing

# Next two import lines for this demo only
from random import choice, random
import time

# Because you'll want to define the logging configurations
# listener and worker process functions take a configurer parameter
# which they use for communication.
#
# In practice, you can configure the listener however you want,
# simple example, the listener does not apply level or filter logic
# In practice, you would probably want to do this logic in the worker processes
# sending events which would be filtered out between processes.
#
# The size of the rotated files is made small so you can see the results easily.
def listener_configurer():
    root = logging.getLogger()
    h = logging.handlers.RotatingFileHandler('mptest.log',
    f = logging.Formatter('%(asctime)s	%(processName)-10s	%(name)s	%(levelname)-8s	%(message)s',
    h.setFormatter(f)
    root.addHandler(h)
```

# This is the listener process top-level loop: wait
# (LogRecords) on the queue and handle them, quit when
# LogRecord.

def listener_process(queue, configurer):
    configurer()
    while True:
        try:
            record = queue.get()
            if record is None:  # We send this as a sentinel to tell the listener to quit.
                break
            logger = logging.getLogger(record.name)
            logger.handle(record)  # No level or filter logic applied - just do it!
        except (KeyboardInterrupt, SystemExit):
            raise
        except:
            import sys, traceback
            print('Whoops! Problem:', file=sys.stderr)
            traceback.print_exc(file=sys.stderr)

# Arrays used for random selections in this demo

LEVELS = [logging.DEBUG, logging.INFO, logging.WARN, logging.ERROR, logging.CRITICAL]

LOGGERS = ['a.b.c', 'd.e.f']

MESSAGES = [
    'Random message #1',
    'Random message #2',
    'Random message #3',
]

# The worker configuration is done at the start of the worker process run.
# Note that on Windows you can't rely on fork semantics, so will run the logging configuration code when it starts.

def worker_configurer(queue):
    h = logging.handlers.QueueHandler(queue)  # Just
    root = logging.getLogger()
    root.addHandler(h)
root.setLevel(logging.DEBUG)  # send all messages

# This is the worker process top-level loop, which just logs
# random intervening delays before terminating.
# The print messages are just so you know it's doing

def worker_process(queue, configurer):
    configurer(queue)
    name = multiprocessing.current_process().name
    print('Worker started: %s' % name)
    for i in range(10):
        time.sleep(random())
        logger = logging.getLogger(choice(LOGGERS))
        level = choice(LEVELS)
        message = choice(MESSAGES)
        logger.log(level, message)
        print('Worker finished: %s' % name)

# Here's where the demo gets orchestrated. Create the
# listener, create ten workers and start them, wait
# for them to finish, then send a None to the queue to tell the listener

def main():
    queue = multiprocessing.Queue(-1)
    listener = multiprocessing.Process(target=listener_process,
                                        args=(queue,
                                               listener.start())
    workers = []
    for i in range(10):
        worker = multiprocessing.Process(target=worker_process,
                                           args=(queue,
                                                 workers.append(worker)
                                                 worker.start())
    for w in workers:
        w.join()
    queue.put_nowait(None)
    listener.join()

if __name__ == '__main__':
A variant of the above script keeps the logging in the main process, in a separate thread:

```python
import logging
import logging.config
import logging.handlers
from multiprocessing import Process, Queue
import random
import threading
import time

def logger_thread(q):
    while True:
        record = q.get()
        if record is None:
            break
        logger = logging.getLogger(record.name)
        logger.handle(record)

def worker_process(q):
    qh = logging.handlers.QueueHandler(q)
    root = logging.getLogger()
    root.setLevel(logging.DEBUG)
    root.addHandler(qh)
    levels = [logging.DEBUG, logging.INFO, logging.WARNING, logging.CRITICAL]
    loggers = ['foo', 'foo.bar', 'foo.bar.baz', 'spam', 'spam.ham', 'spam.ham.eggs']
    for i in range(100):
        lvl = random.choice(levels)
        logger = logging.getLogger(random.choice(loggers))
        logger.log(lvl, 'Message no. %d', i)
```
if __name__ == '__main__':
    q = Queue()
    d = {
        'version': 1,
        'formatters': {
            'detailed': {
                'class': 'logging.Formatter',
                'format': '%(asctime)s %(name)-15s %(levelname)-8s %(processName)-10s %(message)s'
            }
        },

'root': {
    'level': 'DEBUG',
    'handlers': ['console', 'file', 'errors']
}
}

workers = []
for i in range(5):
    wp = Process(target=worker_process, name='worker %d' % i)
    workers.append(wp)
    wp.start()
logging.config.dictConfig(d)
lp = threading.Thread(target=logger_thread, args=())
lp.start()

# At this point, the main process could do some useful work of its own
# Once it's done that, it can wait for the workers to terminate...
for wp in workers:
    wp.join()

# And now tell the logging thread to finish up,
q.put(None)
lp.join()
Using file rotation

Sometimes you want to let a log file grow to a certain size, then open a new file and log to that. You may want to keep a certain number of these files, and when that many files have been created, rotate the files so that the number of files and the size of the files both remain bounded. For this usage pattern, the logging package provides a `RotatingFileHandler`:

```python
import glob
import logging
import logging.handlers

LOG_FILENAME = 'logging_rotatingfile_example.out'

# Set up a specific logger with our desired output level
my_logger = logging.getLogger('MyLogger')
my_logger.setLevel(logging.DEBUG)

# Add the log message handler to the logger
handler = logging.handlers.RotatingFileHandler(
    LOG_FILENAME, maxBytes=20, backupCount
)

my_logger.addHandler(handler)

# Log some messages
for i in range(20):
    my_logger.debug('i = %d' % i)

# See what files are created
logfiles = glob.glob('%s*' % LOG_FILENAME)

for filename in logfiles:
    print(filename)
```
The result should be 6 separate files, each with part of the log history for the application:

logging_rotatingfile_example.out  
logging_rotatingfile_example.out.1  
logging_rotatingfile_example.out.2  
logging_rotatingfile_example.out.3  
logging_rotatingfile_example.out.4  
logging_rotatingfile_example.out.5

The most current file is always logging_rotatingfile_example.out, and each time it reaches the size limit it is renamed with the suffix .1. Each of the existing backup files is renamed to increment the suffix (.1 becomes .2, etc.) and the .6 file is erased.

Obviously this example sets the log length much too small as an extreme example. You would want to set maxBytes to an appropriate value.
Use of alternative formatting styles

When logging was added to the Python standard library, the only way of formatting messages with variable content was to use the %-formatting method. Since then, Python has gained two new formatting approaches: `string.Template` (added in Python 2.4) and `str.format()` (added in Python 2.6).

Logging (as of 3.2) provides improved support for these two additional formatting styles. The Formatter class been enhanced to take an additional, optional keyword parameter named `style`. This defaults to `'%'`, but other possible values are `'{}'` and `$`, which correspond to the other two formatting styles. Backwards compatibility is maintained by default (as you would expect), but by explicitly specifying a style parameter, you get the ability to specify format strings which work with `str.format()` or `string.Template`. Here's an example console session to show the possibilities:

```python
>>> import logging
>>> root = logging.getLogger()  
>>> root.setLevel(logging.DEBUG)  
>>> handler = logging.StreamHandler()  
>>> bf = logging.Formatter('{asctime} {name} {levelname:8s} {message}')  
...  
     style='{'}
>>> handler.setFormatter(bf)  
>>> root.addHandler(handler)  
>>> logger = logging.getLogger('foo.bar')  
>>> logger.debug('This is a DEBUG message')  
2010-10-28 15:11:55,341 foo.bar DEBUG  This is a DEBUG message
>>> logger.critical('This is a CRITICAL message')  
2010-10-28 15:12:11,526 foo.bar CRITICAL This is a CRITICAL message
>>> df = logging.Formatter('${asctime} $name ${levelname} $message')  
...  
     style='$')
```
>>> handler.setFormatter(df)
>>> logger.debug('This is a DEBUG message')
2010-10-28 15:13:06,924 foo.bar DEBUG This is a DEBUG message
>>> logger.critical('This is a CRITICAL message')
2010-10-28 15:13:11,494 foo.bar CRITICAL This is a CRITICAL message

Note that the formatting of logging messages for final output to logs is completely independent of how an individual logging message is constructed. That can still use %-formatting, as shown here:

>>> logger.error('This is an%s %s %s', 'other,', 'ERROR,
2010-10-28 15:19:29,833 foo.bar ERROR This is another

Logging calls (logger.debug(), logger.info() etc.) only take positional parameters for the actual logging message itself, with keyword parameters used only for determining options for how to handle the actual logging call (e.g. the exc_info keyword parameter to indicate that traceback information should be logged, or the extra keyword parameter to indicate additional contextual information to be added to the log). So you cannot directly make logging calls using str.format() or string.Template syntax, because internally the logging package uses %-formatting to merge the format string and the variable arguments. There would no changing this while preserving backward compatibility, since all logging calls which are out there in existing code will be using %-format strings.

There is, however, a way that you can use {}- and $- formatting to construct your individual log messages. Recall that for a message you can use an arbitrary object as a message format string, and that the logging package will call str() on that object to get the actual format
string. Consider the following two classes:

```python
class BraceMessage:
    def __init__(self, fmt, *args, **kwargs):
        self.fmt = fmt
        self.args = args
        self.kwvars = kwargs
    def __str__(self):
        return self.fmt.format(*self.args, **self.kwvars)

class DollarMessage:
    def __init__(self, fmt, **kwargs):
        self.fmt = fmt
        self.kwvars = kwargs
    def __str__(self):
        from string import Template
        return Template(self.fmt).substitute(**self.kwvars)
```

Either of these can be used in place of a format string, to allow {}- or $-formatting to be used to build the actual “message” part which appears in the formatted log output in place of “%(message)s” or “{message}” or “$message”. It’s a little unwieldy to use the class names whenever you want to log something, but it’s quite palatable if you use an alias such as __ (double underscore – not to be confused with _, the single underscore used as a synonym/alias for gettext.gettext() or its brethren).

The above classes are not included in Python, though they’re easy enough to copy and paste into your own code. They can be used as follows (assuming that they’re declared in a module called wherever):
>>> from wherever import BraceMessage as __
>>> print(__('Message with {0} {name}', 2, name='placeholders'))
Message with 2 placeholders
>>> class Point: pass
...
>>> p = Point()
>>> p.x = 0.5
>>> p.y = 0.5
>>> print(__('Message with coordinates: ({point.x:.2f}, {point.y:.2f})', point=p))
Message with coordinates: (0.50, 0.50)
>>> from wherever import DollarMessage as __
>>> print(__('Message with $num $what', num=2, what='Message with 2 placeholders'))
Message with 2 placeholders

While the above examples use print() to show how the formatting works, you would of course use logger.debug() or similar to actually log using this approach.

One thing to note is that you pay no significant performance penalty with this approach: the actual formatting happens not when you make the logging call, but when (and if) the logged message is actually about to be output to a log by a handler. So the only slightly unusual thing which might trip you up is that the parentheses go around the format string and the arguments, not just the format string. That's because the __ notation is just syntax sugar for a constructor call to one of the XXXMessage classes.

If you prefer, you can use a LoggerAdapter to achieve a similar effect to the above, as in the following example:

```python
import logging
```
class Message(object):
    def __init__(self, fmt, args):
        self.fmt = fmt
        self.args = args

    def __str__(self):
        return self.fmt.format(*self.args)

class StyleAdapter(logging.LoggerAdapter):
    def __init__(self, logger, extra=None):
        super(StyleAdapter, self).__init__(logger, extra)

    def log(self, level, msg, *args, **kwargs):
        if self.isEnabledFor(level):
            msg, kwargs = self.process(msg, kwargs)
            self.logger._log(level, Message(msg, args), (level, msg, args))

logger = StyleAdapter(logging.getLogger(__name__))

def main():
    logger.debug('Hello, {}', 'world!')

if __name__ == '__main__':
    logging.basicConfig(level=logging.DEBUG)
    main()

The above script should log the message Hello, world! when run with Python 3.2 or later.
Customising LogRecord

Every logging event is represented by a LogRecord instance. When an event is logged and not filtered out by a logger’s level, a LogRecord is created, populated with information about the event and then passed to the handlers for that logger (and its ancestors, up to and including the logger where further propagation up the hierarchy is disabled). Before Python 3.2, there were only two places where this creation was done:

- Logger.makeRecord(), which is called in the normal process of logging an event. This invoked LogRecord directly to create an instance.
- makeLogRecord(), which is called with a dictionary containing attributes to be added to the LogRecord. This is typically invoked when a suitable dictionary has been received over the network (e.g. in pickle form via a SocketHandler, or in JSON form via an HTTPHandler).

This has usually meant that if you need to do anything special with a LogRecord, you’ve had to do one of the following.

- Create your own Logger subclass, which overrides Logger.makeRecord(), and set it using setLoggerClass() before any loggers that you care about are instantiated.
- Add a Filter to a logger or handler, which does the necessary special manipulation you need when its filter() method is called.

The first approach would be a little unwieldy in the scenario where (say) several different libraries wanted to do different things. Each would attempt to set its own Logger subclass, and the one which did
this last would win.

The second approach works reasonably well for many cases, but does not allow you to e.g. use a specialized subclass of `LogRecord`. Library developers can set a suitable filter on their loggers, but they would have to remember to do this every time they introduced a new logger (which they would do simply by adding new packages or modules and doing

```python
logger = logging.getLogger(__name__)
```

at module level). It's probably one too many things to think about. Developers could also add the filter to a `NullHandler` attached to their top-level logger, but this would not be invoked if an application developer attached a handler to a lower-level library logger – so output from that handler would not reflect the intentions of the library developer.

In Python 3.2 and later, `LogRecord` creation is done through a factory, which you can specify. The factory is just a callable you can set with `setLogRecordFactory()`, and interrogate with `getLogRecordFactory()`. The factory is invoked with the same signature as the `LogRecord` constructor, as `LogRecord` is the default setting for the factory.

This approach allows a custom factory to control all aspects of `LogRecord` creation. For example, you could return a subclass, or just add some additional attributes to the record once created, using a pattern similar to this:

```python
old_factory = logging.getLogRecordFactory()

def record_factory(*args, **kwargs):
    ...
```
record = old_factory(*args, **kwargs)
record.custom_attribute = 0xdeadbeef
return record

logging.setLogRecordFactory(record_factory)

This pattern allows different libraries to chain factories together, and as long as they don't overwrite each other's attributes or unintentionally overwrite the attributes provided as standard, there should be no surprises. However, it should be borne in mind that each link in the chain adds run-time overhead to all logging operations, and the technique should only be used when the use of a Filter does not provide the desired result.
Subclassing QueueHandler - a ZeroMQ example

You can use a QueueHandler subclass to send messages to other kinds of queues, for example a ZeroMQ ‘publish’ socket. In the example below, the socket is created separately and passed to the handler (as its ‘queue’):

```python
import zmq  # using pyzmq, the Python binding for ZeroMQ
import json  # for serializing records portably

ctx = zmq.Context()
sock = zmq.Socket(ctx, zmq.PUB)  # or zmq.PUSH, or other
sock.bind('tcp://*:5556')  # or wherever

class ZeroMQSocketHandler(QueueHandler):
    def enqueue(self, record):
        data = json.dumps(record.__dict__)
        self.queue.send(data)

handler = ZeroMQSocketHandler(sock)
```

Of course there are other ways of organizing this, for example passing in the data needed by the handler to create the socket:

```python

class ZeroMQSocketHandler(QueueHandler):
    def __init__(self, uri, socktype=zmq.PUB, ctx=None):
        self.ctx = ctx or zmq.Context()
        socket = zmq.Socket(self.ctx, socktype)
        socket.bind(uri)
        QueueHandler.__init__(self, socket)

    def enqueue(self, record):
```
data = json.dumps(record.__dict__)
self.queue.send(data)

def close(self):
    self.queue.close()
Subclassing `QueueListener` - a ZeroMQ example

You can also subclass `QueueListener` to get messages from other kinds of queues, for example a ZeroMQ 'subscribe' socket. Here's an example:

```python
class ZeroMQSocketListener(QueueListener):
    def __init__(self, uri, *handlers, **kwargs):
        self.ctx = kwargs.get('ctx') or zmq.Context()
        socket = zmq.Socket(self.ctx, zmq.SUB)
        socket.setsockopt(zmq.SUBSCRIBE, '')  # subscribe to everything
        socket.connect(uri)

    def dequeue(self):
        msg = self.queue.recv()
        return logging.makeLogRecord(json.loads(msg))
```

An example dictionary-based configuration

Below is an example of a logging configuration dictionary - it's taken from the documentation on the Django project. This dictionary is passed to `dictConfig()` to put the configuration into effect:

```
LOGGING = {
    'version': 1,
    'disable_existing_loggers': True,
    'formatters': {
        'verbose': {
            'format': '%(levelname)s %(asctime)s %(module)s %(process)d %(thread)d %(message)s'
        },
        'simple': {
            'format': '%(levelname)s %(message)s'
        }
    },
    'filters': {
        'special': {
            '()': 'project.logging.SpecialFilter',
            'foo': 'bar',
        }
    },
    'handlers': {
        'null': {
            'level': 'DEBUG',
            'class': 'django.utils.log.NullHandler',
        },
        'console': {
            'level': 'DEBUG',
            'class': 'logging.StreamHandler',
            'formatter': 'simple'
        },
        'mail_admins': {
            'level': 'ERROR',
        }
    },
}
```
For more information about this configuration, you can see the relevant section of the Django documentation.
Using a rotator and namer to customise log rotation processing

An example of how you can define a namer and rotator is given in the following snippet, which shows zlib-based compression of the log file:

```python
def namer(name):
    return name + ".gz"

def rotator(source, dest):
    with open(source, "rb") as sf:
        data = sf.read()
        compressed = zlib.compress(data, 9)
    with open(dest, "wb") as df:
        df.write(compressed)
    os.remove(source)

rh = logging.handlers.RotatingFileHandler(...)  
rh.rotator = rotator  
rh.namer = namer
```

These are not “true” .gz files, as they are bare compressed data, with no “container” such as you’d find in an actual gzip file. This snippet is just for illustration purposes.
A more elaborate multiprocessing example

The following working example shows how logging can be used with multiprocessing using configuration files. The configurations are fairly simple, but serve to illustrate how more complex ones could be implemented in a real multiprocessing scenario.

In the example, the main process spawns a listener process and some worker processes. Each of the main process, the listener and the workers have three separate configurations (the workers all share the same configuration). We can see logging in the main process, how the workers log to a QueueHandler and how the listener implements a QueueListener and a more complex logging configuration, and arranges to dispatch events received via the queue to the handlers specified in the configuration. Note that these configurations are purely illustrative, but you should be able to adapt this example to your own scenario.

Here's the script - the docstrings and the comments hopefully explain how it works:

```python
import logging
import logging.config
import logging.handlers
from multiprocessing import Process, Queue, Event, current_process
import os
import random
import time

class MyHandler:
    """
    A simple handler for logging events. It runs in
    dispatches events to loggers based on the name in
```
which then get dispatched, by the logging system, configured for those loggers.

```python
def handle(self, record):
    logger = logging.getLogger(record.name)
    # The process name is transformed just to show that it's the listener doing the logging to files and console
    record.processName = '%s (for %s)' % (current_process, logger.handle(record))

def listener_process(q, stop_event, config):
    """
    This could be done in the main process, but is just done in a separate process for illustrative purposes.

    This initialises logging according to the specified configuration, starts the listener and waits for the main process via the event. The listener is then stopped, and the process exits.
    """
    logging.config.dictConfig(config)
    listener = logging.handlers.QueueListener(q, MyHandler)
    listener.start()
    if os.name == 'posix':
        # On POSIX, the setup logger will have been parent process, but should have been disabled by dictConfig call.
        # On Windows, since fork isn't used, the setup logger will exist in the child, so it would be created and the message would appear - hence the "if posix" clause
        logger = logging.getLogger('setup')
        logger.critical('Should not appear, because
        stop_event.wait()
        listener.stop()

def worker_process(config):
    """
    A number of these are spawned for the purpose of
```
practice, they could be a heterogenous bunch of ones which are identical to each other.

This initialises logging according to the specified configuration and logs a hundred messages with random levels to randomly selected loggers.

A small sleep is added to allow other processes a bit more than if it's left out.

```python
logging.config.dictConfig(config)
levels = [logging.DEBUG, logging.INFO, logging.WARNING, logging.CRITICAL]
loggers = ['foo', 'foo.bar', 'foo.bar.baz', 'spam', 'spam.ham', 'spam.ham.eggs']
if os.name == 'posix':
    # On POSIX, the setup logger will have been parent process, but should have been disabled dictConfig call.
    # On Windows, since fork isn't used, the setup logger won't exist in the child, so it would be created
    # would appear - hence the "if posix" clause
    logger = logging.getLogger('setup')
    logger.critical('Should not appear, because

    for i in range(100):
        lvl = random.choice(levels)
        logger = logging.getLogger(random.choice(loggers))
        logger.log(lvl, 'Message no. %d', i)
        time.sleep(0.01)
```

def main():
    q = Queue()
    # The main process gets a simple configuration
    config_initial = {
        'version': 1,
        'formatters': {}
'detailed': {
    'class': 'logging.Formatter',
    'format': '%(asctime)s	%(name)-15s	%(levelname)-8s	%(processName)-10s	%(message)s'
},

'handlers': {
    'console': {
        'class': 'logging.StreamHandler',
        'level': 'INFO',
    },
},

'root': {
    'level': 'DEBUG',
    'handlers': ['console']
}
}

# The worker process configuration is just a QueueHandler attached to the root logger, which allows all messages to be sent to the queue.
# We disable existing loggers to disable the "setup" logger used in the parent process. This is needed on POSIX because the logger will be there in the child following a fork().
config_worker = {
    'version': 1,
    'disable_existing_loggers': True,
    'handlers': {
        'queue': {
            'class': 'logging.handlers.QueueHandler',
            'queue': q,
        },
    },
    'root': {
        'level': 'DEBUG',
        'handlers': ['queue']
    }
}

# The listener process configuration shows that the full flexibility of logging configuration is available to dispatch events to handlers however...
# you want.
# We disable existing loggers to disable the "setup" logger used in the parent process. This is needed on POSIX because it be there in the child following a fork().

```python
cfg = {
    'version': 1,
    'disable_existing_loggers': True,
    'formatters': {
        'detailed': {
            'class': 'logging.Formatter',
            'format': '%(asctime)s %(name)-15s %(levelname)-8s %(processName)-10s %(message)s',
        },
        'simple': {
            'class': 'logging.Formatter',
            'format': '%(name)-15s %(levelname)-8s %(processName)-10s %(message)s',
        }
    },
    'handlers': {
        'console': {
            'class': 'logging.StreamHandler',
            'level': 'INFO',
            'formatter': 'simple',
        },
        'file': {
            'class': 'logging.FileHandler',
            'filename': 'mplog.log',

'handlers': ['console', 'file', 'errors'
}
},
}

# Log some initial events, just to show that logging normally.
logging.config.dictConfig(config_initial)
logger = logging.getLogger('setup')
logger.info('About to create workers ...')
workers = []
for i in range(5):
    wp = Process(target=worker_process, name='worker%d' % i,
                 args=(config_worker,))
    workers.append(wp)
    wp.start()
    logger.info('Started worker: %s', wp.name)
logger.info('About to create listener ...')
stop_event = Event()
lp = Process(target=listener_process, name='listener',
             args=(q, stop_event, config_listener,))
lp.start()
logger.info('Started listener')
# We now hang around for the workers to finish their work.
for wp in workers:
    wp.join()
# Workers all done, listening can now stop.
# Logging in the parent still works normally.
logger.info('Telling listener to stop ...')
stop_event.set()
lp.join()
logger.info('All done.')

if __name__ == '__main__':
    main()
Inserting a BOM into messages sent to a SysLogHandler

**RFC 5424** requires that a Unicode message be sent to a syslog daemon as a set of bytes which have the following structure: an optional pure-ASCII component, followed by a UTF-8 Byte Order Mark (BOM), followed by Unicode encoded using UTF-8. (See the relevant section of the specification.)

In Python 3.1, code was added to `SysLogHandler` to insert a BOM into the message, but unfortunately, it was implemented incorrectly, with the BOM appearing at the beginning of the message and hence not allowing any pure-ASCII component to appear before it.

As this behaviour is broken, the incorrect BOM insertion code is being removed from Python 3.2.4 and later. However, it is not being replaced, and if you want to produce RFC 5424-compliant messages which include a BOM, an optional pure-ASCII sequence before it and arbitrary Unicode after it, encoded using UTF-8, then you need to do the following:

1. Attach a **Formatter** instance to your `SysLogHandler` instance, with a format string such as:

   ```python
   'ASCII section\ufeffUnicode section'
   ```

   The Unicode code point U+FEFF, when encoded using UTF-8, will be encoded as a UTF-8 BOM – the byte-string `b'\xef\xbb\xbf'`.

2. Replace the ASCII section with whatever placeholders you like, but make sure that the data that appears in there after substitution
is always ASCII (that way, it will remain unchanged after UTF-8 encoding).

3. Replace the Unicode section with whatever placeholders you like; if the data which appears there after substitution contains characters outside the ASCII range, that’s fine – it will be encoded using UTF-8.

The formatted message will be encoded using UTF-8 encoding by SysLogHandler. If you follow the above rules, you should be able to produce RFC 5424-compliant messages. If you don’t, logging may not complain, but your messages will not be RFC 5424-compliant, and your syslog daemon may complain.
Implementing structured logging

Although most logging messages are intended for reading by humans, and thus not readily machine-parseable, there might be circumstances where you want to output messages in a structured format which *is* capable of being parsed by a program (without needing complex regular expressions to parse the log message). This is straightforward to achieve using the logging package. There are a number of ways in which this could be achieved, but the following is a simple approach which uses JSON to serialise the event in a machine-parseable manner:

```python
import json
import logging

class StructuredMessage(object):
    def __init__(self, message, **kwargs):
        self.message = message
        self.kwargs = kwargs

    def __str__(self):
        return '%s >>> %s' % (self.message, json.dumps(self.kwargs))

_ = StructuredMessage  # optional, to improve readability

logging.basicConfig(level=logging.INFO, format='%(message)s')
logging.info(_('message 1', foo='bar', bar='baz', num=123))
```

If the above script is run, it prints:

```plaintext
message 1 >>> {"fnun": 123.456, "num": 123, "bar": "baz", "foo": "bar"}
```
Note that the order of items might be different according to the version of Python used.

If you need more specialised processing, you can use a custom JSON encoder, as in the following complete example:

```python
from __future__ import unicode_literals

import json
import logging

# This next bit is to ensure the script runs unchanged
try:
    unicode
except NameError:
    unicode = str

class Encoder(json.JSONEncoder):
    def default(self, o):
        if isinstance(o, set):
            return tuple(o)
        elif isinstance(o, unicode):
            return o.encode('unicode_escape').decode
        return super(Encoder, self).default(o)

class StructuredMessage(object):
    def __init__(self, message, **kwargs):
        self.message = message
        self.kwargs = kwargs

    def __str__(self):
        s = Encoder().encode(self.kwargs)
        return '%s >>> %s' % (self.message, s)

_ = StructuredMessage  # optional, to improve readability
```
```python
def main():
    logging.basicConfig(level=logging.INFO, format='%(message)s')
    logging.info(_('message 1'), set_value=set([1, 2, 3]))

if __name__ == '__main__':
    main()
```

When the above script is run, it prints:

```
message 1 >>> {'snowman': '☃', 'set_value': [1, 2, 3]}
```

Note that the order of items might be different according to the version of Python used.
Regular Expression HOWTO

Author: A.M. Kuchling <amk@amk.ca>

Abstract

This document is an introductory tutorial to using regular expressions in Python with the re module. It provides a gentler introduction than the corresponding section in the Library Reference.
Introduction

Regular expressions (called REs, or regexes, or regex patterns) are essentially a tiny, highly specialized programming language embedded inside Python and made available through the `re` module. Using this little language, you specify the rules for the set of possible strings that you want to match; this set might contain English sentences, or e-mail addresses, or TeX commands, or anything you like. You can then ask questions such as “Does this string match the pattern?”, or “Is there a match for the pattern anywhere in this string?”. You can also use REs to modify a string or to split it apart in various ways.

Regular expression patterns are compiled into a series of bytecodes which are then executed by a matching engine written in C. For advanced use, it may be necessary to pay careful attention to how the engine will execute a given RE, and write the RE in a certain way in order to produce bytecode that runs faster. Optimization isn’t covered in this document, because it requires that you have a good understanding of the matching engine’s internals.

The regular expression language is relatively small and restricted, so not all possible string processing tasks can be done using regular expressions. There are also tasks that can be done with regular expressions, but the expressions turn out to be very complicated. In these cases, you may be better off writing Python code to do the processing; while Python code will be slower than an elaborate regular expression, it will also probably be more understandable.
Simple Patterns

We'll start by learning about the simplest possible regular expressions. Since regular expressions are used to operate on strings, we'll begin with the most common task: matching characters.

For a detailed explanation of the computer science underlying regular expressions (deterministic and non-deterministic finite automata), you can refer to almost any textbook on writing compilers.

Matching Characters

Most letters and characters will simply match themselves. For example, the regular expression test will match the string test exactly. (You can enable a case-insensitive mode that would let this RE match Test or TEST as well; more about this later.)

There are exceptions to this rule; some characters are special metacharacters, and don’t match themselves. Instead, they signal that some out-of-the-ordinary thing should be matched, or they affect other portions of the RE by repeating them or changing their meaning. Much of this document is devoted to discussing various metacharacters and what they do.

Here's a complete list of the metacharacters; their meanings will be discussed in the rest of this HOWTO.

```
. ^ $ * + ? { } [ ] \ | ( )
```

The first metacharacters we'll look at are [ and ]. They're used for specifying a character class, which is a set of characters that you wish to match. Characters can be listed individually, or a range of
characters can be indicated by giving two characters and separating them by a ' - '. For example, \[abc\] will match any of the characters a, b, or c; this is the same as \[a-c\], which uses a range to express the same set of characters. If you wanted to match only lowercase letters, your RE would be \[a-z\].

Metacharacters are not active inside classes. For example, \[akm$\] will match any of the characters 'a', 'k', 'm', or '$'; '$' is usually a metacharacter, but inside a character class it's stripped of its special nature.

You can match the characters not listed within the class by complementing the set. This is indicated by including a ' ^ ' as the first character of the class; ' ^ ' outside a character class will simply match the ' ^ ' character. For example, \[^5\] will match any character except ' 5 '.

Perhaps the most important metacharacter is the backslash, \. As in Python string literals, the backslash can be followed by various characters to signal various special sequences. It's also used to escape all the metacharacters so you can still match them in patterns; for example, if you need to match a [ or \, you can precede them with a backslash to remove their special meaning: \[ or \\.

Some of the special sequences beginning with ' \' represent predefined sets of characters that are often useful, such as the set of digits, the set of letters, or the set of anything that isn't whitespace.

Let's take an example: \w matches any alphanumeric character. If the regex pattern is expressed in bytes, this is equivalent to the class \[a-zA-Z0-9_\]. If the regex pattern is a string, \w will match all the characters marked as letters in the Unicode database provided by the
The unicodedata module. You can use the more restricted definition of \w in a string pattern by supplying the re.ASCII flag when compiling the regular expression.

The following list of special sequences isn’t complete. For a complete list of sequences and expanded class definitions for Unicode string patterns, see the last part of Regular Expression Syntax in the Standard Library reference. In general, the Unicode versions match any character that’s in the appropriate category in the Unicode database.

\d
  Matches any decimal digit; this is equivalent to the class [0-9].

\D
  Matches any non-digit character; this is equivalent to the class [^0-9].

\s
  Matches any whitespace character; this is equivalent to the class [ \	\n\r\f\v].

\S
  Matches any non-whitespace character; this is equivalent to the class [^ \t\n\r\f\v].

\w
  Matches any alphanumeric character; this is equivalent to the class [a-zA-Z0-9_].

\W
  Matches any non-alphanumeric character; this is equivalent to the class [^a-zA-Z0-9_].

These sequences can be included inside a character class. For example, [\s,.] is a character class that will match any whitespace
character, or ',,' or '.'.

The final metacharacter in this section is . . It matches anything except a newline character, and there's an alternate mode (re.DOTALL) where it will match even a newline. '. ' is often used where you want to match "any character".

Repeating Things

Being able to match varying sets of characters is the first thing regular expressions can do that isn't already possible with the methods available on strings. However, if that was the only additional capability of regexes, they wouldn't be much of an advance. Another capability is that you can specify that portions of the RE must be repeated a certain number of times.

The first metacharacter for repeating things that we'll look at is *. * doesn't match the literal character *; instead, it specifies that the previous character can be matched zero or more times, instead of exactly once.

For example, ca*t will match ct (0 a characters), cat (1 a), caaat (3 a characters), and so forth. The RE engine has various internal limitations stemming from the size of C's int type that will prevent it from matching over 2 billion a characters; patterns are usually not written to match that much data.

Repetitions such as * are greedy; when repeating a RE, the matching engine will try to repeat it as many times as possible. If later portions of the pattern don't match, the matching engine will then back up and try again with few repetitions.
A step-by-step example will make this more obvious. Let's consider the expression \( a[bcd]^*b \). This matches the letter 'a', zero or more letters from the class \([bcd]\), and finally ends with a 'b'. Now imagine matching this RE against the string abcbd.

<table>
<thead>
<tr>
<th>Step</th>
<th>Matched</th>
<th>Explanation</th>
</tr>
</thead>
<tbody>
<tr>
<td>1</td>
<td>a</td>
<td>The a in the RE matches.</td>
</tr>
<tr>
<td>2</td>
<td>abcbd</td>
<td>The engine matches ([bcd]^*), going as far as it can, which is to the end of the string.</td>
</tr>
<tr>
<td>3</td>
<td>Failure</td>
<td>The engine tries to match b, but the current position is at the end of the string, so it fails.</td>
</tr>
<tr>
<td>4</td>
<td>abcb</td>
<td>Back up, so that ([bcd]^*) matches one less character.</td>
</tr>
<tr>
<td>5</td>
<td>Failure</td>
<td>Try b again, but the current position is at the last character, which is a 'd'.</td>
</tr>
<tr>
<td>6</td>
<td>abc</td>
<td>Back up again, so that ([bcd]^*) is only matching bc.</td>
</tr>
<tr>
<td>6</td>
<td>abc</td>
<td>Try b again. This time the character at the current position is 'b', so it succeeds.</td>
</tr>
</tbody>
</table>

The end of the RE has now been reached, and it has matched abc. This demonstrates how the matching engine goes as far as it can at first, and if no match is found it will then progressively back up and retry the rest of the RE again and again. It will back up until it has tried zero matches for \([bcd]^*\), and if that subsequently fails, the engine will conclude that the string doesn't match the RE at all.

Another repeating metacharacter is +, which matches one or more times. Pay careful attention to the difference between * and +; * matches zero or more times, so whatever's being repeated may not be
present at all, while + requires at least one occurrence. To use a similar example, ca+t will match cat (1 a), caaat (3 a's), but won’t match ct.

There are two more repeating qualifiers. The question mark character, ?, matches either once or zero times; you can think of it as marking something as being optional. For example, home-?brev matches either homebrev or home-brev.

The most complicated repeated qualifier is \{m, n\}, where m and n are decimal integers. This qualifier means there must be at least m repetitions, and at most n. For example, a/\{1, 3\}b will match a/b, a//b, and a///b. It won’t match ab, which has no slashes, or a////b, which has four.

You can omit either m or n; in that case, a reasonable value is assumed for the missing value. Omitting m is interpreted as a lower limit of 0, while omitting n results in an upper bound of infinity — actually, the upper bound is the 2-billion limit mentioned earlier, but that might as well be infinity.

Readers of a reductionist bent may notice that the three other qualifiers can all be expressed using this notation. \{0,\} is the same as *, \{1,\} is equivalent to +, and \{0, 1\} is the same as ?. It’s better to use *, +, or ? when you can, simply because they’re shorter and easier to read.
Using Regular Expressions

Now that we’ve looked at some simple regular expressions, how do we actually use them in Python? The `re` module provides an interface to the regular expression engine, allowing you to compile REs into objects and then perform matches with them.

Compiling Regular Expressions

Regular expressions are compiled into pattern objects, which have methods for various operations such as searching for pattern matches or performing string substitutions.

```python
>>> import re
>>> p = re.compile('ab*')
>>> p
<_sre.SRE_Pattern object at 0x...>
```

`re.compile()` also accepts an optional `flags` argument, used to enable various special features and syntax variations. We’ll go over the available settings later, but for now a single example will do:

```python
>>> p = re.compile('ab*', re.IGNORECASE)
```

The RE is passed to `re.compile()` as a string. REs are handled as strings because regular expressions aren’t part of the core Python language, and no special syntax was created for expressing them. (There are applications that don’t need REs at all, so there’s no need to bloat the language specification by including them.) Instead, the `re` module is simply a C extension module included with Python, just like the `socket` or `zlib` modules.
Putting REs in strings keeps the Python language simpler, but has one disadvantage which is the topic of the next section.

**The Backslash Plague**

As stated earlier, regular expressions use the backslash character ('\') to indicate special forms or to allow special characters to be used without invoking their special meaning. This conflicts with Python’s usage of the same character for the same purpose in string literals.

Let’s say you want to write a RE that matches the string `\section`, which might be found in a LaTeX file. To figure out what to write in the program code, start with the desired string to be matched. Next, you must escape any backslashes and other metacharacters by preceding them with a backslash, resulting in the string `\section`. The resulting string that must be passed to `re.compile()` must be `\section`. However, to express this as a Python string literal, both backslashes must be escaped *again*.

<table>
<thead>
<tr>
<th>Characters</th>
<th>Stage</th>
</tr>
</thead>
<tbody>
<tr>
<td><code>\section</code></td>
<td>Text string to be matched</td>
</tr>
<tr>
<td><code>\\section</code></td>
<td>Escaped backslash for <code>re.compile()</code></td>
</tr>
<tr>
<td>&quot;\\section&quot;</td>
<td>Escaped backslashes for a string literal</td>
</tr>
</tbody>
</table>

In short, to match a literal backslash, one has to write `\\\\` as the RE string, because the regular expression must be `\\`, and each backslash must be expressed as `\\` inside a regular Python string literal. In REs that feature backslashes repeatedly, this leads to lots of repeated backslashes and makes the resulting strings difficult to understand.
The solution is to use Python's raw string notation for regular expressions; backslashes are not handled in any special way in a string literal prefixed with `r`, so `r"\n"` is a two-character string containing `\` and `n`, while `\n` is a one-character string containing a newline. Regular expressions will often be written in Python code using this raw string notation.

<table>
<thead>
<tr>
<th>Regular String</th>
<th>Raw string</th>
</tr>
</thead>
<tbody>
<tr>
<td>&quot;ab*&quot;</td>
<td>r&quot;ab*&quot;</td>
</tr>
<tr>
<td>&quot;\section&quot;</td>
<td>r&quot;\section&quot;</td>
</tr>
<tr>
<td>&quot;\w+\s+\1&quot;</td>
<td>r&quot;\w+\s+\1&quot;</td>
</tr>
</tbody>
</table>

Performing Matches

Once you have an object representing a compiled regular expression, what do you do with it? Pattern objects have several methods and attributes. Only the most significant ones will be covered here; consult the `re` docs for a complete listing.

<table>
<thead>
<tr>
<th>Method/Attribute</th>
<th>Purpose</th>
</tr>
</thead>
<tbody>
<tr>
<td>match()</td>
<td>Determine if the RE matches at the beginning of the string.</td>
</tr>
<tr>
<td>search()</td>
<td>Scan through a string, looking for any location where this RE matches.</td>
</tr>
<tr>
<td>.findall()</td>
<td>Find all substrings where the RE matches, and returns them as a list.</td>
</tr>
<tr>
<td>finditer()</td>
<td>Find all substrings where the RE matches, and returns them as an <code>iterator</code>.</td>
</tr>
</tbody>
</table>

`match()` and `search()` return None if no match can be found. If
they're successful, a *match object* instance is returned, containing information about the match: where it starts and ends, the substring it matched, and more.

You can learn about this by interactively experimenting with the `re` module. If you have `tkinter` available, you may also want to look at `Tools/demo/redemo.py`, a demonstration program included with the Python distribution. It allows you to enter REs and strings, and displays whether the RE matches or fails. `redemo.py` can be quite useful when trying to debug a complicated RE. Phil Schwartz’s *Kodos* is also an interactive tool for developing and testing RE patterns.

This HOWTO uses the standard Python interpreter for its examples. First, run the Python interpreter, import the `re` module, and compile a RE:

```
>>> import re
>>> p = re.compile('[a-z]+')
>>> p
<_sre.SRE_Pattern object at 0x...>
```

Now, you can try matching various strings against the RE `[a-z]+`. An empty string shouldn’t match at all, since `+` means ‘one or more repetitions’. `match()` should return `None` in this case, which will cause the interpreter to print no output. You can explicitly print the result of `match()` to make this clear.

```
>>> p.match('')
>>> print(p.match(''))
None
```

Now, let’s try it on a string that it should match, such as `tempo`. In this case, `match()` will return a *match object*, so you should store the
result in a variable for later use.

```python
>>> m = p.match('tempo')
>>> m
<_sre.SRE_Match object at 0x...>```

Now you can query the `match object` for information about the matching string. `match object` instances also have several methods and attributes; the most important ones are:

<table>
<thead>
<tr>
<th>Method/Attribute</th>
<th>Purpose</th>
</tr>
</thead>
<tbody>
<tr>
<td>group()</td>
<td>Return the string matched by the RE</td>
</tr>
<tr>
<td>start()</td>
<td>Return the starting position of the match</td>
</tr>
<tr>
<td>end()</td>
<td>Return the ending position of the match</td>
</tr>
<tr>
<td>span()</td>
<td>Return a tuple containing the (start, end) positions of the match</td>
</tr>
</tbody>
</table>

Trying these methods will soon clarify their meaning:

```python
>>> m.group()
'tempo'
>>> m.start(), m.end()
(0, 5)
>>> m.span()
(0, 5)
```

`group()` returns the substring that was matched by the RE. `start()` and `end()` return the starting and ending index of the match. `span()` returns both start and end indexes in a single tuple. Since the `match()` method only checks if the RE matches at the start of a string, `start()` will always be zero. However, the `search()` method of patterns scans through the string, so the match may not
In actual programs, the most common style is to store the *match object* in a variable, and then check if it was None. This usually looks like:

```python
def example():
    p = re.compile( ... )
    m = p.match( 'string goes here' )
    if m:
        print('Match found: ', m.group())
    else:
        print('No match')
```

Two pattern methods return all of the matches for a pattern. *findall()* returns a list of matching strings:

```python
>>> p = re.compile( '\d+' )
>>> p.findall('12 drummers drumming, 11 pipers piping, 10 lords a-leaping')
['12', '11', '10']
```

*findall()* has to create the entire list before it can be returned as the result. The *finditer()* method returns a sequence of *match object* instances as an *iterator*:

```python
>>> iterator = p.finditer('12 drummers drumming, 11 pipers piping, 12 drummers drumming')
>>> next(iterator)
<re.Match object; span=(0, 12), match='12 drummers drumming'>
```
Module-Level Functions

You don’t have to create a pattern object and call its methods; the re module also provides top-level functions called `match()`, `search()`, `findall()`, `sub()`, and so forth. These functions take the same arguments as the corresponding pattern method with the RE string added as the first argument, and still return either `None` or a `match object` instance.

Under the hood, these functions simply create a pattern object for you and call the appropriate method on it. They also store the compiled object in a cache, so future calls using the same RE won’t need to parse the pattern again and again.

Should you use these module-level functions, or should you get the pattern and call its methods yourself? If you’re accessing a regex within a loop, pre-compiling it will save a few function calls. Outside of loops, there’s not much difference thanks to the internal cache.
Compilation Flags

Compilation flags let you modify some aspects of how regular expressions work. Flags are available in the `re` module under two names, a long name such as `IGNORECASE` and a short, one-letter form such as `I`. (If you’re familiar with Perl’s pattern modifiers, the one-letter forms use the same letters; the short form of `re.VERBOSE` is `re.X`, for example.) Multiple flags can be specified by bitwise OR-ing them; `re.I | re.M` sets both the `I` and `M` flags, for example.

Here’s a table of the available flags, followed by a more detailed explanation of each one.

<table>
<thead>
<tr>
<th>Flag</th>
<th>Meaning</th>
</tr>
</thead>
<tbody>
<tr>
<td>ASCII, A</td>
<td>Makes several escapes like <code>\w</code>, <code>\b</code>, <code>\s</code> and <code>\d</code> match only on ASCII characters with the respective property.</td>
</tr>
<tr>
<td>DOTALL, S</td>
<td>Make <code>.</code> match any character, including newlines</td>
</tr>
<tr>
<td>IGNORECASE, I</td>
<td>Do case-insensitive matches</td>
</tr>
<tr>
<td>LOCALE, L</td>
<td>Do a locale-aware match</td>
</tr>
<tr>
<td>MULTILINE, M</td>
<td>Multi-line matching, affecting <code>^</code> and <code>$</code></td>
</tr>
<tr>
<td>VERBOISE, X (for ‘extended’)</td>
<td>Enable verbose REs, which can be organized more cleanly and understandably.</td>
</tr>
</tbody>
</table>

**I**

**IGNORECASE**

Perform case-insensitive matching; character class and literal
strings will match letters by ignoring case. For example, [A-Z] will match lowercase letters, too, and Spam will match Spam, spam, or spAM. This lowercasing doesn’t take the current locale into account; it will if you also set the LOCALE flag.

L

LOCALE

Make \w, \W, \b, and \B, dependent on the current locale instead of the Unicode database.

Locales are a feature of the C library intended to help in writing programs that take account of language differences. For example, if you’re processing French text, you’d want to be able to write \w+ to match words, but \w only matches the character class [A-Za-z]; it won’t match 'é' or 'ç'. If your system is configured properly and a French locale is selected, certain C functions will tell the program that 'é' should also be considered a letter. Setting the LOCALE flag when compiling a regular expression will cause the resulting compiled object to use these C functions for \w; this is slower, but also enables \w+ to match French words as you’d expect.

M

MULTILINE

(\^ and $ haven’t been explained yet; they’ll be introduced in section More Metacharacters.)

Usually \^ matches only at the beginning of the string, and $ matches only at the end of the string and immediately before the newline (if any) at the end of the string. When this flag is specified, \^ matches at the beginning of the string and at the beginning of each line within the string, immediately following each newline.
Similarly, the $ metacharacter matches either at the end of the string and at the end of each line (immediately preceding each newline).

**S**

**DOTALL**

Makes the '.' special character match any character at all, including a newline; without this flag, ' . ' will match anything except a newline.

**A**

**ASCII**

Make \w, \W, \b, \B, \s and \S perform ASCII-only matching instead of full Unicode matching. This is only meaningful for Unicode patterns, and is ignored for byte patterns.

**X**

**VERBOSE**

This flag allows you to write regular expressions that are more readable by granting you more flexibility in how you can format them. When this flag has been specified, whitespace within the RE string is ignored, except when the whitespace is in a character class or preceded by an unescaped backslash; this lets you organize and indent the RE more clearly. This flag also lets you put comments within a RE that will be ignored by the engine; comments are marked by a ' # ' that's neither in a character class or preceded by an unescaped backslash.

For example, here's a RE that uses `re.VERBOSE`; see how much easier it is to read?

```python
charref = re.compile(r''' &[#] # Start of a numeric entity
```
Without the verbose setting, the RE would look like this:

```python
charref = re.compile("&\#(0[0-7]+" "|\[0-9]+" "|x[0-9a-fA-F]+);")
```

In the above example, Python's automatic concatenation of string literals has been used to break up the RE into smaller pieces, but it's still more difficult to understand than the version using `re.VERBOSE`.
More Pattern Power

So far we’ve only covered a part of the features of regular expressions. In this section, we’ll cover some new metacharacters, and how to use groups to retrieve portions of the text that was matched.

More Metacharacters

There are some metacharacters that we haven’t covered yet. Most of them will be covered in this section.

Some of the remaining metacharacters to be discussed are zero-width assertions. They don’t cause the engine to advance through the string; instead, they consume no characters at all, and simply succeed or fail. For example, \b is an assertion that the current position is located at a word boundary; the position isn’t changed by the \b at all. This means that zero-width assertions should never be repeated, because if they match once at a given location, they can obviously be matched an infinite number of times.

| Alternation, or the “or” operator. If A and B are regular expressions, A|B will match any string that matches either A or B. | has very low precedence in order to make it work reasonably when you’re alternating multi-character strings. Crow|Servo will match either Crow or Servo, not Cro, a 'w' or an 'S', and ervo.

To match a literal |, use \|, or enclose it inside a character class, as in [\|].
Matches at the beginning of lines. Unless the MULTILINE flag has been set, this will only match at the beginning of the string. In MULTILINE mode, this also matches immediately after each newline within the string.

For example, if you wish to match the word From only at the beginning of a line, the RE to use is ^From.

```python
>>> print(re.search('^From', 'From Here to Eternity'))
<_sre.SRE_Match object at 0x...>
>>> print(re.search('^From', 'Reciting From Memory'))
None
```

Matches at the end of a line, which is defined as either the end of the string, or any location followed by a newline character.

```python
>>> print(re.search('}{block}$', '{block}'))
<_sre.SRE_Match object at 0x...>
>>> print(re.search('}{block}$', '{block} '))
None
>>> print(re.search('}{block}$', '{block}\n'))
<_sre.SRE_Match object at 0x...>
```

To match a literal '$', use \$ or enclose it inside a character class, as in [$].

\A

Matches only at the start of the string. When not in MULTILINE mode, \A and ^ are effectively the same. In MULTILINE mode, they’re different: \A still matches only at the beginning of the string, but ^ may match at any location inside the string that follows a newline character.
\Z
Matches only at the end of the string.

\b
Word boundary. This is a zero-width assertion that matches only at the beginning or end of a word. A word is defined as a sequence of alphanumeric characters, so the end of a word is indicated by whitespace or a non-alphanumeric character.

The following example matches \texttt{class} only when it's a complete word; it won't match when it's contained inside another word.

```python
>>> p = re.compile(r'\bclass\b')
>>> print(p.search('no class at all'))
<_sre.SRE_Match object at 0x...>
>>> print(p.search('the declassified algorithm'))
None
>>> print(p.search('one subclass is'))
None
```

There are two subtleties you should remember when using this special sequence. First, this is the worst collision between Python's string literals and regular expression sequences. In Python's string literals, \texttt{\b} is the backspace character, ASCII value 8. If you're not using raw strings, then Python will convert the \texttt{\b} to a backspace, and your RE won't match as you expect it to. The following example looks the same as our previous RE, but omits the \texttt{r} in front of the RE string.

```python
>>> p = re.compile('\bclass\b')
>>> print(p.search('no class at all'))
None
>>> print(p.search('\b' + 'class' + '\b'))
<_sre.SRE_Match object at 0x...>
```
Second, inside a character class, where there's no use for this assertion, \b represents the backspace character, for compatibility with Python’s string literals.

\B

Another zero-width assertion, this is the opposite of \b, only matching when the current position is not at a word boundary.

**Grouping**

Frequently you need to obtain more information than just whether the RE matched or not. Regular expressions are often used to dissect strings by writing a RE divided into several subgroups which match different components of interest. For example, an RFC-822 header line is divided into a header name and a value, separated by a ':', like this:

```
From: author@example.com
User-Agent: Thunderbird 1.5.0.9 (X11/20061227)
MIME-Version: 1.0
To: editor@example.com
```

This can be handled by writing a regular expression which matches an entire header line, and has one group which matches the header name, and another group which matches the header’s value.

Groups are marked by the '(', ')' metacharacters. '(', ' and ')' have much the same meaning as they do in mathematical expressions; they group together the expressions contained inside them, and you can repeat the contents of a group with a repeating qualifier, such as *, +, ?, or {m, n}. For example, (ab)* will match zero or more repetitions of ab.
Groups indicated with `((, ))` also capture the starting and ending index of the text that they match; this can be retrieved by passing an argument to group(), start(), end(), and span(). Groups are numbered starting with 0. Group 0 is always present; it’s the whole RE, so match object methods all have group 0 as their default argument. Later we'll see how to express groups that don’t capture the span of text that they match.

Subgroups are numbered from left to right, from 1 upward. Groups can be nested; to determine the number, just count the opening parenthesis characters, going from left to right.

group() can be passed multiple group numbers at a time, in which case it will return a tuple containing the corresponding values for those
The `groups()` method returns a tuple containing the strings for all the subgroups, from 1 up to however many there are.

```python
>>> m.groups()
('abc', 'b')
```

Backreferences in a pattern allow you to specify that the contents of an earlier capturing group must also be found at the current location in the string. For example, \1 will succeed if the exact contents of group 1 can be found at the current position, and fails otherwise. Remember that Python’s string literals also use a backslash followed by numbers to allow including arbitrary characters in a string, so be sure to use a raw string when incorporating backreferences in a RE.

For example, the following RE detects doubled words in a string.

```python
>>> p = re.compile(r'\b\w+\s+\1')
>>> p.search('Paris in the the spring').group()
'the the'
```

Backreferences like this aren’t often useful for just searching through a string — there are few text formats which repeat data in this way — but you’ll soon find out that they’re very useful when performing string substitutions.

**Non-capturing and Named Groups**

Elaborate REs may use many groups, both to capture substrings of
interest, and to group and structure the RE itself. In complex REs, it becomes difficult to keep track of the group numbers. There are two features which help with this problem. Both of them use a common syntax for regular expression extensions, so we'll look at that first.

Perl 5 is well-known for its powerful additions to standard regular expressions. For these new features the Perl developers couldn't choose new single-keystroke metacharacters or new special sequences beginning with \ without making Perl's regular expressions confusingly different from standard REs. If they chose & as a new metacharacter, for example, old expressions would be assuming that & was a regular character and wouldn't have escaped it by writing \\& or [\&].

The solution chosen by the Perl developers was to use (?...) as the extension syntax. ? immediately after a parenthesis was a syntax error because the ? would have nothing to repeat, so this didn't introduce any compatibility problems. The characters immediately after the ? indicate what extension is being used, so (?=foo) is one thing (a positive lookahead assertion) and (?:foo) is something else (a non-capturing group containing the subexpression foo).

Python supports several of Perl's extensions and adds an extension syntax to Perl's extension syntax. If the first character after the question mark is a P, you know that it's an extension that's specific to Python.

Now that we've looked at the general extension syntax, we can return to the features that simplify working with groups in complex REs.

Sometimes you'll want to use a group to denote a part of a regular expression, but aren't interested in retrieving the group's contents. You
can make this fact explicit by using a non-capturing group: (?::...), where you can replace the ... with any other regular expression.

```python
>>> m = re.match("([abc])+", "abc")
>>> m.groups()
('c',)
>>> m = re.match("(?:[abc])+", "abc")
>>> m.groups()
()
```

Except for the fact that you can’t retrieve the contents of what the group matched, a non-capturing group behaves exactly the same as a capturing group; you can put anything inside it, repeat it with a repetition metacharacter such as *, and nest it within other groups (capturing or non-capturing). (?::...) is particularly useful when modifying an existing pattern, since you can add new groups without changing how all the other groups are numbered. It should be mentioned that there’s no performance difference in searching between capturing and non-capturing groups; neither form is any faster than the other.

A more significant feature is named groups: instead of referring to them by numbers, groups can be referenced by a name.

The syntax for a named group is one of the Python-specific extensions: (?P<name>...). name is, obviously, the name of the group. Named groups behave exactly like capturing groups, and additionally associate a name with a group. The `match object` methods that deal with capturing groups all accept either integers that refer to the group by number or strings that contain the desired group’s name. Named groups are still given numbers, so you can retrieve information about a group in two ways:
Named groups are handy because they let you use easily-remembered names, instead of having to remember numbers. Here's an example RE from the imaplib module:

```python
InternalDate = re.compile(r'INTERNALDATE "
   r'(?P<day>\[123][0-9])-(?P<mon>[A-Z][a-z][a-z])-
   r'(?P<year>[0-9][0-9][0-9][0-9])
   r' (?P<hour>[0-9][0-9]):(?P<min>[0-9][0-9]):(?P<sec>[0-9][0-9])
   r' (?P<zonen>[+-])(?P<zoneh>[0-9][0-9])(?P<zonem>[0-9][0-9])"')
```

It's obviously much easier to retrieve `m.group('zonem')`, instead of having to remember to retrieve group 9.

The syntax for backreferences in an expression such as `( ... )\1` refers to the number of the group. There’s naturally a variant that uses the group name instead of the number. This is another Python extension: `(?P=name)` indicates that the contents of the group called `name` should again be matched at the current point. The regular expression for finding doubled words, `(\b\w+)\s+\1` can also be written as `(?P<word>\b\w+)\s+(?P=word):

```python
>>> p = re.compile(r'( ?P<word>\b\w+)\s+(?P=word)')
>>> p.search('Paris in the the spring').group()
'the the'
```
Lookahead Assertions

Another zero-width assertion is the lookahead assertion. Lookahead assertions are available in both positive and negative form, and look like this:

(?=...)  
Positive lookahead assertion. This succeeds if the contained regular expression, represented here by ..., successfully matches at the current location, and fails otherwise. But, once the contained expression has been tried, the matching engine doesn't advance at all; the rest of the pattern is tried right where the assertion started.

(?!...)  
Negative lookahead assertion. This is the opposite of the positive assertion; it succeeds if the contained expression doesn't match at the current position in the string.

To make this concrete, let's look at a case where a lookahead is useful. Consider a simple pattern to match a filename and split it apart into a base name and an extension, separated by a .. For example, in news.rc, news is the base name, and rc is the filename's extension.

The pattern to match this is quite simple:

.*[.].*$

Notice that the . needs to be treated specially because it's a metacharacter, so it's inside a character class to only match that specific character. Also notice the trailing $; this is added to ensure that all the rest of the string must be included in the extension. This regular expression matches foo.bar and autoexec.bat and sendmail.cf and printers.conf.
Now, consider complicating the problem a bit; what if you want to match filenames where the extension is not bat? Some incorrect attempts:

`.+[.][^b].*` The first attempt above tries to exclude bat by requiring that the first character of the extension is not a b. This is wrong, because the pattern also doesn't match foo.bar.

`.+[.]([^b].|[^a].|[^t])$`

The expression gets messier when you try to patch up the first solution by requiring one of the following cases to match: the first character of the extension isn’t b; the second character isn’t a; or the third character isn’t t. This accepts foo.bar and rejects autoexec.bat, but it requires a three-letter extension and won’t accept a filename with a two-letter extension such as sendmail.cf. We’ll complicate the pattern again in an effort to fix it.

`.+[.]([^b].|[^a].|[^t])$`

In the third attempt, the second and third letters are all made optional in order to allow matching extensions shorter than three characters, such as sendmail.cf.

The pattern’s getting really complicated now, which makes it hard to read and understand. Worse, if the problem changes and you want to exclude both bat and exe as extensions, the pattern would get even more complicated and confusing.

A negative lookahead cuts through all this confusion:

`.+[.](?!bat$).*` The negative lookahead means: if the
expression `bat` doesn’t match at this point, try the rest of the pattern; if `bat$` does match, the whole pattern will fail. The trailing `$` is required to ensure that something like `sample.batch`, where the extension only starts with `bat`, will be allowed.

Excluding another filename extension is now easy; simply add it as an alternative inside the assertion. The following pattern excludes filenames that end in either `bat` or `exe`:

```
.*[.](!bat$|exe$).*$
```
Modifying Strings

Up to this point, we’ve simply performed searches against a static string. Regular expressions are also commonly used to modify strings in various ways, using the following pattern methods:

<table>
<thead>
<tr>
<th>Method/Attribute</th>
<th>Purpose</th>
</tr>
</thead>
<tbody>
<tr>
<td><code>split()</code></td>
<td>Split the string into a list, splitting it wherever the RE matches</td>
</tr>
<tr>
<td><code>sub()</code></td>
<td>Find all substrings where the RE matches, and replace them with a different string</td>
</tr>
<tr>
<td><code>subn()</code></td>
<td>Does the same thing as <code>sub()</code>, but returns the new string and the number of replacements</td>
</tr>
</tbody>
</table>

Splitting Strings

The `split()` method of a pattern splits a string apart wherever the RE matches, returning a list of the pieces. It’s similar to the `split()` method of strings but provides much more generality in the delimiters that you can split by; string `split()` only supports splitting by whitespace or by a fixed string. As you’d expect, there’s a module-level `re.split()` function, too.

```python
.split(string[, maxsplit=0])
```

Split `string` by the matches of the regular expression. If capturing parentheses are used in the RE, then their contents will also be returned as part of the resulting list. If `maxsplit` is nonzero, at most `maxsplit` splits are performed.

You can limit the number of splits made, by passing a value for `maxsplit`. When `maxsplit` is nonzero, at most `maxsplit` splits will be
made, and the remainder of the string is returned as the final element of the list. In the following example, the delimiter is any sequence of non-alphanumeric characters.

```python
>>> p = re.compile(r'\W+')
>>> p.split('This is a test, short and sweet, of split().')
['This', 'is', 'a', 'test', 'short', 'and', 'sweet', '

Sometimes you’re not only interested in what the text between delimiters is, but also need to know what the delimiter was. If capturing parentheses are used in the RE, then their values are also returned as part of the list. Compare the following calls:

```python
>>> p = re.compile(r'\W+')
>>> p2 = re.compile(r'(\W+)')
>>> p.split('This... is a test.')
['This', 'is', 'a', 'test', '']
>>> p2.split('This... is a test.')
['This', '...', 'is', '', 'a', '', 'test', '.

The module-level function `re.split()` adds the RE to be used as the first argument, but is otherwise the same.

```python
>>> re.split('[][\W]+', 'Words, words, words.')
['Words', 'words', 'words', '']
>>> re.split('[][\W]+', 'Words, words, words.')
['Words', '', '', 'words', '', '', 'words', '.

Search and Replace
Another common task is to find all the matches for a pattern, and replace them with a different string. The sub() method takes a replacement value, which can be either a string or a function, and the string to be processed.

```
sub(replacement, string[, count=0])
```

Returns the string obtained by replacing the leftmost non-overlapping occurrences of the RE in string by the replacement replacement. If the pattern isn’t found, string is returned unchanged.

The optional argument count is the maximum number of pattern occurrences to be replaced; count must be a non-negative integer. The default value of 0 means to replace all occurrences.

Here’s a simple example of using the sub() method. It replaces colour names with the word colour:

```
>>> p = re.compile( '(blue|white|red)' )
>>> p.sub( 'colour', 'blue socks and red shoes' )
'colour socks and colour shoes'
```

The subn() method does the same work, but returns a 2-tuple containing the new string value and the number of replacements that were performed:

```
>>> p = re.compile( '(blue|white|red)' )
>>> p.subn( 'colour', 'blue socks and red shoes' )
('colour socks and colour shoes', 2)
```
Empty matches are replaced only when they're not adjacent to a previous match.

```python
>>> p = re.compile(r'x*')
>>> p.sub('-', 'abxd')
'a-b-d-
```

If `replacement` is a string, any backslash escapes in it are processed. That is, \n is converted to a single newline character, \r is converted to a carriage return, and so forth. Unknown escapes such as \j are left alone. Backreferences, such as \6, are replaced with the substring matched by the corresponding group in the RE. This lets you incorporate portions of the original text in the resulting replacement string.

This example matches the word `section` followed by a string enclosed in `{, }`, and changes `section` to `subsection`:

```python
>>> p = re.compile(r'section{ ( [^}]* ) }', re.VERBOSE)
>>> p.sub(r'subsection{\1}', 'section{First} section{Second}')
'subsection{First} subsection{Second}'
```

There's also a syntax for referring to named groups as defined by the (?P<name>...) syntax. \g<name> will use the substring matched by the group named name, and \g<number> uses the corresponding group number. \g<2> is therefore equivalent to \2, but isn't ambiguous in a replacement string such as \g<2>0. (\20 would be interpreted as a reference to group 20, not a reference to group 2 followed by the literal character '0'.) The following substitutions are all equivalent, but use all three variations of the replacement string.
replacement can also be a function, which gives you even more control. If replacement is a function, the function is called for every non-overlapping occurrence of pattern. On each call, the function is passed a match object argument for the match and can use this information to compute the desired replacement string and return it.

In the following example, the replacement function translates decimals into hexadecimal:

```python
>>> def hexrepl(match):
...     value = int(match.group())
...     return hex(value)
...  
>>> p = re.compile(r'\d+')
>>> p.sub(hexrepl, 'Call 65490 for printing, 49152 for user code.')
'Call 0xffd2 for printing, 0xc000 for user code.'
```

When using the module-level `re.sub()` function, the pattern is passed as the first argument. The pattern may be provided as an object or as a string; if you need to specify regular expression flags, you must either use a pattern object as the first parameter, or use embedded modifiers in the pattern string, e.g. `sub("(?i)b+", "x", "bbbb BBBB")` returns `"x x"`. 
Common Problems

Regular expressions are a powerful tool for some applications, but in some ways their behaviour isn’t intuitive and at times they don't behave the way you may expect them to. This section will point out some of the most common pitfalls.

Use String Methods

Sometimes using the `re` module is a mistake. If you’re matching a fixed string, or a single character class, and you're not using any `re` features such as the IGNORECASE flag, then the full power of regular expressions may not be required. Strings have several methods for performing operations with fixed strings and they're usually much faster, because the implementation is a single small C loop that's been optimized for the purpose, instead of the large, more generalized regular expression engine.

One example might be replacing a single fixed string with another one; for example, you might replace `word` with `deed`. `re.sub()` seems like the function to use for this, but consider the `replace()` method. Note that `replace()` will also replace `word` inside words, turning `swordfish` into `sdeedfish`, but the naive RE `word` would have done that, too. (To avoid performing the substitution on parts of words, the pattern would have to be `\bword\b`, in order to require that `word` have a word boundary on either side. This takes the job beyond `replace()`'s abilities.)

Another common task is deleting every occurrence of a single character from a string or replacing it with another single character.
You might do this with something like `re.sub('\n', '', S)`, but `translate()` is capable of doing both tasks and will be faster than any regular expression operation can be.

In short, before turning to the `re` module, consider whether your problem can be solved with a faster and simpler string method.

### match() versus search()

The `match()` function only checks if the RE matches at the beginning of the string while `search()` will scan forward through the string for a match. It's important to keep this distinction in mind. Remember, `match()` will only report a successful match which will start at 0; if the match wouldn't start at zero, `match()` will not report it.

```python
>>> print(re.match('super', 'superstition').span())
(0, 5)
>>> print(re.match('super', 'insuperable'))
None
```

On the other hand, `search()` will scan forward through the string, reporting the first match it finds.

```python
>>> print(re.search('super', 'superstition').span())
(0, 5)
>>> print(re.search('super', 'insuperable').span())
(2, 7)
```

Sometimes you'll be tempted to keep using `re.match()`, and just add `.*` to the front of your RE. Resist this temptation and use `re.search()` instead. The regular expression compiler does some analysis of REs in order to speed up the process of looking for a
match. One such analysis figures out what the first character of a match must be; for example, a pattern starting with `Crow` must match starting with a `'C'`. The analysis lets the engine quickly scan through the string looking for the starting character, only trying the full match if a `'C'` is found.

Adding `.*` defeats this optimization, requiring scanning to the end of the string and then backtracking to find a match for the rest of the RE. Use `re.search()` instead.

**Greedy versus Non-Greedy**

When repeating a regular expression, as in `a*`, the resulting action is to consume as much of the pattern as possible. This fact often bites you when you're trying to match a pair of balanced delimiters, such as the angle brackets surrounding an HTML tag. The naive pattern for matching a single HTML tag doesn't work because of the greedy nature of `.*`.

```python
>>> s = '<html><head><title>Title</title>'
>>> len(s)
32
>>> print(re.match('<.*>', s).span())
(0, 32)
>>> print(re.match('<.*>', s).group())
<html><head><title>Title</title>
```

The RE matches the `<` in `<html>`, and the `.*` consumes the rest of the string. There's still more left in the RE, though, and the `>` can't match at the end of the string, so the regular expression engine has to backtrack character by character until it finds a match for the `>`. The final match extends from the `<` in `<html>` to the `>` in `</title>`,
which isn't what you want.

In this case, the solution is to use the non-greedy qualifiers `*?`, `+?`, `??`, or `{m,n}?`, which match as little text as possible. In the above example, the `'>` is tried immediately after the first `<` matches, and when it fails, the engine advances a character at a time, retrying the `'>` at every step. This produces just the right result:

```python
>>> print(re.match(''<.*?>', s).group())
<html>
```

(Note that parsing HTML or XML with regular expressions is painful. Quick-and-dirty patterns will handle common cases, but HTML and XML have special cases that will break the obvious regular expression; by the time you’ve written a regular expression that handles all of the possible cases, the patterns will be very complicated. Use an HTML or XML parser module for such tasks.)

**Using re.VERBOSE**

By now you've probably noticed that regular expressions are a very compact notation, but they're not terribly readable. REs of moderate complexity can become lengthy collections of backslashes, parentheses, and metacharacters, making them difficult to read and understand.

For such REs, specifying the `re.VERBOSE` flag when compiling the regular expression can be helpful, because it allows you to format the regular expression more clearly.

The `re.VERBOSE` flag has several effects. Whitespace in the regular expression that isn’t inside a character class is ignored. This means
that an expression such as `dog | cat` is equivalent to the less readable `dog|cat`, but `[a b]` will still match the characters 'a', 'b', or a space. In addition, you can also put comments inside a RE; comments extend from a `#` character to the next newline. When used with triple-quoted strings, this enables REs to be formatted more neatly:

```python
pat = re.compile(r""
    \s*  # Skip leading whitespace
    (?P<header>[^:]+)  # Header name
    \s* :  # Whitespace, and a colon
    (?P<value>.*?)  # The header's value -- *? used
    \s*$  # lose the following trailing ws
    
    """, re.VERBOSE)
```

This is far more readable than:

```python
pat = re.compile(r"\s*(?P<header>[^:]+)\s*:\(?P<value>.*?)\s*$")
```
Feedback

Regular expressions are a complicated topic. Did this document help you understand them? Were there parts that were unclear, or Problems you encountered that weren't covered here? If so, please send suggestions for improvements to the author.

The most complete book on regular expressions is almost certainly Jeffrey Friedl's Mastering Regular Expressions, published by O'Reilly. Unfortunately, it exclusively concentrates on Perl and Java’s flavours of regular expressions, and doesn't contain any Python material at all, so it won't be useful as a reference for programming in Python. (The first edition covered Python’s now-removed regex module, which won't help you much.) Consider checking it out from your library.
Socket Programming HOWTO

Author: Gordon McMillan

Abstract

Sockets are used nearly everywhere, but are one of the most severely misunderstood technologies around. This is a 10,000 foot overview of sockets. It’s not really a tutorial - you’ll still have work to do in getting things operational. It doesn’t cover the fine points (and there are a lot of them), but I hope it will give you enough background to begin using them decently.
Sockets

I'm only going to talk about INET (i.e. IPv4) sockets, but they account for at least 99% of the sockets in use. And I'll only talk about STREAM (i.e. TCP) sockets - unless you really know what you're doing (in which case this HOWTO isn't for you!), you'll get better behavior and performance from a STREAM socket than anything else. I will try to clear up the mystery of what a socket is, as well as some hints on how to work with blocking and non-blocking sockets. But I'll start by talking about blocking sockets. You'll need to know how they work before dealing with non-blocking sockets.

Part of the trouble with understanding these things is that “socket” can mean a number of subtly different things, depending on context. So first, let's make a distinction between a “client” socket - an endpoint of a conversation, and a “server” socket, which is more like a switchboard operator. The client application (your browser, for example) uses “client” sockets exclusively; the web server it's talking to uses both “server” sockets and “client” sockets.

History

Of the various forms of IPC, sockets are by far the most popular. On any given platform, there are likely to be other forms of IPC that are faster, but for cross-platform communication, sockets are about the only game in town.

They were invented in Berkeley as part of the BSD flavor of Unix. They spread like wildfire with the Internet. With good reason — the combination of sockets with INET makes talking to arbitrary machines around the world unbelievably easy (at least compared to other
schemes).
Creating a Socket

Roughly speaking, when you clicked on the link that brought you to this page, your browser did something like the following:

```
# create an INET, STREAMing socket
s = socket.socket(socket.AF_INET, socket.SOCK_STREAM)
# now connect to the web server on port 80 - the normal http port
s.connect(('www.python.org', 80))
```

When the `connect` completes, the socket `s` can be used to send in a request for the text of the page. The same socket will read the reply, and then be destroyed. That's right, destroyed. Client sockets are normally only used for one exchange (or a small set of sequential exchanges).

What happens in the web server is a bit more complex. First, the web server creates a “server socket”:

```
# create an INET, STREAMing socket
serversocket = socket.socket(socket.AF_INET, socket.SOCK_STREAM)
# bind the socket to a public host, and a well-known port
serversocket.bind((socket.gethostname(), 80))
# become a server socket
serversocket.listen(5)
```

A couple things to notice: we used `socket.gethostname()` so that the socket would be visible to the outside world. If we had used `s.bind(('localhost', 80))` or `s.bind(('127.0.0.1', 80))` we would still have a “server” socket, but one that was only visible within the same machine. `s.bind(('', 80))` specifies that
the socket is reachable by any address the machine happens to have.

A second thing to note: low number ports are usually reserved for “well known” services (HTTP, SNMP etc). If you’re playing around, use a nice high number (4 digits).

Finally, the argument to listen tells the socket library that we want it to queue up as many as 5 connect requests (the normal max) before refusing outside connections. If the rest of the code is written properly, that should be plenty.

Now that we have a “server” socket, listening on port 80, we can enter the mainloop of the web server:

```python
while True:
    # accept connections from outside
    (clientsocket, address) = serversocket.accept()
    # now do something with the clientsocket
    # in this case, we'll pretend this is a threaded
    ct = client_thread(clientsocket)
    ct.run()
```

There's actually 3 general ways in which this loop could work - dispatching a thread to handle `clientsocket`, create a new process to handle `clientsocket`, or restructure this app to use non-blocking sockets, and multiplex between our “server” socket and any active `clientsockets` using `select`. More about that later. The important thing to understand now is this: this is all a “server” socket does. It doesn’t send any data. It doesn’t receive any data. It just produces “client” sockets. Each `clientsocket` is created in response to some other “client” socket doing a `connect()` to the host and port we're bound to. As soon as we've created that `clientsocket`, we go back to listening for more connections. The two “clients” are free to chat it
up - they are using some dynamically allocated port which will be recycled when the conversation ends.

**IPC**

If you need fast IPC between two processes on one machine, you should look into pipes or shared memory. If you do decide to use AF_INET sockets, bind the “server” socket to `localhost`. On most platforms, this will take a shortcut around a couple of layers of network code and be quite a bit faster.

**See also:** The `multiprocessing` integrates cross-platform IPC into a higher-level API.
Using a Socket

The first thing to note, is that the web browser’s “client” socket and the web server’s “client” socket are identical beasts. That is, this is a “peer to peer” conversation. Or to put it another way, as the designer, you will have to decide what the rules of etiquette are for a conversation. Normally, the connecting socket starts the conversation, by sending in a request, or perhaps a signon. But that’s a design decision - it’s not a rule of sockets.

Now there are two sets of verbs to use for communication. You can use send and recv, or you can transform your client socket into a file-like beast and use read and write. The latter is the way Java presents its sockets. I’m not going to talk about it here, except to warn you that you need to use flush on sockets. These are buffered “files”, and a common mistake is to write something, and then read for a reply. Without a flush in there, you may wait forever for the reply, because the request may still be in your output buffer.

Now we come to the major stumbling block of sockets - send and recv operate on the network buffers. They do not necessarily handle all the bytes you hand them (or expect from them), because their major focus is handling the network buffers. In general, they return when the associated network buffers have been filled (send) or emptied (recv). They then tell you how many bytes they handled. It is your responsibility to call them again until your message has been completely dealt with.

When a recv returns 0 bytes, it means the other side has closed (or is in the process of closing) the connection. You will not receive any more data on this connection. Ever. You may be able to send data
successfully; I'll talk more about this later.

A protocol like HTTP uses a socket for only one transfer. The client sends a request, then reads a reply. That's it. The socket is discarded. This means that a client can detect the end of the reply by receiving 0 bytes.

But if you plan to reuse your socket for further transfers, you need to realize that there is no EOT on a socket. I repeat: if a socket send or recv returns after handling 0 bytes, the connection has been broken. If the connection has not been broken, you may wait on a recv forever, because the socket will not tell you that there's nothing more to read (for now). Now if you think about that a bit, you'll come to realize a fundamental truth of sockets: messages must either be fixed length (yuck), or be delimited (shrug), or indicate how long they are (much better), or end by shutting down the connection. The choice is entirely yours, (but some ways are righter than others).

Assuming you don't want to end the connection, the simplest solution is a fixed length message:

class mysocket:
    """demonstration class only
    - coded for clarity, not efficiency
    """

    def __init__(self, sock=None):
        if sock is None:
            self.sock = socket.socket(socket.AF_INET, socket.SOCK_STREAM)
        else:
            self.sock = sock

    def connect(self, host, port):
The sending code here is usable for almost any messaging scheme - in Python you send strings, and you can use `len()` to determine its length (even if it has embedded \0 characters). It's mostly the receiving code that gets more complex. (And in C, it's not much worse, except you can't use `strlen` if the message has embedded \0s.)

The easiest enhancement is to make the first character of the message an indicator of message type, and have the type determine the length. Now you have two `recv` - the first to get (at least) that first character so you can look up the length, and the second in a loop to get the rest. If you decide to go the delimited route, you'll be receiving in some arbitrary chunk size, (4096 or 8192 is frequently a good match for network buffer sizes), and scanning what you've received for a delimiter.
One complication to be aware of: if your conversational protocol allows multiple messages to be sent back to back (without some kind of reply), and you pass `recv` an arbitrary chunk size, you may end up reading the start of a following message. You'll need to put that aside and hold onto it, until it's needed.

Prefixing the message with it's length (say, as 5 numeric characters) gets more complex, because (believe it or not), you may not get all 5 characters in one `recv`. In playing around, you'll get away with it; but in high network loads, your code will very quickly break unless you use two `recv` loops - the first to determine the length, the second to get the data part of the message. Nasty. This is also when you'll discover that `send` does not always manage to get rid of everything in one pass. And despite having read this, you will eventually get bit by it!

In the interests of space, building your character, (and preserving my competitive position), these enhancements are left as an exercise for the reader. Lets move on to cleaning up.

**Binary Data**

It is perfectly possible to send binary data over a socket. The major problem is that not all machines use the same formats for binary data. For example, a Motorola chip will represent a 16 bit integer with the value 1 as the two hex bytes 00 01. Intel and DEC, however, are byte-reversed - that same 1 is 01 00. Socket libraries have calls for converting 16 and 32 bit integers - `ntohl`, `htonl`, `ntohs`, `htons` where “n” means network and “h” means host, “s” means short and “l” means long. Where network order is host order, these do nothing, but where the machine is byte-reversed, these swap the bytes around appropriately.
In these days of 32 bit machines, the ascii representation of binary data is frequently smaller than the binary representation. That's because a surprising amount of the time, all those longs have the value 0, or maybe 1. The string “0” would be two bytes, while binary is four. Of course, this doesn’t fit well with fixed-length messages. Decisions, decisions.
Disconnecting

Strictly speaking, you’re supposed to use `shutdown` on a socket before you `close` it. The `shutdown` is an advisory to the socket at the other end. Depending on the argument you pass it, it can mean “I’m not going to send anymore, but I’ll still listen”, or “I’m not listening, good riddance!”. Most socket libraries, however, are so used to programmers neglecting to use this piece of etiquette that normally a `close` is the same as `shutdown(); close()`. So in most situations, an explicit `shutdown` is not needed.

One way to use `shutdown` effectively is in an HTTP-like exchange. The client sends a request and then does a `shutdown(1)`. This tells the server “This client is done sending, but can still receive.” The server can detect “EOF” by a receive of 0 bytes. It can assume it has the complete request. The server sends a reply. If the `send` completes successfully then, indeed, the client was still receiving.

Python takes the automatic shutdown a step further, and says that when a socket is garbage collected, it will automatically do a `close` if it’s needed. But relying on this is a very bad habit. If your socket just disappears without doing a `close`, the socket at the other end may hang indefinitely, thinking you’re just being slow. Please `close` your sockets when you’re done.

When Sockets Die

Probably the worst thing about using blocking sockets is what happens when the other side comes down hard (without doing a `close`). Your socket is likely to hang. TCP is a reliable protocol, and it will wait a
long, long time before giving up on a connection. If you’re using threads, the entire thread is essentially dead. There's not much you can do about it. As long as you aren't doing something dumb, like holding a lock while doing a blocking read, the thread isn’t really consuming much in the way of resources. Do not try to kill the thread - part of the reason that threads are more efficient than processes is that they avoid the overhead associated with the automatic recycling of resources. In other words, if you do manage to kill the thread, your whole process is likely to be screwed up.
Non-blocking Sockets

If you’ve understood the preceding, you already know most of what you need to know about the mechanics of using sockets. You’ll still use the same calls, in much the same ways. It’s just that, if you do it right, your app will be almost inside-out.

In Python, you use `socket.setblocking(0)` to make it non-blocking. In C, it’s more complex, (for one thing, you’ll need to choose between the BSD flavor `O_NONBLOCK` and the almost indistinguishable Posix flavor `O_NDELAY`, which is completely different from `TCP_NODELAY`), but it’s the exact same idea. You do this after creating the socket, but before using it. (Actually, if you’re nuts, you can switch back and forth.)

The major mechanical difference is that `send`, `recv`, `connect` and `accept` can return without having done anything. You have (of course) a number of choices. You can check return code and error codes and generally drive yourself crazy. If you don’t believe me, try it sometime. Your app will grow large, buggy and suck CPU. So let’s skip the brain-dead solutions and do it right.

Use `select`.

In C, coding `select` is fairly complex. In Python, it's a piece of cake, but it's close enough to the C version that if you understand `select` in Python, you'll have little trouble with it in C:

```python
ready_to_read, ready_to_write, in_error = \n    select.select(\n        potential_readers,\n        potential_writers,\n```
You pass `select` three lists: the first contains all sockets that you might want to try reading; the second all the sockets you might want to try writing to, and the last (normally left empty) those that you want to check for errors. You should note that a socket can go into more than one list. The `select` call is blocking, but you can give it a timeout. This is generally a sensible thing to do - give it a nice long timeout (say a minute) unless you have good reason to do otherwise.

In return, you will get three lists. They contain the sockets that are actually readable, writable and in error. Each of these lists is a subset (possibly empty) of the corresponding list you passed in.

If a socket is in the output readable list, you can be as-close-to-certain-as-we-ever-get-in-this-business that a `recv` on that socket will return `something`. Same idea for the writable list. You’ll be able to send `something`. Maybe not all you want to, but `something` is better than nothing. (Actually, any reasonably healthy socket will return as writable - it just means outbound network buffer space is available.)

If you have a “server” socket, put it in the `potential_readers` list. If it comes out in the readable list, your `accept` will (almost certainly) work. If you have created a new socket to `connect` to someone else, put it in the `potential_writers` list. If it shows up in the writable list, you have a decent chance that it has connected.

Actually, `select` can be handy even with blocking sockets. It’s one way of determining whether you will block - the socket returns as readable when there’s something in the buffers. However, this still doesn’t help with the problem of determining whether the other end is done, or just busy with something else.
**Portability alert:** On Unix, `select` works both with the sockets and files. Don’t try this on Windows. On Windows, `select` works with sockets only. Also note that in C, many of the more advanced socket options are done differently on Windows. In fact, on Windows I usually use threads (which work very, very well) with my sockets.
Python lists have a built-in `list.sort()` method that modifies the list in-place. There is also a `sorted()` built-in function that builds a new sorted list from an iterable.

In this document, we explore the various techniques for sorting data using Python.
Sorting Basics

A simple ascending sort is very easy: just call the `sorted()` function. It returns a new sorted list:

```python
>>> sorted([5, 2, 3, 1, 4])
[1, 2, 3, 4, 5]
```

You can also use the `list.sort()` method. It modifies the list in-place (and returns `None` to avoid confusion). Usually it's less convenient than `sorted()` - but if you don't need the original list, it's slightly more efficient.

```python
>>> a = [5, 2, 3, 1, 4]
>>> a.sort()
>>> a
[1, 2, 3, 4, 5]
```

Another difference is that the `list.sort()` method is only defined for lists. In contrast, the `sorted()` function accepts any iterable.

```python
[1, 2, 3, 4, 5]
```
Key Functions

Both `list.sort()` and `sorted()` have a key parameter to specify a function to be called on each list element prior to making comparisons.

For example, here’s a case-insensitive string comparison:

```python
>>> sorted("This is a test string from Andrew".split ['a', 'Andrew', 'from', 'is', 'string', 'test', 'This]

The value of the key parameter should be a function that takes a single argument and returns a key to use for sorting purposes. This technique is fast because the key function is called exactly once for each input record.

A common pattern is to sort complex objects using some of the object’s indices as keys. For example:

```python
>>> student_tuples = [ ('john', 'A', 15),
                      ('jane', 'B', 12),
                      ('dave', 'B', 10),
                    ]
>>> sorted(student_tuples, key=lambda student: student[0], 'dave', 'B', 10), ('jane', 'B', 12), ('john', 'A',

The same technique works for objects with named attributes. For example:

```python
>>> class Student:
    def __init__(self, name, grade, age):
```
```python
self.name = name
self.grade = grade
self.age = age
def __repr__(self):
    return repr((self.name, self.grade, self.age))
```

```python
>>> student_objects = [
    Student('john', 'A', 15),
    Student('jane', 'B', 12),
    Student('dave', 'B', 10),
]
```

```python
>>> sorted(student_objects, key=lambda student: student[1])
[('dave', 'B', 10), ('jane', 'B', 12), ('john', 'A', 15)]
```
Operator Module Functions

The key-function patterns shown above are very common, so Python provides convenience functions to make accessor functions easier and faster. The operator module has `itemgetter()`, `attrgetter()`, and a `methodcaller()` function.

Using those functions, the above examples become simpler and faster:

```python
>>> from operator import itemgetter, attrgetter

>>> sorted(student_tuples, key=itemgetter(2))
[('dave', 'B', 10), ('jane', 'B', 12), ('john', 'A', 15)]

>>> sorted(student_objects, key=attrgetter('age'))
[('dave', 'B', 10), ('jane', 'B', 12), ('john', 'A', 15)]

The operator module functions allow multiple levels of sorting. For example, to sort by grade then by age:

```
Ascending and Descending

Both `list.sort()` and `sorted()` accept a `reverse` parameter with a boolean value. This is used to flag descending sorts. For example, to get the student data in reverse `age` order:

```python
>>> sorted(student_tuples, key=itemgetter(2), reverse=True)
[('dave', 'B', 10), ('jane', 'B', 12), ('john', 'A', 15)]
```

```python
>>> sorted(student_objects, key=attrgetter('age'), reverse=True)
[('dave', 'B', 10), ('jane', 'B', 12), ('john', 'A', 15)]
```
Sort Stability and Complex Sorts

Sorts are guaranteed to be stable. That means that when multiple records have the same key, their original order is preserved.

```python
>>> data = [('red', 1), ('blue', 1), ('red', 2), ('blue', 2), ('red', 1), ('red', 2)]
>>> sorted(data, key=itemgetter(0))
[('blue', 1), ('blue', 2), ('red', 1), ('red', 2)]
```

Notice how the two records for blue retain their original order so that ('blue', 1) is guaranteed to precede ('blue', 2).

This wonderful property lets you build complex sorts in a series of sorting steps. For example, to sort the student data by descending grade and then ascending age, do the age sort first and then sort again using grade:

```python
>>> s = sorted(student_objects, key=attrgetter('age'))
>>> sorted(s, key=attrgetter('grade'), reverse=True)
[('dave', 'B', 10), ('jane', 'B', 12), ('john', 'A',)
```

The Timsort algorithm used in Python does multiple sorts efficiently because it can take advantage of any ordering already present in a dataset.
The Old Way Using Decorate-Sort-Undecorate

This idiom is called Decorate-Sort-Undecorate after its three steps:

- First, the initial list is decorated with new values that control the sort order.
- Second, the decorated list is sorted.
- Finally, the decorations are removed, creating a list that contains only the initial values in the new order.

For example, to sort the student data by grade using the DSU approach:

```python
>>> decorated = [(student.grade, i, student) for i, student in decorated]
>>> decorated.sort()
>>> [student for grade, i, student in decorated]
[('john', 'A', 15), ('jane', 'B', 12), ('dave', 'B', 10)]
```

This idiom works because tuples are compared lexicographically; the first items are compared; if they are the same then the second items are compared, and so on.

It is not strictly necessary in all cases to include the index $i$ in the decorated list, but including it gives two benefits:

- The sort is stable – if two items have the same key, their order will be preserved in the sorted list.
- The original items do not have to be comparable because the ordering of the decorated tuples will be determined by at most the first two items. So for example the original list could contain complex numbers which cannot be sorted directly.
Another name for this idiom is Schwartzian transform, after Randal L. Schwartz, who popularized it among Perl programmers.

Now that Python sorting provides key-functions, this technique is not often needed.
The Old Way Using the *cmp* Parameter

Many constructs given in this HOWTO assume Python 2.4 or later. Before that, there was no `sorted()` builtin and `list.sort()` took no keyword arguments. Instead, all of the Py2.x versions supported a *cmp* parameter to handle user specified comparison functions.

In Py3.0, the *cmp* parameter was removed entirely (as part of a larger effort to simplify and unify the language, eliminating the conflict between rich comparisons and the `__cmp__()` magic method).

In Py2.x, sort allowed an optional function which can be called for doing the comparisons. That function should take two arguments to be compared and then return a negative value for less-than, return zero if they are equal, or return a positive value for greater-than. For example, we can do:

```python
>>> def numeric_compare(x, y):
    return x - y

>>> sorted([5, 2, 4, 1, 3], cmp=numeric_compare)
[1, 2, 3, 4, 5]
```

Or you can reverse the order of comparison with:

```python
>>> def reverse_numeric(x, y):
    return y - x

>>> sorted([5, 2, 4, 1, 3], cmp=reverse_numeric)
[5, 4, 3, 2, 1]
```

When porting code from Python 2.x to 3.x, the situation can arise when you have the user supplying a comparison function and you need to convert that to a key function. The following wrapper makes that easy to do:
To convert to a key function, just wrap the old comparison function:

```python
>>> sorted([5, 2, 4, 1, 3], key=cmp_to_key(reverse_numeric))
[5, 4, 3, 2, 1]
```

In Python 3.2, the `functools.cmp_to_key()` function was added to the `functools` module in the standard library.
Odd and Ends

- For locale aware sorting, use `locale.strxfrm()` for a key function or `locale.strcoll()` for a comparison function.

- The `reverse` parameter still maintains sort stability (so that records with equal keys retain the original order). Interestingly, that effect can be simulated without the parameter by using the built-in `reversed()` function twice:

  ```python
  >>> data = [('red', 1), ('blue', 1), ('red', 2),
  >>> assert sorted(data, reverse=True) == list(reversed(data))
  ```

- The sort routines are guaranteed to use `__lt__()` when making comparisons between two objects. So, it is easy to add a standard sort order to a class by defining an `__lt__()` method:

  ```python
  >>> Student.__lt__ = lambda self, other: self.age < other.age
  >>> sorted(student_objects)
  [('dave', 'B', 10), ('jane', 'B', 12), ('john', 'A', 15)]
  ```

- Key functions need not depend directly on the objects being sorted. A key function can also access external resources. For instance, if the student grades are stored in a dictionary, they can be used to sort a separate list of student names:

  ```python
  >>> students = ['dave', 'john', 'jane']
  >>> newgrades = {'john': 'F', 'jane': 'A', 'dave': 'B'}
  >>> sorted(students, key=newgrades.__getitem__)
  ['jane', 'dave', 'john']
  ```
Unicode HOWTO

| Release: | 1.12 |

This HOWTO discusses Python support for Unicode, and explains various problems that people commonly encounter when trying to work with Unicode.
Introduction to Unicode

History of Character Codes

In 1968, the American Standard Code for Information Interchange, better known by its acronym ASCII, was standardized. ASCII defined numeric codes for various characters, with the numeric values running from 0 to 127. For example, the lowercase letter ‘a’ is assigned 97 as its code value.

ASCII was an American-developed standard, so it only defined unaccented characters. There was an ‘e’, but no ‘é’ or ‘Í’. This meant that languages which required accented characters couldn’t be faithfully represented in ASCII. (Actually the missing accents matter for English, too, which contains words such as ‘naïve’ and ‘café’, and some publications have house styles which require spellings such as ‘coöperate’.)

For a while people just wrote programs that didn’t display accents. In the mid-1980s an Apple II BASIC program written by a French speaker might have lines like these:

```
PRINT "FICHIER EST COMPLETE."
PRINT "CARACTERE NON ACCEPTE."
```

Those messages should contain accents (completé, caractère, accepté), and they just look wrong to someone who can read French.

In the 1980s, almost all personal computers were 8-bit, meaning that bytes could hold values ranging from 0 to 255. ASCII codes only went up to 127, so some machines assigned values between 128 and 255 to accented characters. Different machines had different codes,
however, which led to problems exchanging files. Eventually various commonly used sets of values for the 128–255 range emerged. Some were true standards, defined by the International Standards Organization, and some were de facto conventions that were invented by one company or another and managed to catch on.

255 characters aren't very many. For example, you can't fit both the accented characters used in Western Europe and the Cyrillic alphabet used for Russian into the 128–255 range because there are more than 127 such characters.

You could write files using different codes (all your Russian files in a coding system called KOI8, all your French files in a different coding system called Latin1), but what if you wanted to write a French document that quotes some Russian text? In the 1980s people began to want to solve this problem, and the Unicode standardization effort began.

Unicode started out using 16-bit characters instead of 8-bit characters. 16 bits means you have $2^{16} = 65,536$ distinct values available, making it possible to represent many different characters from many different alphabets; an initial goal was to have Unicode contain the alphabets for every single human language. It turns out that even 16 bits isn't enough to meet that goal, and the modern Unicode specification uses a wider range of codes, 0 through 1,114,111 (0x10FFFF in base 16).

There's a related ISO standard, ISO 10646. Unicode and ISO 10646 were originally separate efforts, but the specifications were merged with the 1.1 revision of Unicode.

(This discussion of Unicode's history is highly simplified. The precise historical details aren't necessary for understanding how to use
Unicode effectively, but if you’re curious, consult the Unicode consortium site listed in the References or the Wikipedia entry for Unicode for more information.)

Definitions

A character is the smallest possible component of a text. ‘A’, ‘B’, ‘C’, etc., are all different characters. So are ‘È’ and ‘Í’. Characters are abstractions, and vary depending on the language or context you’re talking about. For example, the symbol for ohms (Ω) is usually drawn much like the capital letter omega (Ω) in the Greek alphabet (they may even be the same in some fonts), but these are two different characters that have different meanings.

The Unicode standard describes how characters are represented by code points. A code point is an integer value, usually denoted in base 16. In the standard, a code point is written using the notation \texttt{U+12CA} to mean the character with value \texttt{0x12ca} (4,810 decimal). The Unicode standard contains a lot of tables listing characters and their corresponding code points:

<table>
<thead>
<tr>
<th>Code Point</th>
<th>Character</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>0061</td>
<td>'a'</td>
<td>LATIN SMALL LETTER A</td>
</tr>
<tr>
<td>0062</td>
<td>'b'</td>
<td>LATIN SMALL LETTER B</td>
</tr>
<tr>
<td>0063</td>
<td>'c'</td>
<td>LATIN SMALL LETTER C</td>
</tr>
<tr>
<td>...</td>
<td></td>
<td></td>
</tr>
<tr>
<td>007B</td>
<td>'{'</td>
<td>LEFT CURLY BRACKET</td>
</tr>
</tbody>
</table>

Strictly, these definitions imply that it’s meaningless to say ‘this is character \texttt{U+12CA’}. \texttt{U+12CA} is a code point, which represents some particular character; in this case, it represents the character ‘ETHIOPIC SYLLABLE WI’. In informal contexts, this distinction between code points and characters will sometimes be forgotten.
A character is represented on a screen or on paper by a set of graphical elements that's called a *glyph*. The glyph for an uppercase A, for example, is two diagonal strokes and a horizontal stroke, though the exact details will depend on the font being used. Most Python code doesn't need to worry about glyphs; figuring out the correct glyph to display is generally the job of a GUI toolkit or a terminal's font renderer.

**Encodings**

To summarize the previous section: a Unicode string is a sequence of code points, which are numbers from 0 through \(0x10FFFF\) (1,114,111 decimal). This sequence needs to be represented as a set of bytes (meaning, values from 0 through 255) in memory. The rules for translating a Unicode string into a sequence of bytes are called an *encoding*.

The first encoding you might think of is an array of 32-bit integers. In this representation, the string “Python” would look like this:

```
P  y  t  h  o  n
0x50 00 00 00 79 00 00 00 74 00 00 00 68 00 00 00 6f 00 00 00 6e 00 00 00
```

This representation is straightforward but using it presents a number of problems.

1. It's not portable; different processors order the bytes differently.
2. It's very wasteful of space. In most texts, the majority of the code points are less than 127, or less than 255, so a lot of space is occupied by \(0x00\) bytes. The above string takes 24 bytes compared to the 6 bytes needed for an ASCII representation.
Increased RAM usage doesn’t matter too much (desktop computers have gigabytes of RAM, and strings aren’t usually that large), but expanding our usage of disk and network bandwidth by a factor of 4 is intolerable.

3. It’s not compatible with existing C functions such as `strlen()`, so a new family of wide string functions would need to be used.

4. Many Internet standards are defined in terms of textual data, and can’t handle content with embedded zero bytes.

Generally people don’t use this encoding, instead choosing other encodings that are more efficient and convenient. UTF-8 is probably the most commonly supported encoding; it will be discussed below.

Encodings don’t have to handle every possible Unicode character, and most encodings don’t. The rules for converting a Unicode string into the ASCII encoding, for example, are simple; for each code point:

1. If the code point is < 128, each byte is the same as the value of the code point.
2. If the code point is 128 or greater, the Unicode string can’t be represented in this encoding. (Python raises a `UnicodeEncodeError` exception in this case.)

Latin-1, also known as ISO-8859-1, is a similar encoding. Unicode code points 0–255 are identical to the Latin-1 values, so converting to this encoding simply requires converting code points to byte values; if a code point larger than 255 is encountered, the string can’t be encoded into Latin-1.

Encodings don’t have to be simple one-to-one mappings like Latin-1. Consider IBM’s EBCDIC, which was used on IBM mainframes. Letter values weren’t in one block: ‘a’ through ‘i’ had values from 129 to 137, but ‘j’ through ‘r’ were 145 through 153. If you wanted to use EBCDIC as an encoding, you’d probably use some sort of lookup table to
perform the conversion, but this is largely an internal detail.

UTF-8 is one of the most commonly used encodings. UTF stands for “Unicode Transformation Format”, and the ‘8’ means that 8-bit numbers are used in the encoding. (There are also a UTF-16 and UTF-32 encodings, but they are less frequently used than UTF-8.) UTF-8 uses the following rules:

1. If the code point is < 128, it’s represented by the corresponding byte value.
2. If the code point is >= 128, it’s turned into a sequence of two, three, or four bytes, where each byte of the sequence is between 128 and 255.

UTF-8 has several convenient properties:

1. It can handle any Unicode code point.
2. A Unicode string is turned into a string of bytes containing no embedded zero bytes. This avoids byte-ordering issues, and means UTF-8 strings can be processed by C functions such as `strcpy()` and sent through protocols that can’t handle zero bytes.
3. A string of ASCII text is also valid UTF-8 text.
4. UTF-8 is fairly compact; the majority of commonly used characters can be represented with one or two bytes.
5. If bytes are corrupted or lost, it’s possible to determine the start of the next UTF-8-encoded code point and resynchronize. It’s also unlikely that random 8-bit data will look like valid UTF-8.

References

The Unicode Consortium site has character charts, a glossary, and PDF versions of the Unicode specification. Be prepared for some difficult reading. A chronology of the origin and development of
Unicode is also available on the site.

To help understand the standard, Jukka Korpela has written an introductory guide to reading the Unicode character tables.

Another good introductory article was written by Joel Spolsky. If this introduction didn’t make things clear to you, you should try reading this alternate article before continuing.

Wikipedia entries are often helpful; see the entries for “character encoding” and UTF-8, for example.
Python’s Unicode Support

Now that you’ve learned the rudiments of Unicode, we can look at Python’s Unicode features.

The String Type

Since Python 3.0, the language features a `str` type that contain Unicode characters, meaning any string created using "unicode rocks!", 'unicode rocks!', or the triple-quoted string syntax is stored as Unicode.

The default encoding for Python source code is UTF-8, so you can simply include a Unicode character in a string literal:

```
try:
    with open('/tmp/input.txt', 'r') as f:
        ...
except IOError:
    # 'File not found' error message.
    print("Fichier non trouvé")
```

You can use a different encoding from UTF-8 by putting a specially-formatted comment as the first or second line of the source code:

```
# -*- coding: <encoding name> -*-
```

Side note: Python 3 also supports using Unicode characters in identifiers:

```
répertoire = "/tmp/records.log"
with open(répertoire, "w") as f:
```
If you can't enter a particular character in your editor or want to keep the source code ASCII-only for some reason, you can also use escape sequences in string literals. (Depending on your system, you may see the actual capital-delta glyph instead of a u escape.)

```python
>>> "\\N{GREEK CAPITAL LETTER DELTA}"  # Using the character name
'\u0394'
>>> "\\u0394"                          # Using a 16-bit hex value
'\u0394'
>>> "\\U00000394"                      # Using a 32-bit hex value
'\u0394'
```

In addition, one can create a string using the `decode()` method of `bytes`. This method takes an `encoding` argument, such as UTF-8, and optionally an `errors` argument.

The `errors` argument specifies the response when the input string can't be converted according to the encoding's rules. Legal values for this argument are 'strict' (raise a `UnicodeDecodeError` exception), 'replace' (use U+FFFD, REPLACEMENT CHARACTER), or 'ignore' (just leave the character out of the Unicode result). The following examples show the differences:

```python
>>> b'\x80abc'.decode("utf-8", "strict")
Traceback (most recent call last):
  ...
UnicodeDecodeError: 'utf-8' codec can't decode byte invalid start byte
>>> b'\x80abc'.decode("utf-8", "replace")
'\ufffdabc'
>>> b'\x80abc'.decode("utf-8", "ignore")
'abc'
```
(In this code example, the Unicode replacement character has been replaced by a question mark because it may not be displayed on some systems.)

Encodings are specified as strings containing the encoding’s name. Python 3.2 comes with roughly 100 different encodings; see the Python Library Reference at *Standard Encodings* for a list. Some encodings have multiple names; for example, 'latin-1', 'iso_8859_1' and '8859' are all synonyms for the same encoding.

One-character Unicode strings can also be created with the *chr()* built-in function, which takes integers and returns a Unicode string of length 1 that contains the corresponding code point. The reverse operation is the built-in *ord()* function that takes a one-character Unicode string and returns the code point value:

```python
>>> chr(57344)
'\ue000'
>>> ord('\ue000')
57344
```

**Converting to Bytes**

The opposite method of *bytes.decode()* is *str.encode()* which returns a *bytes* representation of the Unicode string, encoded in the requested *encoding*.

The *errors* parameter is the same as the parameter of the *decode()* method but supports a few more possible handlers. As well as 'strict', 'ignore', and 'replace' (which in this case inserts a question mark instead of the unencodable character), there is also
The following example shows the different results:

```python
>>> u = chr(40960) + 'abcd' + chr(1972)
>>> u.encode('utf-8')
b'\xea\x80\x80abcd\xde\xb4'
>>> u.encode('ascii')
Traceback (most recent call last):
  ...
UnicodeEncodeError: 'ascii' codec can't encode character ' ' in position 0: ordinal not in range(128)
>>> u.encode('ascii', 'ignore')
b'abcd'
>>> u.encode('ascii', 'replace')
b'?abcd?'
>>> u.encode('ascii', 'xmlcharrefreplace')
b'ꆤabcd޴'
>>> u.encode('ascii', 'backslashreplace')
b'\ua000abcd\u07b4'
```

The low-level routines for registering and accessing the available encodings are found in the `codecs` module. Implementing new encodings also requires understanding the `codecs` module. However, the encoding and decoding functions returned by this module are usually more low-level than is comfortable, and writing new encodings is a specialized task, so the module won’t be covered in this HOWTO.

**Unicode Literals in Python Source Code**

In Python source code, specific Unicode code points can be written using the `\u` escape sequence, which is followed by four hex digits.
giving the code point. The \U escape sequence is similar, but expects eight hex digits, not four:

```python
>>> s = "a\xac\u1234\u20ac\U00008000"
... # ^^^^ two-digit hex escape
... # ^^^^^^^ four-digit Unicode escape
... # ^^^^^^^^^ eight-digit Unicode escape
>>> [ord(c) for c in s]
[97, 172, 4660, 8364, 32768]
```

Using escape sequences for code points greater than 127 is fine in small doses, but becomes an annoyance if you’re using many accented characters, as you would in a program with messages in French or some other accent-using language. You can also assemble strings using the `chr()` built-in function, but this is even more tedious.

Ideally, you’d want to be able to write literals in your language’s natural encoding. You could then edit Python source code with your favorite editor which would display the accented characters naturally, and have the right characters used at runtime.

Python supports writing source code in UTF-8 by default, but you can use almost any encoding if you declare the encoding being used. This is done by including a special comment as either the first or second line of the source file:

```python
#!/usr/bin/env python
# -*- coding: latin-1 -*-

u = 'abcdé'
print(ord(u[-1]))
```

The syntax is inspired by Emacs's notation for specifying variables
local to a file. Emacs supports many different variables, but Python only supports ‘coding’. The \*-\* symbols indicate to Emacs that the comment is special; they have no significance to Python but are a convention. Python looks for `coding: name` or `coding=name` in the comment.

If you don’t include such a comment, the default encoding used will be UTF-8 as already mentioned. See also PEP 263 for more information.

Unicode Properties

The Unicode specification includes a database of information about code points. For each defined code point, the information includes the character’s name, its category, the numeric value if applicable (Unicode has characters representing the Roman numerals and fractions such as one-third and four-fifths). There are also properties related to the code point’s use in bidirectional text and other display-related properties.

The following program displays some information about several characters, and prints the numeric value of one particular character:

```python
import unicodedata

u = chr(233) + chr(0x0bf2) + chr(3972) + chr(6000) +

for i, c in enumerate(u):
    print(i, '%04x' % ord(c), unicodedata.category(c),
    print(unicodedata.name(c))

# Get numeric value of second character
print(unicodedata.numeric(u[1]))
```
When run, this prints:

0 00e9 Ll LATIN SMALL LETTER E WITH ACUTE
1 0bf2 No TAMIL NUMBER ONE THOUSAND
2 0f84 Mn TIBETAN MARK HALANTA
3 1770 Lo TAGBANWA LETTER SA
4 33af So SQUARE RAD OVER S SQUARED
1000.0

The category codes are abbreviations describing the nature of the character. These are grouped into categories such as “Letter”, “Number”, “Punctuation”, or “Symbol”, which in turn are broken up into subcategories. To take the codes from the above output, 'Ll' means ‘Letter, lowercase’, 'No' means “Number, other”, 'Mn' is “Mark, nonspacing”, and 'So' is “Symbol, other”. See the General Category Values section of the Unicode Character Database documentation for a list of category codes.

**Unicode Regular Expressions**

The regular expressions supported by the `re` module can be provided either as bytes or strings. Some of the special character sequences such as \d and \w have different meanings depending on whether the pattern is supplied as bytes or a string. For example, \d will match the characters `[0-9]` in bytes but in strings will match any character that's in the 'Nd' category.

The string in this example has the number 57 written in both Thai and Arabic numerals:

```python
import re
p = re.compile('\d+')
```
s = "Over \u0e55\u0e57 57 flavours"
m = p.search(s)
print(repr(m.group()))

When executed, \d+ will match the Thai numerals and print them out. If you supply the re.ASCII flag to compile(), \d+ will match the substring “57” instead.

Similarly, \w matches a wide variety of Unicode characters but only [a-zA-Z0-9_] in bytes or if re.ASCII is supplied, and \s will match either Unicode whitespace characters or [ \t\n\r\f\v].

Marc-André Lemburg gave a presentation titled “Python and Unicode” (PDF slides) at EuroPython 2002. The slides are an excellent overview of the design of Python 2’s Unicode features (where the Unicode string type is called unicode and literals start with u).
Reading and Writing Unicode Data

Once you’ve written some code that works with Unicode data, the next problem is input/output. How do you get Unicode strings into your program, and how do you convert Unicode into a form suitable for storage or transmission?

It’s possible that you may not need to do anything depending on your input sources and output destinations; you should check whether the libraries used in your application support Unicode natively. XML parsers often return Unicode data, for example. Many relational databases also support Unicode-valued columns and can return Unicode values from an SQL query.

Unicode data is usually converted to a particular encoding before it gets written to disk or sent over a socket. It’s possible to do all the work yourself: open a file, read an 8-bit bytes object from it, and convert the string with `bytes.decode(encoding)`. However, the manual approach is not recommended.

One problem is the multi-byte nature of encodings; one Unicode character can be represented by several bytes. If you want to read the file in arbitrary-sized chunks (say, 1024 or 4096 bytes), you need to write error-handling code to catch the case where only part of the bytes encoding a single Unicode character are read at the end of a chunk. One solution would be to read the entire file into memory and then perform the decoding, but that prevents you from working with files that are extremely large; if you need to read a 2 GiB file, you need 2 GiB of RAM. (More, really, since for at least a moment you’d need to have both the encoded string and its Unicode version in memory.)

The solution would be to use the low-level decoding interface to catch
the case of partial coding sequences. The work of implementing this has already been done for you: the built-in `open()` function can return a file-like object that assumes the file's contents are in a specified encoding and accepts Unicode parameters for methods such as `read()` and `write()`. This works through `open()`'s `encoding` and `errors` parameters which are interpreted just like those in `str.encode()` and `bytes.decode()`.

Reading Unicode from a file is therefore simple:

```python
with open('unicode.txt', encoding='utf-8') as f:
    for line in f:
        print(repr(line))
```

It's also possible to open files in update mode, allowing both reading and writing:

```python
with open('test', encoding='utf-8', mode='w+') as f:
    f.write('\u4500 blah blah blah\n')
    f.seek(0)
    print(repr(f.readline()[:1]))
```

The Unicode character `U+FEFF` is used as a byte-order mark (BOM), and is often written as the first character of a file in order to assist with autodetection of the file's byte ordering. Some encodings, such as UTF-16, expect a BOM to be present at the start of a file; when such an encoding is used, the BOM will be automatically written as the first character and will be silently dropped when the file is read. There are variants of these encodings, such as ‘utf-16-le’ and ‘utf-16-be’ for little-endian and big-endian encodings, that specify one particular byte ordering and don’t skip the BOM.

In some areas, it is also convention to use a “BOM” at the start of
UTF-8 encoded files; the name is misleading since UTF-8 is not byte-order dependent. The mark simply announces that the file is encoded in UTF-8. Use the ‘utf-8-sig’ codec to automatically skip the mark if present for reading such files.

**Unicode filenames**

Most of the operating systems in common use today support filenames that contain arbitrary Unicode characters. Usually this is implemented by converting the Unicode string into some encoding that varies depending on the system. For example, Mac OS X uses UTF-8 while Windows uses a configurable encoding; on Windows, Python uses the name “mbcs” to refer to whatever the currently configured encoding is. On Unix systems, there will only be a filesystem encoding if you’ve set the `LANG` or `LC_CTYPE` environment variables; if you haven’t, the default encoding is UTF-8.

The `sys.getfilesystemencoding()` function returns the encoding to use on your current system, in case you want to do the encoding manually, but there’s not much reason to bother. When opening a file for reading or writing, you can usually just provide the Unicode string as the filename, and it will be automatically converted to the right encoding for you:

```python
filename = 'filename\u4500abc'
with open(filename, 'w') as f:
    f.write('blah
')
```

Functions in the `os` module such as `os.stat()` will also accept Unicode filenames.

The `os.listdir()` function returns filenames and raises an issue:
should it return the Unicode version of filenames, or should it return bytes containing the encoded versions? `os.listdir()` will do both, depending on whether you provided the directory path as bytes or a Unicode string. If you pass a Unicode string as the path, filenames will be decoded using the filesystem's encoding and a list of Unicode strings will be returned, while passing a byte path will return the filenames as bytes. For example, assuming the default filesystem encoding is UTF-8, running the following program:

```python
fn = 'filename\u4500abc'
f = open(fn, 'w')
f.close()

import os
print(os.listdir(b'.'))
print(os.listdir('.'))
```

will produce the following output:

```
[\'filename\xe4\x94\x80abc\', ...]
[\'filename\u4500abc\', ...]
```

The first list contains UTF-8-encoded filenames, and the second list contains the Unicode versions.

Note that on most occasions, the Unicode APIs should be used. The bytes APIs should only be used on systems where undecodable filenames can be present, i.e. Unix systems.

**Tips for Writing Unicode-aware Programs**

This section provides some suggestions on writing software that deals
The most important tip is:

Software should only work with Unicode strings internally, decoding the input data as soon as possible and encoding the output only at the end.

If you attempt to write processing functions that accept both Unicode and byte strings, you will find your program vulnerable to bugs wherever you combine the two different kinds of strings. There is no automatic encoding or decoding: if you do e.g. `str + bytes`, a `TypeError` will be raised.

When using data coming from a web browser or some other untrusted source, a common technique is to check for illegal characters in a string before using the string in a generated command line or storing it in a database. If you’re doing this, be careful to check the decoded string, not the encoded bytes data; some encodings may have interesting properties, such as not being bijective or not being fully ASCII-compatible. This is especially true if the input data also specifies the encoding, since the attacker can then choose a clever way to hide malicious text in the encoded bytestream.

Converting Between File Encodings

The `StreamRecoder` class can transparently convert between encodings, taking a stream that returns data in encoding #1 and behaving like a stream returning data in encoding #2.

For example, if you have an input file `f` that’s in Latin-1, you can wrap it with a `StreamRecoder` to return bytes encoded in UTF-8:

```python
new_f = codecs.StreamRecoder(f,
```

with Unicode.
# en/decoder: used by read() to encode its results
# by write() to decode its input.
codecs.getencoder('utf-8'), codecs.getdecoder('utf-8')

# reader/writer: used to read and write to the stream.
codecs.getreader('latin-1'), codecs.getwriter('latin-1')

Files in an Unknown Encoding

What can you do if you need to make a change to a file, but don't know the file's encoding? If you know the encoding is ASCII-compatible and only want to examine or modify the ASCII parts, you can open the file with the surrogateescape error handler:

```python
with open(fname, 'r', encoding="ascii", errors="surrogateescape") as f:
    data = f.read()

# make changes to the string 'data'
with open(fname + '.new', 'w',
          encoding="ascii", errors="surrogateescape") as f:
    f.write(data)
```

The `surrogateescape` error handler will decode any non-ASCII bytes as code points in the Unicode Private Use Area ranging from U+DC80 to U+DCFF. These private code points will then be turned back into the same bytes when the surrogateescape error handler is used when encoding the data and writing it back out.

HOWTO Fetch Internet Resources Using The urllib Package

**Author:** Michael Foord

**Note:** There is a French translation of an earlier revision of this HOWTO, available at [urllib2 - Le Manuel manquant](urllib2 - Le Manuel manquant).
Introduction

`urllib.request` is a *Python* module for fetching URLs (Uniform Resource Locators). It offers a very simple interface, in the form of the `urlopen` function. This is capable of fetching URLs using a variety of different protocols. It also offers a slightly more complex interface for handling common situations - like basic authentication, cookies, proxies and so on. These are provided by objects called handlers and openers.

`urllib.request` supports fetching URLs for many “URL schemes” (identified by the string before the “:” in URL - for example “ftp” is the URL scheme of “ftp://python.org/”) using their associated network protocols (e.g. FTP, HTTP). This tutorial focuses on the most common case, HTTP.

For straightforward situations `urlopen` is very easy to use. But as soon as you encounter errors or non-trivial cases when opening HTTP URLs, you will need some understanding of the HyperText Transfer Protocol. The most comprehensive and authoritative reference to HTTP is **RFC 2616**. This is a technical document and not intended to be easy to read. This HOWTO aims to illustrate using `urllib`, with enough detail about HTTP to help you through. It is not intended to replace the `urllib.request` docs, but is supplementary to them.
Fetching URLs

The simplest way to use urllib.request is as follows:

```python
import urllib.request
response = urllib.request.urlopen('http://python.org/
html = response.read()
```

If you wish to retrieve a resource via URL and store it in a temporary location, you can do so via the `urlretrieve()` function:

```python
import urllib.request
local_filename, headers = urllib.request.urlretrieve
html = open(local_filename)
```

Many uses of urllib will be that simple (note that instead of an ‘http:' URL we could have used an URL starting with ‘ftp:', ‘file:', etc.). However, it's the purpose of this tutorial to explain the more complicated cases, concentrating on HTTP.

HTTP is based on requests and responses - the client makes requests and servers send responses. urllib.request mirrors this with a Request object which represents the HTTP request you are making. In its simplest form you create a Request object that specifies the URL you want to fetch. Calling `urlopen` with this Request object returns a response object for the URL requested. This response is a file-like object, which means you can for example call `.read()` on the response:

```python
import urllib.request
```
Note that urllib.request makes use of the same Request interface to handle all URL schemes. For example, you can make an FTP request like so:

```python
req = urllib.request.Request('ftp://example.com/')
```

In the case of HTTP, there are two extra things that Request objects allow you to do: First, you can pass data to be sent to the server. Second, you can pass extra information (“metadata”) about the data or the about request itself, to the server - this information is sent as HTTP “headers”. Let's look at each of these in turn.

Data

Sometimes you want to send data to a URL (often the URL will refer to a CGI (Common Gateway Interface) script [1] or other web application). With HTTP, this is often done using what’s known as a **POST** request. This is often what your browser does when you submit a HTML form that you filled in on the web. Not all POSTs have to come from forms: you can use a POST to transmit arbitrary data to your own application. In the common case of HTML forms, the data needs to be encoded in a standard way, and then passed to the Request object as the `data` argument. The encoding is done using a function from the `urllib.parse` library.

```python
import urllib.parse
import urllib.request
```
url = 'http://www.someserver.com/cgi-bin/register.cgi
values = {'name': 'Michael Foord',
          'location': 'Northampton',
          'language': 'Python'}

data = urllib.parse.urlencode(values)
data = data.encode('utf-8')  # data should be bytes
req = urllib.request.Request(url, data)
response = urllib.request.urlopen(req)
the_page = response.read()

Note that other encodings are sometimes required (e.g. for file upload from HTML forms - see HTML Specification, Form Submission for more details).

If you do not pass the data argument, urllib uses a GET request. One way in which GET and POST requests differ is that POST requests often have “side-effects”: they change the state of the system in some way (for example by placing an order with the website for a hundredweight of tinned spam to be delivered to your door). Though the HTTP standard makes it clear that POSTs are intended to always cause side-effects, and GET requests never to cause side-effects, nothing prevents a GET request from having side-effects, nor a POST requests from having no side-effects. Data can also be passed in an HTTP GET request by encoding it in the URL itself.

This is done as follows:

```python
>>> import urllib.request
>>> import urllib.parse
>>> data = {}
>>> data['name'] = 'Somebody Here'
>>> data['location'] = 'Northampton'
>>> data['language'] = 'Python'
```
Notice that the full URL is created by adding a ? to the URL, followed by the encoded values.

Headers

We'll discuss here one particular HTTP header, to illustrate how to add headers to your HTTP request.

Some websites [2] dislike being browsed by programs, or send different versions to different browsers [3]. By default urllib identifies itself as Python-urllib/x.y (where x and y are the major and minor version numbers of the Python release, e.g. Python-urllib/2.5), which may confuse the site, or just plain not work. The way a browser identifies itself is through the User-Agent header [4]. When you create a Request object you can pass a dictionary of headers in. The following example makes the same request as above, but identifies itself as a version of Internet Explorer [5].

```python
import urllib.parse
import urllib.request

url = 'http://www.someserver.com/cgi-bin/register.cgi'
user_agent = 'Mozilla/4.0 (compatible; MSIE 5.5; Windows NT)'
values = {'name' : 'Michael Foord',
          'location' : 'Northampton',
          'language' : 'Python' }
```
headers = { 'User-Agent' : user_agent }

data = urllib.parse.urlencode(values)
data = data.encode('utf-8')
req = urllib.request.Request(url, data, headers)
response = urllib.request.urlopen(req)
the_page = response.read()

The response also has two useful methods. See the section on info and geturl which comes after we have a look at what happens when things go wrong.
Handling Exceptions

`urlopen` raises `URLError` when it cannot handle a response (though as usual with Python APIs, built-in exceptions such as `ValueError`, `TypeError` etc. may also be raised).

`HTTPError` is the subclass of `URLError` raised in the specific case of HTTP URLs.

The exception classes are exported from the `urllib.error` module.

**URLError**

Often, `URLError` is raised because there is no network connection (no route to the specified server), or the specified server doesn’t exist. In this case, the exception raised will have a ‘reason’ attribute, which is a tuple containing an error code and a text error message.

E.g.

```python
>>> req = urllib.request.Request('http://www.pretend_server.org')
>>> try:
...    urllib.request.urlopen(req)
... except urllib.error.URLError as e:
...    print(e.reason)
... (4, 'getaddrinfo failed')
```

**HTTPError**

Every HTTP response from the server contains a numeric “status code”. Sometimes the status code indicates that the server is unable
to fulfil the request. The default handlers will handle some of these responses for you (for example, if the response is a “redirection” that requests the client fetch the document from a different URL, urllib will handle that for you). For those it can’t handle, urlopen will raise an HTTPError. Typical errors include ‘404’ (page not found), ‘403’ (request forbidden), and ‘401’ (authentication required).

See section 10 of RFC 2616 for a reference on all the HTTP error codes.

The HTTPError instance raised will have an integer ‘code’ attribute, which corresponds to the error sent by the server.

Error Codes

Because the default handlers handle redirects (codes in the 300 range), and codes in the 100-299 range indicate success, you will usually only see error codes in the 400-599 range.

`http.server.BaseHTTPRequestHandler.responses` is a useful dictionary of response codes in that shows all the response codes used by RFC 2616. The dictionary is reproduced here for convenience

```python
# Table mapping response codes to messages; entries # form {code: (shortmessage, longmessage)}.
responses = {
    100: ('Continue', 'Request received, please cont
    101: ('Switching Protocols',
        'Switching to new protocol; obey Upgrade H
    200: ('OK', 'Request fulfilled, document follows
    201: ('Created', 'Document created, URL follows'
    202: ('Accepted',
        'Request accepted, processing continues of
```
203: ('Non-Authoritative Information', 'Request fulfilled, nothing added.'),
204: ('No Content', 'Request fulfilled, nothing follows.'),
205: ('Reset Content', 'Clear input form for further input.'),
206: ('Partial Content', 'Partial content follows.'),
300: ('Multiple Choices', 'Object has several resources -- see URI list.'),
301: ('Moved Permanently', 'Object moved permanently -- see URI list.'),
302: ('Found', 'Object moved temporarily -- see URI list.'),
303: ('See Other', 'Object moved -- see Method and URL list.'),
304: ('Not Modified', 'Document has not changed since given time.'),
305: ('Use Proxy', 'You must use proxy specified in Location resource.'),
307: ('Temporary Redirect', 'Object moved temporarily -- see URI list.'),
400: ('Bad Request', 'Bad request syntax or unsupported method.'),
401: ('Unauthorized', 'No permission -- see authorization schemes.'),
402: ('Payment Required', 'No payment -- see charging schemes.'),
403: ('Forbidden', 'Request forbidden -- authorization will not help.'),
404: ('Not Found', 'Nothing matches the given URI.'),
405: ('Method Not Allowed', 'Specified method is invalid for this server.'),
406: ('Not Acceptable', 'URI not available in preferred format.'),
407: ('Proxy Authentication Required', 'You must authenticate with this proxy before proceeding.'),
408: ('Request Timeout', 'Request timed out; try again later.'),
409: ('Conflict', 'Request conflict.'),
410: ('Gone', 'URI no longer exists and has been permanently removed.'),
411: ('Length Required', 'Client must specify Content-Length.')
When an error is raised the server responds by returning an HTTP error code and an error page. You can use the HTTPError instance as a response on the page returned. This means that as well as the code attribute, it also has read, geturl, and info, methods as returned by the urllib.response module:

```python
code = e.code
read = e.read()
```
Wrapping it Up

So if you want to be prepared for HTTPError or URLError there are two basic approaches. I prefer the second approach.

Number 1

```python
from urllib.request import Request, urlopen
from urllib.error import URLError, HTTPError
req = Request(someurl)
try:
    response = urlopen(req)
except HTTPError as e:
    print('The server couldn\'t fulfill the request.
    print('Error code: ', e.code)
except URLError as e:
    print('We failed to reach a server.\')
    print('Reason: ', e.reason)
else:
    # everything is fine
```

**Note:** The except HTTPError must come first, otherwise except URLError will also catch an HTTPError.

Number 2

```python
from urllib.request import Request, urlopen
```
from urllib.error import URLError
req = Request(someurl)
try:
    response = urlopen(req)
except URLError as e:
    if hasattr(e, 'reason'):
        print('We failed to reach a server.')
        print('Reason: ', e.reason)
    elif hasattr(e, 'code'):
        print('The server couldn\'t fulfill the request.')
        print('Error code: ', e.code)
else:
    # everything is fine
info and geturl

The response returned by urlopen (or the HTTPError instance) has two useful methods info() and geturl() and is defined in the module urllib.response..

geturl - this returns the real URL of the page fetched. This is useful because urlopen (or the opener object used) may have followed a redirect. The URL of the page fetched may not be the same as the URL requested.

info - this returns a dictionary-like object that describes the page fetched, particularly the headers sent by the server. It is currently an http.client.HTTPMessage instance.

Typical headers include ‘Content-length’, ‘Content-type’, and so on. See the Quick Reference to HTTP Headers for a useful listing of HTTP headers with brief explanations of their meaning and use.
Openers and Handlers

When you fetch a URL you use an opener (an instance of the perhaps confusingly-named `urllib.request.OpenerDirector`). Normally we have been using the default opener - via `urlopen` - but you can create custom openers. Openers use handlers. All the “heavy lifting” is done by the handlers. Each handler knows how to open URLs for a particular URL scheme (http, ftp, etc.), or how to handle an aspect of URL opening, for example HTTP redirections or HTTP cookies.

You will want to create openers if you want to fetch URLs with specific handlers installed, for example to get an opener that handles cookies, or to get an opener that does not handle redirections.

To create an opener, instantiate an `OpenerDirector`, and then call `.add_handler(some_handler_instance)` repeatedly.

Alternatively, you can use `build_opener`, which is a convenience function for creating opener objects with a single function call. `build_opener` adds several handlers by default, but provides a quick way to add more and/or override the default handlers.

Other sorts of handlers you might want to can handle proxies, authentication, and other common but slightly specialised situations.

`install_opener` can be used to make an `opener` object the (global) default opener. This means that calls to `urlopen` will use the opener you have installed.

Opener objects have an `open` method, which can be called directly to fetch urls in the same way as the `urlopen` function: there’s no need to call `install_opener`, except as a convenience.
Basic Authentication

To illustrate creating and installing a handler we will use the HTTPBasicAuthHandler. For a more detailed discussion of this subject – including an explanation of how Basic Authentication works - see the Basic Authentication Tutorial.

When authentication is required, the server sends a header (as well as the 401 error code) requesting authentication. This specifies the authentication scheme and a ‘realm’. The header looks like: 

```
WWW-Authenticate: SCHEME realm="REALM"
```

e.g.

```
WWW-Authenticate: Basic realm="cPanel Users"
```

The client should then retry the request with the appropriate name and password for the realm included as a header in the request. This is ‘basic authentication’. In order to simplify this process we can create an instance of HTTPBasicAuthHandler and an opener to use this handler.

The HTTPBasicAuthHandler uses an object called a password manager to handle the mapping of URLs and realms to passwords and usernames. If you know what the realm is (from the authentication header sent by the server), then you can use a HTTPPasswordMgr. Frequently one doesn’t care what the realm is. In that case, it is convenient to use HTTPPasswordMgrWithDefaultRealm. This allows you to specify a default username and password for a URL. This will be supplied in the absence of you providing an alternative combination for a specific realm. We indicate this by providing None
as the realm argument to the `add_password` method.

The top-level URL is the first URL that requires authentication. URLs “deeper” than the URL you pass to `.add_password()` will also match.

```python
# create a password manager
password_mgr = urllib.request.HTTPPasswordMgrWithDefaultRealm

# Add the username and password.
# If we knew the realm, we could use it instead of None.
top_level_url = "http://example.com/foo/"
password_mgr.add_password(None, top_level_url, username)

handler = urllib.request.HTTPBasicAuthHandler(password_mgr)

# create "opener" (OpenerDirector instance)
opener = urllib.request.build_opener(handler)

# use the opener to fetch a URL
opener.open(a_url)

# Install the opener.
# Now all calls to urllib.request.urlopen use our opener
urllib.request.install_opener(opener)
```

**Note:** In the above example we only supplied our `HTTPBasicAuthHandler` to `build_opener`. By default openers have the handlers for normal situations – `ProxyHandler` (if a proxy setting such as an `http_proxy` environment variable is set), `UnknownHandler`, `HTTPHandler`, `HTTPDefaultErrorHandler`, `HTTPRedirectHandler`, `FTPHandler`, `FileHandler`, `HTTPErrorProcessor`. 
top_level_url is in fact either a full URL (including the ‘http’ scheme component and the hostname and optionally the port number) e.g. “http://example.com/” or an “authority” (i.e. the hostname, optionally including the port number) e.g. “example.com” or “example.com:8080” (the latter example includes a port number). The authority, if present, must NOT contain the “userinfo” component - for example “joe@password:example.com” is not correct.
Proxies

urllib will auto-detect your proxy settings and use those. This is through the ProxyHandler, which is part of the normal handler chain when a proxy setting is detected. Normally that’s a good thing, but there are occasions when it may not be helpful [6]. One way to do this is to setup our own ProxyHandler, with no proxies defined. This is done using similar steps to setting up a Basic Authentication handler:

```python
>>> proxy_support = urllib.request.ProxyHandler({})
>>> opener = urllib.request.build_opener(proxy_support)
>>> urllib.request.install_opener(opener)
```

**Note:** Currently urllib.request does not support fetching of https locations through a proxy. However, this can be enabled by extending urllib.request as shown in the recipe [7].
Sockets and Layers

The Python support for fetching resources from the web is layered. urllib uses the `http.client` library, which in turn uses the socket library.

As of Python 2.3 you can specify how long a socket should wait for a response before timing out. This can be useful in applications which have to fetch web pages. By default the socket module has no timeout and can hang. Currently, the socket timeout is not exposed at the http.client or urllib.request levels. However, you can set the default timeout globally for all sockets using

```
import socket
import urllib.request

# timeout in seconds
timeout = 10
socket.setdefaulttimeout(timeout)

# this call to urllib.request.urlopen now uses the default timeout
req = urllib.request.Request('http://www.voidspace.org.uk')
response = urllib.request.urlopen(req)
```
Footnotes

This document was reviewed and revised by John Lee.

[1] For an introduction to the CGI protocol see Writing Web Applications in Python.

Like Google for example. The proper way to use google from a program is to use PyGoogle of course. See Voidspace Google for some examples of using the Google API.

Browser sniffing is a very bad practise for website design - building sites using web standards is much more sensible. Unfortunately a lot of sites still send different versions to different browsers.

[3] The user agent for MSIE 6 is ‘Mozilla/4.0 (compatible; MSIE 6.0; Windows NT 5.1; SV1; .NET CLR 1.1.4322)’

[4] For details of more HTTP request headers, see Quick Reference to HTTP Headers.

In my case I have to use a proxy to access the internet at work. If you attempt to fetch localhost URLs through this proxy it blocks them. IE is set to use the proxy, which urllib picks up on. In order to test scripts with a localhost server, I have to prevent urllib from using the proxy.

HOWTO Use Python in the web

Author: Marek Kubica

Abstract

This document shows how Python fits into the web. It presents some ways to integrate Python with a web server, and general practices useful for developing web sites.

Programming for the Web has become a hot topic since the rise of “Web 2.0”, which focuses on user-generated content on web sites. It has always been possible to use Python for creating web sites, but it was a rather tedious task. Therefore, many frameworks and helper tools have been created to assist developers in creating faster and more robust sites. This HOWTO describes some of the methods used to combine Python with a web server to create dynamic content. It is not meant as a complete introduction, as this topic is far too broad to be covered in one single document. However, a short overview of the most popular libraries is provided.

See also: While this HOWTO tries to give an overview of Python in the web, it cannot always be as up to date as desired. Web development in Python is rapidly moving forward, so the wiki page on Web Programming may be more in sync with recent development.
The Low-Level View

When a user enters a web site, their browser makes a connection to the site's web server (this is called the *request*). The server looks up the file in the file system and sends it back to the user's browser, which displays it (this is the *response*). This is roughly how the underlying protocol, HTTP, works.

Dynamic web sites are not based on files in the file system, but rather on programs which are run by the web server when a request comes in, and which *generate* the content that is returned to the user. They can do all sorts of useful things, like display the postings of a bulletin board, show your email, configure software, or just display the current time. These programs can be written in any programming language the server supports. Since most servers support Python, it is easy to use Python to create dynamic web sites.

Most HTTP servers are written in C or C++, so they cannot execute Python code directly – a bridge is needed between the server and the program. These bridges, or rather interfaces, define how programs interact with the server. There have been numerous attempts to create the best possible interface, but there are only a few worth mentioning.

Not every web server supports every interface. Many web servers only support old, now-obsolete interfaces; however, they can often be extended using third-party modules to support newer ones.

Common Gateway Interface

This interface, most commonly referred to as “CGI”, is the oldest, and is supported by nearly every web server out of the box. Programs
using CGI to communicate with their web server need to be started by the server for every request. So, every request starts a new Python interpreter – which takes some time to start up – thus making the whole interface only usable for low load situations.

The upside of CGI is that it is simple – writing a Python program which uses CGI is a matter of about three lines of code. This simplicity comes at a price: it does very few things to help the developer.

Writing CGI programs, while still possible, is no longer recommended. With WSGI, a topic covered later in this document, it is possible to write programs that emulate CGI, so they can be run as CGI if no better option is available.

**See also:** The Python standard library includes some modules that are helpful for creating plain CGI programs:

- **cgi** – Handling of user input in CGI scripts
- **cgitb** – Displays nice tracebacks when errors happen in CGI applications, instead of presenting a “500 Internal Server Error” message

The Python wiki features a page on **CGI scripts** with some additional information about CGI in Python.

**Simple script for testing CGI**

To test whether your web server works with CGI, you can use this short and simple CGI program:

```
#!/usr/bin/env python
# -*- coding: UTF-8 -*-

# enable debugging
```
```python
import cgitb

cgitb.enable()

print("Content-Type: text/plain;charset=utf-8")
print()
print("Hello World!")
```

Depending on your web server configuration, you may need to save this code with a `.py` or `.cgi` extension. Additionally, this file may also need to be in a `cgi-bin` folder, for security reasons.

You might wonder what the `cgitb` line is about. This line makes it possible to display a nice traceback instead of just crashing and displaying an “Internal Server Error” in the user’s browser. This is useful for debugging, but it might risk exposing some confidential data to the user. You should not use `cgitb` in production code for this reason. You should always catch exceptions, and display proper error pages – end-users don’t like to see nondescript “Internal Server Errors” in their browsers.

### Setting up CGI on your own server

If you don’t have your own web server, this does not apply to you. You can check whether it works as-is, and if not you will need to talk to the administrator of your web server. If it is a big host, you can try filing a ticket asking for Python support.

If you are your own administrator or want to set up CGI for testing purposes on your own computers, you have to configure it by yourself. There is no single way to configure CGI, as there are many web servers with different configuration options. Currently the most widely used free web server is Apache HTTPd, or Apache for short. Apache
can be easily installed on nearly every system using the system’s package management tool. lighttpd is another alternative and is said to have better performance. On many systems this server can also be installed using the package management tool, so manually compiling the web server may not be needed.

- On Apache you can take a look at the Dynamic Content with CGI tutorial, where everything is described. Most of the time it is enough just to set +ExecCGI. The tutorial also describes the most common gotchas that might arise.
- On lighttpd you need to use the CGI module, which can be configured in a straightforward way. It boils down to setting cgi.assign properly.

Common problems with CGI scripts

Using CGI sometimes leads to small annoyances while trying to get these scripts to run. Sometimes a seemingly correct script does not work as expected, the cause being some small hidden problem that’s difficult to spot.

Some of these potential problems are:

- The Python script is not marked as executable. When CGI scripts are not executable most web servers will let the user download it, instead of running it and sending the output to the user. For CGI scripts to run properly on Unix-like operating systems, the +x bit needs to be set. Using `chmod a+x your_script.py` may solve this problem.
- On a Unix-like system, The line endings in the program file must be Unix style line endings. This is important because the web server checks the first line of the script (called shebang) and tries to run the program specified there. It gets easily confused by Windows line endings (Carriage Return & Line Feed, also called
CRLF), so you have to convert the file to Unix line endings (only Line Feed, LF). This can be done automatically by uploading the file via FTP in text mode instead of binary mode, but the preferred way is just telling your editor to save the files with Unix line endings. Most editors support this.

- Your web server must be able to read the file, and you need to make sure the permissions are correct. On unix-like systems, the server often runs as user and group www-data, so it might be worth a try to change the file ownership, or making the file world readable by using chmod a+r your_script.py.

- The web server must know that the file you're trying to access is a CGI script. Check the configuration of your web server, as it may be configured to expect a specific file extension for CGI scripts.

- On Unix-like systems, the path to the interpreter in the shebang (#!/usr/bin/env python) must be correct. This line calls /usr/bin/env to find Python, but it will fail if there is no /usr/bin/env, or if Python is not in the web server's path. If you know where your Python is installed, you can also use that full path. The commands whereis python and type -p python could help you find where it is installed. Once you know the path, you can change the shebang accordingly: #!/usr/bin/python.

- The file must not contain a BOM (Byte Order Mark). The BOM is meant for determining the byte order of UTF-16 and UTF-32 encodings, but some editors write this also into UTF-8 files. The BOM interferes with the shebang line, so be sure to tell your editor not to write the BOM.

- If the web server is using mod_python, mod_python may be having problems. mod_python is able to handle CGI scripts by itself, but it can also be a source of issues.
People coming from PHP often find it hard to grasp how to use Python in the web. Their first thought is mostly mod_python, because they think that this is the equivalent to mod_php. Actually, there are many differences. What mod_python does is embed the interpreter into the Apache process, thus speeding up requests by not having to start a Python interpreter for each request. On the other hand, it is not “Python intermixed with HTML” in the way that PHP is often intermixed with HTML. The Python equivalent of that is a template engine. mod_python itself is much more powerful and provides more access to Apache internals. It can emulate CGI, work in a “Python Server Pages” mode (similar to JSP) which is “HTML intermingled with Python”, and it has a “Publisher” which designates one file to accept all requests and decide what to do with them.

mod_python does have some problems. Unlike the PHP interpreter, the Python interpreter uses caching when executing files, so changes to a file will require the web server to be restarted. Another problem is the basic concept – Apache starts child processes to handle the requests, and unfortunately every child process needs to load the whole Python interpreter even if it does not use it. This makes the whole web server slower. Another problem is that, because mod_python is linked against a specific version of libpython, it is not possible to switch from an older version to a newer (e.g. 2.4 to 2.5) without recompiling mod_python. mod_python is also bound to the Apache web server, so programs written for mod_python cannot easily run on other web servers.

These are the reasons why mod_python should be avoided when writing new programs. In some circumstances it still might be a good idea to use mod_python for deployment, but WSGI makes it possible to run WSGI programs under mod_python as well.
FastCGI and SCGI

FastCGI and SCGI try to solve the performance problem of CGI in another way. Instead of embedding the interpreter into the web server, they create long-running background processes. There is still a module in the web server which makes it possible for the web server to “speak” with the background process. As the background process is independent of the server, it can be written in any language, including Python. The language just needs to have a library which handles the communication with the webservice.

The difference between FastCGI and SCGI is very small, as SCGI is essentially just a “simpler FastCGI”. As the web server support for SCGI is limited, most people use FastCGI instead, which works the same way. Almost everything that applies to SCGI also applies to FastCGI as well, so we'll only cover the latter.

These days, FastCGI is never used directly. Just like mod_python, it is only used for the deployment of WSGI applications.

See also:

- FastCGI, SCGI, and Apache: Background and Future is a discussion on why the concept of FastCGI and SCGI is better than that of mod_python.

Setting up FastCGI

Each web server requires a specific module.

- Apache has both mod_fastcgi and mod_fcgid. mod_fastcgi is the original one, but it has some licensing issues, which is why it is sometimes considered non-free. mod_fcgid is a smaller,
compatible alternative. One of these modules needs to be loaded by Apache.
- lighttpd ships its own FastCGI module as well as an SCGI module.
- nginx also supports FastCGI.

Once you have installed and configured the module, you can test it with the following WSGI-application:

```python
#!/usr/bin/env python
# -*- coding: UTF-8 -*-

import sys, os
from html import escape
from flup.server.fcgi import WSGIServer

def app(environ, start_response):
    start_response('200 OK', [('Content-Type', 'text/html')])
    yield '<h1>FastCGI Environment</h1>'
    yield '<table>
    for k, v in sorted(environ.items()):
        yield '<tr><th>{0}</th><td>{1}</td></tr>'.format(escape(k), escape(v))
    yield '</table>'

WSGIServer(app).run()
```

This is a simple WSGI application, but you need to install flup first, as flup handles the low level FastCGI access.

**See also:** There is some documentation on setting up Django with FastCGI, most of which can be reused for other WSGI-compliant frameworks and libraries. Only the `manage.py` part has to be...
changed, the example used here can be used instead. Django does more or less the exact same thing.

**mod_wsgi**

*mod_wsgi* is an attempt to get rid of the low level gateways. Given that FastCGI, SCGI, and mod_python are mostly used to deploy WSGI applications, *mod_wsgi* was started to directly embed WSGI applications into the Apache web server. *mod_wsgi* is specifically designed to host WSGI applications. It makes the deployment of WSGI applications much easier than deployment using other low level methods, which need glue code. The downside is that *mod_wsgi* is limited to the Apache web server; other servers would need their own implementations of *mod_wsgi*.

*mod_wsgi* supports two modes: embedded mode, in which it integrates with the Apache process, and daemon mode, which is more FastCGI-like. Unlike FastCGI, *mod_wsgi* handles the worker-processes by itself, which makes administration easier.
Step back: WSGI

WSGI has already been mentioned several times, so it has to be something important. In fact it really is, and now it is time to explain it.

The *Web Server Gateway Interface*, or WSGI for short, is defined in **PEP 333** and is currently the best way to do Python web programming. While it is great for programmers writing frameworks, a normal web developer does not need to get in direct contact with it. When choosing a framework for web development it is a good idea to choose one which supports WSGI.

The big benefit of WSGI is the unification of the application programming interface. When your program is compatible with WSGI – which at the outer level means that the framework you are using has support for WSGI – your program can be deployed via any web server interface for which there are WSGI wrappers. You do not need to care about whether the application user uses mod_python or FastCGI or mod_wsgi – with WSGI your application will work on any gateway interface. The Python standard library contains its own WSGI server, *wsgiref*, which is a small web server that can be used for testing.

A really great WSGI feature is middleware. Middleware is a layer around your program which can add various functionality to it. There is quite a bit of *middleware* already available. For example, instead of writing your own session management (HTTP is a stateless protocol, so to associate multiple HTTP requests with a single user your application must create and manage such state via a session), you can just download middleware which does that, plug it in, and get on with coding the unique parts of your application. The same thing with compression – there is existing middleware which handles compressing your HTML using gzip to save on your server’s
bandwidth. Authentication is another a problem easily solved using existing middleware.

Although WSGI may seem complex, the initial phase of learning can be very rewarding because WSGI and the associated middleware already have solutions to many problems that might arise while developing web sites.

**WSGI Servers**

The code that is used to connect to various low level gateways like CGI or mod_python is called a *WSGI server*. One of these servers is flup, which supports FastCGI and SCGI, as well as AJP. Some of these servers are written in Python, as flup is, but there also exist others which are written in C and can be used as drop-in replacements.

There are many servers already available, so a Python web application can be deployed nearly anywhere. This is one big advantage that Python has compared with other web technologies.

**See also:** A good overview of WSGI-related code can be found in the [WSGI homepage](https://www.python.org/dev/peps/pep-0333/), which contains an extensive list of WSGI servers which can be used by *any* application supporting WSGI.

You might be interested in some WSGI-supporting modules already contained in the standard library, namely:

- **wsgiref** – some tiny utilities and servers for WSGI

**Case study: MoinMoin**
What does WSGI give the web application developer? Let’s take a look at an application that’s been around for a while, which was written in Python without using WSGI.

One of the most widely used wiki software packages is MoinMoin. It was created in 2000, so it predates WSGI by about three years. Older versions needed separate code to run on CGI, mod_python, FastCGI and standalone.

It now includes support for WSGI. Using WSGI, it is possible to deploy MoinMoin on any WSGI compliant server, with no additional glue code. Unlike the pre-WSGI versions, this could include WSGI servers that the authors of MoinMoin know nothing about.
Model-View-Controller

The term MVC is often encountered in statements such as “framework foo supports MVC”. MVC is more about the overall organization of code, rather than any particular API. Many web frameworks use this model to help the developer bring structure to their program. Bigger web applications can have lots of code, so it is a good idea to have an effective structure right from the beginning. That way, even users of other frameworks (or even other languages, since MVC is not Python-specific) can easily understand the code, given that they are already familiar with the MVC structure.

MVC stands for three components:

- The **model**. This is the data that will be displayed and modified. In Python frameworks, this component is often represented by the classes used by an object-relational mapper.
- The **view**. This component’s job is to display the data of the model to the user. Typically this component is implemented via templates.
- The **controller**. This is the layer between the user and the model. The controller reacts to user actions (like opening some specific URL), tells the model to modify the data if necessary, and tells the view code what to display,

While one might think that MVC is a complex design pattern, in fact it is not. It is used in Python because it has turned out to be useful for creating clean, maintainable web sites.

**Note:** While not all Python frameworks explicitly support MVC, it is often trivial to create a web site which uses the MVC pattern by separating the data logic (the model) from the user interaction logic
(the controller) and the templates (the view). That's why it is important not to write unnecessary Python code in the templates – it works against the MVC model and creates chaos in the code base, making it harder to understand and modify.

**See also:** The English Wikipedia has an article about the Model-View-Controller pattern. It includes a long list of web frameworks for various programming languages.
Ingredients for Websites

Websites are complex constructs, so tools have been created to help web developers make their code easier to write and more maintainable. Tools like these exist for all web frameworks in all languages. Developers are not forced to use these tools, and often there is no “best” tool. It is worth learning about the available tools because they can greatly simplify the process of developing a website.

See also: There are far more components than can be presented here. The Python wiki has a page about these components, called Web Components.

Templates

Mixing of HTML and Python code is made possible by a few libraries. While convenient at first, it leads to horribly unmaintainable code. That’s why templates exist. Templates are, in the simplest case, just HTML files with placeholders. The HTML is sent to the user’s browser after filling in the placeholders.

Python already includes a way to build simple templates:

```python
# a simple template
template = "<html><body><h1>Hello {who}!</h1></body>
print(template.format(who="Reader"))
```

To generate complex HTML based on non-trivial model data, conditional and looping constructs like Python’s `for` and `if` are generally needed. Template engines support templates of this complexity.
There are a lot of template engines available for Python which can be used with or without a framework. Some of these define a plain-text programming language which is easy to learn, partly because it is limited in scope. Others use XML, and the template output is guaranteed to be always be valid XML. There are many other variations.

Some frameworks ship their own template engine or recommend one in particular. In the absence of a reason to use a different template engine, using the one provided by or recommended by the framework is a good idea.

Popular template engines include:

- Mako
- Genshi
- Jinja

See also: There are many template engines competing for attention, because it is pretty easy to create them in Python. The page Templating in the wiki lists a big, ever-growing number of these. The three listed above are considered “second generation” template engines and are a good place to start.

Data persistence

Data persistence, while sounding very complicated, is just about storing data. This data might be the text of blog entries, the postings on a bulletin board or the text of a wiki page. There are, of course, a number of different ways to store information on a web server.

Often, relational database engines like MySQL or PostgreSQL are used because of their good performance when handling very large
databases consisting of millions of entries. There is also a small
database engine called SQLite, which is bundled with Python in the
sqlite3 module, and which uses only one file. It has no other
dependencies. For smaller sites SQLite is just enough.

Relational databases are queried using a language called SQL.
Python programmers in general do not like SQL too much, as they
prefer to work with objects. It is possible to save Python objects into a
database using a technology called ORM (Object Relational Mapping).
ORM translates all object-oriented access into SQL code under the
hood, so the developer does not need to think about it. Most
frameworks use ORMs, and it works quite well.

A second possibility is storing data in normal, plain text files (some
times called “flat files”). This is very easy for simple sites, but can be
difficult to get right if the web site is performing many updates to the
stored data.

A third possibility are object oriented databases (also called “object
databases”). These databases store the object data in a form that
closely parallels the way the objects are structured in memory during
program execution. (By contrast, ORMs store the object data as rows
of data in tables and relations between those rows.) Storing the
objects directly has the advantage that nearly all objects can be saved
in a straightforward way, unlike in relational databases where some
objects are very hard to represent.

Frameworks often give hints on which data storage method to choose.
It is usually a good idea to stick to the data store recommended by the
framework unless the application has special requirements better
satisfied by an alternate storage mechanism.

See also:
- **Persistence Tools** lists possibilities on how to save data in the file system. Some of these modules are part of the standard library.
- **Database Programming** helps with choosing a method for saving data.
- **SQLAlchemy**, the most powerful OR-Mapper for Python, and **Elixir**, which makes SQLAlchemy easier to use.
- **SQLObject**, another popular OR-Mapper.
- **ZODB** and **Durus**, two object oriented databases.
Frameworks

The process of creating code to run web sites involves writing code to provide various services. The code to provide a particular service often works the same way regardless of the complexity or purpose of the web site in question. Abstracting these common solutions into reusable code produces what are called “frameworks” for web development. Perhaps the most well-known framework for web development is Ruby on Rails, but Python has its own frameworks. Some of these were partly inspired by Rails, or borrowed ideas from Rails, but many existed a long time before Rails.

Originally Python web frameworks tended to incorporate all of the services needed to develop web sites as a giant, integrated set of tools. No two web frameworks were interoperable: a program developed for one could not be deployed on a different one without considerable re-engineering work. This led to the development of “minimalist” web frameworks that provided just the tools to communicate between the Python code and the http protocol, with all other services to be added on top via separate components. Some ad hoc standards were developed that allowed for limited interoperability between frameworks, such as a standard that allowed different template engines to be used interchangeably.

Since the advent of WSGI, the Python web framework world has been evolving toward interoperability based on the WSGI standard. Now many web frameworks, whether “full stack” (providing all the tools one needs to deploy the most complex web sites) or minimalist, or anything in between, are built from collections of reusable components that can be used with more than one framework.

The majority of users will probably want to select a “full stack”
framework that has an active community. These frameworks tend to be well documented, and provide the easiest path to producing a fully functional web site in minimal time.

Some notable frameworks

There are an incredible number of frameworks, so they cannot all be covered here. Instead we will briefly touch on some of the most popular.

Django

Django is a framework consisting of several tightly coupled elements which were written from scratch and work together very well. It includes an ORM which is quite powerful while being simple to use, and has a great online administration interface which makes it possible to edit the data in the database with a browser. The template engine is text-based and is designed to be usable for page designers who cannot write Python. It supports template inheritance and filters (which work like Unix pipes). Django has many handy features bundled, such as creation of RSS feeds or generic views, which make it possible to create web sites almost without writing any Python code.

It has a big, international community, the members of which have created many web sites. There are also a lot of add-on projects which extend Django’s normal functionality. This is partly due to Django’s well written online documentation and the Django book.

Note: Although Django is an MVC-style framework, it names the elements differently, which is described in the Django FAQ.

TurboGears
Another popular web framework for Python is TurboGears. TurboGears takes the approach of using already existing components and combining them with glue code to create a seamless experience. TurboGears gives the user flexibility in choosing components. For example the ORM and template engine can be changed to use packages different from those used by default.

The documentation can be found in the TurboGears wiki, where links to screencasts can be found. TurboGears has also an active user community which can respond to most related questions. There is also a TurboGears book published, which is a good starting point.

The newest version of TurboGears, version 2.0, moves even further in direction of WSGI support and a component-based architecture. TurboGears 2 is based on the WSGI stack of another popular component-based web framework, Pylons.

Zope

The Zope framework is one of the “old original” frameworks. Its current incarnation in Zope2 is a tightly integrated full-stack framework. One of its most interesting feature is its tight integration with a powerful object database called the ZODB (Zope Object Database). Because of its highly integrated nature, Zope wound up in a somewhat isolated ecosystem: code written for Zope wasn’t very usable outside of Zope, and vice-versa. To solve this problem the Zope 3 effort was started. Zope 3 re-engineers Zope as a set of more cleanly isolated components. This effort was started before the advent of the WSGI standard, but there is WSGI support for Zope 3 from the Repoze project. Zope components have many years of production use behind them, and the Zope 3 project gives access to these components to the wider Python community. There is even a separate framework based
on the Zope components: **Grok**.

Zope is also the infrastructure used by the **Plone** content management system, one of the most powerful and popular content management systems available.

**Other notable frameworks**

Of course these are not the only frameworks that are available. There are many other frameworks worth mentioning.

Another framework that’s already been mentioned is **Pylons**. Pylons is much like TurboGears, but with an even stronger emphasis on flexibility, which comes at the cost of being more difficult to use. Nearly every component can be exchanged, which makes it necessary to use the documentation of every single component, of which there are many. Pylons builds upon **Paste**, an extensive set of tools which are handy for WSGI.

And that’s still not everything. The most up-to-date information can always be found in the Python wiki.

**See also:** The Python wiki contains an extensive list of web frameworks.

Most frameworks also have their own mailing lists and IRC channels, look out for these on the projects’ web sites. There is also a general “Python in the Web” IRC channel on freenode called **#python.web**.
Argparse Tutorial

**author:** Tshepang Lekhonkhobe

This tutorial is intended to be a gentle introduction to *argparse*, the recommended command-line parsing module in the Python standard library.

**Note:** There are two other modules that fulfill the same task, namely *getopt* (an equivalent for *getopt()* from the C language) and the deprecated *optparse*. Note also that *argparse* is based on *optparse*, and therefore very similar in terms of usage.
Conceps

Let's show the sort of functionality that we are going to explore in this introductory tutorial by making use of the \texttt{ls} command:

$ ls
cpython devguide prog.py pypy rm-unused-function
$ ls pypy
ctypes_configure demo dotviewer include lib_pypy
$ ls -l
total 20
drwxr-xr-x 19 wena wena 4096 Feb 18 18:51 cpython
drwxr-xr-x 4 wena wena 4096 Feb  8 12:04 devguide
-rwxr-xr-x  1 wena wena  535 Feb 19 00:05 prog.py
drwxr-xr-x 14 wena wena 4096 Feb  7 00:59 pypy
-rw-r--r--  1 wena wena  741 Feb 18 01:01 rm-unused-function
$ ls --help
Usage: ls [OPTION]... [FILE]...
List information about the FILEs (the current directory by default)
Sort entries alphabetically \textbf{if} none of -cftuvSUX nor --sort is specified.

A few concepts we can learn from the four commands:

- The \texttt{ls} command is useful when run without any options at all. It defaults to displaying the contents of the current directory.
- If we want beyond what it provides by default, we tell it a bit more. In this case, we want it to display a different directory, \texttt{pypy}. What we did is specify what is known as a positional argument. It's named so because the program should know what to do with the value, solely based on where it appears on the command line. This concept is more relevant to a command like \texttt{cp}, whose most basic usage is \texttt{cp SRC DEST}. The first position is \textit{what you want copied,} and the second position is \textit{where you want it copied to.}
• Now, say we want to change behaviour of the program. In our example, we display more info for each file instead of just showing the file names. The `-l` in that case is known as an optional argument.

• That's a snippet of the help text. It's very useful in that you can come across a program you have never used before, and can figure out how it works simply by reading its help text.
The basics

Let us start with a very simple example which does (almost) nothing:

```python
import argparse
parser = argparse.ArgumentParser()
parser.parse_args()
```

Following is a result of running the code:

```
$ python3 prog.py
$ python3 prog.py --help
usage: prog.py [-h]
optional arguments:
   -h, --help    show this help message and exit
$ python3 prog.py --verbose
usage: prog.py [-h]
prog.py: error: unrecognized arguments: --verbose
$ python3 prog.py foo
usage: prog.py [-h]
prog.py: error: unrecognized arguments: foo
```

Here is what is happening:

- Running the script without any options results in nothing displayed to stdout. Not so useful.
- The second one starts to display the usefulness of the `argparse` module. We have done almost nothing, but already we get a nice help message.
- The `--help` option, which can also be shortened to `-h`, is the only option we get for free (i.e. no need to specify it). Specifying anything else results in an error. But even then, we do get a useful usage message, also for free.
Introducing Positional arguments

An example:

```python
import argparse
parser = argparse.ArgumentParser()
parser.add_argument("echo")
args = parser.parse_args()
print(args.echo)
```

And running the code:

```
$ python3 prog.py
usage: prog.py [-h] echo
prog.py: error: the following arguments are required
$ python3 prog.py --help
usage: prog.py [-h] echo

positional arguments:
  echo

optional arguments:
  -h, --help    show this help message and exit
$ python3 prog.py foo
foo
```

Here is what's happening:

- We've added the `add_argument()` method, which is what we use to specify which command-line options the program is willing to accept. In this case, I've named it `echo` so that it's in line with its function.
- Calling our program now requires us to specify an option.
- The `parse_args()` method actually returns some data from the
options specified, in this case, `echo`.
- The variable is some form of ‘magic’ that `argparse` performs for free (i.e. no need to specify which variable that value is stored in).
  You will also notice that its name matches the string argument given to the method, `echo`.

Note however that, although the help display looks nice and all, it currently is not as helpful as it can be. For example we see that we got `echo` as a positional argument, but we don’t know what it does, other than by guessing or by reading the source code. So, let’s make it a bit more useful:

```python
import argparse
parser = argparse.ArgumentParser()
parser.add_argument("echo", help="echo the string you use here")
args = parser.parse_args()
print(args.echo)
```

And we get:

```
$ python3 prog.py -h
usage: prog.py [-h] echo

positional arguments:
  echo echo the string you use here

optional arguments:
  -h, --help   show this help message and exit
```

Now, how about doing something even more useful:

```python
import argparse
parser = argparse.ArgumentParser()
parser.add_argument("square", help="display a square
```
args = parser.parse_args()
print(args.square**2)

Following is a result of running the code:

```
$ python3 prog.py 4
Traceback (most recent call last):
  File "prog.py", line 5, in <module>
    print(args.square**2)
TypeError: unsupported operand type(s) for ** or pow
```

That didn't go so well. That's because `argparse` treats the options we give it as strings, unless we tell it otherwise. So, let's tell `argparse` to treat that input as an integer:

```python
import argparse
parser = argparse.ArgumentParser()
parser.add_argument("square", help="display a square of given number", type=int)
args = parser.parse_args()
print(args.square**2)
```

Following is a result of running the code:

```
$ python3 prog.py 4
16
$ python3 prog.py four
usage: prog.py [-h] square
prog.py: error: argument square: invalid int value:
```

That went well. The program now even helpfully quits on bad illegal input before proceeding.
Introducing Optional arguments

So far we, have been playing with positional arguments. Let us have a look on how to add optional ones:

```python
import argparse
parser = argparse.ArgumentParser()
parser.add_argument("--verbosity", help="increase output verbosity")
args = parser.parse_args()
if args.verbosity:
    print("verbosity turned on")
```

And the output:

```
$ python3 prog.py --verbosity 1
verbosity turned on
$ python3 prog.py
$ python3 prog.py --help
usage: prog.py [-h] [--verbosity VERBOSITY]
optional arguments:
  -h, --help            show this help message and exit
  --verbosity VERBOSITY increase output verbosity
$ python3 prog.py --verbosity
usage: prog.py [-h] [--verbosity VERBOSITY]
prog.py: error: argument --verbosity: expected one argument
```

Here is what is happening:

- The program is written so as to display something when `--verbosity` is specified and display nothing when not.
- To show that the option is actually optional, there is no error when
running the program without it. Note that by default, if an optional argument isn't used, the relevant variable, in this case args.verbosity, is given None as a value, which is the reason it fails the truth test of the if statement.

- The help message is a bit different.
- When using the --verbosity option, one must also specify some value, any value.

The above example accepts arbitrary integer values for --verbosity, but for our simple program, only two values are actually useful, True or False. Let's modify the code accordingly:

```python
import argparse
parser = argparse.ArgumentParser()
parser.add_argument("--verbose", help="increase output verbosity", action="store_true")
args = parser.parse_args()
if args.verbose:
    print("verbosity turned on")
```

And the output:

```
$ python3 prog.py --verbose
verbosity turned on
$ python3 prog.py --verbose 1
usage: prog.py [-h] [--verbose]
prog.py: error: unrecognized arguments: 1
$ python3 prog.py --help
usage: prog.py [-h] [--verbose]

optional arguments:
  -h, --help    show this help message and exit
  --verbose     increase output verbosity
```
Here is what is happening:

- The option is now more of a flag than something that requires a value. We even changed the name of the option to match that idea. Note that we now specify a new keyword, `action`, and give it the value "store_true". This means that, if the option is specified, assign the value True to `args.verbose`. Not specifying it implies False.
- It complains when you specify a value, in true spirit of what flags actually are.
- Notice the different help text.

Short options

If you are familiar with command line usage, you will notice that I haven’t yet touched on the topic of short versions of the options. It’s quite simple:

```python
import argparse
parser = argparse.ArgumentParser()
parser.add_argument("-v", "--verbose", help="increase output verbosity", action="store_true")
args = parser.parse_args()
if args.verbose:
    print("verbosity turned on")
```

And here goes:

```
$ python3 prog.py -v
verbosity turned on
$ python3 prog.py --help
usage: prog.py [-h] [-v]
optional arguments:
```
Note that the new ability is also reflected in the help text.
Combining Positional and Optional arguments

Our program keeps growing in complexity:

```python
import argparse
parser = argparse.ArgumentParser()
parser.add_argument("square", type=int,
    help="display a square of a given number")
parser.add_argument("-v", "--verbose", action="store_true",
    help="increase output verbosity")
args = parser.parse_args()
answer = args.square**2
if args.verbose:
    print("the square of {} equals {}".format(args.square))
else:
    print(answer)
```

And now the output:

```
$ python3 prog.py
usage: prog.py [-h] [-v] square
prog.py: error: the following arguments are required
$ python3 prog.py 4
16
$ python3 prog.py 4 --verbose
the square of 4 equals 16
$ python3 prog.py --verbose 4
the square of 4 equals 16
```

- We’ve brought back a positional argument, hence the complaint.
- Note that the order does not matter.
How about we give this program of ours back the ability to have multiple verbosity values, and actually get to use them:

```python
import argparse
parser = argparse.ArgumentParser()
parser.add_argument("square", type=int,
    help="display a square of a given number")
parser.add_argument("-v", "--verbosity", type=int,
    help="increase output verbosity")
args = parser.parse_args()
answer = args.square**2
if args.verbosity == 2:
    print("the square of {} equals {}".format(args.square, answer))
elif args.verbosity == 1:
    print("{}^2 == {}".format(args.square, answer))
else:
    print(answer)
```

And the output:

```
$ python3 prog.py 4
16
$ python3 prog.py 4 -v
```

```
usage: prog.py [-h] [-v VERBOSITY] square
prog.py: error: argument -v/--verbosity: expected one argument
```

```
$ python3 prog.py 4 -v 1
4^2 == 16
$ python3 prog.py 4 -v 2
the square of 4 equals 16
$ python3 prog.py 4 -v 3
16
```

These all look good except the last one, which exposes a bug in our program. Let’s fix it by restricting the values the `--verbosity` option
can accept:

```python
import argparse
parser = argparse.ArgumentParser()
parser.add_argument("square", type=int,
    help="display a square of a given number")
parser.add_argument("-v", "--verbosity", type=int, choices=0,1,2,
    help="increase output verbosity")
args = parser.parse_args()
answer = args.square**2
if args.verbosity == 2:
    print("the square of {} equals {}".format(args.square, answer))
elif args.verbosity == 1:
    print("{}^2 == {}".format(args.square, answer))
else:
    print(answer)
```

And the output:

```
$ python3 prog.py 4 -v 3
usage: prog.py [-h] [-v {0,1,2}] square
prog.py: error: argument -v/--verbosity: invalid choice: 3 (choose from 0, 1, 2)
$ python3 prog.py 4 -h
usage: prog.py [-h] [-v {0,1,2}] square

positional arguments:
    square: display a square of a given number

optional arguments:
    -h, --help: show this help message and exit
    -v {0,1,2}, --verbosity {0,1,2}: increase output verbosity
```

Note that the change also reflects both in the error message as well as the help string.
Now, let's use a different approach of playing with verbosity, which is pretty common. It also matches the way the CPython executable handles its own verbosity argument (check the output of `python --help`):

```python
import argparse
parser = argparse.ArgumentParser()
parser.add_argument("square", type=int,
    help="display the square of a given number")
parser.add_argument("-v", "--verbosity", action="count",
    help="increase output verbosity")
args = parser.parse_args()
answer = args.square**2
if args.verbosity == 2:
    print("the square of {} equals {}".format(args.square, answer))
elif args.verbosity == 1:
    print("{}^2 == {}".format(args.square, answer))
else:
    print(answer)
```

We have introduced another action, “count”, to count the number of occurrences of a specific optional arguments:

```
$ python3 prog.py 4
16
$ python3 prog.py 4 -v
4^2 == 16
$ python3 prog.py 4 -vv
the square of 4 equals 16
$ python3 prog.py 4 --verbosity --verbosity
the square of 4 equals 16
$ python3 prog.py 4 -v 1
usage: prog.py [-h] [-v] square
prog.py: error: unrecognized arguments: 1
$ python3 prog.py 4 -h
```
usage: prog.py [-h] [-v] square

positional arguments:
  square display a square of a given number

optional arguments:
  -h, --help          show this help message and exit
  -v, --verbosity    increase output verbosity

$ python3 prog.py 4 -vvv
16

- Yes, it's now more of a flag (similar to action="store_true") in the previous version of our script. That should explain the complaint.
- It also behaves similar to “store_true” action.
- Now here's a demonstration of what the “count” action gives. You've probably seen this sort of usage before.
- And, just like the “store_true” action, if you don't specify the -v flag, that flag is considered to have None value.
- As should be expected, specifying the long form of the flag, we should get the same output.
- Sadly, our help output isn't very informative on the new ability our script has acquired, but that can always be fixed by improving the documentation for our script (e.g. via the help keyword argument).
- That last output exposes a bug in our program.

Let's fix:

```python
import argparse
parser = argparse.ArgumentParser()
parser.add_argument("square", type=int,
  help="display a square of a given number")
parser.add_argument("-v", "--verbosity", action="count",
  help="increase output verbosity")
```
args = parser.parse_args()
answer = args.square**2

# bugfix: replace == with >=
if args.verbosity >= 2:
    print("the square of {} equals {}".format(args.square, answer))
elif args.verbosity >= 1:
    print("{}^2 == {}".format(args.square, answer))
else:
    print(answer)

And this is what it gives:

$ python3 prog.py 4 -vvv
the square of 4 equals 16
$ python3 prog.py 4 -vvvv
the square of 4 equals 16
$ python3 prog.py 4
Traceback (most recent call last):
  File "prog.py", line 11, in <module>
    if args.verbosity >= 2:
TypeError: unorderable types: NoneType() >= int()

- First output went well, and fixes the bug we had before. That is, we want any value >= 2 to be as verbose as possible.
- Third output not so good.

Let's fix that bug:

```python
import argparse
parser = argparse.ArgumentParser()
parser.add_argument("square", type=int,
    help="display a square of a given")
parser.add_argument("-v", "--verbosity", action="count",
    help="increase output verbosity")
args = parser.parse_args()
```
```python
answer = args.square**2
if args.verbosity >= 2:
    print("the square of {} equals {}".format(args.square, answer))
elif args.verbosity >= 1:
    print("{}^2 == {}".format(args.square, answer))
else:
    print(answer)
```

We've just introduced yet another keyword, `default`. We've set it to 0 in order to make it comparable to the other int values. Remember that by default, if an optional argument isn't specified, it gets the None value, and that cannot be compared to an int value (hence the `TypeError` exception).

And:

```
$ python3 prog.py 4
16
```

You can go quite far just with what we've learned so far, and we have only scratched the surface. The `argparse` module is very powerful, and we'll explore a bit more of it before we end this tutorial.
Getting a little more advanced

What if we wanted to expand our tiny program to perform other powers, not just squares:

```python
import argparse
parser = argparse.ArgumentParser()
parser.add_argument("x", type=int, help="the base")
parser.add_argument("y", type=int, help="the exponent")
parser.add_argument("-v", "--verbosity", action="count")
args = parser.parse_args()
answer = args.x**args.y
if args.verbosity >= 2:
    print("{} to the power {} equals {}".format(args.x, args.y, answer))
elif args.verbosity >= 1:
    print("{}^{} == {}".format(args.x, args.y, answer))
else:
    print(answer)
```

Output:

```
$ python3 prog.py
usage: prog.py [-h] [-v] x y
prog.py: error: the following arguments are required
$ python3 prog.py -h
usage: prog.py [-h] [-v] x y

positional arguments:
  x       the base
  y       the exponent

optional arguments:
  -h, --help    show this help message and exit
  -v, --verbosity
```
Notice that so far we’ve been using verbosity level to change the text that gets displayed. The following example instead uses verbosity level to display more text instead:

```python
import argparse
parser = argparse.ArgumentParser()
parser.add_argument("x", type=int, help="the base")
parser.add_argument("y", type=int, help="the exponent")
parser.add_argument("-v", "--verbosity", action="count")
args = parser.parse_args()
answer = args.x**args.y
if args.verbosity >= 2:
    print("Running '{}'".format(__file__))
if args.verbosity >= 1:
    print("{}^{} == " .format(args.x, args.y), end=""
print(answer)
```

Output:

```
$ python3 prog.py 4 2
16
$ python3 prog.py 4 2 -v
4^2 == 16
$ python3 prog.py 4 2 -vv
Running 'prog.py'
4^2 == 16
```

Conflicting options

So far, we have been working with two methods of an
**argparse.ArgumentParser** instance. Let's introduce a third one, `add_mutually_exclusive_group()`. It allows for us to specify options that conflict with each other. Let's also change the rest of the program so that the new functionality makes more sense: we'll introduce the `--quiet` option, which will be the opposite of the `--verbose` one:

```python
import argparse

parser = argparse.ArgumentParser()
group = parser.add_mutually_exclusive_group()
group.add_argument("-v", "--verbose", action="store_true")
group.add_argument("-q", "--quiet", action="store_true")
parser.add_argument("x", type=int, help="the base")
parser.add_argument("y", type=int, help="the exponent")

args = parser.parse_args()
answer = args.x**args.y

if args.quiet:
    print(answer)
elif args.verbose:
    print("{} to the power {} equals {}".format(args.x, args.y, answer))
else:
    print("{}^{} == {}".format(args.x, args.y, answer))
```

Our program is now simpler, and we've lost some functionality for the sake of demonstration. Anyways, here's the output:

```
$ python3 prog.py 4 2
4^2 == 16
$ python3 prog.py 4 2 -q
16
$ python3 prog.py 4 2 -v
4 to the power 2 equals 16
```
That should be easy to follow. I've added that last output so you can see the sort of flexibility you get, i.e. mixing long form options with short form ones.

Before we conclude, you probably want to tell your users the main purpose of your program, just in case they don't know:

```python
import argparse

parser = argparse.ArgumentParser(description="calculate X to the power Y")
group = parser.add_mutually_exclusive_group()
group.add_argument("-v", "--verbose", action="store_true")
group.add_argument("-q", "--quiet", action="store_true")
parser.add_argument("x", type=int, help="the base")
parser.add_argument("y", type=int, help="the exponent")

args = parser.parse_args()

answer = args.x**args.y

if args.quiet:
    print(answer)
elif args.verbose:
    print("{} to the power {} equals {}".format(args.x, args.y, answer))
else:
    print("{}^{} == {}".format(args.x, args.y, answer))
```

Note that slight difference in the usage text. Note the `[-v | -q]`, which tells us that we can either use `-v` or `-q`, but not both at the
same time:

```
$ python3 prog.py --help
usage: prog.py [-h] [-v | -q] x y

calculate X to the power of Y

positional arguments:
  x               the base
  y               the exponent

optional arguments:
  -h, --help      show this help message and exit
  -v, --verbose
  -q, --quiet
```
Conclusion

The argparse module offers a lot more than shown here. Its docs are quite detailed and thorough, and full of examples. Having gone through this tutorial, you should easily digest them without feeling overwhelmed.
An introduction to the ipaddress module

author: Peter Moody
author: Nick Coghlan

Overview

This document aims to provide a gentle introduction to the ipaddress module. It is aimed primarily at users that aren't already familiar with IP networking terminology, but may also be useful to network engineers wanting an overview of how ipaddress represents IP network addressing concepts.
Creating Address/Network/Interface objects

Since `ipaddress` is a module for inspecting and manipulating IP addresses, the first thing you'll want to do is create some objects. You can use `ipaddress` to create objects from strings and integers.

A Note on IP Versions

For readers that aren't particularly familiar with IP addressing, it's important to know that the Internet Protocol is currently in the process of moving from version 4 of the protocol to version 6. This transition is occurring largely because version 4 of the protocol doesn't provide enough addresses to handle the needs of the whole world, especially given the increasing number of devices with direct connections to the internet.

Explaining the details of the differences between the two versions of the protocol is beyond the scope of this introduction, but readers need to at least be aware that these two versions exist, and it will sometimes be necessary to force the use of one version or the other.

IP Host Addresses

Addresses, often referred to as “host addresses” are the most basic unit when working with IP addressing. The simplest way to create addresses is to use the `ipaddress.ip_address()` factory function, which automatically determines whether to create an IPv4 or IPv6 address based on the passed in value:
Addresses can also be created directly from integers. Values that will fit within 32 bits are assumed to be IPv4 addresses:

```python
>>> ipaddress.ip_address('192.0.2.1')
IPv4Address('192.0.2.1')
>>> ipaddress.ip_address('2001:DB8::1')
IPv6Address('2001:db8::1')
```

To force the use of IPv4 or IPv6 addresses, the relevant classes can be invoked directly. This is particularly useful to force creation of IPv6 addresses for small integers:

```python
>>> ipaddress.ip_address(3221225985)
IPv4Address('192.0.2.1')
>>> ipaddress.ip_address(42540766411285928569039849)
IPv6Address('2001:db8::1')
```

### Defining Networks

Host addresses are usually grouped together into IP networks, so `ipaddress` provides a way to create, inspect and manipulate network definitions. IP network objects are constructed from strings that define the range of host addresses that are part of that network. The simplest form for that information is a “network address/network prefix” pair, where the prefix defines the number of leading bits that are compared to determine whether or not an address is part of the network and the
network address defines the expected value of those bits.

As for addresses, a factory function is provided that determines the correct IP version automatically:

```python
>>> ipaddress.ip_network('192.0.2.0/24')
IPv4Network('192.0.2.0/24')
>>> ipaddress.ip_network('2001:db8::0/96')
IPv6Network('2001:db8::/96')
```

Network objects cannot have any host bits set. The practical effect of this is that `192.0.2.1/24` does not describe a network. Such definitions are referred to as interface objects since the ip-on-a-network notation is commonly used to describe network interfaces of a computer on a given network and are described further in the next section.

By default, attempting to create a network object with host bits set will result in `ValueError` being raised. To request that the additional bits instead be coerced to zero, the flag `strict=False` can be passed to the constructor:

```python
>>> ipaddress.ip_network('192.0.2.1/24')
Traceback (most recent call last):
 ... 
ValueError: 192.0.2.1/24 has host bits set
>>> ipaddress.ip_network('192.0.2.1/24', strict=False)
IPv4Network('192.0.2.0/24')
```

While the string form offers significantly more flexibility, networks can also be defined with integers, just like host addresses. In this case, the network is considered to contain only the single address identified by the integer, so the network prefix includes the entire network address:
As with addresses, creation of a particular kind of network can be forced by calling the class constructor directly instead of using the factory function.

**Host Interfaces**

As mentioned just above, if you need to describe an address on a particular network, neither the address nor the network classes are sufficient. Notation like `192.0.2.1/24` is commonly used by network engineers and the people who write tools for firewalls and routers as shorthand for “the host 192.0.2.1 on the network 192.0.2.0/24”, Accordingly, `ipaddress` provides a set of hybrid classes that associate an address with a particular network. The interface for creation is identical to that for defining network objects, except that the address portion isn’t constrained to being a network address.

```python
>>> ipaddress.ip_interface('192.0.2.1/24')
IPv4Interface('192.0.2.1/24')
>>> ipaddress.ip_interface('2001:db8::1/96')
IPv6Interface('2001:db8::1/96')
```

Integer inputs are accepted (as with networks), and use of a particular IP version can be forced by calling the relevant constructor directly.
Inspecting Address/Network/Interface Objects

You’ve gone to the trouble of creating an IPv(4|6) (Address|Network|Interface) object, so you probably want to get information about it. `ipaddress` tries to make doing this easy and intuitive.

Extracting the IP version:

```python
>>> addr4 = ipaddress.ip_address('192.0.2.1')
>>> addr6 = ipaddress.ip_address('2001:db8::1')
>>> addr6.version
6
>>> addr4.version
4
```

Obtaining the network from an interface:

```python
>>> host4 = ipaddress.ip_interface('192.0.2.1/24')
>>> host4.network
IPv4Network('192.0.2.0/24')
>>> host6 = ipaddress.ip_interface('2001:db8::1/96')
>>> host6.network
IPv6Network('2001:db8::/96')
```

Finding out how many individual addresses are in a network:

```python
>>> net4 = ipaddress.ip_network('192.0.2.0/24')
>>> net4.num_addresses
256
>>> net6 = ipaddress.ip_network('2001:db8::/96')
>>> net6.num_addresses
```
Iterating through the “usable” addresses on a network:

```python
>>> net4 = ipaddress.ip_network('192.0.2.0/24')
>>> for x in net4.hosts():
...    print(x)
192.0.2.1
192.0.2.2
192.0.2.3
192.0.2.4
...
192.0.2.252
192.0.2.253
192.0.2.254
```

Obtaining the netmask (i.e. set bits corresponding to the network prefix) or the hostmask (any bits that are not part of the netmask):

```python
>>> net4 = ipaddress.ip_network('192.0.2.0/24')
>>> net4.netmask
IPv4Address('255.255.255.0')
>>> net4.hostmask
IPv4Address('0.0.0.255')
>>> net6 = ipaddress.ip_network('2001:db8::0/96')
>>> net6.netmask
>>> net6.hostmask
IPv6Address('::ffff:ffff')
```

Exploding or compressing the address:

```python
>>> addr6.exploded
'2001:0db8:0000:0000:0000:0000:0000:0001'
>>> addr6.compressed
'2001:db8::1'
```
While IPv4 doesn't support explosion or compression, the associated objects still provide the relevant properties so that version neutral code can easily ensure the most concise or most verbose form is used for IPv6 addresses while still correctly handling IPv4 addresses.
Networks as lists of Addresses

It’s sometimes useful to treat networks as lists. This means it is possible to index them like this:

```
>>> net4[1]
IPv4Address('192.0.2.1')
>>> net4[-1]
IPv4Address('192.0.2.255')
>>> net6[1]
IPv6Address('2001:db8::1')
>>> net6[-1]
IPv6Address('2001:db8::ffff:ffff')
```

It also means that network objects lend themselves to using the list membership test syntax like this:

```python
if address in network:
    # do something
```

Containment testing is done efficiently based on the network prefix:

```python
>>> addr4 = ipaddress.ip_address('192.0.2.1')
>>> addr4 in ipaddress.ip_network('192.0.2.0/24')
True
>>> addr4 in ipaddress.ip_network('192.0.3.0/24')
False
```
Comparisons

`ipaddress` provides some simple, hopefully intuitive ways to compare objects, where it makes sense:

```python
>>> ipaddress.ip_address('192.0.2.1') < ipaddress.ip_address('192.0.2.2')
True
```

A `TypeError` exception is raised if you try to compare objects of different versions or different types.
Using IP Addresses with other modules

Other modules that use IP addresses (such as `socket`) usually won’t accept objects from this module directly. Instead, they must be coerced to an integer or string that the other module will accept:

```python
>>> addr4 = ipaddress.ip_address('192.0.2.1')
>>> str(addr4)
'192.0.2.1'
>>> int(addr4)
3221225985
```
Getting more detail when instance creation fails

When creating address/network/interface objects using the version-agnostic factory functions, any errors will be reported as `ValueError` with a generic error message that simply says the passed in value was not recognized as an object of that type. The lack of a specific error is because it's necessary to know whether the value is supposed to be IPv4 or IPv6 in order to provide more detail on why it has been rejected.

To support use cases where it is useful to have access to this additional detail, the individual class constructors actually raise the `ValueError` subclasses `ipaddress.AddressValueError` and `ipaddress.NetmaskValueError` to indicate exactly which part of the definition failed to parse correctly.

The error messages are significantly more detailed when using the class constructors directly. For example:

```python
>>> ipaddress.ip_address("192.168.0.256")
Traceback (most recent call last):
...
ValueError: '192.168.0.256' does not appear to be an IPv4 or IPv6 address

>>> ipaddress.IPv4Address("192.168.0.256")
Traceback (most recent call last):
...
ipaddress.AddressValueError: Octet 256 (> 255) not permitted in '192.168.0.256'

>>> ipaddress.ip_network("192.168.0.1/64")
Traceback (most recent call last):
...
ValueError: '192.168.0.1/64' does not appear to be a network
```
>>> ipAddress.IPv4Network("192.168.0.1/64")
Traceback (most recent call last):
...
ipaddress.NetmaskValueError: '64' is not a valid net

However, both of the module specific exceptions have ValueError as their parent class, so if you’re not concerned with the particular type of error, you can still write code like the following:

```python
try:
    network = ipAddress.IPv4Network(address)
except ValueError:
    print('address/netmask is invalid for IPv4:', address)
```

General Information

What is Python?

Python is an interpreted, interactive, object-oriented programming language. It incorporates modules, exceptions, dynamic typing, very high level dynamic data types, and classes. Python combines remarkable power with very clear syntax. It has interfaces to many system calls and libraries, as well as to various window systems, and is extensible in C or C++. It is also usable as an extension language for applications that need a programmable interface. Finally, Python is portable: it runs on many Unix variants, on the Mac, and on Windows 2000 and later.

To find out more, start with *The Python Tutorial*. The Beginner’s Guide to Python links to other introductory tutorials and resources for learning Python.

What is the Python Software Foundation?

The Python Software Foundation is an independent non-profit organization that holds the copyright on Python versions 2.1 and newer. The PSF’s mission is to advance open source technology related to the Python programming language and to publicize the use of Python. The PSF’s home page is at http://www.python.org/psf/.

Donations to the PSF are tax-exempt in the US. If you use Python and find it helpful, please contribute via the PSF donation page.

Are there copyright restrictions on the use of Python?
You can do anything you want with the source, as long as you leave the copyrights in and display those copyrights in any documentation about Python that you produce. If you honor the copyright rules, it's OK to use Python for commercial use, to sell copies of Python in source or binary form (modified or unmodified), or to sell products that incorporate Python in some form. We would still like to know about all commercial use of Python, of course.

See the PSF license page to find further explanations and a link to the full text of the license.

The Python logo is trademarked, and in certain cases permission is required to use it. Consult the Trademark Usage Policy for more information.

**Why was Python created in the first place?**

Here's a very brief summary of what started it all, written by Guido van Rossum:

I had extensive experience with implementing an interpreted language in the ABC group at CWI, and from working with this group I had learned a lot about language design. This is the origin of many Python features, including the use of indentation for statement grouping and the inclusion of very-high-level data types (although the details are all different in Python).

I had a number of gripes about the ABC language, but also liked many of its features. It was impossible to extend the ABC language (or its implementation) to remedy my complaints – in fact its lack of extensibility was one of its biggest problems. I had some experience with using Modula-2+ and talked with the designers of Modula-3 and read the Modula-3 report. Modula-3 is
the origin of the syntax and semantics used for exceptions, and some other Python features.

I was working in the Amoeba distributed operating system group at CWI. We needed a better way to do system administration than by writing either C programs or Bourne shell scripts, since Amoeba had its own system call interface which wasn't easily accessible from the Bourne shell. My experience with error handling in Amoeba made me acutely aware of the importance of exceptions as a programming language feature.

It occurred to me that a scripting language with a syntax like ABC but with access to the Amoeba system calls would fill the need. I realized that it would be foolish to write an Amoeba-specific language, so I decided that I needed a language that was generally extensible.

During the 1989 Christmas holidays, I had a lot of time on my hand, so I decided to give it a try. During the next year, while still mostly working on it in my own time, Python was used in the Amoeba project with increasing success, and the feedback from colleagues made me add many early improvements.

In February 1991, after just over a year of development, I decided to post to USENET. The rest is in the Misc/HISTORY file.

What is Python good for?

Python is a high-level general-purpose programming language that can be applied to many different classes of problems.

The language comes with a large standard library that covers areas such as string processing (regular expressions, Unicode, calculating
differences between files), Internet protocols (HTTP, FTP, SMTP, XML-RPC, POP, IMAP, CGI programming), software engineering (unit testing, logging, profiling, parsing Python code), and operating system interfaces (system calls, filesystems, TCP/IP sockets). Look at the table of contents for *The Python Standard Library* to get an idea of what’s available. A wide variety of third-party extensions are also available. Consult the *Python Package Index* to find packages of interest to you.

**How does the Python version numbering scheme work?**

Python versions are numbered A.B.C or A.B. A is the major version number – it is only incremented for really major changes in the language. B is the minor version number, incremented for less earth-shattering changes. C is the micro-level – it is incremented for each bugfix release. See PEP 6 for more information about bugfix releases.

Not all releases are bugfix releases. In the run-up to a new major release, a series of development releases are made, denoted as alpha, beta, or release candidate. Alphas are early releases in which interfaces aren’t yet finalized; it’s not unexpected to see an interface change between two alpha releases. Betas are more stable, preserving existing interfaces but possibly adding new modules, and release candidates are frozen, making no changes except as needed to fix critical bugs.

Alpha, beta and release candidate versions have an additional suffix. The suffix for an alpha version is “aN” for some small number N, the suffix for a beta version is “bN” for some small number N, and the suffix for a release candidate version is “cN” for some small number N. In other words, all versions labeled 2.0aN precede the versions
labeled 2.0bN, which precede versions labeled 2.0cN, and those precede 2.0.

You may also find version numbers with a “+” suffix, e.g. “2.2+”. These are unreleased versions, built directly from the Subversion trunk. In practice, after a final minor release is made, the Subversion trunk is incremented to the next minor version, which becomes the “a0” version, e.g. “2.4a0”.

See also the documentation for `sys.version`, `sys.hexversion`, and `sys.version_info`.

**How do I obtain a copy of the Python source?**

The source distribution is a gzipped tar file containing the complete C source, Sphinx-formatted documentation, Python library modules, example programs, and several useful pieces of freely distributable software. The source will compile and run out of the box on most UNIX platforms.

Consult the [Developer FAQ](http://docs.python.org/) for more information on getting the source code and compiling it.

**How do I get documentation on Python?**

The standard documentation for the current stable version of Python is available at [http://docs.python.org/](http://docs.python.org/). PDF, plain text, and downloadable
I’ve never programmed before. Is there a Python tutorial?

There are numerous tutorials and books available. The standard documentation includes *The Python Tutorial*.

Consult the Beginner’s Guide to find information for beginning Python programmers, including lists of tutorials.

Is there a newsgroup or mailing list devoted to Python?

There is a newsgroup, *comp.lang.python*, and a mailing list, *python-list*. The newsgroup and mailing list are gatewayed into each other – if you can read news it’s unnecessary to subscribe to the mailing list. *comp.lang.python* is high-traffic, receiving hundreds of postings every day, and Usenet readers are often more able to cope with this volume.

Announcements of new software releases and events can be found in comp.lang.python.announce, a low-traffic moderated list that receives about five postings per day. It’s available as the python-announce mailing list.

More info about other mailing lists and newsgroups can be found at http://www.python.org/community/lists/.
How do I get a beta test version of Python?

Alpha and beta releases are available from http://www.python.org/download/. All releases are announced on the comp.lang.python and comp.lang.python.announce newsgroups and on the Python home page at http://www.python.org/; an RSS feed of news is available.

You can also access the development version of Python through Subversion. See http://docs.python.org/devguide/faq for details.

How do I submit bug reports and patches for Python?

To report a bug or submit a patch, please use the Roundup installation at http://bugs.python.org/.

You must have a Roundup account to report bugs; this makes it possible for us to contact you if we have follow-up questions. It will also enable Roundup to send you updates as we act on your bug. If you had previously used SourceForge to report bugs to Python, you can obtain your Roundup password through Roundup's password reset procedure.

For more information on how Python is developed, consult the Python Developer’s Guide.

Are there any published articles about Python that I can reference?

It's probably best to cite your favorite book about Python.
The very first article about Python was written in 1991 and is now quite outdated.

Are there any books on Python?

Yes, there are many, and more are being published. See the python.org wiki at http://wiki.python.org/moin/PythonBooks for a list.

You can also search online bookstores for “Python” and filter out the Monty Python references; or perhaps search for “Python” and “language”.

Where in the world is www.python.org located?

It’s currently in Amsterdam, graciously hosted by XS4ALL. Thanks to Thomas Wouters for his work in arranging python.org’s hosting.

Why is it called Python?

When he began implementing Python, Guido van Rossum was also reading the published scripts from “Monty Python’s Flying Circus”, a BBC comedy series from the 1970s. Van Rossum thought he needed a name that was short, unique, and slightly mysterious, so he decided to call the language Python.

Do I have to like “Monty Python’s Flying Circus”? 
No, but it helps. :(
Python in the real world

How stable is Python?

Very stable. New, stable releases have been coming out roughly every 6 to 18 months since 1991, and this seems likely to continue. Currently there are usually around 18 months between major releases.

The developers issue “bugfix” releases of older versions, so the stability of existing releases gradually improves. Bugfix releases, indicated by a third component of the version number (e.g. 2.5.3, 2.6.2), are managed for stability; only fixes for known problems are included in a bugfix release, and it’s guaranteed that interfaces will remain the same throughout a series of bugfix releases.

The latest stable releases can always be found on the Python download page. There are two recommended production-ready versions at this point in time, because at the moment there are two branches of stable releases: 2.x and 3.x. Python 3.x may be less useful than 2.x, since currently there is more third party software available for Python 2 than for Python 3. Python 2 code will generally not run unchanged in Python 3.

How many people are using Python?

There are probably tens of thousands of users, though it’s difficult to obtain an exact count.

Python is available for free download, so there are no sales figures, and it’s available from many different sites and packaged with many Linux distributions, so download statistics don’t tell the whole story either.
The comp.lang.python newsgroup is very active, but not all Python users post to the group or even read it.

**Have any significant projects been done in Python?**

See [http://python.org/about/success](http://python.org/about/success) for a list of projects that use Python. Consulting the proceedings for past Python conferences will reveal contributions from many different companies and organizations.

High-profile Python projects include the Mailman mailing list manager and the Zope application server. Several Linux distributions, most notably Red Hat, have written part or all of their installer and system administration software in Python. Companies that use Python internally include Google, Yahoo, and Lucasfilm Ltd.

**What new developments are expected for Python in the future?**

See [http://www.python.org/dev/peps/](http://www.python.org/dev/peps/) for the Python Enhancement Proposals (PEPs). PEPs are design documents describing a suggested new feature for Python, providing a concise technical specification and a rationale. Look for a PEP titled “Python X.Y Release Schedule”, where X.Y is a version that hasn’t been publicly released yet.

New development is discussed on the python-dev mailing list.

**Is it reasonable to propose incompatible changes to Python?**
In general, no. There are already millions of lines of Python code around the world, so any change in the language that invalidates more than a very small fraction of existing programs has to be frowned upon. Even if you can provide a conversion program, there’s still the problem of updating all documentation; many books have been written about Python, and we don’t want to invalidate them all at a single stroke.

Providing a gradual upgrade path is necessary if a feature has to be changed. **PEP 5** describes the procedure followed for introducing backward-incompatible changes while minimizing disruption for users.

**Is Python Y2K (Year 2000) Compliant?**

As of August, 2003 no major problems have been reported and Y2K compliance seems to be a non-issue.

Python does very few date calculations and for those it does perform relies on the C library functions. Python generally represents times either as seconds since 1970 or as a `(year, month, day, ...)` tuple where the year is expressed with four digits, which makes Y2K bugs unlikely. So as long as your C library is okay, Python should be okay. Of course, it’s possible that a particular application written in Python makes assumptions about 2-digit years.

Because Python is available free of charge, there are no absolute guarantees. If there are unforeseen problems, liability is the user’s problem rather than the developers’, and there is nobody you can sue for damages. The Python copyright notice contains the following disclaimer:

4. PSF is making Python 2.3 available to Licensee on an “AS IS” basis. **PSF MAKES NO REPRESENTATIONS OR WARRANTIES,**
EXPRESS OR IMPLIED. BY WAY OF EXAMPLE, BUT NOT LIMITATION, PSF MAKES NO AND DISCLAIMS ANY REPRESENTATION OR WARRANTY OF MERCHANTABILITY OR FITNESS FOR ANY PARTICULAR PURPOSE OR THAT THE USE OF PYTHON 2.3 WILL NOT INFRINGE ANY THIRD PARTY RIGHTS.

5. PSF SHALL NOT BE LIABLE TO LICENSEE OR ANY OTHER USERS OF PYTHON 2.3 FOR ANY INCIDENTAL, SPECIAL, OR CONSEQUENTIAL DAMAGES OR LOSS AS A RESULT OF MODIFYING, DISTRIBUTING, OR OTHERWISE USING PYTHON 2.3, OR ANY DERIVATIVE THEREOF, EVEN IF ADVISED OF THE POSSIBILITY THEREOF.

The good news is that if you encounter a problem, you have full source available to track it down and fix it. This is one advantage of an open source programming environment.

Is Python a good language for beginning programmers?

Yes.

It is still common to start students with a procedural and statically typed language such as Pascal, C, or a subset of C++ or Java. Students may be better served by learning Python as their first language. Python has a very simple and consistent syntax and a large standard library and, most importantly, using Python in a beginning programming course lets students concentrate on important programming skills such as problem decomposition and data type design. With Python, students can be quickly introduced to basic concepts such as loops and procedures. They can probably even work
with user-defined objects in their very first course.

For a student who has never programmed before, using a statically typed language seems unnatural. It presents additional complexity that the student must master and slows the pace of the course. The students are trying to learn to think like a computer, decompose problems, design consistent interfaces, and encapsulate data. While learning to use a statically typed language is important in the long term, it is not necessarily the best topic to address in the students' first programming course.

Many other aspects of Python make it a good first language. Like Java, Python has a large standard library so that students can be assigned programming projects very early in the course that *do* something. Assignments aren’t restricted to the standard four-function calculator and check balancing programs. By using the standard library, students can gain the satisfaction of working on realistic applications as they learn the fundamentals of programming. Using the standard library also teaches students about code reuse. Third-party modules such as PyGame are also helpful in extending the students' reach.

Python's interactive interpreter enables students to test language features while they're programming. They can keep a window with the interpreter running while they enter their program's source in another window. If they can't remember the methods for a list, they can do something like this:

```python
>>> L = []
>>> dir(L)
['append', 'count', 'extend', 'index', 'insert', 'pop', 'remove', 'reverse', 'sort']
>>> help(L.append)
```
Help on built-in function append:

```python
append(...)  
    L.append(object) -- append object to end
>>> L.append(1)
>>> L
[1]
```

With the interpreter, documentation is never far from the student as he’s programming.

There are also good IDEs for Python. IDLE is a cross-platform IDE for Python that is written in Python using Tkinter. PythonWin is a Windows-specific IDE. Emacs users will be happy to know that there is a very good Python mode for Emacs. All of these programming environments provide syntax highlighting, auto-indenting, and access to the interactive interpreter while coding. Consult http://www.python.org/editors/ for a full list of Python editing environments.

If you want to discuss Python’s use in education, you may be interested in joining the edu-sig mailing list.

  - How do I create a .pyc file?
  - How do I find the current module name?
  - How can I have modules that mutually import each other?
  - __import__(‘x.y.z’) returns <module ‘x’>; how do I get z?
  - When I edit an imported module and reimport it, the changes don’t show up. Why does this happen?
General Questions

Is there a source code level debugger with breakpoints, single-stepping, etc.?

Yes.

The pdb module is a simple but adequate console-mode debugger for Python. It is part of the standard Python library, and is documented in the Library Reference Manual. You can also write your own debugger by using the code for pdb as an example.

The IDLE interactive development environment, which is part of the standard Python distribution (normally available as Tools/scripts/idle), includes a graphical debugger. There is documentation for the IDLE debugger at http://www.python.org/idle/doc/idle2.html#Debugger.

PythonWin is a Python IDE that includes a GUI debugger based on pdb. The Pythonwin debugger colors breakpoints and has quite a few cool features such as debugging non-Pythonwin programs. Pythonwin is available as part of the Python for Windows Extensions project and as a part of the ActivePython distribution (see http://www.activestate.com/Products/ActivePython/index.html).

Boa Constructor is an IDE and GUI builder that uses wxWidgets. It offers visual frame creation and manipulation, an object inspector, many views on the source like object browsers, inheritance hierarchies, doc string generated html documentation, an advanced debugger, integrated help, and Zope support.

Eric is an IDE built on PyQt and the Scintilla editing component.
Pydb is a version of the standard Python debugger pdb, modified for use with DDD (Data Display Debugger), a popular graphical debugger front end. Pydb can be found at http://bashdb.sourceforge.net/pydb/ and DDD can be found at http://www.gnu.org/software/ddd.

There are a number of commercial Python IDEs that include graphical debuggers. They include:

- Wing IDE (http://wingware.com/)
- Komodo IDE (http://www.activestate.com/Products/Komodo)

Is there a tool to help find bugs or perform static analysis?

Yes.

PyChecker is a static analysis tool that finds bugs in Python source code and warns about code complexity and style. You can get PyChecker from http://pychecker.sf.net.

Pylint is another tool that checks if a module satisfies a coding standard, and also makes it possible to write plug-ins to add a custom feature. In addition to the bug checking that PyChecker performs, Pylint offers some additional features such as checking line length, whether variable names are well-formed according to your coding standard, whether declared interfaces are fully implemented, and more. http://www.logilab.org/card/pylint_manual provides a full list of Pylint’s features.

How can I create a stand-alone binary from a Python script?
You don’t need the ability to compile Python to C code if all you want is a stand-alone program that users can download and run without having to install the Python distribution first. There are a number of tools that determine the set of modules required by a program and bind these modules together with a Python binary to produce a single executable.

One is to use the freeze tool, which is included in the Python source tree as `Tools/freeze`. It converts Python byte code to C arrays; a C compiler you can embed all your modules into a new program, which is then linked with the standard Python modules.

It works by scanning your source recursively for import statements (in both forms) and looking for the modules in the standard Python path as well as in the source directory (for built-in modules). It then turns the bytecode for modules written in Python into C code (array initializers that can be turned into code objects using the marshal module) and creates a custom-made config file that only contains those built-in modules which are actually used in the program. It then compiles the generated C code and links it with the rest of the Python interpreter to form a self-contained binary which acts exactly like your script.

Obviously, freeze requires a C compiler. There are several other utilities which don’t. One is Thomas Heller’s py2exe (Windows only) at http://www.py2exe.org/

Another is Christian Tismer’s SQFREEZE which appends the byte code to a specially-prepared Python interpreter that can find the byte code in the executable.

Other tools include Fredrik Lundh’s Squeeze and Anthony Tuininga’s
Are there coding standards or a style guide for Python programs?

Yes. The coding style required for standard library modules is documented as PEP 8.
Core Language

Why am I getting an UnboundLocalError when the variable has a value?

It can be a surprise to get the UnboundLocalError in previously working code when it is modified by adding an assignment statement somewhere in the body of a function.

This code:

```python
>>> x = 10
>>> def bar():
...     print(x)
>>> bar()
10
```

works, but this code:

```python
>>> x = 10
>>> def foo():
...     print(x)
...     x += 1
```

results in an UnboundLocalError:

```python
>>> foo()
Traceback (most recent call last):
...
UnboundLocalError: local variable 'x' referenced before assignment
```

This is because when you make an assignment to a variable in a scope, that variable becomes local to that scope and shadows any
similarly named variable in the outer scope. Since the last statement in foo assigns a new value to \(x\), the compiler recognizes it as a local variable. Consequently when the earlier \texttt{print}(x)\) attempts to print the uninitialized local variable and an error results.

In the example above you can access the outer scope variable by declaring it global:

```python
>>> x = 10
>>> def foobar():
...     global x
...     print(x)
...     x += 1
>>> foobar()
10
```

This explicit declaration is required in order to remind you that (unlike the superficially analogous situation with class and instance variables) you are actually modifying the value of the variable in the outer scope:

```python
>>> print(x)
11
```

You can do a similar thing in a nested scope using the \texttt{nonlocal} keyword:

```python
>>> def foo():
...     x = 10
...     def bar():
...         nonlocal x
...         print(x)
...         x += 1
...         bar()
...         print(x)
>>> foo()
```
What are the rules for local and global variables in Python?

In Python, variables that are only referenced inside a function are implicitly global. If a variable is assigned a new value anywhere within the function's body, it's assumed to be a local. If a variable is ever assigned a new value inside the function, the variable is implicitly local, and you need to explicitly declare it as 'global'.

Though a bit surprising at first, a moment’s consideration explains this. On one hand, requiring `global` for assigned variables provides a bar against unintended side-effects. On the other hand, if `global` was required for all global references, you’d be using `global` all the time. You’d have to declare as global every reference to a built-in function or to a component of an imported module. This clutter would defeat the usefulness of the `global` declaration for identifying side-effects.

Why do lambdas defined in a loop with different values all return the same result?

Assume you use a for loop to define a few different lambdas (or even plain functions), e.g.:

```python
>>> squares = []
>>> for x in range(5):
...     squares.append(lambda: x**2)
```

This gives you a list that contains 5 lambdas that calculate `x**2`. You
might expect that, when called, they would return, respectively, 0, 1, 4, 9, and 16. However, when you actually try you will see that they all return 16:

```
>>> squares[2]()
16
>>> squares[4]()
16
```

This happens because $x$ is not local to the lambdas, but is defined in the outer scope, and it is accessed when the lambda is called — not when it is defined. At the end of the loop, the value of $x$ is 4, so all the functions now return $4**2$, i.e. 16. You can also verify this by changing the value of $x$ and see how the results of the lambdas change:

```
>>> x = 8
```

```
>>> squares[2]()
64
```

In order to avoid this, you need to save the values in variables local to the lambdas, so that they don't rely on the value of the global $x$:

```
>>> squares = []
>>> for x in range(5):
...     squares.append(lambda n=x: n**2)
```

Here, $n=x$ creates a new variable $n$ local to the lambda and computed when the lambda is defined so that it has the same value that $x$ had at that point in the loop. This means that the value of $n$ will be 0 in the first lambda, 1 in the second, 2 in the third, and so on. Therefore each lambda will now return the correct result:
Note that this behaviour is not peculiar to lambdas, but applies to regular functions too.

**How do I share global variables across modules?**

The canonical way to share information across modules within a single program is to create a special module (often called config or cfg). Just import the config module in all modules of your application; the module then becomes available as a global name. Because there is only one instance of each module, any changes made to the module object get reflected everywhere. For example:

```python
config.py:

```x = 0  # Default value of the 'x' configuration setting```

mod.py:

```python
import config
cfg.x = 1
```

main.py:

```python
import config
import mod
print(config.x)
```

Note that using a module is also the basis for implementing the
Singleton design pattern, for the same reason.

What are the “best practices” for using import in a module?

In general, don’t use `from modulename import *`. Doing so clutters the importer’s namespace. Some people avoid this idiom even with the few modules that were designed to be imported in this manner. Modules designed in this manner include `tkinter`, and `threading`.

Import modules at the top of a file. Doing so makes it clear what other modules your code requires and avoids questions of whether the module name is in scope. Using one import per line makes it easy to add and delete module imports, but using multiple imports per line uses less screen space.

It’s good practice if you import modules in the following order:

1. standard library modules – e.g. `sys`, `os`, `getopt`, `re`
2. third-party library modules (anything installed in Python’s site-packages directory) – e.g. `mx.DateTime`, `ZODB`, `PIL.Image`, etc.
3. locally-developed modules

Never use relative package imports. If you’re writing code that’s in the `package.sub.m1` module and want to import `package.sub.m2`, do not just write `from . import m2`, even though it’s legal. Write `from package.sub import m2` instead. See PEP 328 for details.

It is sometimes necessary to move imports to a function or class to avoid problems with circular imports. Gordon McMillan says:

Circular imports are fine where both modules use the “import
<module>" form of import. They fail when the 2nd module wants to grab a name out of the first ("from module import name") and the import is at the top level. That's because names in the 1st are not yet available, because the first module is busy importing the 2nd.

In this case, if the second module is only used in one function, then the import can easily be moved into that function. By the time the import is called, the first module will have finished initializing, and the second module can do its import.

It may also be necessary to move imports out of the top level of code if some of the modules are platform-specific. In that case, it may not even be possible to import all of the modules at the top of the file. In this case, importing the correct modules in the corresponding platform-specific code is a good option.

Only move imports into a local scope, such as inside a function definition, if it's necessary to solve a problem such as avoiding a circular import or are trying to reduce the initialization time of a module. This technique is especially helpful if many of the imports are unnecessary depending on how the program executes. You may also want to move imports into a function if the modules are only ever used in that function. Note that loading a module the first time may be expensive because of the one time initialization of the module, but loading a module multiple times is virtually free, costing only a couple of dictionary lookups. Even if the module name has gone out of scope, the module is probably available in sys.modules.

If only instances of a specific class use a module, then it is reasonable to import the module in the class's __init__ method and then assign the module to an instance variable so that the module is always available (via that instance variable) during the life of the object. Note that to delay an import until the class is instantiated, the import must
be inside a method. Putting the import inside the class but outside of any method still causes the import to occur when the module is initialized.

How can I pass optional or keyword parameters from one function to another?

Collect the arguments using the * and ** specifiers in the function’s parameter list; this gives you the positional arguments as a tuple and the keyword arguments as a dictionary. You can then pass these arguments when calling another function by using * and **:

```python
def f(x, *args, **kwargs):
    ...
    kwargs['width'] = '14.3c'
    ...
g(x, *args, **kwargs)
```

What is the difference between arguments and parameters?

Parameters are defined by the names that appear in a function definition, whereas arguments are the values actually passed to a function when calling it. Parameters define what types of arguments a function can accept. For example, given the function definition:

```python
def func(foo, bar=None, **kwargs):
    pass
```

`foo, bar` and `kwargs` are parameters of `func`. However, when calling `func`, for example:
How do I write a function with output parameters (call by reference)?

Remember that arguments are passed by assignment in Python. Since assignment just creates references to objects, there's no alias between an argument name in the caller and callee, and so no call-by-reference per se. You can achieve the desired effect in a number of ways.

1. By returning a tuple of the results:

```python
def func2(a, b):
a = 'new-value'
    # a and b are local names
b = b + 1
    # assigned to new objects
return a, b
    # return new values
```

```python
x, y = 'old-value', 99
x, y = func2(x, y)
print(x, y)  # output: new-value 100
```

This is almost always the clearest solution.

2. By using global variables. This isn't thread-safe, and is not recommended.

3. By passing a mutable (changeable in-place) object:

```python
def func1(a):
a[0] = 'new-value'
    # 'a' references a mutable
```
4. By passing in a dictionary that gets mutated:

```python
def func3(args):
    args['a'] = 'new-value'  # args is a mutable
    args['b'] = args['b'] + 1  # change it in-place

args = {'a': 'old-value', 'b': 99}
func3(args)
print(args['a'], args['b'])
```

5. Or bundle up values in a class instance:

```python
class callByRef:
    def __init__(self, **args):
        for (key, value) in args.items():
            setattr(self, key, value)

def func4(args):
    args.a = 'new-value'  # args is a mutable
    args.b = args.b + 1  # change object in-place

args = callByRef(a='old-value', b=99)
func4(args)
print(args.a, args.b)
```

There's almost never a good reason to get this complicated.

Your best choice is to return a tuple containing the multiple results.
How do you make a higher order function in Python?

You have two choices: you can use nested scopes or you can use callable objects. For example, suppose you wanted to define \( \text{linear}(a, b) \) which returns a function \( f(x) \) that computes the value \( a \times x + b \). Using nested scopes:

```python
def linear(a, b):
    def result(x):
        return a * x + b
    return result
```

Or using a callable object:

```python
class linear:
    def __init__(self, a, b):
        self.a, self.b = a, b
    def __call__(self, x):
        return self.a * x + self.b
```

In both cases,

```python
taxes = linear(0.3, 2)
```

gives a callable object where \( \text{taxes}(10\text{e}6) = 0.3 \times 10\text{e}6 + 2 \).

The callable object approach has the disadvantage that it is a bit slower and results in slightly longer code. However, note that a collection of callables can share their signature via inheritance:
```python
class exponential(linear):
    # __init__ inherited
    def __call__(self, x):
        return self.a * (x ** self.b)
```

Object can encapsulate state for several methods:

```python
class counter:
    value = 0

    def set(self, x):
        self.value = x

    def up(self):
        self.value = self.value + 1

    def down(self):
        self.value = self.value - 1

count = counter()
inc, dec, reset = count.up, count.down, count.set
```

Here `inc()`, `dec()` and `reset()` act like functions which share the same counting variable.

**How do I copy an object in Python?**

In general, try `copy.copy()` or `copy.deepcopy()` for the general case. Not all objects can be copied, but most can.

Some objects can be copied more easily. Dictionaries have a `copy()` method:
Sequences can be copied by slicing:

```python
new_l = l[:]
```

How can I find the methods or attributes of an object?

For an instance `x` of a user-defined class, `dir(x)` returns an alphabetized list of the names containing the instance attributes and methods and attributes defined by its class.

How can my code discover the name of an object?

Generally speaking, it can’t, because objects don’t really have names. Essentially, assignment always binds a name to a value; The same is true of `def` and `class` statements, but in that case the value is a callable. Consider the following code:

```python
class A:
    pass
B = A
a = B()
b = a
print(b)
<__main__.A object at 0x16D07CC>
print(a)
<__main__.A object at 0x16D07CC>
```
Arguably the class has a name: even though it is bound to two names and invoked through the name B the created instance is still reported as an instance of class A. However, it is impossible to say whether the instance’s name is a or b, since both names are bound to the same value.

Generally speaking it should not be necessary for your code to “know the names” of particular values. Unless you are deliberately writing introspective programs, this is usually an indication that a change of approach might be beneficial.

In comp.lang.python, Fredrik Lundh once gave an excellent analogy in answer to this question:

The same way as you get the name of that cat you found on your porch: the cat (object) itself cannot tell you its name, and it doesn’t really care – so the only way to find out what it’s called is to ask all your neighbours (namespaces) if it’s their cat (object)...

....and don’t be surprised if you’ll find that it’s known by many names, or no name at all!

What’s up with the comma operator’s precedence?

Comma is not an operator in Python. Consider this session:

```python
>>> "a" in "b", "a"
(False, 'a')
```

Since the comma is not an operator, but a separator between expressions the above is evaluated as if you had entered:
The same is true of the various assignment operators (=, += etc). They are not truly operators but syntactic delimiters in assignment statements.

**Is there an equivalent of C’s ”?:” ternary operator?**

Yes, there is. The syntax is as follows:

```python
[on_true] if [expression] else [on_false]
```

```python
x, y = 50, 25
small = x if x < y else y
```

Before this syntax was introduced in Python 2.5, a common idiom was to use logical operators:

```python
[expression] and [on_true] or [on_false]
```

However, this idiom is unsafe, as it can give wrong results when `on_true` has a false boolean value. Therefore, it is always better to use the `... if ... else ...` form.

**Is it possible to write obfuscated one-liners in Python?**

Yes. Usually this is done by nesting `lambda` within `lambda`. See the
following three examples, due to Ulf Bartelt:

```python
from functools import reduce

# Primes < 1000
print(list(filter(lambda y: reduce(lambda x, y: y % x, range(2, int(pow(y, 0.5) + 1))), y)), 1),

# First 10 Fibonacci numbers
print(list(map(lambda x, f=reduce(lambda x, y: x * y, y): (f(x - 1, f) + f(x - 2), f(x, y), range(10))), f))

# Mandelbrot set
print(((lambda Ru, Ro, Io, IM, Sx, Sy: reduce(lambda x, y: reduce(lambda x, y: x + y, map(lambda x, xc=Ru, yc=Io, IM, Sx, Sy: reduce(lambda x, y: x + y, map(lambda x, y, k: lambda xc, yc, x, y, k: x == 4.0 or 1 + f(x, y, x * x + y * y + xc, 2.0 * x * y + yc, k - 1, f): f(x, 64 + F(Ru + x * (Ro - Ru) / Sx, yc, 0, 0, i)), range(Sx))): L(Iu + y * (Sx))), r))(-2.1, 0.7, -1.2, 1.2, 30, 80, 24)))

# ___ ___/ ___ ___/ | | | ___ lines on screen
# V V | | | | | | columns on screen
# | | | | | | | maximum of "i"
# | | | | | | | range on y axis
# | | | | | | | range on x axis
```

Don’t try this at home, kids!
Numbers and strings

How do I specify hexadecimal and octal integers?

To specify an octal digit, precede the octal value with a zero, and then a lower or uppercase “o”. For example, to set the variable “a” to the octal value “10” (8 in decimal), type:

```
>>> a = 0o10
>>> a
8
```

Hexadecimal is just as easy. Simply precede the hexadecimal number with a zero, and then a lower or uppercase “x”. Hexadecimal digits can be specified in lower or uppercase. For example, in the Python interpreter:

```
>>> a = 0xa5
>>> a
165
>>> b = 0XB2
>>> b
178
```

Why does -22 // 10 return -3?

It’s primarily driven by the desire that \( i \% j \) have the same sign as \( j \). If you want that, and also want:

\[
i == (i \div j) \times j + (i \% j)\]

then integer division has to return the floor. C also requires that identity
to hold, and then compilers that truncate $i \div j$ need to make $i \% j$ have the same sign as $i$.

There are few real use cases for $i \% j$ when $j$ is negative. When $j$ is positive, there are many, and in virtually all of them it's more useful for $i \% j$ to be $\geq 0$. If the clock says 10 now, what did it say 200 hours ago? $\ -190 \ 12 == 2$ is useful; $\ -190 \ 12 == -10$ is a bug waiting to bite.

**How do I convert a string to a number?**

For integers, use the built-in `int()` type constructor, e.g. `int('144') == 144`. Similarly, `float()` converts to floating-point, e.g. `float('144') == 144.0`.

By default, these interpret the number as decimal, so that `int('0144') == 144` and `int('0x144')` raises `ValueError`. `int(string, base)` takes the base to convert from as a second optional argument, so `int('0x144', 16) == 324`. If the base is specified as 0, the number is interpreted using Python's rules: a leading '0' indicates octal, and '0x' indicates a hex number.

Do not use the built-in function `eval()` if all you need is to convert strings to numbers. `eval()` will be significantly slower and it presents a security risk: someone could pass you a Python expression that might have unwanted side effects. For example, someone could pass `__import__('os').system("rm -rf $HOME")` which would erase your home directory.

`eval()` also has the effect of interpreting numbers as Python expressions, so that e.g. `eval('09')` gives a syntax error because
Python does not allow leading ‘0’ in a decimal number (except ‘0’).

**How do I convert a number to a string?**

To convert, e.g., the number 144 to the string ‘144’, use the built-in type constructor `str()`. If you want a hexadecimal or octal representation, use the built-in functions `hex()` or `oct()`. For fancy formatting, see the *String Formatting* section, e.g. "{:04d}".format(144) yields '0144' and "{::.3f}".format(1/3) yields '0.333'.

**How do I modify a string in place?**

You can’t, because strings are immutable. In most situations, you should simply construct a new string from the various parts you want to assemble it from. However, if you need an object with the ability to modify in-place unicode data, try using a `io.StringIO` object or the `array` module:

```python
>>> import io
>>> s = "Hello, world"
>>> sio = io.StringIO(s)
>>> sio.getvalue()
'Hello, world'
>>> sio.seek(7)
7
>>> sio.write("there!")
6
>>> sio.getvalue()
'Hello, there!'

>>> import array
>>> a = array.array('u', s)
```
How do I use strings to call functions/methods?

There are various techniques.

- The best is to use a dictionary that maps strings to functions. The primary advantage of this technique is that the strings do not need to match the names of the functions. This is also the primary technique used to emulate a case construct:

```python
def a():
    pass

def b():
    pass

dispatch = {'go': a, 'stop': b}  # Note lack of parens for funcs

dispatch[get_input]()  # Note trailing parens to call function
```

- Use the built-in function `getattr()`:

```python
import foo
getattr(foo, 'bar')()
```

Note that `getattr()` works on any object, including classes, class instances, modules, and so on.
This is used in several places in the standard library, like this:

```python
class Foo:
    def do_foo(self):
        ...

    def do_bar(self):
        ...

f = getattr(foo_instance, 'do_' + opname)
f()
```

- Use `locals()` or `eval()` to resolve the function name:

```python
def myFunc():
    print("hello")

fname = "myFunc"

f = locals()[fname]
f()

f = eval(fname)
f()
```

Note: Using `eval()` is slow and dangerous. If you don’t have absolute control over the contents of the string, someone could pass a string that resulted in an arbitrary function being executed.

**Is there an equivalent to Perl’s chomp() for removing trailing newlines from strings?**

You can use `S.rstrip("\r\n")` to remove all occurrences of any line terminator from the end of the string `S` without removing other
trailing whitespace. If the string \texttt{S} represents more than one line, with several empty lines at the end, the line terminators for all the blank lines will be removed:

```python
>>> lines = ("line 1 \r\n... "\r\n... "\r\n")
>>> lines.rstrip("\n\r")
'line 1'
```

Since this is typically only desired when reading text one line at a time, using \texttt{S.rstrip()} this way works well.

**Is there a scanf() or sscanf() equivalent?**

Not as such.

For simple input parsing, the easiest approach is usually to split the line into whitespace-delimited words using the \texttt{split()} method of string objects and then convert decimal strings to numeric values using \texttt{int()} or \texttt{float()}. \texttt{split()} supports an optional “sep” parameter which is useful if the line uses something other than whitespace as a separator.

For more complicated input parsing, regular expressions are more powerful than C’s \texttt{sscanf()} and better suited for the task.

**What does ‘UnicodeDecodeError’ or ‘UnicodeEncodeError’ error mean?**

See the \textit{Unicode HOWTO}. 
Performance

My program is too slow. How do I speed it up?

That’s a tough one, in general. First, here are a list of things to remember before diving further:

- Performance characteristics vary across Python implementations. This FAQ focusses on *CPython*.
- Behaviour can vary across operating systems, especially when talking about I/O or multi-threading.
- You should always find the hot spots in your program *before* attempting to optimize any code (see the *profile* module).
- Writing benchmark scripts will allow you to iterate quickly when searching for improvements (see the *timeit* module).
- It is highly recommended to have good code coverage (through unit testing or any other technique) before potentially introducing regressions hidden in sophisticated optimizations.

That being said, there are many tricks to speed up Python code. Here are some general principles which go a long way towards reaching acceptable performance levels:

- Making your algorithms faster (or changing to faster ones) can yield much larger benefits than trying to sprinkle micro-optimization tricks all over your code.
- Use the right data structures. Study documentation for the *Built-in Types* and the *collections* module.
- When the standard library provides a primitive for doing something, it is likely (although not guaranteed) to be faster than any alternative you may come up with. This is doubly true for primitives written in C, such as builtins and some extension types. For example, be sure to use either the *list.sort()* built-in
method or the related `sorted()` function to do sorting (and see the sorting mini-HOWTO for examples of moderately advanced usage).

- Abstractions tend to create indirections and force the interpreter to work more. If the levels of indirection outweigh the amount of useful work done, your program will be slower. You should avoid excessive abstraction, especially under the form of tiny functions or methods (which are also often detrimental to readability).

If you have reached the limit of what pure Python can allow, there are tools to take you further away. For example, Cython can compile a slightly modified version of Python code into a C extension, and can be used on many different platforms. Cython can take advantage of compilation (and optional type annotations) to make your code significantly faster than when interpreted. If you are confident in your C programming skills, you can also write a C extension module yourself.

**See also:** The wiki page devoted to performance tips.

**What is the most efficient way to concatenate many strings together?**

`str` and `bytes` objects are immutable, therefore concatenating many strings together is inefficient as each concatenation creates a new object. In the general case, the total runtime cost is quadratic in the total string length.

To accumulate many `str` objects, the recommended idiom is to place them into a list and call `str.join()` at the end:

```
chunks = []
for s in my_strings:
    chunks.append(s)
```
result = ''.join(chunks)

(another reasonably efficient idiom is to use `io.StringIO`)

To accumulate many `bytes` objects, the recommended idiom is to extend a `bytearray` object using in-place concatenation (the `+=` operator):

```python
result = bytearray()
for b in my_bytes_objects:
    result += b
```
Sequences (Tuples/Lists)

How do I convert between tuples and lists?

The type constructor \texttt{tuple(seq)} converts any sequence (actually, any iterable) into a tuple with the same items in the same order.

For example, \texttt{tuple([1, 2, 3])} yields (1, 2, 3) and \texttt{tuple('abc')} yields ('a', 'b', 'c'). If the argument is a tuple, it does not make a copy but returns the same object, so it is cheap to call \texttt{tuple()} when you aren't sure that an object is already a tuple.

The type constructor \texttt{list(seq)} converts any sequence or iterable into a list with the same items in the same order. For example, \texttt{list((1, 2, 3))} yields [1, 2, 3] and \texttt{list('abc')} yields ['a', 'b', 'c']. If the argument is a list, it makes a copy just like \texttt{seq[:]} would.

What’s a negative index?

Python sequences are indexed with positive numbers and negative numbers. For positive numbers 0 is the first index 1 is the second index and so forth. For negative indices -1 is the last index and -2 is the penultimate (next to last) index and so forth. Think of \texttt{seq[-n]} as the same as \texttt{seq[len(seq)-n]}.

Using negative indices can be very convenient. For example \texttt{S[:-1]} is all of the string except for its last character, which is useful for removing the trailing newline from a string.
How do I iterate over a sequence in reverse order?

Use the `reversed()` built-in function, which is new in Python 2.4:

```python
for x in reversed(sequence):
    ... # do something with x...
```

This won't touch your original sequence, but build a new copy with reversed order to iterate over.

With Python 2.3, you can use an extended slice syntax:

```python
for x in sequence[:len(sequence)-1:-1]:
    ... # do something with x...
```

How do you remove duplicates from a list?

See the Python Cookbook for a long discussion of many ways to do this:

```
http://aspn.activestate.com/ASPN/Cookbook/Python/Recipe/52560
```

If you don’t mind reordering the list, sort it and then scan from the end of the list, deleting duplicates as you go:

```python
if mylist:
    mylist.sort()
    last = mylist[-1]
    for i in range(len(mylist)-2, -1, -1):
        if last == mylist[i]:
            del mylist[i]
        else:
            last = mylist[i]
```
If all elements of the list may be used as set keys (i.e. they are all *hashable*) this is often faster

```python
mylist = list(set(mylist))
```

This converts the list into a set, thereby removing duplicates, and then back into a list.

**How do you make an array in Python?**

Use a list:

```python
["this", 1, "is", "an", "array"]
```

Lists are equivalent to C or Pascal arrays in their time complexity; the primary difference is that a Python list can contain objects of many different types.

The `array` module also provides methods for creating arrays of fixed types with compact representations, but they are slower to index than lists. Also note that the Numeric extensions and others define array-like structures with various characteristics as well.

To get Lisp-style linked lists, you can emulate cons cells using tuples:

```python
lisp_list = ("like", ("this", ("example", None))
```

If mutability is desired, you could use lists instead of tuples. Here the analogue of lisp car is `lisp_list[0]` and the analogue of cdr is `lisp_list[1]`. Only do this if you’re sure you really need to, because it’s usually a lot slower than using Python lists.
How do I create a multidimensional list?

You probably tried to make a multidimensional array like this:

```python
>>> A = [[None] * 2] * 3
```

This looks correct if you print it:

```python
>>> A
[[None, None], [None, None], [None, None]]
```

But when you assign a value, it shows up in multiple places:

```python
>>> A[0][0] = 5
>>> A
[[5, None], [5, None], [5, None]]
```

The reason is that replicating a list with `*` doesn’t create copies, it only creates references to the existing objects. The `*3` creates a list containing 3 references to the same list of length two. Changes to one row will show in all rows, which is almost certainly not what you want.

The suggested approach is to create a list of the desired length first and then fill in each element with a newly created list:

```python
A = [None] * 3
for i in range(3):
    A[i] = [None] * 2
```

This generates a list containing 3 different lists of length two. You can also use a list comprehension:

```python
w, h = 2, 3
A = [[[None] * w for i in range(h)]
```
Or, you can use an extension that provides a matrix datatype; Numeric Python is the best known.

**How do I apply a method to a sequence of objects?**

Use a list comprehension:

```python
result = [obj.method() for obj in mylist]
```

**Why does a_tuple[i] += ['item'] raise an exception when the addition works?**

This is because of a combination of the fact that augmented assignment operators are *assignment* operators, and the difference between mutable and immutable objects in Python.

This discussion applies in general when augmented assignment operators are applied to elements of a tuple that point to mutable objects, but we'll use a list and `+=` as our exemplar.

If you wrote:

```python
>>> a_tuple = (1, 2)
>>> a_tuple[0] += 1
Traceback (most recent call last):
  ...
TypeError: 'tuple' object does not support item assignment
```

The reason for the exception should be immediately clear: 1 is added to the object `a_tuple[0]` points to (1), producing the result object,
2, but when we attempt to assign the result of the computation, \(2\), to element 0 of the tuple, we get an error because we can't change what an element of a tuple points to.

Under the covers, what this augmented assignment statement is doing is approximately this:

```python
>>> result = a_tuple[0] + 1
>>> a_tuple[0] = result
```

```
Traceback (most recent call last):
...
TypeError: 'tuple' object does not support item assignment
```

It is the assignment part of the operation that produces the error, since a tuple is immutable.

When you write something like:

```python
>>> a_tuple = (["foo"], 'bar')
>>> a_tuple[0] += ["item"]
```

```
Traceback (most recent call last):
...
TypeError: 'tuple' object does not support item assignment
```

The exception is a bit more surprising, and even more surprising is the fact that even though there was an error, the append worked:

```python
>>> a_tuple[0]
['foo', 'item']
```

To see why this happens, you need to know that (a) if an object implements an `__iadd__` magic method, it gets called when the `+=` augmented assignment is executed, and its return value is what gets
used in the assignment statement; and (b) for lists, `__iadd__` is equivalent to calling `extend` on the list and returning the list. That's why we say that for lists, `+=` is a “shorthand” for `list.extend`:

```python
>>> a_list = []
>>> a_list += [1]
>>> a_list
[1]
```

This is equivalent to:

```python
>>> result = a_list.__iadd__([1])
>>> a_list = result
```

The object pointed to by `a_list` has been mutated, and the pointer to the mutated object is assigned back to `a_list`. The end result of the assignment is a no-op, since it is a pointer to the same object that `a_list` was previously pointing to, but the assignment still happens.

Thus, in our tuple example what is happening is equivalent to:

```python
>>> result = a_tuple[0].__iadd__(['item'])
>>> a_tuple[0] = result
Traceback (most recent call last):
  ...  
TypeError: 'tuple' object does not support item assignment
```

The `__iadd__` succeeds, and thus the list is extended, but even though `result` points to the same object that `a_tuple[0]` already points to, that final assignment still results in an error, because tuples are immutable.
Dictionaries

How can I get a dictionary to display its keys in a consistent order?

You can’t. Dictionaries store their keys in an unpredictable order, so the display order of a dictionary’s elements will be similarly unpredictable.

This can be frustrating if you want to save a printable version to a file, make some changes and then compare it with some other printed dictionary. In this case, use the `pprint` module to pretty-print the dictionary; the items will be presented in order sorted by the key.

A more complicated solution is to subclass `dict` to create a `SortedDict` class that prints itself in a predictable order. Here’s one simpleminded implementation of such a class:

```python
class SortedDict(dict):
    def __repr__(self):
        keys = sorted(self.keys())
        result = ("{}: {}").format(k, self[k])
        return "{}\n        __str__ = __repr__
```

This will work for many common situations you might encounter, though it’s far from a perfect solution. The largest flaw is that if some values in the dictionary are also dictionaries, their values won’t be presented in any particular order.

I want to do a complicated sort: can you do a
Schwartzian Transform in Python?

The technique, attributed to Randal Schwartz of the Perl community, sorts the elements of a list by a metric which maps each element to its “sort value”. In Python, just use the `key` argument for the `sort()` method:

```python
Isorted = L[:]
Isorted.sort(key=lambda s: int(s[10:15]))
```

The `key` argument is new in Python 2.4, for older versions this kind of sorting is quite simple to do with list comprehensions. To sort a list of strings by their uppercase values:

```python
tmp1 = [(x.upper(), x) for x in L]  # Schwartzian transform
tmp1.sort()
Usorted = [x[1] for x in tmp1]
```

To sort by the integer value of a subfield extending from positions 10-15 in each string:

```python
tmp2 = [(int(s[10:15]), s) for s in L]  # Schwartzian transform
tmp2.sort()
Isorted = [x[1] for x in tmp2]
```

For versions prior to 3.0, `Isorted` may also be computed by

```python
def intfield(s):
    return int(s[10:15])

def Icmp(s1, s2):
    return cmp(intfield(s1), intfield(s2))
```
Isorted = L[:]
Isorted.sort(Icmp)

but since this method calls intfield() many times for each element
of L, it is slower than the Schwartzian Transform.

How can I sort one list by values from another list?

Merge them into an iterator of tuples, sort the resulting list, and then
pick out the element you want.

```python
>>> list1 = ['what', 'I'm', 'sorting', 'by']
>>> list2 = ['something', 'else', 'to', 'sort']
>>> pairs = zip(list1, list2)
>>> pairs = sorted(pairs)
>>> pairs
[('I'm', 'else'), ('by', 'sort'), ('sorting', 'to'), ('what', 'something')]
```

An alternative for the last step is:

```python
>>> result = []
>>> for p in pairs: result.append(p[1])
```

If you find this more legible, you might prefer to use this instead of the
final list comprehension. However, it is almost twice as slow for long
lists. Why? First, the append() operation has to reallocate memory,
and while it uses some tricks to avoid doing that each time, it still has
to do it occasionally, and that costs quite a bit. Second, the expression
“result.append” requires an extra attribute lookup, and third, there’s a
speed reduction from having to make all those function calls.
Objects

What is a class?

A class is the particular object type created by executing a class statement. Class objects are used as templates to create instance objects, which embody both the data (attributes) and code (methods) specific to a datatype.

A class can be based on one or more other classes, called its base class(es). It then inherits the attributes and methods of its base classes. This allows an object model to be successively refined by inheritance. You might have a generic Mailbox class that provides basic accessor methods for a mailbox, and subclasses such as MboxMailbox, MaildirMailbox, OutlookMailbox that handle various specific mailbox formats.

What is a method?

A method is a function on some object $x$ that you normally call as $x$.name(arguments...). Methods are defined as functions inside the class definition:

```python
class C:
    def meth (self, arg):
        return arg * 2 + self.attribute
```

What is self?

Self is merely a conventional name for the first argument of a method. A method defined as `meth(self, a, b, c)` should be called as
x.meth(a, b, c) for some instance x of the class in which the definition occurs; the called method will think it is called as meth(x, a, b, c).

See also Why must ‘self’ be used explicitly in method definitions and calls?

How do I check if an object is an instance of a given class or of a subclass of it?

Use the built-in function isinstance(obj, cls). You can check if an object is an instance of any of a number of classes by providing a tuple instead of a single class, e.g. isinstance(obj, (class1, class2, ...)), and can also check whether an object is one of Python’s built-in types, e.g. isinstance(obj, str) or isinstance(obj, (int, float, complex)).

Note that most programs do not use isinstance() on user-defined classes very often. If you are developing the classes yourself, a more proper object-oriented style is to define methods on the classes that encapsulate a particular behaviour, instead of checking the object’s class and doing a different thing based on what class it is. For example, if you have a function that does something:

```python
def search(obj):
    if isinstance(obj, Mailbox):
        # ... code to search a mailbox
    elif isinstance(obj, Document):
        # ... code to search a document
    elif ...
```

A better approach is to define a search() method on all the classes
and just call it:

```python
class Mailbox:
    def search(self):
        # ... code to search a mailbox

class Document:
    def search(self):
        # ... code to search a document

obj.search()
```

**What is delegation?**

Delegation is an object oriented technique (also called a design pattern). Let's say you have an object `x` and want to change the behaviour of just one of its methods. You can create a new class that provides a new implementation of the method you're interested in changing and delegates all other methods to the corresponding method of `x`.

Python programmers can easily implement delegation. For example, the following class implements a class that behaves like a file but converts all written data to uppercase:

```python
class UpperOut:
    def __init__(self, outfile):
        self._outfile = outfile

    def write(self, s):
        self._outfile.write(s.upper())

    def __getattr__(self, name):
```
```python
return getattr(self._outfile, name)
```

Here the UpperOut class redefines the `write()` method to convert the argument string to uppercase before calling the underlying `self.__outfile.write()` method. All other methods are delegated to the underlying `self.__outfile` object. The delegation is accomplished via the `__getattr__` method; consult the language reference for more information about controlling attribute access.

Note that for more general cases delegation can get trickier. When attributes must be set as well as retrieved, the class must define a `__setattr__()` method too, and it must do so carefully. The basic implementation of `__setattr__()` is roughly equivalent to the following:

```python
class X:
    ...
    def __setattr__(self, name, value):
        self.__dict__[name] = value
    ...
```

Most `__setattr__()` implementations must modify `self.__dict__` to store local state for `self` without causing an infinite recursion.

**How do I call a method defined in a base class from a derived class that overrides it?**

Use the built-in `super()` function:

```python
class Derived(Base):
    def meth(self):
```
For version prior to 3.0, you may be using classic classes: For a class definition such as

```python
class Derived(Base):
...
```

you can call method `meth()` defined in `Base` (or one of `Base`'s base classes) as `Base.meth(self, arguments...)`. Here, `Base.meth` is an unbound method, so you need to provide the `self` argument.

### How can I organize my code to make it easier to change the base class?

You could define an alias for the base class, assign the real base class to it before your class definition, and use the alias throughout your class. Then all you have to change is the value assigned to the alias. Incidentally, this trick is also handy if you want to decide dynamically (e.g. depending on availability of resources) which base class to use.

Example:

```python
BaseAlias = <real base class>

class Derived(BaseAlias):
    def meth(self):
        BaseAlias.meth(self)
    ...
```

### How do I create static class data and static class methods?

Both static data and static methods (in the sense of C++ or Java) are supported in Python.

For static data, simply define a class attribute. To assign a new value...
to the attribute, you have to explicitly use the class name in the assignment:

```python
class C:
    count = 0  # number of times C.__init__ called

    def __init__(self):
        C.count = C.count + 1

    def getcount(self):
        return C.count  # or return self.count
```

count also refers to C.count for any c such that `isinstance(c, C)` holds, unless overridden by c itself or by some class on the base-class search path from c.__class__ back to C.

Caution: within a method of C, an assignment like `self.count = 42` creates a new and unrelated instance named “count” in self’s own dict. Rebinding of a class-static data name must always specify the class whether inside a method or not:

```python
C.count = 314
```

Static methods are possible:

```python
class C:
    @staticmethod
def static(arg1, arg2, arg3):
        # No 'self' parameter!
        ...
```

However, a far more straightforward way to get the effect of a static method is via a simple module-level function:
def getcount():
    return C.count

If your code is structured so as to define one class (or tightly related class hierarchy) per module, this supplies the desired encapsulation.

How can I overload constructors (or methods) in Python?

This answer actually applies to all methods, but the question usually comes up first in the context of constructors.

In C++ you’d write

```cpp
class C {
    C() { cout << "No arguments\n"; }
    C(int i) { cout << "Argument is " << i << "\n"; }
}
```

In Python you have to write a single constructor that catches all cases using default arguments. For example:

```python
class C:
    def __init__(self, i=None):
        if i is None:
            print("No arguments")
        else:
            print("Argument is", i)
```

This is not entirely equivalent, but close enough in practice.

You could also try a variable-length argument list, e.g.
The same approach works for all method definitions.

I try to use __spam and I get an error about _SomeClassName__spam.

Variable names with double leading underscores are “mangled” to provide a simple but effective way to define class private variables. Any identifier of the form __spam (at least two leading underscores, at most one trailing underscore) is textually replaced with _classname__spam, where classname is the current class name with any leading underscores stripped.

This doesn’t guarantee privacy: an outside user can still deliberately access the “_classname__spam” attribute, and private values are visible in the object's _dict_. Many Python programmers never bother to use private variable names at all.

My class defines __del__ but it is not called when I delete the object.

There are several possible reasons for this.

The del statement does not necessarily call __del__() – it simply decrements the object’s reference count, and if this reaches zero __del__() is called.

If your data structures contain circular links (e.g. a tree where each child has a parent reference and each parent has a list of children) the reference counts will never go back to zero. Once in a while Python
runs an algorithm to detect such cycles, but the garbage collector might run some time after the last reference to your data structure vanishes, so your \_\_del\_\_() method may be called at an inconvenient and random time. This is inconvenient if you’re trying to reproduce a problem. Worse, the order in which object’s \_\_del\_\_() methods are executed is arbitrary. You can run gc.collect() to force a collection, but there are pathological cases where objects will never be collected.

Despite the cycle collector, it’s still a good idea to define an explicit close() method on objects to be called whenever you’re done with them. The close() method can then remove attributes that refer to subobjects. Don’t call \_\_del\_\_() directly — \_\_del\_\_() should call close() and close() should make sure that it can be called more than once for the same object.

Another way to avoid cyclical references is to use the weakref module, which allows you to point to objects without incrementing their reference count. Tree data structures, for instance, should use weak references for their parent and sibling references (if they need them!).

Finally, if your \_\_del\_\_() method raises an exception, a warning message is printed to sys.stdout.

How do I get a list of all instances of a given class?

Python does not keep track of all instances of a class (or of a built-in type). You can program the class’s constructor to keep track of all instances by keeping a list of weak references to each instance.
Why does the result of `id()` appear to be not unique?

The `id()` builtin returns an integer that is guaranteed to be unique during the lifetime of the object. Since in CPython, this is the object’s memory address, it happens frequently that after an object is deleted from memory, the next freshly created object is allocated at the same position in memory. This is illustrated by this example:

```python
>>> id(1000)
13901272
>>> id(2000)
13901272
```

The two ids belong to different integer objects that are created before, and deleted immediately after execution of the `id()` call. To be sure that objects whose id you want to examine are still alive, create another reference to the object:

```python
>>> a = 1000; b = 2000
>>> id(a)
13901272
>>> id(b)
13891296
```
Modules

How do I create a .pyc file?

When a module is imported for the first time (or when the source is more recent than the current compiled file) a .pyc file containing the compiled code should be created in the same directory as the .py file.

One reason that a .pyc file may not be created is permissions problems with the directory. This can happen, for example, if you develop as one user but run as another, such as if you are testing with a web server. Creation of a .pyc file is automatic if you’re importing a module and Python has the ability (permissions, free space, etc...) to write the compiled module back to the directory.

Running Python on a top level script is not considered an import and no .pyc will be created. For example, if you have a top-level module foo.py that imports another module xyz.py, when you run foo, xyz.pyc will be created since xyz is imported, but no foo.pyc file will be created since foo.py isn't being imported.

If you need to create foo.pyc – that is, to create a .pyc file for a module that is not imported – you can, using the py_compile and compileall modules.

The py_compile module can manually compile any module. One way is to use the compile() function in that module interactively:

```py
>>> import py_compile
>>> py_compile.compile('foo.py')
```

This will write the .pyc to the same location as foo.py (or you can
override that with the optional parameter `cfile`).

You can also automatically compile all files in a directory or directories using the `compileall` module. You can do it from the shell prompt by running `compileall.py` and providing the path of a directory containing Python files to compile:

```
python -m compileall .
```

**How do I find the current module name?**

A module can find out its own module name by looking at the predefined global variable `__name__`. If this has the value `'__main__'`, the program is running as a script. Many modules that are usually used by importing them also provide a command-line interface or a self-test, and only execute this code after checking `__name__`:

```python
def main():
    print('Running test...')
    ...

if __name__ == '__main__':
    main()
```

**How can I have modules that mutually import each other?**

Suppose you have the following modules:

```
foo.py:
```
from bar import bar_var
foo_var = 1

bar.py:

from foo import foo_var
bar_var = 2

The problem is that the interpreter will perform the following steps:

- main imports foo
- Empty globals for foo are created
- foo is compiled and starts executing
- foo imports bar
- Empty globals for bar are created
- bar is compiled and starts executing
- bar imports foo (which is a no-op since there already is a module named foo)
- bar.foo_var = foo.foo_var

The last step fails, because Python isn’t done with interpreting foo yet and the global symbol dictionary for foo is still empty.

The same thing happens when you use import foo, and then try to access foo.foo_var in global code.

There are (at least) three possible workarounds for this problem.

Guido van Rossum recommends avoiding all uses of from <module> import ..., and placing all code inside functions. Initializations of global variables and class variables should use constants or built-in functions only. This means everything from an imported module is referenced as <module>.<name>.
Jim Roskind suggests performing steps in the following order in each module:

- exports (globals, functions, and classes that don’t need imported base classes)
- import statements
- active code (including globals that are initialized from imported values).

van Rossum doesn’t like this approach much because the imports appear in a strange place, but it does work.

Matthias Urlichs recommends restructuring your code so that the recursive import is not necessary in the first place.

These solutions are not mutually exclusive.

```
__import__('x.y.z') returns <module ‘x’>; how do I get z?
```

Try:

```
__import__('x.y.z').y.z
```

For more realistic situations, you may have to do something like

```
importlib
```

See `importlib` for a convenience function called `import_module()`. 
When I edit an imported module and reimport it, the changes don’t show up. Why does this happen?

For reasons of efficiency as well as consistency, Python only reads the module file on the first time a module is imported. If it didn’t, in a program consisting of many modules where each one imports the same basic module, the basic module would be parsed and re-parsed many times. To force rereading of a changed module, do this:

```python
import imp
import modname
imp.reload(modname)
```

Warning: this technique is not 100% fool-proof. In particular, modules containing statements like

```python
from modname import some_objects
```

will continue to work with the old version of the imported objects. If the module contains class definitions, existing class instances will not be updated to use the new class definition. This can result in the following paradoxical behaviour:

```python
>>> import imp
>>> import cls
>>> c = cls.C()          # Create an instance
>>> imp.reload(cls)
<module 'cls' from 'cls.py'>
>>> isinstance(c, cls.C)  # isinstance is false
False
```
The nature of the problem is made clear if you print out the “identity” of the class objects:

```python
>>> hex(id(c.__class__))
'0x7352a0'
>>> hex(id(cls.C))
'0x4198d0'
```
Design and History FAQ
Why does Python use indentation for grouping of statements?

Guido van Rossum believes that using indentation for grouping is extremely elegant and contributes a lot to the clarity of the average Python program. Most people learn to love this feature after a while.

Since there are no begin/end brackets there cannot be a disagreement between grouping perceived by the parser and the human reader. Occasionally C programmers will encounter a fragment of code like this:

```
if (x <= y)
    x++;  
    y--; 
z++; 
```

Only the `x++` statement is executed if the condition is true, but the indentation leads you to believe otherwise. Even experienced C programmers will sometimes stare at it a long time wondering why `y` is being decremented even for `x > y`.

Because there are no begin/end brackets, Python is much less prone to coding-style conflicts. In C there are many different ways to place the braces. If you’re used to reading and writing code that uses one style, you will feel at least slightly uneasy when reading (or being required to write) another style.

Many coding styles place begin/end brackets on a line by themselves. This makes programs considerably longer and wastes valuable screen space, making it harder to get a good overview of a program. Ideally, a function should fit on one screen (say, 20-30 lines). 20 lines of Python
can do a lot more work than 20 lines of C. This is not solely due to the lack of begin/end brackets – the lack of declarations and the high-level data types are also responsible – but the indentation-based syntax certainly helps.
Why am I getting strange results with simple arithmetic operations?

See the next question.
Why are floating-point calculations so inaccurate?

Users are often surprised by results like this:

```plaintext
>>> 1.2 - 1.0
0.199999999999999996
```

and think it is a bug in Python. It's not. This has little to do with Python, and much more to do with how the underlying platform handles floating-point numbers.

The `float` type in CPython uses a C `double` for storage. A `float` object's value is stored in binary floating-point with a fixed precision (typically 53 bits) and Python uses C operations, which in turn rely on the hardware implementation in the processor, to perform floating-point operations. This means that as far as floating-point operations are concerned, Python behaves like many popular languages including C and Java.

Many numbers that can be written easily in decimal notation cannot be expressed exactly in binary floating-point. For example, after:

```plaintext
>>> x = 1.2
```

the value stored for `x` is a (very good) approximation to the decimal value 1.2, but is not exactly equal to it. On a typical machine, the actual stored value is:

```
1.0011001100110011001100110011001100110011001100110011
```
which is exactly:

```
1.19999999999999995559107901499373838305473327636719
```

The typical precision of 53 bits provides Python floats with 15-16 decimal digits of accuracy.

For a fuller explanation, please see the *floating point arithmetic* chapter in the Python tutorial.
Why are Python strings immutable?

There are several advantages.

One is performance: knowing that a string is immutable means we can allocate space for it at creation time, and the storage requirements are fixed and unchanging. This is also one of the reasons for the distinction between tuples and lists.

Another advantage is that strings in Python are considered as “elemental” as numbers. No amount of activity will change the value 8 to anything else, and in Python, no amount of activity will change the string “eight” to anything else.
Why must ‘self’ be used explicitly in method definitions and calls?

The idea was borrowed from Modula-3. It turns out to be very useful, for a variety of reasons.

First, it’s more obvious that you are using a method or instance attribute instead of a local variable. Reading `self.x` or `self.meth()` makes it absolutely clear that an instance variable or method is used even if you don’t know the class definition by heart. In C++, you can sort of tell by the lack of a local variable declaration (assuming globals are rare or easily recognizable) – but in Python, there are no local variable declarations, so you’d have to look up the class definition to be sure. Some C++ and Java coding standards call for instance attributes to have an `m_` prefix, so this explicitness is still useful in those languages, too.

Second, it means that no special syntax is necessary if you want to explicitly reference or call the method from a particular class. In C++, if you want to use a method from a base class which is overridden in a derived class, you have to use the `::` operator – in Python you can write `baseclass.methodname(self, <argument list>). This is particularly useful for `__init__()` methods, and in general in cases where a derived class method wants to extend the base class method of the same name and thus has to call the base class method somehow.

Finally, for instance variables it solves a syntactic problem with assignment: since local variables in Python are (by definition!) those variables to which a value is assigned in a function body (and that aren’t explicitly declared global), there has to be some way to tell the
interpreter that an assignment was meant to assign to an instance variable instead of to a local variable, and it should preferably be syntactic (for efficiency reasons). C++ does this through declarations, but Python doesn't have declarations and it would be a pity having to introduce them just for this purpose. Using the explicit `self.var` solves this nicely. Similarly, for using instance variables, having to write `self.var` means that references to unqualified names inside a method don't have to search the instance's directories. To put it another way, local variables and instance variables live in two different namespaces, and you need to tell Python which namespace to use.
Why can’t I use an assignment in an expression?

Many people used to C or Perl complain that they want to use this C idiom:

```c
while (line = readline(f)) {
    // do something with line
}
```

where in Python you’re forced to write this:

```python
while True:
    line = f.readline()
    if not line:
        break
    ... # do something with line
```

The reason for not allowing assignment in Python expressions is a common, hard-to-find bug in those other languages, caused by this construct:

```python
if (x = 0) {
    // error handling
}
else {
    // code that only works for nonzero x
}
```

The error is a simple typo: \( x = 0 \), which assigns 0 to the variable \( x \), was written while the comparison \( x == 0 \) is certainly what was intended.
Many alternatives have been proposed. Most are hacks that save some typing but use arbitrary or cryptic syntax or keywords, and fail the simple criterion for language change proposals: it should intuitively suggest the proper meaning to a human reader who has not yet been introduced to the construct.

An interesting phenomenon is that most experienced Python programmers recognize the `while True` idiom and don’t seem to be missing the assignment in expression construct much; it’s only newcomers who express a strong desire to add this to the language.

There’s an alternative way of spelling this that seems attractive but is generally less robust than the “while True” solution:

```python
line = f.readline()
while line:
    ... # do something with line...
    line = f.readline()
```

The problem with this is that if you change your mind about exactly how you get the next line (e.g. you want to change it into `sys.stdin.readline()`) you have to remember to change two places in your program – the second occurrence is hidden at the bottom of the loop.

The best approach is to use iterators, making it possible to loop through objects using the `for` statement. For example, `file objects` support the iterator protocol, so you can write simply:

```python
for line in f:
    ... # do something with line...
```
Why does Python use methods for some functionality (e.g. list.index()) but functions for other (e.g. len(list))?

The major reason is history. Functions were used for those operations that were generic for a group of types and which were intended to work even for objects that didn’t have methods at all (e.g. tuples). It is also convenient to have a function that can readily be applied to an amorphous collection of objects when you use the functional features of Python (map(), zip() et al).

In fact, implementing len(), max(), min() as a built-in function is actually less code than implementing them as methods for each type. One can quibble about individual cases but it’s a part of Python, and it’s too late to make such fundamental changes now. The functions have to remain to avoid massive code breakage.

**Note:** For string operations, Python has moved from external functions (the string module) to methods. However, len() is still a function.
Why is \texttt{join()} a string method instead of a list or tuple method?

Strings became much more like other standard types starting in Python 1.6, when methods were added which give the same functionality that has always been available using the functions of the string module. Most of these new methods have been widely accepted, but the one which appears to make some programmers feel uncomfortable is:

\begin{verbatim}
"", ", .join(['1', '2', '4', '8', '16'])
\end{verbatim}

which gives the result:

\begin{verbatim}
"1, 2, 4, 8, 16"
\end{verbatim}

There are two common arguments against this usage.

The first runs along the lines of: “It looks really ugly using a method of a string literal (string constant)”, to which the answer is that it might, but a string literal is just a fixed value. If the methods are to be allowed on names bound to strings there is no logical reason to make them unavailable on literals.

The second objection is typically cast as: “I am really telling a sequence to join its members together with a string constant”. Sadly, you aren’t. For some reason there seems to be much less difficulty with having \texttt{split()} as a string method, since in that case it is easy to see that

\begin{verbatim}
"1, 2, 4, 8, 16".split("", ")
\end{verbatim}
is an instruction to a string literal to return the substrings delimited by the given separator (or, by default, arbitrary runs of white space).

\texttt{join()} is a string method because in using it you are telling the separator string to iterate over a sequence of strings and insert itself between adjacent elements. This method can be used with any argument which obeys the rules for sequence objects, including any new classes you might define yourself. Similar methods exist for bytes and bytearray objects.
How fast are exceptions?

A try/except block is extremely efficient if no exceptions are raised. Actually catching an exception is expensive. In versions of Python prior to 2.0 it was common to use this idiom:

```python
try:
    value = mydict[key]
except KeyError:
    mydict[key] = getvalue(key)
    value = mydict[key]
```

This only made sense when you expected the dict to have the key almost all the time. If that wasn’t the case, you coded it like this:

```python
if key in mydict:
    value = mydict[key]
else:
    value = mydict[key] = getvalue(key)
```

For this specific case, you could also use `value = dict.setdefault(key, getvalue(key))`, but only if the `getvalue()` call is cheap enough because it is evaluated in all cases.
Why isn’t there a switch or case statement in Python?

You can do this easily enough with a sequence of `if... elif... elif... else`. There have been some proposals for switch statement syntax, but there is no consensus (yet) on whether and how to do range tests. See PEP 275 for complete details and the current status.

For cases where you need to choose from a very large number of possibilities, you can create a dictionary mapping case values to functions to call. For example:

```python
def function_1(...):
    ...

functions = {'a': function_1,
             'b': function_2,
             'c': self.method_1,
            ...
        }

func = functions[value]
func()
```

For calling methods on objects, you can simplify yet further by using the `getattr()` built-in to retrieve methods with a particular name:

```python
def visit_a(self, ...):
    ...
    ...

def dispatch(self, value):
    method_name = 'visit_' + str(value)
    method = getattr(self, method_name)
```
method()

It's suggested that you use a prefix for the method names, such as `visit_` in this example. Without such a prefix, if values are coming from an untrusted source, an attacker would be able to call any method on your object.
Can’t you emulate threads in the interpreter instead of relying on an OS-specific thread implementation?

Answer 1: Unfortunately, the interpreter pushes at least one C stack frame for each Python stack frame. Also, extensions can call back into Python at almost random moments. Therefore, a complete threads implementation requires thread support for C.

Answer 2: Fortunately, there is Stackless Python, which has a completely redesigned interpreter loop that avoids the C stack.
Why can’t lambda expressions contain statements?

Python lambda expressions cannot contain statements because Python's syntactic framework can't handle statements nested inside expressions. However, in Python, this is not a serious problem. Unlike lambda forms in other languages, where they add functionality, Python lambdas are only a shorthand notation if you're too lazy to define a function.

Functions are already first class objects in Python, and can be declared in a local scope. Therefore the only advantage of using a lambda instead of a locally-defined function is that you don’t need to invent a name for the function – but that's just a local variable to which the function object (which is exactly the same type of object that a lambda expression yields) is assigned!
Can Python be compiled to machine code, C or some other language?

Practical answer:

Cython and Pyrex compile a modified version of Python with optional annotations into C extensions. Weave makes it easy to intermingle Python and C code in various ways to increase performance. Nuitka is an up-and-coming compiler of Python into C++ code, aiming to support the full Python language.

Theoretical answer:

Not trivially. Python’s high level data types, dynamic typing of objects and run-time invocation of the interpreter (using eval() or exec()) together mean that a naïvely “compiled” Python program would probably consist mostly of calls into the Python run-time system, even for seemingly simple operations like \( x + 1 \).

Several projects described in the Python newsgroup or at past Python conferences have shown that this approach is feasible, although the speedups reached so far are only modest (e.g. 2x). Jython uses the same strategy for compiling to Java bytecode. (Jim Hugunin has demonstrated that in combination with whole-program analysis, speedups of 1000x are feasible for small demo programs. See the proceedings from the 1997 Python conference for more information.)
How does Python manage memory?

The details of Python memory management depend on the implementation. The standard implementation of Python, CPython, uses reference counting to detect inaccessible objects, and another mechanism to collect reference cycles, periodically executing a cycle detection algorithm which looks for inaccessible cycles and deletes the objects involved. The gc module provides functions to perform a garbage collection, obtain debugging statistics, and tune the collector's parameters.

Other implementations (such as Jython or PyPy), however, can rely on a different mechanism such as a full-blown garbage collector. This difference can cause some subtle porting problems if your Python code depends on the behavior of the reference counting implementation.

In some Python implementations, the following code (which is fine in CPython) will probably run out of file descriptors:

```python
for file in very_long_list_of_files:
    f = open(file)
    c = f.read(1)
```

Indeed, using CPython's reference counting and destructor scheme, each new assignment to f closes the previous file. With a traditional GC, however, those file objects will only get collected (and closed) at varying and possibly long intervals.

If you want to write code that will work with any Python implementation, you should explicitly close the file or use the with statement; this will work regardless of memory management scheme:
for file in very_long_list_of_files:
    with open(file) as f:
        c = f.read(1)
Why doesn’t CPython use a more traditional garbage collection scheme?

For one thing, this is not a C standard feature and hence it’s not portable. (Yes, we know about the Boehm GC library. It has bits of assembler code for most common platforms, not for all of them, and although it is mostly transparent, it isn’t completely transparent; patches are required to get Python to work with it.)

Traditional GC also becomes a problem when Python is embedded into other applications. While in a standalone Python it’s fine to replace the standard malloc() and free() with versions provided by the GC library, an application embedding Python may want to have its own substitute for malloc() and free(), and may not want Python’s. Right now, CPython works with anything that implements malloc() and free() properly.
Why isn’t all memory freed when CPython exits?

Objects referenced from the global namespaces of Python modules are not always deallocated when Python exits. This may happen if there are circular references. There are also certain bits of memory that are allocated by the C library that are impossible to free (e.g. a tool like Purify will complain about these). Python is, however, aggressive about cleaning up memory on exit and does try to destroy every single object.

If you want to force Python to delete certain things on deallocation use the `atexit` module to run a function that will force those deletions.
Why are there separate tuple and list data types?

Lists and tuples, while similar in many respects, are generally used in fundamentally different ways. Tuples can be thought of as being similar to Pascal records or C structs; they’re small collections of related data which may be of different types which are operated on as a group. For example, a Cartesian coordinate is appropriately represented as a tuple of two or three numbers.

Lists, on the other hand, are more like arrays in other languages. They tend to hold a varying number of objects all of which have the same type and which are operated on one-by-one. For example, `os.listdir('.')` returns a list of strings representing the files in the current directory. Functions which operate on this output would generally not break if you added another file or two to the directory.

Tuples are immutable, meaning that once a tuple has been created, you can’t replace any of its elements with a new value. Lists are mutable, meaning that you can always change a list's elements. Only immutable elements can be used as dictionary keys, and hence only tuples and not lists can be used as keys.
How are lists implemented?

Python's lists are really variable-length arrays, not Lisp-style linked lists. The implementation uses a contiguous array of references to other objects, and keeps a pointer to this array and the array's length in a list head structure.

This makes indexing a list \( a[i] \) an operation whose cost is independent of the size of the list or the value of the index.

When items are appended or inserted, the array of references is resized. Some cleverness is applied to improve the performance of appending items repeatedly; when the array must be grown, some extra space is allocated so the next few times don't require an actual resize.
How are dictionaries implemented?

Python’s dictionaries are implemented as resizable hash tables. Compared to B-trees, this gives better performance for lookup (the most common operation by far) under most circumstances, and the implementation is simpler.

Dictionaries work by computing a hash code for each key stored in the dictionary using the `hash()` built-in function. The hash code varies widely depending on the key and a per-process seed; for example, “Python” could hash to -539294296 while “python”, a string that differs by a single bit, could hash to 1142331976. The hash code is then used to calculate a location in an internal array where the value will be stored. Assuming that you’re storing keys that all have different hash values, this means that dictionaries take constant time – O(1), in computer science notation – to retrieve a key. It also means that no sorted order of the keys is maintained, and traversing the array as the `.keys()` and `.items()` do will output the dictionary’s content in some arbitrary jumbled order that can change with every invocation of a program.
Why must dictionary keys be immutable?

The hash table implementation of dictionaries uses a hash value calculated from the key value to find the key. If the key were a mutable object, its value could change, and thus its hash could also change. But since whoever changes the key object can't tell that it was being used as a dictionary key, it can't move the entry around in the dictionary. Then, when you try to look up the same object in the dictionary it won't be found because its hash value is different. If you tried to look up the old value it wouldn't be found either, because the value of the object found in that hash bin would be different.

If you want a dictionary indexed with a list, simply convert the list to a tuple first; the function `tuple(L)` creates a tuple with the same entries as the list `L`. Tuples are immutable and can therefore be used as dictionary keys.

Some unacceptable solutions that have been proposed:

- Hash lists by their address (object ID). This doesn't work because if you construct a new list with the same value it won't be found; e.g.:

```python
mydict = {[1, 2]: '12'}
print(mydict[[1, 2]])
```

would raise a KeyError exception because the id of the `[1, 2]` used in the second line differs from that in the first line. In other words, dictionary keys should be compared using `==`, not using `is`.

- Make a copy when using a list as a key. This doesn't work
because the list, being a mutable object, could contain a reference to itself, and then the copying code would run into an infinite loop.

- Allow lists as keys but tell the user not to modify them. This would allow a class of hard-to-track bugs in programs when you forgot or modified a list by accident. It also invalidates an important invariant of dictionaries: every value in \texttt{d.keys()} is usable as a key of the dictionary.

- Mark lists as read-only once they are used as a dictionary key. The problem is that it’s not just the top-level object that could change its value; you could use a tuple containing a list as a key. Entering anything as a key into a dictionary would require marking all objects reachable from there as read-only – and again, self-referential objects could cause an infinite loop.

There is a trick to get around this if you need to, but use it at your own risk: You can wrap a mutable structure inside a class instance which has both a \texttt{__eq__()} and a \texttt{__hash__()} method. You must then make sure that the hash value for all such wrapper objects that reside in a dictionary (or other hash based structure), remain fixed while the object is in the dictionary (or other structure).

```python
class ListWrapper:
    def __init__(self, the_list):
        self.the_list = the_list
    def __eq__(self, other):
        return self.the_list == other.the_list
    def __hash__(self):
        l = self.the_list
        result = 98767 - len(l)*555
        for i, el in enumerate(l):
            try:
                
```
Note that the hash computation is complicated by the possibility that some members of the list may be unhashable and also by the possibility of arithmetic overflow.

Furthermore it must always be the case that if \( o1 == o2 \) (ie \( o1.__eq__(o2) \) is True) then \( \text{hash}(o1) == \text{hash}(o2) \) (ie, \( o1.__hash__() == o2.__hash__() \)), regardless of whether the object is in a dictionary or not. If you fail to meet these restrictions dictionaries and other hash based structures will misbehave.

In the case of ListWrapper, whenever the wrapper object is in a dictionary the wrapped list must not change to avoid anomalies. Don’t do this unless you are prepared to think hard about the requirements and the consequences of not meeting them correctly. Consider yourself warned.
Why doesn’t list.sort() return the sorted list?

In situations where performance matters, making a copy of the list just to sort it would be wasteful. Therefore, `list.sort()` sorts the list in place. In order to remind you of that fact, it does not return the sorted list. This way, you won’t be fooled into accidentally overwriting a list when you need a sorted copy but also need to keep the unsorted version around.

If you want to return a new list, use the built-in `sorted()` function instead. This function creates a new list from a provided iterable, sorts it and returns it. For example, here’s how to iterate over the keys of a dictionary in sorted order:

```python
for key in sorted(mydict):
    ... # do whatever with mydict[key]...
```
How do you specify and enforce an interface spec in Python?

An interface specification for a module as provided by languages such as C++ and Java describes the prototypes for the methods and functions of the module. Many feel that compile-time enforcement of interface specifications helps in the construction of large programs.

Python 2.6 adds an `abc` module that lets you define Abstract Base Classes (ABCs). You can then use `isinstance()` and `issubclass()` to check whether an instance or a class implements a particular ABC. The `collections.abc` module defines a set of useful ABCs such as `Iterable`, `Container`, and `MutableMapping`.

For Python, many of the advantages of interface specifications can be obtained by an appropriate test discipline for components. There is also a tool, PyChecker, which can be used to find problems due to subclassing.

A good test suite for a module can both provide a regression test and serve as a module interface specification and a set of examples. Many Python modules can be run as a script to provide a simple “self test.” Even modules which use complex external interfaces can often be tested in isolation using trivial “stub” emulations of the external interface. The `doctest` and `unittest` modules or third-party test frameworks can be used to construct exhaustive test suites that exercise every line of code in a module.

An appropriate testing discipline can help build large complex applications in Python as well as having interface specifications would.
In fact, it can be better because an interface specification cannot test certain properties of a program. For example, the `append()` method is expected to add new elements to the end of some internal list; an interface specification cannot test that your `append()` implementation will actually do this correctly, but it's trivial to check this property in a test suite.

Writing test suites is very helpful, and you might want to design your code with an eye to making it easily tested. One increasingly popular technique, test-directed development, calls for writing parts of the test suite first, before you write any of the actual code. Of course Python allows you to be sloppy and not write test cases at all.
Why are default values shared between objects?

This type of bug commonly bites neophyte programmers. Consider this function:

```python
def foo(mydict={}):  # Danger: shared reference to one dict for all calls
    ... compute something ...
    mydict[key] = value
    return mydict
```

The first time you call this function, `mydict` contains a single item. The second time, `mydict` contains two items because when `foo()` begins executing, `mydict` starts out with an item already in it.

It is often expected that a function call creates new objects for default values. This is not what happens. Default values are created exactly once, when the function is defined. If that object is changed, like the dictionary in this example, subsequent calls to the function will refer to this changed object.

By definition, immutable objects such as numbers, strings, tuples, and None, are safe from change. Changes to mutable objects such as dictionaries, lists, and class instances can lead to confusion.

Because of this feature, it is good programming practice to not use mutable objects as default values. Instead, use None as the default value and inside the function, check if the parameter is None and create a new list/dictionary/whatever if it is. For example, don’t write:

```python
def foo(mydict={}):
```
but:

```python
def foo(mydict=None):
    if mydict is None:
        mydict = {}  # create a new dict for local namespace
```

This feature can be useful. When you have a function that's time-consuming to compute, a common technique is to cache the parameters and the resulting value of each call to the function, and return the cached value if the same value is requested again. This is called “memoizing”, and can be implemented like this:

```python
# Callers will never provide a third parameter for this function.
def expensive(arg1, arg2, _cache={}):
    if (arg1, arg2) in _cache:
        return _cache[(arg1, arg2)]

    # Calculate the value
    result = ...  # expensive computation ...
    _cache[(arg1, arg2)] = result  # Store result in the cache
    return result
```

You could use a global variable containing a dictionary instead of the default value; it's a matter of taste.
Why is there no goto?

You can use exceptions to provide a “structured goto” that even works across function calls. Many feel that exceptions can conveniently emulate all reasonable uses of the “go” or “goto” constructs of C, Fortran, and other languages. For example:

```python
class label(Exception): pass  # declare a label
try:
    ...
    if condition: raise label()  # goto label
    ...
except label:  # where to goto
    pass
    ...
```

This doesn't allow you to jump into the middle of a loop, but that's usually considered an abuse of goto anyway. Use sparingly.
Why can’t raw strings (r-strings) end with a backslash?

More precisely, they can’t end with an odd number of backslashes: the unpaired backslash at the end escapes the closing quote character, leaving an unterminated string.

Raw strings were designed to ease creating input for processors (chiefly regular expression engines) that want to do their own backslash escape processing. Such processors consider an unmatched trailing backslash to be an error anyway, so raw strings disallow that. In return, they allow you to pass on the string quote character by escaping it with a backslash. These rules work well when r-strings are used for their intended purpose.

If you’re trying to build Windows pathnames, note that all Windows system calls accept forward slashes too:

```python
f = open("/mydir/file.txt")  # works fine!
```

If you’re trying to build a pathname for a DOS command, try e.g. one of

```python
dir = r"\this\is\my\dos\dir" "\"
dir = r"\this\is\my\dos\dir\ "[:-1]
dir = "\\this\\is\\my\\dos\\dir\\"
```
Why doesn’t Python have a “with” statement for attribute assignments?

Python has a ‘with’ statement that wraps the execution of a block, calling code on the entrance and exit from the block. Some language have a construct that looks like this:

```python
with obj:
    a = 1  # equivalent to obj.a = 1
    total = total + 1  # obj.total = obj.total + 1
```

In Python, such a construct would be ambiguous.

Other languages, such as Object Pascal, Delphi, and C++, use static types, so it’s possible to know, in an unambiguous way, what member is being assigned to. This is the main point of static typing – the compiler always knows the scope of every variable at compile time.

Python uses dynamic types. It is impossible to know in advance which attribute will be referenced at runtime. Member attributes may be added or removed from objects on the fly. This makes it impossible to know, from a simple reading, what attribute is being referenced: a local one, a global one, or a member attribute?

For instance, take the following incomplete snippet:

```python
def foo(a):
    with a:
        print(x)
```

The snippet assumes that “a” must have a member attribute called “x”. However, there is nothing in Python that tells the interpreter this. What
should happen if “a” is, let us say, an integer? If there is a global variable named “x”, will it be used inside the with block? As you see, the dynamic nature of Python makes such choices much harder.

The primary benefit of “with” and similar language features (reduction of code volume) can, however, easily be achieved in Python by assignment. Instead of:

```python
function(args).mydict[index][index].a = 21
function(args).mydict[index][index].b = 42
function(args).mydict[index][index].c = 63
```

write this:

```python
ref = function(args).mydict[index][index]
ref.a = 21
ref.b = 42
ref.c = 63
```

This also has the side-effect of increasing execution speed because name bindings are resolved at run-time in Python, and the second version only needs to perform the resolution once.
Why are colons required for the if/while/def/class statements?

The colon is required primarily to enhance readability (one of the results of the experimental ABC language). Consider this:

```
if a == b
    print(a)
```

versus

```
if a == b:
    print(a)
```

Notice how the second one is slightly easier to read. Notice further how a colon sets off the example in this FAQ answer; it's a standard usage in English.

Another minor reason is that the colon makes it easier for editors with syntax highlighting; they can look for colons to decide when indentation needs to be increased instead of having to do a more elaborate parsing of the program text.
Why does Python allow commas at the end of lists and tuples?

Python lets you add a trailing comma at the end of lists, tuples, and dictionaries:

```
[1, 2, 3,]
('a', 'b', 'c',)
d = {
    "A": [1, 5],
    "B": [6, 7],  # last trailing comma is optional
}
```

There are several reasons to allow this.

When you have a literal value for a list, tuple, or dictionary spread across multiple lines, it's easier to add more elements because you don't have to remember to add a comma to the previous line. The lines can also be reordered without creating a syntax error.

Accidentally omitting the comma can lead to errors that are hard to diagnose. For example:

```
x = [
    "fee",
    "fie",
    "foo",
    "fum"
]
```

This list looks like it has four elements, but it actually contains three: “fee”, “fiefoo” and “fum”. Always adding the comma avoids this source
of error.

Allowing the trailing comma may also make programmatic code generation easier.

General Library Questions

How do I find a module or application to perform task X?

Check *the Library Reference* to see if there's a relevant standard library module. (Eventually you'll learn what's in the standard library and will be able to skip this step.)

For third-party packages, search the Python Package Index or try Google or another Web search engine. Searching for “Python” plus a keyword or two for your topic of interest will usually find something helpful.

**Where is the math.py (socket.py, regex.py, etc.) source file?**

If you can’t find a source file for a module it may be a built-in or dynamically loaded module implemented in C, C++ or other compiled language. In this case you may not have the source file or it may be something like *mathmodule.c*, somewhere in a C source directory (not on the Python Path).

There are (at least) three kinds of modules in Python:

1. modules written in Python (.py);

2. modules written in C and dynamically loaded (.dll, .pyd, .so, .sl, etc);

3. modules written in C and linked with the interpreter; to get a list of these, type:
import sys
print(sys.builtin_module_names)

How do I make a Python script executable on Unix?

You need to do two things: the script file’s mode must be executable and the first line must begin with `#!` followed by the path of the Python interpreter.

The first is done by executing `chmod +x scriptfile` or perhaps `chmod 755 scriptfile`.

The second can be done in a number of ways. The most straightforward way is to write

```bash
#!/usr/local/bin/python
```

as the very first line of your file, using the pathname for where the Python interpreter is installed on your platform.

If you would like the script to be independent of where the Python interpreter lives, you can use the `env` program. Almost all Unix variants support the following, assuming the Python interpreter is in a directory on the user’s PATH:

```bash
#!/usr/bin/env python
```

Don’t do this for CGI scripts. The PATH variable for CGI scripts is often very minimal, so you need to use the actual absolute pathname of the interpreter.
Occasionally, a user’s environment is so full that the `/usr/bin/env` program fails; or there’s no `env` program at all. In that case, you can try the following hack (due to Alex Rezinsky):

```bash
#!/bin/sh
""":" exec python $0 ${1+"$@"} """
```

The minor disadvantage is that this defines the script's `__doc__` string. However, you can fix that by adding

```python
__doc__ = """...Whatever..."""
```

**Is there a curses/termcap package for Python?**

For Unix variants: The standard Python source distribution comes with a curses module in the `Modules` subdirectory, though it’s not compiled by default. (Note that this is not available in the Windows distribution – there is no curses module for Windows.)

The `curses` module supports basic curses features as well as many additional functions from ncurses and SYSV curses such as colour, alternative character set support, pads, and mouse support. This means the module isn't compatible with operating systems that only have BSD curses, but there don’t seem to be any currently maintained OSes that fall into this category.

For Windows: use the `consolelib` module.

**Is there an equivalent to C’s onexit() in Python?**
The `atexit` module provides a register function that is similar to C's `onexit()`.

**Why don’t my signal handlers work?**

The most common problem is that the signal handler is declared with the wrong argument list. It is called as

```
handler(signum, frame)
```

so it should be declared with two arguments:

```
def handler(signum, frame):
    ...
```
Common tasks

How do I test a Python program or component?

Python comes with two testing frameworks. The `doctest` module finds examples in the docstrings for a module and runs them, comparing the output with the expected output given in the docstring.

The `unittest` module is a fancier testing framework modelled on Java and Smalltalk testing frameworks.

To make testing easier, you should use good modular design in your program. Your program should have almost all functionality encapsulated in either functions or class methods – and this sometimes has the surprising and delightful effect of making the program run faster (because local variable accesses are faster than global accesses). Furthermore the program should avoid depending on mutating global variables, since this makes testing much more difficult to do.

The “global main logic” of your program may be as simple as

```python
if __name__ == "__main__":
    main_logic()
```

at the bottom of the main module of your program.

Once your program is organized as a tractable collection of functions and class behaviours you should write test functions that exercise the behaviours. A test suite that automates a sequence of tests can be associated with each module. This sounds like a lot of work, but since Python is so terse and flexible it’s surprisingly easy. You can make
coding much more pleasant and fun by writing your test functions in parallel with the “production code”, since this makes it easy to find bugs and even design flaws earlier.

“Support modules” that are not intended to be the main module of a program may include a self-test of the module.

```python
if __name__ == "__main__":
    self_test()
```

Even programs that interact with complex external interfaces may be tested when the external interfaces are unavailable by using “fake” interfaces implemented in Python.

**How do I create documentation from doc strings?**

The `pydoc` module can create HTML from the doc strings in your Python source code. An alternative for creating API documentation purely from docstrings is `epydoc`. `Sphinx` can also include docstring content.

**How do I get a single keypress at a time?**

For Unix variants there are several solutions. It’s straightforward to do this using curses, but curses is a fairly large module to learn.
Threads

How do I program using threads?

Be sure to use the `threading` module and not the `_thread` module. The `threading` module builds convenient abstractions on top of the low-level primitives provided by the `_thread` module.

Aahz has a set of slides from his threading tutorial that are helpful; see http://www.pythoncraft.com/OSCON2001/.

None of my threads seem to run: why?

As soon as the main thread exits, all threads are killed. Your main thread is running too quickly, giving the threads no time to do any work.

A simple fix is to add a sleep to the end of the program that's long enough for all the threads to finish:

```python
import threading, time

def thread_task(name, n):
    for i in range(n):
        print(name, i)

for i in range(10):
    T = threading.Thread(target=thread_task, args=(str(T.start()),))
    T.join()

time.sleep(10)  # <---------------------------!
```

But now (on many platforms) the threads don’t run in parallel, but
appear to run sequentially, one at a time! The reason is that the OS thread scheduler doesn’t start a new thread until the previous thread is blocked.

A simple fix is to add a tiny sleep to the start of the run function:

```python
def thread_task(name, n):
    time.sleep(0.001)  # ------------------!
    for i in range(n):
        print(name, i)

for i in range(10):
    T = threading.Thread(target=thread_task, args=(str(T.start()),))
    T.start()

time.sleep(10)
```

Instead of trying to guess a good delay value for `time.sleep()`, it’s better to use some kind of semaphore mechanism. One idea is to use the `queue` module to create a queue object, let each thread append a token to the queue when it finishes, and let the main thread read as many tokens from the queue as there are threads.

**How do I parcel out work among a bunch of worker threads?**

The easiest way is to use the new `concurrent.futures` module, especially the `ThreadPoolExecutor` class.

Or, if you want fine control over the dispatching algorithm, you can write your own logic manually. Use the `queue` module to create a queue containing a list of jobs. The `Queue` class maintains a list of objects and has a `.put(obj)` method that adds items to the queue
and a `.get()` method to return them. The class will take care of the locking necessary to ensure that each job is handed out exactly once.

Here's a trivial example:

```python
import threading, queue, time

# The worker thread gets jobs off the queue. When the queue is empty, it assumes there will be no more work and exits. (Realistically workers will run until terminated.)
def worker():
    print('Running worker')
    time.sleep(0.1)
    while True:
        try:
            arg = q.get(block=False)
        except queue.Empty:
            print('Worker', threading.currentThread(), 'queue empty')
            break
        else:
            print('Worker', threading.currentThread(), 'running with argument', arg)
            time.sleep(0.5)

# Create queue
q = queue.Queue()

# Start a pool of 5 workers
for i in range(5):
    t = threading.Thread(target=worker, name='worker%i' % i)
    t.start()

# Begin adding work to the queue
for i in range(50):
    q.put(i)
```
# Give threads time to run

```python
print('Main thread sleeping')
time.sleep(5)
```

When run, this will produce the following output:

```
Running worker
Running worker
Running worker
Running worker
Running worker
Main thread sleeping
Worker <Thread(worker 1, started 130283832797456)> running with argument 0

...
```

Consult the module’s documentation for more details; the `Queue` class provides a featureful interface.

**What kinds of global value mutation are thread-safe?**

A *global interpreter lock* (GIL) is used internally to ensure that only one thread runs in the Python VM at a time. In general, Python offers to switch among threads only between bytecode instructions; how frequently it switches can be set via `sys.setswitchinterval()`. Each bytecode instruction and therefore all the C implementation code reached from each instruction is therefore atomic from the point of
view of a Python program.

In theory, this means an exact accounting requires an exact understanding of the PVM bytecode implementation. In practice, it means that operations on shared variables of built-in data types (ints, lists, dicts, etc) that “look atomic” really are.

For example, the following operations are all atomic (L, L1, L2 are lists, D, D1, D2 are dicts, x, y are objects, i, j are ints):

```python
L.append(x)
L1.extend(L2)
x = L[i]
x = L.pop()
L1[i:j] = L2
L.sort()
x = y
x.field = y
D[x] = y
D1.update(D2)
D.keys()
```

These aren’t:

```python
i = i+1
L.append(L[-1])
L[i] = L[j]
D[x] = D[x] + 1
```

Operations that replace other objects may invoke those other objects’ `__del__()` method when their reference count reaches zero, and that can affect things. This is especially true for the mass updates to dictionaries and lists. When in doubt, use a mutex!
Can’t we get rid of the Global Interpreter Lock?

The *global interpreter lock* (GIL) is often seen as a hindrance to Python’s deployment on high-end multiprocessor server machines, because a multi-threaded Python program effectively only uses one CPU, due to the insistence that (almost) all Python code can only run while the GIL is held.

Back in the days of Python 1.5, Greg Stein actually implemented a comprehensive patch set (the “free threading” patches) that removed the GIL and replaced it with fine-grained locking. Adam Olsen recently did a similar experiment in his *python-safethread* project. Unfortunately, both experiments exhibited a sharp drop in single-thread performance (at least 30% slower), due to the amount of fine-grained locking necessary to compensate for the removal of the GIL.

This doesn’t mean that you can’t make good use of Python on multi-CPU machines! You just have to be creative with dividing the work up between multiple *processes* rather than multiple *threads*. The *ProcessPoolExecutor* class in the new *concurrent.futures* module provides an easy way of doing so; the *multiprocessing* module provides a lower-level API in case you want more control over dispatching of tasks.

Judicious use of C extensions will also help; if you use a C extension to perform a time-consuming task, the extension can release the GIL while the thread of execution is in the C code and allow other threads to get some work done. Some standard library modules such as *zlib* and *hashlib* already do this.

It has been suggested that the GIL should be a per-interpreter-state lock rather than truly global; interpreters then wouldn’t be able to share
objects. Unfortunately, this isn’t likely to happen either. It would be a tremendous amount of work, because many object implementations currently have global state. For example, small integers and short strings are cached; these caches would have to be moved to the interpreter state. Other object types have their own free list; these free lists would have to be moved to the interpreter state. And so on.

And I doubt that it can even be done in finite time, because the same problem exists for 3rd party extensions. It is likely that 3rd party extensions are being written at a faster rate than you can convert them to store all their global state in the interpreter state.

And finally, once you have multiple interpreters not sharing any state, what have you gained over running each interpreter in a separate process?
How do I delete a file? (And other file questions...)

Use `os.remove(filename)` or `os.unlink(filename)`; for documentation, see the `os` module. The two functions are identical; `unlink()` is simply the name of the Unix system call for this function.

To remove a directory, use `os.rmdir()`; use `os.mkdir()` to create one. `os.makedirs(path)` will create any intermediate directories in `path` that don't exist. `os.removedirs(path)` will remove intermediate directories as long as they're empty; if you want to delete an entire directory tree and its contents, use `shutil.rmtree()`.

To rename a file, use `os.rename(old_path, new_path)`.

To truncate a file, open it using `f = open(filename, "rb+"), and use `f.truncate(offset)`; offset defaults to the current seek position. There's also `os.ftruncate(fd, offset)` for files opened with `os.open()`, where `fd` is the file descriptor (a small integer).

The `shutil` module also contains a number of functions to work on files including `copyfile()`, `copytree()`, and `rmtree()`.

How do I copy a file?

The `shutil` module contains a `copyfile()` function. Note that on MacOS 9 it doesn’t copy the resource fork and Finder info.

How do I read (or write) binary data?
To read or write complex binary data formats, it's best to use the `struct` module. It allows you to take a string containing binary data (usually numbers) and convert it to Python objects; and vice versa.

For example, the following code reads two 2-byte integers and one 4-byte integer in big-endian format from a file:

```python
import struct

with open(filename, "rb") as f:
    s = f.read(8)
    x, y, z = struct.unpack(">hhl", s)
```

The ‘>’ in the format string forces big-endian data; the letter ‘h’ reads one “short integer” (2 bytes), and ‘l’ reads one “long integer” (4 bytes) from the string.

For data that is more regular (e.g. a homogeneous list of ints or floats), you can also use the `array` module.

**Note:** To read and write binary data, it is mandatory to open the file in binary mode (here, passing "rb" to `open()`). If you use "r" instead (the default), the file will be open in text mode and `f.read()` will return `str` objects rather than `bytes` objects.

I can’t seem to use os.read() on a pipe created with os.popen(); why?

`os.read()` is a low-level function which takes a file descriptor, a small integer representing the opened file. `os.popen()` creates a high-level file object, the same type returned by the built-in `open()`
function. Thus, to read \( n \) bytes from a pipe \( p \) created with \texttt{os.popen()} , you need to use \texttt{p.read(n)}.

**How do I access the serial (RS232) port?**

For Win32, POSIX (Linux, BSD, etc.), Jython:

\texttt{http://pyserial.sourceforge.net}

For Unix, see a Usenet post by Mitch Chapman:

\texttt{http://groups.google.com/groups?selm=34A04430.CF9@ohioee.com}

**Why doesn’t closing \texttt{sys.stdout} (stdin, stderr) really close it?**

Python *file objects* are a high-level layer of abstraction on low-level C file descriptors.

For most file objects you create in Python via the built-in \texttt{open()} function, \texttt{f.close()} marks the Python file object as being closed from Python’s point of view, and also arranges to close the underlying C file descriptor. This also happens automatically in \texttt{f}’s destructor, when \texttt{f} becomes garbage.

But stdin, stdout and stderr are treated specially by Python, because of the special status also given to them by C. Running \texttt{sys.stdout.close()} marks the Python-level file object as being closed, but does *not* close the associated C file descriptor.

To close the underlying C file descriptor for one of these three, you should first be sure that’s what you really want to do (e.g., you may
confuse extension modules trying to do I/O). If it is, use `os.close()`:

```python
os.close(stdin.fileno())
os.close(stdout.fileno())
os.close(stderr.fileno())
```

Or you can use the numeric constants 0, 1 and 2, respectively.
Network/Internet Programming

What WWW tools are there for Python?

See the chapters titled *Internet Protocols and Support* and *Internet Data Handling* in the Library Reference Manual. Python has many modules that will help you build server-side and client-side web systems.

How can I mimic CGI form submission (METHOD=POST)?

I would like to retrieve web pages that are the result of POSTing a form. Is there existing code that would let me do this easily?

Yes. Here's a simple example that uses urllib.request:

```python
#!/usr/local/bin/python

import urllib.request

### build the query string
qs = "First=Josephine&MI=Q&Last=Public"

### connect and send the server a path
req = urllib.request.urlopen('http://www.some-server.out-there/cgi-bin/some-cgi-script'
```
Note that in general for percent-encoded POST operations, query strings must be quoted using `urllib.parse.urlencode()`. For example, to send name=Guy Steele, Jr.:

```python
>>> import urllib.parse
>>> urllib.parse.urlencode({'name': 'Guy Steele, Jr.
'name=Guy+Steele%2C+Jr.'
```

See also: [HOWTO Fetch Internet Resources Using The urllib Package](#) for extensive examples.

**What module should I use to help with generating HTML?**

You can find a collection of useful links on the Web Programming wiki page.

**How do I send mail from a Python script?**

Use the standard library module `smtplib`.

Here's a very simple interactive mail sender that uses it. This method will work on any host that supports an SMTP listener.

```python
import sys, smtplib
fromaddr = input("From: ")
toaddrs = input("To: ").split(',', )
print("Enter message, end with ^D:")
```
```python
msg = ''
while True:
    line = sys.stdin.readline()
    if not line:
        break
    msg += line

# The actual mail send
server = smtplib.SMTP('localhost')
server.sendmail(fromaddr, toaddrs, msg)
server.quit()
```

A Unix-only alternative uses sendmail. The location of the sendmail program varies between systems; sometimes it is /usr/lib/sendmail, sometimes /usr/sbin/sendmail. The sendmail manual page will help you out. Here’s some sample code:

```python
SENDMAIL = "/usr/sbin/sendmail"  # sendmail location
import os
p = os.popen("%s -t -i" % SENDMAIL, "w")
p.write("To: receiver@example.com\n")
p.write("Subject: test\n")
p.write("\n")  # blank line separating headers from
p.write("Some text\n")
p.write("some more text\n")
sts = p.close()
if sts != 0:
    print("Sendmail exit status", sts)
```

How do I avoid blocking in the connect() method of a socket?

The `select` module is commonly used to help with asynchronous I/O on sockets.
To prevent the TCP connect from blocking, you can set the socket to non-blocking mode. Then when you do the `connect()`, you will either connect immediately (unlikely) or get an exception that contains the error number as `.errno`. `errno.EINPROGRESS` indicates that the connection is in progress, but hasn't finished yet. Different OSes will return different values, so you're going to have to check what's returned on your system.

You can use the `connect_ex()` method to avoid creating an exception. It will just return the `errno` value. To poll, you can call `connect_ex()` again later – 0 or `errno.EISCONN` indicate that you're connected – or you can pass this socket to select to check if it's writable.

**Note:** The `asyncore` module presents a framework-like approach to the problem of writing non-blocking networking code. The third-party `Twisted` library is a popular and feature-rich alternative.
Databases

Are there any interfaces to database packages in Python?

Yes.

Interfaces to disk-based hashes such as DBM and GDBM are also included with standard Python. There is also the sqlite3 module, which provides a lightweight disk-based relational database.

Support for most relational databases is available. See the DatabaseProgramming wiki page for details.

How do you implement persistent objects in Python?

The pickle library module solves this in a very general way (though you still can’t store things like open files, sockets or windows), and the shelve library module uses pickle and (g)dbm to create persistent mappings containing arbitrary Python objects.
Mathematics and Numerics

How do I generate random numbers in Python?

The standard module `random` implements a random number generator. Usage is simple:

```python
import random
random.random()
```

This returns a random floating point number in the range \([0, 1)\).

There are also many other specialized generators in this module, such as:

- `randrange(a, b)` chooses an integer in the range \([a, b)\).
- `uniform(a, b)` chooses a floating point number in the range \([a, b)\).
- `normalvariate(mean, sdev)` samples the normal (Gaussian) distribution.

Some higher-level functions operate on sequences directly, such as:

- `choice(S)` chooses random element from a given sequence
- `shuffle(L)` shuffles a list in-place, i.e. permutes it randomly

There's also a `Random` class you can instantiate to create independent multiple random number generators.

Can I create my own functions in C?

Yes, you can create built-in modules containing functions, variables, exceptions and even new types in C. This is explained in the document *Extending and Embedding the Python Interpreter*.

Most intermediate or advanced Python books will also cover this topic.
Can I create my own functions in C++?

Yes, using the C compatibility features found in C++. Place `extern "C" { ... }` around the Python include files and put `extern "C"` before each function that is going to be called by the Python interpreter. Global or static C++ objects with constructors are probably not a good idea.
Writing C is hard; are there any alternatives?

There are a number of alternatives to writing your own C extensions, depending on what you're trying to do.

Cython and its relative Pyrex are compilers that accept a slightly modified form of Python and generate the corresponding C code. Cython and Pyrex make it possible to write an extension without having to learn Python's C API.

If you need to interface to some C or C++ library for which no Python extension currently exists, you can try wrapping the library's data types and functions with a tool such as SWIG. SIP, CXX Boost, or Weave are also alternatives for wrapping C++ libraries.
How can I execute arbitrary Python statements from C?

The highest-level function to do this is `PyRun_SimpleString()` which takes a single string argument to be executed in the context of the module `__main__` and returns 0 for success and -1 when an exception occurred (including `SyntaxError`). If you want more control, use `PyRun_String()`; see the source for `PyRun_SimpleString()` in `Python/pythonrun.c`. 
How can I evaluate an arbitrary Python expression from C?

Call the function `PyRun_String()` from the previous question with the start symbol `Py_eval_input`; it parses an expression, evaluates it and returns its value.
How do I extract C values from a Python object?

That depends on the object's type. If it's a tuple, PyTuple_Size() returns its length and PyTuple_GetItem() returns the item at a specified index. Lists have similar functions, PyList_Size() and PyList_GetItem().

For bytes, PyBytes_Size() returns its length and PyBytes_AsStringAndSize() provides a pointer to its value and its length. Note that Python bytes objects may contain null bytes so C’s strlen() should not be used.

To test the type of an object, first make sure it isn't NULL, and then use PyBytes_Check(), PyTuple_Check(), PyList_Check(), etc.

There is also a high-level API to Python objects which is provided by the so-called ‘abstract’ interface – read Include/abstract.h for further details. It allows interfacing with any kind of Python sequence using calls like PySequence_Length(), PySequence_GetItem(), etc.) as well as many other useful protocols such as numbers (PyNumber_Index() et. al.) and mappings in the PyMapping APIs.
How do I use `Py_BuildValue()` to create a tuple of arbitrary length?

You can't. Use `PyTuple_Pack()` instead.
How do I call an object’s method from C?

The `PyObject_CallMethod()` function can be used to call an arbitrary method of an object. The parameters are the object, the name of the method to call, a format string like that used with `Py_BuildValue()`, and the argument values:

```
PyObject *
PyObject_CallMethod(PyObject *object, char *method_name,
                    char *arg_format, ...);
```

This works for any object that has methods – whether built-in or user-defined. You are responsible for eventually `Py_XDECREF()`‘ing the return value.

To call, e.g., a file object’s “seek” method with arguments 10, 0 (assuming the file object pointer is “f”):

```
res = PyObject_CallMethod(f, "seek", "(ii)", 10, 0);
if (res == NULL) {
    ... an exception occurred ...
}
else {
    Py_XDECREF(res);
}
```

Note that since `PyObject_CallObject()` always wants a tuple for the argument list, to call a function without arguments, pass “()” for the format, and to call a function with one argument, surround the argument in parentheses, e.g. “(i)”.  

How do I catch the output from PyErr_Print() (or anything that prints to stdout/stderr)?

In Python code, define an object that supports the `write()` method. Assign this object to `sys.stdout` and `sys.stderr`. Call `print_error`, or just allow the standard traceback mechanism to work. Then, the output will go wherever your `write()` method sends it.

The easiest way to do this is to use the `io.StringIO` class:

```python
>>> import io, sys
>>> sys.stdout = io.StringIO()
>>> print('foo')
>>> print('hello world!')
>>> sys.stderr.write(sys.stdout.getvalue())
foo
hello world!
```

A custom object to do the same would look like this:

```python
>>> import io, sys
>>> class StdoutCatcher(io.TextIOBase):
...     def __init__(self):
...         self.data = []
...     def write(self, stuff):
...         self.data.append(stuff)
... >>> import sys
>>> sys.stdout = StdoutCatcher()
>>> print('foo')
>>> print('hello world!')
>>> sys.stderr.write('
'.join(sys.stdout.data))
```
foo
hello world!
How do I access a module written in Python from C?

You can get a pointer to the module object as follows:

```c
module = PyImport_ImportModule("<modulename>");
```

If the module hasn't been imported yet (i.e. it is not yet present in `sys.modules`), this initializes the module; otherwise it simply returns the value of `sys.modules["<modulename>"]`. Note that it doesn't enter the module into any namespace – it only ensures it has been initialized and is stored in `sys.modules`.

You can then access the module's attributes (i.e. any name defined in the module) as follows:

```c
attr = PyObject_GetAttrString(module, "<attrname>");
```

Calling `PyObject_SetAttrString()` to assign to variables in the module also works.
How do I interface to C++ objects from Python?

Depending on your requirements, there are many approaches. To do this manually, begin by reading the “Extending and Embedding” document. Realize that for the Python run-time system, there isn’t a whole lot of difference between C and C++ – so the strategy of building a new Python type around a C structure (pointer) type will also work for C++ objects.

For C++ libraries, see Writing C is hard; are there any alternatives?. 
I added a module using the Setup file and the make fails; why?

Setup must end in a newline, if there is no newline there, the build process fails. (Fixing this requires some ugly shell script hackery, and this bug is so minor that it doesn't seem worth the effort.)
How do I debug an extension?

When using GDB with dynamically loaded extensions, you can’t set a breakpoint in your extension until your extension is loaded.

In your `.gdbinit` file (or interactively), add the command:

```
br _PyImport_LoadDynamicModule
```

Then, when you run GDB:

```
$ gdb /local/bin/python
gdb) run myscript.py
```

```
gdb) continue # repeat until your extension is loaded
```n
```
gdb) finish    # so that your extension is loaded
```

```
gdb) br myfunction.c:50
```

```
gdb) continue
```
I want to compile a Python module on my Linux system, but some files are missing. Why?

Most packaged versions of Python don’t include the `/usr/lib/python2.x/config/` directory, which contains various files required for compiling Python extensions.

For Red Hat, install the python-devel RPM to get the necessary files.

For Debian, run `apt-get install python-dev`. 
What does “SystemError: _PyImport_FixupExtension: module yourmodule not loaded” mean?

This means that you have created an extension module named “yourmodule”, but your module init function does not initialize with that name.

Every module init function will have a line similar to:

```python
module = Py_InitModule("yourmodule", yourmodule_functions)
```

If the string passed to this function is not the same name as your extension module, the `SystemError` exception will be raised.
How do I tell “incomplete input” from “invalid input”?  

Sometimes you want to emulate the Python interactive interpreter’s behavior, where it gives you a continuation prompt when the input is incomplete (e.g. you typed the start of an “if” statement or you didn’t close your parentheses or triple string quotes), but it gives you a syntax error message immediately when the input is invalid.

In Python you can use the `codeop` module, which approximates the parser’s behavior sufficiently. IDLE uses this, for example.

The easiest way to do it in C is to call `PyRun_InteractiveLoop()` (perhaps in a separate thread) and let the Python interpreter handle the input for you. You can also set the `PyOS_ReadlineFunctionPointer()` to point at your custom input function. See `Modules/readline.c` and `Parser/myreadline.c` for more hints.

However sometimes you have to run the embedded Python interpreter in the same thread as your rest application and you can’t allow the `PyRun_InteractiveLoop()` to stop while waiting for user input. The one solution then is to call `PyParser_ParseString()` and test for `e.error` equal to `E_EOF`, which means the input is incomplete.

Here’s a sample code fragment, untested, inspired by code from Alex Farber:

```c
#include <Python.h>
#include <node.h>
#include <errcode.h>
#include <grammar.h>
#include <parsetok.h>
```
```c
#include <compile.h>

int testcomplete(char *code) {
    /* code should end in \n */
    /* return -1 for error, 0 for incomplete, 1 for complete */
    
    node *n;
    perrdetail e;

    n = PyParser_ParseString(code, &_PyParser_Grammar, Py_file_input, &e);
    if (n == NULL) {
        if (e.error == E_EOF) return 0;
        return -1;
    }

    PyNode_Free(n);
    return 1;
}
```

Another solution is trying to compile the received string with `Py_CompileString()`. If it compiles without errors, try to execute the returned code object by calling `PyEval_EvalCode()`. Otherwise save the input for later. If the compilation fails, find out if it's an error or just more input is required - by extracting the message string from the exception tuple and comparing it to the string “unexpected EOF while parsing”. Here is a complete example using the GNU readline library (you may want to ignore `SIGINT` while calling readline()):

```c
#include <stdio.h>
#include <readline.h>

#include <Python.h>
#include <object.h>
```
#include <compile.h>
#include <eval.h>

int main (int argc, char* argv[]) {
    int i, j, done = 0;    /* lengths of line, code */
    char ps1[] = ">>> ";
    char ps2[] = "... ";
    char *prompt = ps1;
    char *msg, *line, *code = NULL;
    PyObject *src, *glb, *loc;

    Py_Initialize ();
    loc = PyDict_New ();
    glb = PyDict_New ();
    PyDict_SetItemString (glb, "__builtins__", PyEval_GetBuiltins);

    while (!done)
    {
        line = readline (prompt);

        if (NULL == line)    /* CTRL-D pressed */
        {
            done = 1;
        }
        else
        {
            i = strlen (line);

            if (i > 0)
                add_history (line);    /* save non-empty lines */

            if (NULL == code)
                j = 0;    /* no previous code */
            else
                j = strlen (code);

            if (i < j)
                break;
        }
    }
}
code = realloc (code, i + j + 2);
if (NULL == code) /* out */
    exit (1);
if (0 == j) /* code */
    code[0] = '\0'; /* keep
strncat (code, line, i); /* append
    code[i + j] = '\n'; /* append
    code[i + j + 1] = '\0';

src = Py_CompileString (code, "<stdin>", Py_single_input
if (NULL != src) /* code */
{
    if (ps1 == prompt ||
        '
' == code[i + j - 1]) /* ",
    {
        dum = PyEval_EvalCode (src, glb, loc);
P_XDECREF (dum);
P_XDECREF (src);
free (code);
code = NULL;
    if (PyErr_Occurred ())
        PyErr_Print ();
prompt = ps1;
    }
}
else if (PyErr_ExceptionMatches (PyExc_SyntaxError))
{
    PyErr_Fetch (&exc, &val, &trb); /* clear
    if (PyArg_ParseTuple (val, "sO", &msg, &obj)
        !strcmp (msg, "unexpected EOF while parsing")
    {
        Py_XDECREF (exc);
    }
else if (PyErr_ExceptionMatches (PyExc_SyntaxError))
{
Py_XDECREF (val);
Py_XDECREF (trb);
prompt = ps2;
}

else
{
    PyErr_Restore (exc, val, trb);
    PyErr_Print ();
    free (code);
    code = NULL;
    prompt = ps1;
}

free (line);
}

Py_XDECREF (glb);
Py_XDECREF (loc);
Py_Finalize();
exit(0);
How do I find undefined g++ symbols __builtin_new or __pure_virtual?

To dynamically load g++ extension modules, you must recompile Python, relink it using g++ (change LINKCC in the Python Modules Makefile), and link your extension module using g++ (e.g., g++ -shared -o mymodule.so mymodule.o).
Can I create an object class with some methods implemented in C and others in Python (e.g. through inheritance)?

In Python 2.2, you can inherit from built-in classes such as \texttt{int}, \texttt{list}, \texttt{dict}, etc.

The Boost Python Library (BPL, http://www.boost.org/libs/python/doc/index.html) provides a way of doing this from C++ (i.e. you can inherit from an extension class written in C++ using the BPL).

How do I run a Python program under Windows?

This is not necessarily a straightforward question. If you are already familiar with running programs from the Windows command line then everything will seem obvious; otherwise, you might need a little more guidance.

Unless you use some sort of integrated development environment, you will end up **typing** Windows commands into what is variously referred to as a “DOS window” or “Command prompt window”. Usually you can create such a window from your Start menu; under Windows 7 the menu selection is **Start ▶ Programs ▶ Accessories ▶ Command Prompt**. You should be able to recognize when you have started such a window because you will see a Windows “command prompt”, which usually looks like this:

```
C:\>
```

The letter may be different, and there might be other things after it, so you might just as easily see something like:

```
D:\YourName\Projects\Python>
```
depending on how your computer has been set up and what else you have recently done with it. Once you have started such a window, you are well on the way to running Python programs.

You need to realize that your Python scripts have to be processed by another program called the Python interpreter. The interpreter reads your script, compiles it into bytecodes, and then executes the bytecodes to run your program. So, how do you arrange for the interpreter to handle your Python?

First, you need to make sure that your command window recognises the word “python” as an instruction to start the interpreter. If you have opened a command window, you should try entering the command python and hitting return.:

```
C:\Users\YourName> python
```

You should then see something like:

```
Python 3.3.0 (v3.3.0:bd8af90ebf2, Sep 29 2012, 10:5
Type "help", "copyright", "credits" or "license" for
>>>
```

You have started the interpreter in “interactive mode”. That means you can enter Python statements or expressions interactively and have them executed or evaluated while you wait. This is one of Python’s strongest features. Check it by entering a few expressions of your choice and seeing the results:

```
>>> print("Hello")
Hello
>>> "Hello" * 3
HelloHelloHello
```
Adding Python to DOS Path

Python is not added to the DOS path by default. This screencast will walk you through the steps to add the correct entry to the System Path, allowing Python to be executed from the command-line by all users.

Many people use the interactive mode as a convenient yet highly programmable calculator. When you want to end your interactive Python session, hold the Ctrl key down while you enter a Z, then hit the “Enter” key to get back to your Windows command prompt.

You may also find that you have a Start-menu entry such as Start ▶ Programs ▶ Python 3.3 ▶ Python (command line) that results in you seeing the >>> prompt in a new window. If so, the window will disappear after you enter the Ctrl-Z character; Windows is running a single “python” command in the window, and closes it when you terminate the interpreter.

If the python command, instead of displaying the interpreter prompt >>>, gives you a message like:

```
'python' is not recognized as an internal or external command
```
or:

```
Bad command or filename
```

then you need to make sure that your computer knows where to find the Python interpreter. To do this you will have to modify a setting called PATH, which is a list of directories where Windows will look for programs.

You should arrange for Python’s installation directory to be added to the PATH of every command window as it starts. If you installed Python...
fairly recently then the command

```
dir C:\py*
```

will probably tell you where it is installed; the usual location is something like C:\Python33. Otherwise you will be reduced to a search of your whole disk ... use Tools ▶ Find or hit the Search button and look for “python.exe”. Supposing you discover that Python is installed in the C:\Python33 directory (the default at the time of writing), you should make sure that entering the command

```
c:\Python33\python
```

starts up the interpreter as above (and don’t forget you’ll need a “CTRL-Z” and an “Enter” to get out of it). Once you have verified the directory, you can add it to the system path to make it easier to start Python by just running the python command. This is currently an option in the installer as of CPython 3.3.

More information about environment variables can be found on the *Using Python on Windows* page.
How do I make Python scripts executable?

On Windows, the standard Python installer already associates the .py extension with a file type (Python.File) and gives that file type an open command that runs the interpreter (D:\Program Files\Python\python.exe "%1" %*). This is enough to make scripts executable from the command prompt as ‘foo.py’. If you’d rather be able to execute the script by simple typing ‘foo’ with no extension you need to add .py to the PATHEXT environment variable.
Why does Python sometimes take so long to start?

Usually Python starts very quickly on Windows, but occasionally there are bug reports that Python suddenly begins to take a long time to start up. This is made even more puzzling because Python will work fine on other Windows systems which appear to be configured identically.

The problem may be caused by a misconfiguration of virus checking software on the problem machine. Some virus scanners have been known to introduce startup overhead of two orders of magnitude when the scanner is configured to monitor all reads from the filesystem. Try checking the configuration of virus scanning software on your systems to ensure that they are indeed configured identically. McAfee, when configured to scan all file system read activity, is a particular offender.
How do I make an executable from a Python script?

See http://www.py2exe.org/ for a distutils extension that allows you to create console and GUI executables from Python code.
Is a *.pyd file the same as a DLL?

Yes, .pyd files are dll's, but there are a few differences. If you have a DLL named foo.pyd, then it must have a function initfoo(). You can then write Python “import foo”, and Python will search for foo.pyd (as well as foo.py, foo.pyc) and if it finds it, will attempt to call initfoo() to initialize it. You do not link your .exe with foo.lib, as that would cause Windows to require the DLL to be present.

Note that the search path for foo.pyd is PYTHONPATH, not the same as the path that Windows uses to search for foo.dll. Also, foo.pyd need not be present to run your program, whereas if you linked your program with a dll, the dll is required. Of course, foo.pyd is required if you want to say import foo. In a DLL, linkage is declared in the source code with __declspec(dllexport). In a .pyd, linkage is defined in a list of available functions.
How can I embed Python into a Windows application?

Embedding the Python interpreter in a Windows app can be summarized as follows:

1. Do _not_ build Python into your .exe file directly. On Windows, Python must be a DLL to handle importing modules that are themselves DLL's. (This is the first key undocumented fact.) Instead, link to pythonNN.dll; it is typically installed in C:\Windows\System. NN is the Python version, a number such as “33” for Python 3.3.

You can link to Python in two different ways. Load-time linking means linking against pythonNN.lib, while run-time linking means linking against pythonNN.dll. (General note: pythonNN.lib is the so-called “import lib” corresponding to pythonNN.dll. It merely defines symbols for the linker.)

Run-time linking greatly simplifies link options; everything happens at run time. Your code must load pythonNN.dll using the Windows LoadLibraryEx() routine. The code must also use access routines and data in pythonNN.dll (that is, Python's C API's) using pointers obtained by the Windows GetProcAddress() routine. Macros can make using these pointers transparent to any C code that calls routines in Python's C API.

Borland note: convert pythonNN.lib to OMF format using Coff2Omf.exe first.
2. If you use SWIG, it is easy to create a Python “extension module” that will make the app’s data and methods available to Python. SWIG will handle just about all the grungy details for you. The result is C code that you link into your .exe file (!) You do _not_ have to create a DLL file, and this also simplifies linking.

3. SWIG will create an init function (a C function) whose name depends on the name of the extension module. For example, if the name of the module is leo, the init function will be called initleo(). If you use SWIG shadow classes, as you should, the init function will be called initleoc(). This initializes a mostly hidden helper class used by the shadow class.

   The reason you can link the C code in step 2 into your .exe file is that calling the initialization function is equivalent to importing the module into Python! (This is the second key undocumented fact.)

4. In short, you can use the following code to initialize the Python interpreter with your extension module.

   ```c
   #include "python.h"
   ...
   Py_Initialize(); // Initialize Python.
   initmyAppc();    // Initialize (import) the helper
   PyRun_SimpleString("import myApp"); // Import
   ```

5. There are two problems with Python’s C API which will become apparent if you use a compiler other than MSVC, the compiler used to build pythonNN.dll.

   Problem 1: The so-called “Very High Level” functions that take FILE * arguments will not work in a multi-compiler environment because each compiler’s notion of a struct FILE will be different.
From an implementation standpoint these are very _low_ level functions.

Problem 2: SWIG generates the following code when generating wrappers to void functions:

```cpp
Py_INCREF(Py_None);
_resultobj = Py_None;
return _resultobj;
```

Alas, Py_None is a macro that expands to a reference to a complex data structure called _Py_NoneStruct inside pythonNN.dll. Again, this code will fail in a mult-compiler environment. Replace such code by:

```cpp
return Py_BuildValue(""");
```

It may be possible to use SWIG’s %typemap command to make the change automatically, though I have not been able to get this to work (I’m a complete SWIG newbie).

6. Using a Python shell script to put up a Python interpreter window from inside your Windows app is not a good idea; the resulting window will be independent of your app’s windowing system. Rather, you (or the wxPythonWindow class) should create a “native” interpreter window. It is easy to connect that window to the Python interpreter. You can redirect Python’s i/o to _any_ object that supports read and write, so all you need is a Python object (defined in your extension module) that contains read() and write() methods.
How do I keep editors from inserting tabs into my Python source?

The FAQ does not recommend using tabs, and the Python style guide, PEP 8, recommends 4 spaces for distributed Python code; this is also the Emacs python-mode default.

Under any editor, mixing tabs and spaces is a bad idea. MSVC is no different in this respect, and is easily configured to use spaces: Take Tools ▶ Options ▶ Tabs, and for file type “Default” set “Tab size” and “Indent size” to 4, and select the “Insert spaces” radio button.

If you suspect mixed tabs and spaces are causing problems in leading whitespace, run Python with the -t switch or run Tools/Scripts/tabnanny.py to check a directory tree in batch mode.
How do I check for a keypress without blocking?

Use the msvcrt module. This is a standard Windows-specific extension module. It defines a function `kbhit()` which checks whether a keyboard hit is present, and `getch()` which gets one character without echoing it.
How do I emulate os.kill() in Windows?

Prior to Python 2.7 and 3.2, to terminate a process, you can use ctypes:

```python
import ctypes

def kill(pid):
    """kill function for Win32"""
    kernel32 = ctypes.windll.kernel32
    handle = kernel32.OpenProcess(1, 0, pid)
    return (0 != kernel32.TerminateProcess(handle, 0))
```

In 2.7 and 3.2, `os.kill()` is implemented similar to the above function, with the additional feature of being able to send CTRL+C and CTRL+BREAK to console subprocesses which are designed to handle those signals. See `os.kill()` for further details.
How do I extract the downloaded documentation on Windows?

Sometimes, when you download the documentation package to a Windows machine using a web browser, the file extension of the saved file ends up being .EXE. This is a mistake; the extension should be .TGZ.

Simply rename the downloaded file to have the .TGZ extension, and WinZip will be able to handle it. (If your copy of WinZip doesn’t, get a newer one from http://www.winzip.com.)

General GUI Questions
What platform-independent GUI toolkits exist for Python?

Depending on what platform(s) you are aiming at, there are several. Some of them haven’t been ported to Python 3 yet. At least Tkinter and Qt are known to be Python 3-compatible.

Tkinter

Standard builds of Python include an object-oriented interface to the Tcl/Tk widget set, called tkinter. This is probably the easiest to install (since it comes included with most binary distributions of Python) and use. For more info about Tk, including pointers to the source, see the Tcl/Tk home page. Tcl/Tk is fully portable to the MacOS, Windows, and Unix platforms.

wxWidgets

wxWidgets (http://www.wxwidgets.org) is a free, portable GUI class library written in C++ that provides a native look and feel on a number of platforms, with Windows, MacOS X, GTK, X11, all listed as current stable targets. Language bindings are available for a number of languages including Python, Perl, Ruby, etc.

wxPython (http://www.wxpython.org) is the Python binding for wxwidgets. While it often lags slightly behind the official wxWidgets releases, it also offers a number of features via pure Python extensions that are not available in other language bindings. There is an active wxPython user and developer community.

Both wxWidgets and wxPython are free, open source, software with
permissive licences that allow their use in commercial products as well as in freeware or shareware.

**Qt**

There are bindings available for the Qt toolkit (using either PyQt or PySide) and for KDE (PyKDE). PyQt is currently more mature than PySide, but you must buy a PyQt license from Riverbank Computing if you want to write proprietary applications. PySide is free for all applications.

Qt 4.5 upwards is licensed under the LGPL license; also, commercial licenses are available from Nokia.

**Gtk+**

The GObject introspection bindings for Python allow you to write GTK+ 3 applications. There is also a Python GTK+ 3 Tutorial.

The older PyGtk bindings for the Gtk+ 2 toolkit have been implemented by James Henstridge; see <http://www.pygtk.org>.

**FLTK**

Python bindings for the FLTK toolkit, a simple yet powerful and mature cross-platform windowing system, are available from the PyFLTK project.

**FOX**

A wrapper for the FOX toolkit called FXpy is available. FOX supports
both Unix variants and Windows.

**OpenGL**

For OpenGL bindings, see [PyOpenGL](https://www.opengl.org/).
What platform-specific GUI toolkits exist for Python?

The Mac port by Jack Jansen has a rich and ever-growing set of modules that support the native Mac toolbox calls. The port supports MacOS X's Carbon libraries.

By installing the PyObjc Objective-C bridge, Python programs can use MacOS X's Cocoa libraries. See the documentation that comes with the Mac port.

Pythonwin by Mark Hammond includes an interface to the Microsoft Foundation Classes and a Python programming environment that's written mostly in Python using the MFC classes.
Tkinter questions

How do I freeze Tkinter applications?

Freeze is a tool to create stand-alone applications. When freezing Tkinter applications, the applications will not be truly stand-alone, as the application will still need the Tcl and Tk libraries.

One solution is to ship the application with the Tcl and Tk libraries, and point to them at run-time using the TCL_LIBRARY and TK_LIBRARY environment variables.

To get truly stand-alone applications, the Tcl scripts that form the library have to be integrated into the application as well. One tool supporting that is SAM (stand-alone modules), which is part of the Tix distribution (http://tix.sourceforge.net/).

Build Tix with SAM enabled, perform the appropriate call to TcIsam_init(), etc. inside Python's Modules/tkappinit.c, and link with libtclsam and libtksam (you might include the Tix libraries as well).

Can I have Tk events handled while waiting for I/O?

Yes, and you don’t even need threads! But you’ll have to restructure your I/O code a bit. Tk has the equivalent of Xt's XtAddInput() call, which allows you to register a callback function which will be called from the Tk mainloop when I/O is possible on a file descriptor. Here’s what you need:

```python
from Tkinter import tkinter
```
tkinter.createfilehandler(file, mask, callback)

The file may be a Python file or socket object (actually, anything with a fileno() method), or an integer file descriptor. The mask is one of the constants tkinter.READABLE or tkinter.WRITABLE. The callback is called as follows:

callback(file, mask)

You must unregister the callback when you're done, using

tkinter.deletefilehandler(file)

Note: since you don't know how many bytes are available for reading, you can't use the Python file object's read or readline methods, since these will insist on reading a predefined number of bytes. For sockets, the recv() or recvfrom() methods will work fine; for other files, use os.read(file.fileno(), maxbytecount).

I can't get key bindings to work in Tkinter: why?

An often-heard complaint is that event handlers bound to events with the bind() method don't get handled even when the appropriate key is pressed.

The most common cause is that the widget to which the binding applies doesn't have “keyboard focus”. Check out the Tk documentation for the focus command. Usually a widget is given the keyboard focus by clicking in it (but not for labels; see the takefocus option).
“Why is Python Installed on my Computer?” FAQ
What is Python?

Python is a programming language. It’s used for many different applications. It’s used in some high schools and colleges as an introductory programming language because Python is easy to learn, but it’s also used by professional software developers at places such as Google, NASA, and Lucasfilm Ltd.

If you wish to learn more about Python, start with the Beginner’s Guide to Python.
Why is Python installed on my machine?

If you find Python installed on your system but don’t remember installing it, there are several possible ways it could have gotten there.

- Perhaps another user on the computer wanted to learn programming and installed it; you’ll have to figure out who’s been using the machine and might have installed it.
- A third-party application installed on the machine might have been written in Python and included a Python installation. There are many such applications, from GUI programs to network servers and administrative scripts.
- Some Windows machines also have Python installed. At this writing we’re aware of computers from Hewlett-Packard and Compaq that include Python. Apparently some of HP/Compaq’s administrative tools are written in Python.
- Many Unix-compatible operating systems, such as Mac OS X and some Linux distributions, have Python installed by default; it’s included in the base installation.
Can I delete Python?

That depends on where Python came from.

If someone installed it deliberately, you can remove it without hurting anything. On Windows, use the Add/Remove Programs icon in the Control Panel.

If Python was installed by a third-party application, you can also remove it, but that application will no longer work. You should use that application's uninstaller rather than removing Python directly.

If Python came with your operating system, removing it is not recommended. If you remove it, whatever tools were written in Python will no longer run, and some of them might be important to you. Reinstalling the whole system would then be required to fix things again.
Glossary

>>> The default Python prompt of the interactive shell. Often seen for code examples which can be executed interactively in the interpreter.

... The default Python prompt of the interactive shell when entering code for an indented code block or within a pair of matching left and right delimiters (parentheses, square brackets or curly braces).

2to3

A tool that tries to convert Python 2.x code to Python 3.x code by handling most of the incompatibilities which can be detected by parsing the source and traversing the parse tree.

2to3 is available in the standard library as lib2to3; a standalone entry point is provided as Tools/scripts/2to3. See 2to3 - Automated Python 2 to 3 code translation.

abstract base class

Abstract base classes complement duck-typing by providing a way to define interfaces when other techniques like hasattr() would be clumsy or subtly wrong (for example with magic methods). ABCs introduce virtual subclasses, which are classes that don't inherit from a class but are still recognized by isinstance() and issubclass(); see the abc module documentation. Python comes with many built-in ABCs for data structures (in the collections.abc module), numbers (in the numbers module), streams (in the io module), import finders and loaders (in the importlib.abc module). You can create your own ABCs with the abc module.
**argument**

A value passed to a *function* (or *method*) when calling the function. There are two types of arguments:

- **keyword argument**: an argument preceded by an identifier (e.g. `name=`) in a function call or passed as a value in a dictionary preceded by `**`. For example, `3` and `5` are both keyword arguments in the following calls to `complex()`:

```python
complex(real=3, imag=5)
complex(**{'real': 3, 'imag': 5})
```

- **positional argument**: an argument that is not a keyword argument. Positional arguments can appear at the beginning of an argument list and/or be passed as elements of an *iterable* preceded by `*`. For example, `3` and `5` are both positional arguments in the following calls:

```python
complex(3, 5)
complex(*(3, 5))
```

Arguments are assigned to the named local variables in a function body. See the *Calls* section for the rules governing this assignment. Syntactically, any expression can be used to represent an argument; the evaluated value is assigned to the local variable.

See also the *parameter* glossary entry, the FAQ question on *the difference between arguments and parameters*, and **PEP 362**.

**attribute**

A value associated with an object which is referenced by name using dotted expressions. For example, if an object `o` has an attribute `a` it would be referenced as `o.a`. 
BDFL
Benevolent Dictator For Life, a.k.a. Guido van Rossum, Python’s creator.

bytes-like object
An object that supports the Buffer Protocol, like bytes, bytearray or memoryview. Bytes-like objects can be used for various operations that expect binary data, such as compression, saving to a binary file or sending over a socket. Some operations need the binary data to be mutable, in which case not all bytes-like objects can apply.

bytecode
Python source code is compiled into bytecode, the internal representation of a Python program in the CPython interpreter. The bytecode is also cached in .pyc and .pyo files so that executing the same file is faster the second time (recompilation from source to bytecode can be avoided). This “intermediate language” is said to run on a virtual machine that executes the machine code corresponding to each bytecode. Do note that bytecodes are not expected to work between different Python virtual machines, nor to be stable between Python releases.

A list of bytecode instructions can be found in the documentation for the dis module.

class
A template for creating user-defined objects. Class definitions normally contain method definitions which operate on instances of the class.

coercion
The implicit conversion of an instance of one type to another during an operation which involves two arguments of the same type. For example, \texttt{int(3.15)} converts the floating point number to the
integer 3, but in 3+4.5, each argument is of a different type (one int, one float), and both must be converted to the same type before they can be added or it will raise a TypeError. Without coercion, all arguments of even compatible types would have to be normalized to the same value by the programmer, e.g., float(3)+4.5 rather than just 3+4.5.

**complex number**
An extension of the familiar real number system in which all numbers are expressed as a sum of a real part and an imaginary part. Imaginary numbers are real multiples of the imaginary unit (the square root of -1), often written i in mathematics or j in engineering. Python has built-in support for complex numbers, which are written with this latter notation; the imaginary part is written with a j suffix, e.g., 3+1j. To get access to complex equivalents of the math module, use cmath. Use of complex numbers is a fairly advanced mathematical feature. If you’re not aware of a need for them, it’s almost certain you can safely ignore them.

**context manager**
An object which controls the environment seen in a with statement by defining __enter__() and __exit__() methods. See PEP 343.

**CPython**
The canonical implementation of the Python programming language, as distributed on python.org. The term “CPython” is used when necessary to distinguish this implementation from others such as Jython or IronPython.

**decorator**
A function returning another function, usually applied as a function transformation using the @wrapper syntax. Common examples for decorators are classmethod() and staticmethod().
The decorator syntax is merely syntactic sugar, the following two function definitions are semantically equivalent:

```python
def f(...):
    ...

f = staticmethod(f)

@staticmethod
def f(...):
    ...
```

The same concept exists for classes, but is less commonly used there. See the documentation for function definitions and class definitions for more about decorators.

descriptor
Any object which defines the methods `__get__`, `__set__`, or `__delete__`. When a class attribute is a descriptor, its special binding behavior is triggered upon attribute lookup. Normally, using `a.b` to get, set or delete an attribute looks up the object named `b` in the class dictionary for `a`, but if `b` is a descriptor, the respective descriptor method gets called. Understanding descriptors is a key to a deep understanding of Python because they are the basis for many features including functions, methods, properties, class methods, static methods, and reference to super classes.

For more information about descriptors’ methods, see Implementing Descriptors.

dictionary
An associative array, where arbitrary keys are mapped to values. The keys can be any object with `__hash__` and `__eq__` methods. Called a hash in Perl.
**docstring**
A string literal which appears as the first expression in a class, function or module. While ignored when the suite is executed, it is recognized by the compiler and put into the __doc__ attribute of the enclosing class, function or module. Since it is available via introspection, it is the canonical place for documentation of the object.

**duck-typing**
A programming style which does not look at an object's type to determine if it has the right interface; instead, the method or attribute is simply called or used (“If it looks like a duck and quacks like a duck, it must be a duck.”) By emphasizing interfaces rather than specific types, well-designed code improves its flexibility by allowing polymorphic substitution. Duck-typing avoids tests using type() or isinstance(). (Note, however, that duck-typing can be complemented with abstract base classes.) Instead, it typically employs hasattr() tests or EAFP programming.

**EAFP**
Easier to ask for forgiveness than permission. This common Python coding style assumes the existence of valid keys or attributes and catches exceptions if the assumption proves false. This clean and fast style is characterized by the presence of many try and except statements. The technique contrasts with the LBYL style common to many other languages such as C.

**expression**
A piece of syntax which can be evaluated to some value. In other words, an expression is an accumulation of expression elements like literals, names, attribute access, operators or function calls which all return a value. In contrast to many other languages, not all language constructs are expressions. There are also statements which cannot be used as expressions, such as if. Assignments are also statements, not expressions.
extension module
A module written in C or C++, using Python's C API to interact with the core and with user code.

file object
An object exposing a file-oriented API (with methods such as read() or write()) to an underlying resource. Depending on the way it was created, a file object can mediate access to a real on-disk file or to another type of storage or communication device (for example standard input/output, in-memory buffers, sockets, pipes, etc.). File objects are also called file-like objects or streams.

There are actually three categories of file objects: raw binary files, buffered binary files and text files. Their interfaces are defined in the io module. The canonical way to create a file object is by using the open() function.

file-like object
A synonym for file object.

finder
An object that tries to find the loader for a module. It must implement either a method named find_loader() or a method named find_module(). See PEP 302 and PEP 420 for details and importlib.abc.Finder for an abstract base class.

floor division
Mathematical division that rounds down to nearest integer. The floor division operator is // . For example, the expression 11 // 4 evaluates to 2 in contrast to the 2.75 returned by float true division. Note that (-11) // 4 is -3 because that is -2.75 rounded downward. See PEP 238.

function
A series of statements which returns some value to a caller. It can
also be passed zero or more *arguments* which may be used in the execution of the body. See also *parameter*, *method*, and the *Function definitions* section.

**function annotation**

An arbitrary metadata value associated with a function parameter or return value. Its syntax is explained in section *Function definitions*. Annotations may be accessed via the `__annotations__` special attribute of a function object.

Python itself does not assign any particular meaning to function annotations. They are intended to be interpreted by third-party libraries or tools. See PEP 3107, which describes some of their potential uses.

**__future__**

A pseudo-module which programmers can use to enable new language features which are not compatible with the current interpreter.

By importing the `__future__` module and evaluating its variables, you can see when a new feature was first added to the language and when it becomes the default:

```python
>>> import __future__
>>> __future__.division
.Feature((2, 2, 0, 'alpha', 2), (3, 0, 0, 'alpha')
```

**garbage collection**

The process of freeing memory when it is not used anymore. Python performs garbage collection via reference counting and a cyclic garbage collector that is able to detect and break reference cycles.
generator
A function which returns an iterator. It looks like a normal function except that it contains `yield` statements for producing a series a values usable in a for-loop or that can be retrieved one at a time with the `next()` function. Each `yield` temporarily suspends processing, remembering the location execution state (including local variables and pending try-statements). When the generator resumes, it picks-up where it left-off (in contrast to functions which start fresh on every invocation).

generator expression
An expression that returns an iterator. It looks like a normal expression followed by a `for` expression defining a loop variable, range, and an optional `if` expression. The combined expression generates values for an enclosing function:

```python
>>> sum(i*i for i in range(10))  # sum of
285
```

GIL
See `global interpreter lock`.

global interpreter lock
The mechanism used by the CPython interpreter to assure that only one thread executes Python bytecode at a time. This simplifies the CPython implementation by making the object model (including critical built-in types such as `dict`) implicitly safe against concurrent access. Locking the entire interpreter makes it easier for the interpreter to be multi-threaded, at the expense of much of the parallelism afforded by multi-processor machines.

However, some extension modules, either standard or third-party, are designed so as to release the GIL when doing computationally-
intensive tasks such as compression or hashing. Also, the GIL is always released when doing I/O.

Past efforts to create a “free-threaded” interpreter (one which locks shared data at a much finer granularity) have not been successful because performance suffered in the common single-processor case. It is believed that overcoming this performance issue would make the implementation much more complicated and therefore costlier to maintain.

**hashable**

An object is *hashable* if it has a hash value which never changes during its lifetime (it needs a `__hash__()` method), and can be compared to other objects (it needs an `__eq__()` method). Hashable objects which compare equal must have the same hash value.

Hashability makes an object usable as a dictionary key and a set member, because these data structures use the hash value internally.

All of Python’s immutable built-in objects are hashable, while no mutable containers (such as lists or dictionaries) are. Objects which are instances of user-defined classes are hashable by default; they all compare unequal (except with themselves), and their hash value is their `id()`.

**IDLE**

An Integrated Development Environment for Python. IDLE is a basic editor and interpreter environment which ships with the standard distribution of Python.

**immutable**

An object with a fixed value. Immutable objects include numbers,
strings and tuples. Such an object cannot be altered. A new object has to be created if a different value has to be stored. They play an important role in places where a constant hash value is needed, for example as a key in a dictionary.

**import path**

A list of locations (or *path entries*) that are searched by the *path based finder* for modules to import. During import, this list of locations usually comes from *sys.path*, but for subpackages it may also come from the parent package's `__path__` attribute.

**importing**

The process by which Python code in one module is made available to Python code in another module.

**importer**

An object that both finds and loads a module; both a *finder* and *loader* object.

**interactive**

Python has an interactive interpreter which means you can enter statements and expressions at the interpreter prompt, immediately execute them and see their results. Just launch `python` with no arguments (possibly by selecting it from your computer’s main menu). It is a very powerful way to test out new ideas or inspect modules and packages (remember `help(x)`).

**interpreted**

Python is an interpreted language, as opposed to a compiled one, though the distinction can be blurry because of the presence of the bytecode compiler. This means that source files can be run directly without explicitly creating an executable which is then run. Interpreted languages typically have a shorter development/debug cycle than compiled ones, though their programs generally also run more slowly. See also *interactive*.

**iterable**
An object capable of returning its members one at a time. Examples of iterables include all sequence types (such as `list`, `str`, and `tuple`) and some non-sequence types like `dict`, `file objects`, and objects of any classes you define with an `__iter__() or __getitem__()` method. Iterables can be used in a `for` loop and in many other places where a sequence is needed (`zip()`, `map()`, ...). When an iterable object is passed as an argument to the built-in function `iter()`, it returns an iterator for the object. This iterator is good for one pass over the set of values. When using iterables, it is usually not necessary to call `iter()` or deal with iterator objects yourself. The `for` statement does that automatically for you, creating a temporary unnamed variable to hold the iterator for the duration of the loop. See also `iterator`, `sequence`, and `generator`.

**iterator**

An object representing a stream of data. Repeated calls to the iterator’s `__next__() method (or passing it to the built-in function `next()`) return successive items in the stream. When no more data are available a `StopIteration` exception is raised instead. At this point, the iterator object is exhausted and any further calls to its `__next__() method just raise `StopIteration` again.

Iterators are required to have an `__iter__()` method that returns the iterator object itself so every iterator is also iterable and may be used in most places where other iterables are accepted. One notable exception is code which attempts multiple iteration passes. A container object (such as a `list`) produces a fresh new iterator each time you pass it to the `iter()` function or use it in a `for` loop. Attempting this with an iterator will just return the same exhausted iterator object used in the previous iteration pass, making it appear like an empty container.

More information can be found in `Iterator Types`. 
key function
A key function or collation function is a callable that returns a value used for sorting or ordering. For example, `locale.strxfrm()` is used to produce a sort key that is aware of locale specific sort conventions.

A number of tools in Python accept key functions to control how elements are ordered or grouped. They include `min()`, `max()`, `sorted()`, `list.sort()`, `heapq.nsmallest()`, `heapq.nlargest()`, and `itertools.groupby()`.

There are several ways to create a key function. For example, the `str.lower()` method can serve as a key function for case insensitive sorts. Alternatively, an ad-hoc key function can be built from a `lambda` expression such as `lambda r: (r[0], r[2])`. Also, the `operator` module provides three key function constructors: `attrgetter()`, `itemgetter()`, and `methodcaller()`. See the Sorting HOW TO for examples of how to create and use key functions.

keyword argument
See *argument*.

lambda
An anonymous inline function consisting of a single *expression* which is evaluated when the function is called. The syntax to create a lambda function is `lambda [arguments]: expression`

LBYL
Look before you leap. This coding style explicitly tests for pre-conditions before making calls or lookups. This style contrasts with the *EAFP* approach and is characterized by the presence of many
if statements.

In a multi-threaded environment, the LBYL approach can risk introducing a race condition between “the looking” and “the leaping”. For example, the code, if key in mapping: return mapping[key] can fail if another thread removes key from mapping after the test, but before the lookup. This issue can be solved with locks or by using the EAFP approach.

list
A built-in Python sequence. Despite its name it is more akin to an array in other languages than to a linked list since access to elements are O(1).

list comprehension
A compact way to process all or part of the elements in a sequence and return a list with the results. result = ['{:04x}'.format(x) for x in range(256) if x % 2 == 0] generates a list of strings containing even hex numbers (0x..) in the range from 0 to 255. The if clause is optional. If omitted, all elements in range(256) are processed.

loader
An object that loads a module. It must define a method named load_module(). A loader is typically returned by a finder. See PEP 302 for details and importlib.abc.Loader for an abstract base class.

mapping
A container object that supports arbitrary key lookups and implements the methods specified in the Mapping or MutableMapping abstract base classes. Examples include dict, collections.defaultdict, collections.OrderedDict and collections.Counter.
**meta path finder**

A finder returned by a search of `sys.meta_path`. Meta path finders are related to, but different from *path entry finders*.

**metaclass**

The class of a class. Class definitions create a class name, a class dictionary, and a list of base classes. The metaclass is responsible for taking those three arguments and creating the class. Most object oriented programming languages provide a default implementation. What makes Python special is that it is possible to create custom metaclasses. Most users never need this tool, but when the need arises, metaclasses can provide powerful, elegant solutions. They have been used for logging attribute access, adding thread-safety, tracking object creation, implementing singletons, and many other tasks.

More information can be found in *Customizing class creation*.

**method**

A function which is defined inside a class body. If called as an attribute of an instance of that class, the method will get the instance object as its first *argument* (which is usually called `self`). See *function* and *nested scope*.

**method resolution order**

Method Resolution Order is the order in which base classes are searched for a member during lookup. See *The Python 2.3 Method Resolution Order*.

**module**

An object that serves as an organizational unit of Python code. Modules have a namespace containing arbitrary Python objects. Modules are loaded into Python by the process of *importing*.

See also *package*.
MRO
See *method resolution order*.

**mutable**
Mutable objects can change their value but keep their `id()`. See also *immutable*.

**named tuple**
Any tuple-like class whose indexable elements are also accessible using named attributes (for example, `time.localtime()` returns a tuple-like object where the `year` is accessible either with an index such as `t[0]` or with a named attribute like `t.tm_year`).

A named tuple can be a built-in type such as `time.struct_time`, or it can be created with a regular class definition. A full featured named tuple can also be created with the factory function `collections.namedtuple()`. The latter approach automatically provides extra features such as a self-documenting representation like `Employee(name='jones', title='programmer')`.

**namespace**
The place where a variable is stored. Namespaces are implemented as dictionaries. There are the local, global and built-in namespaces as well as nested namespaces in objects (in methods). Namespaces support modularity by preventing naming conflicts. For instance, the functions `builtins.open` and `os.open()` are distinguished by their namespaces. Namespaces also aid readability and maintainability by making it clear which module implements a function. For instance, writing `random.seed()` or `itertools.islice()` makes it clear that those functions are implemented by the `random` and `itertools` modules, respectively.
namespace package

A **PEP 420 package** which serves only as a container for subpackages. Namespace packages may have no physical representation, and specifically are not like a regular package because they have no `__init__.py` file.

See also *module*.

nested scope

The ability to refer to a variable in an enclosing definition. For instance, a function defined inside another function can refer to variables in the outer function. Note that nested scopes by default work only for reference and not for assignment. Local variables both read and write in the innermost scope. Likewise, global variables read and write to the global namespace. The **nonlocal** allows writing to outer scopes.

new-style class

Old name for the flavor of classes now used for all class objects. In earlier Python versions, only new-style classes could use Python's newer, versatile features like `__slots__`, descriptors, properties, `__getattribute__()`, class methods, and static methods.

object

Any data with state (attributes or value) and defined behavior (methods). Also the ultimate base class of any **new-style class**.

package

A Python **module** which can contain submodules or recursively, subpackages. Technically, a package is a Python module with an `__path__` attribute.

See also *regular package* and *namespace package*.

parameter
A named entity in a function (or method) definition that specifies an argument (or in some cases, arguments) that the function can accept. There are five types of parameters:

- **positional-or-keyword**: specifies an argument that can be passed either *positionally* or as a *keyword argument*. This is the default kind of parameter, for example `foo` and `bar` in the following:

```python
def func(foo, bar=None): ...
```

- **positional-only**: specifies an argument that can be supplied only by position. Python has no syntax for defining positional-only parameters. However, some built-in functions have positional-only parameters (e.g. `abs()`).

- **keyword-only**: specifies an argument that can be supplied only by keyword. Keyword-only parameters can be defined by including a single var-positional parameter or bare `*` in the parameter list of the function definition before them, for example `kw_only1` and `kw_only2` in the following:

```python
def func(arg, *, kw_only1, kw_only2): ...
```

- **var-positional**: specifies that an arbitrary sequence of positional arguments can be provided (in addition to any positional arguments already accepted by other parameters). Such a parameter can be defined by prepending the parameter name with `*`, for example `args` in the following:

```python
def func(*args, **kwargs): ...
```

- **var-keyword**: specifies that arbitrarily many keyword
arguments can be provided (in addition to any keyword arguments already accepted by other parameters). Such a parameter can be defined by prepending the parameter name with `**`, for example `kwargs` in the example above.

Parameters can specify both optional and required arguments, as well as default values for some optional arguments.

See also the argument glossary entry, the FAQ question on the difference between arguments and parameters, the `inspect.Parameter` class, the Function definitions section, and PEP 362.

**path entry**
A single location on the import path which the path based finder consults to find modules for importing.

**path entry finder**
A `finder` returned by a callable on `sys.path_hooks` (i.e. a path entry hook) which knows how to locate modules given a path entry.

**path entry hook**
A callable on the `sys.path_hook` list which returns a path entry finder if it knows how to find modules on a specific path entry.

**path based finder**
One of the default meta path finders which searches an import path for modules.

**portion**
A set of files in a single directory (possibly stored in a zip file) that contribute to a namespace package, as defined in PEP 420.

**positional argument**
See argument.
**provisional package**

A provisional package is one which has been deliberately excluded from the standard library's backwards compatibility guarantees. While major changes to such packages are not expected, as long as they are marked provisional, backwards incompatible changes (up to and including removal of the package) may occur if deemed necessary by core developers. Such changes will not be made gratuitously – they will occur only if serious flaws are uncovered that were missed prior to the inclusion of the package.

This process allows the standard library to continue to evolve over time, without locking in problematic design errors for extended periods of time. See [PEP 411](https://www.python.org/dev/peps/pep-0411/) for more details.

**Python 3000**

Nickname for the Python 3.x release line (coined long ago when the release of version 3 was something in the distant future.) This is also abbreviated “Py3k”.

**Pythonic**

An idea or piece of code which closely follows the most common idioms of the Python language, rather than implementing code using concepts common to other languages. For example, a common idiom in Python is to loop over all elements of an iterable using a `for` statement. Many other languages don’t have this type of construct, so people unfamiliar with Python sometimes use a numerical counter instead:

```python
for i in range(len(food)):
    print(food[i])
```

As opposed to the cleaner, Pythonic method:
qualified name
A dotted name showing the “path” from a module’s global scope to a class, function or method defined in that module, as defined in PEP 3155. For top-level functions and classes, the qualified name is the same as the object’s name:

```python
>>> class C:
...     class D:
...         def meth(self):
...             pass
...
>>> C.__qualname__
'C'
>>> C.D.__qualname__
'C.D'
>>> C.D.meth.__qualname__
'C.D.meth'
```

When used to refer to modules, the fully qualified name means the entire dotted path to the module, including any parent packages, e.g. `email.mime.text`:

```python
>>> import email.mime.text
>>> email.mime.text.__name__
'email.mime.text'
```

reference count
The number of references to an object. When the reference count of an object drops to zero, it is deallocated. Reference counting is generally not visible to Python code, but it is a key element of the CPython implementation. The `sys` module defines a
getrefcount() function that programmers can call to return the reference count for a particular object.

regular package
A traditional package, such as a directory containing an __init__.py file.

See also namespace package.

__slots__
A declaration inside a class that saves memory by pre-declaring space for instance attributes and eliminating instance dictionaries. Though popular, the technique is somewhat tricky to get right and is best reserved for rare cases where there are large numbers of instances in a memory-critical application.

sequence
An iterable which supports efficient element access using integer indices via the __getitem__() special method and defines a __len__() method that returns the length of the sequence. Some built-in sequence types are list, str, tuple, and bytes. Note that dict also supports __getitem__() and __len__(), but is considered a mapping rather than a sequence because the lookups use arbitrary immutable keys rather than integers.

slice
An object usually containing a portion of a sequence. A slice is created using the subscript notation, [] with colons between numbers when several are given, such as in variable_name[1:3:5]. The bracket (subscript) notation uses slice objects internally.

special method
A method that is called implicitly by Python to execute a certain operation on a type, such as addition. Such methods have names
starting and ending with double underscores. Special methods are documented in *Special method names*.

**statement**
A statement is part of a suite (a “block” of code). A statement is either an *expression* or one of several constructs with a keyword, such as *if, while* or *for*.

**struct sequence**
A tuple with named elements. Struct sequences expose an interface similar to *named tuple* in that elements can either be accessed either by index or as an attribute. However, they do not have any of the named tuple methods like *_make()* or *_asdict()*.

Examples of struct sequences include *sys.float_info* and the return value of *os.stat()*.

**triple-quoted string**
A string which is bound by three instances of either a quotation mark ("') or an apostrophe ('). While they don’t provide any functionality not available with single-quoted strings, they are useful for a number of reasons. They allow you to include unescaped single and double quotes within a string and they can span multiple lines without the use of the continuation character, making them especially useful when writing docstrings.

**type**
The type of a Python object determines what kind of object it is; every object has a type. An object’s type is accessible as its *__class__* attribute or can be retrieved with *type(obj)*.

**universal newlines**
A manner of interpreting text streams in which all of the following are recognized as ending a line: the Unix end-of-line convention '\n', the Windows convention '\r\n', and the old Macintosh convention '\r'. See PEP 278 and PEP 3116, as well as *str.splitlines()* for an additional use.
view

The objects returned from `dict.keys()`, `dict.values()`, and `dict.items()` are called dictionary views. They are lazy sequences that will see changes in the underlying dictionary. To force the dictionary view to become a full list use `list(dictview)`. See *Dictionary view objects*.

virtual machine

A computer defined entirely in software. Python’s virtual machine executes the *bytecode* emitted by the bytecode compiler.

Zen of Python

Listing of Python design principles and philosophies that are helpful in understanding and using the language. The listing can be found by typing “import this” at the interactive prompt.
About these documents

These documents are generated from reStructuredText sources by Sphinx, a document processor specifically written for the Python documentation.

Development of the documentation and its toolchain takes place on the docs@python.org mailing list. We’re always looking for volunteers wanting to help with the docs, so feel free to send a mail there!

Many thanks go to:

- Fred L. Drake, Jr., the creator of the original Python documentation toolset and writer of much of the content;
- the Docutils project for creating reStructuredText and the Docutils suite;
- Fredrik Lundh for his Alternative Python Reference project from which Sphinx got many good ideas.

See Reporting Bugs for information how to report bugs in this documentation, or Python itself.
Contributors to the Python Documentation

Many people have contributed to the Python language, the Python standard library, and the Python documentation. See Misc/ACKS in the Python source distribution for a partial list of contributors.

It is only with the input and contributions of the Python community that Python has such wonderful documentation – Thank You!
Reporting Bugs

Python is a mature programming language which has established a reputation for stability. In order to maintain this reputation, the developers would like to know of any deficiencies you find in Python.
Documentation bugs

If you find a bug in this documentation or would like to propose an improvement, please send an e-mail to docs@python.org describing the bug and where you found it. If you have a suggestion how to fix it, include that as well.

docs@python.org is a mailing list run by volunteers; your request will be noticed, even if it takes a while to be processed.

Of course, if you want a more persistent record of your issue, you can use the issue tracker for documentation bugs as well.
Using the Python issue tracker

Bug reports for Python itself should be submitted via the Python Bug Tracker (http://bugs.python.org/). The bug tracker offers a Web form which allows pertinent information to be entered and submitted to the developers.

The first step in filing a report is to determine whether the problem has already been reported. The advantage in doing so, aside from saving the developers time, is that you learn what has been done to fix it; it may be that the problem has already been fixed for the next release, or additional information is needed (in which case you are welcome to provide it if you can!). To do this, search the bug database using the search box on the top of the page.

If the problem you’re reporting is not already in the bug tracker, go back to the Python Bug Tracker and log in. If you don’t already have a tracker account, select the “Register” link or, if you use OpenID, one of the OpenID provider logos in the sidebar. It is not possible to submit a bug report anonymously.

Being now logged in, you can submit a bug. Select the “Create New” link in the sidebar to open the bug reporting form.

The submission form has a number of fields. For the “Title” field, enter a very short description of the problem; less than ten words is good. In the “Type” field, select the type of your problem; also select the “Component” and “Versions” to which the bug relates.

In the “Comment” field, describe the problem in detail, including what you expected to happen and what did happen. Be sure to include whether any extension modules were involved, and what hardware
and software platform you were using (including version information as appropriate).

Each bug report will be assigned to a developer who will determine what needs to be done to correct the problem. You will receive an update each time action is taken on the bug.

History and License
History of the software

Python was created in the early 1990s by Guido van Rossum at Stichting Mathematisch Centrum (CWI, see http://www.cwi.nl/) in the Netherlands as a successor of a language called ABC. Guido remains Python’s principal author, although it includes many contributions from others.

In 1995, Guido continued his work on Python at the Corporation for National Research Initiatives (CNRI, see http://www.cnri.reston.va.us/) in Reston, Virginia where he released several versions of the software.

In May 2000, Guido and the Python core development team moved to BeOpen.com to form the BeOpen PythonLabs team. In October of the same year, the PythonLabs team moved to Digital Creations (now Zope Corporation; see http://www.zope.com/). In 2001, the Python Software Foundation (PSF, see http://www.python.org/psf/) was formed, a non-profit organization created specifically to own Python-related Intellectual Property. Zope Corporation is a sponsoring member of the PSF.

All Python releases are Open Source (see http://www.opensource.org/ for the Open Source Definition). Historically, most, but not all, Python releases have also been GPL-compatible; the table below summarizes the various releases.

**Note:** GPL-compatible doesn't mean that we’re distributing Python under the GPL. All Python licenses, unlike the GPL, let you distribute a modified version without making your changes open source. The GPL-compatible licenses make it possible to combine Python with other software that is released under the GPL; the others don’t.

Thanks to the many outside volunteers who have worked under Guido’s direction to make these releases possible.
Terms and conditions for accessing or otherwise using Python

PSF LICENSE AGREEMENT FOR PYTHON 3.3.3rc2

1. This LICENSE AGREEMENT is between the Python Software Foundation (“PSF”), and the Individual or Organization (“Licensee”) accessing and otherwise using Python 3.3.3rc2 software in source or binary form and its associated documentation.

2. Subject to the terms and conditions of this License Agreement, PSF hereby grants Licensee a nonexclusive, royalty-free, worldwide license to reproduce, analyze, test, perform and/or display publicly, prepare derivative works, distribute, and otherwise use Python 3.3.3rc2 alone or in any derivative version, provided, however, that PSF’s License Agreement and PSF’s notice of copyright, i.e., “Copyright © 2001-2013 Python Software Foundation; All Rights Reserved” are retained in Python 3.3.3rc2 alone or in any derivative version prepared by Licensee.

3. In the event Licensee prepares a derivative work that is based on or incorporates Python 3.3.3rc2 or any part thereof, and wants to make the derivative work available to others as provided herein, then Licensee hereby agrees to include in any such work a brief summary of the changes made to Python 3.3.3rc2.

4. PSF is making Python 3.3.3rc2 available to Licensee on an “AS IS” basis. PSF MAKES NO REPRESENTATIONS OR WARRANTIES, EXPRESS OR IMPLIED. BY WAY OF EXAMPLE, BUT NOT LIMITATION, PSF MAKES NO AND DISCLAIMS ANY REPRESENTATION OR WARRANTY OF MERCHANTABILITY OR FITNESS FOR ANY PARTICULAR PURPOSE OR THAT THE USE OF PYTHON 3.3.3rc2 WILL NOT INFRINGE ANY THIRD PARTY RIGHTS.

5. PSF SHALL NOT BE LIABLE TO LICENSEE OR ANY OTHER
6. This License Agreement will automatically terminate upon a material breach of its terms and conditions.
7. Nothing in this License Agreement shall be deemed to create any relationship of agency, partnership, or joint venture between PSF and Licensee. This License Agreement does not grant permission to use PSF trademarks or trade name in a trademark sense to endorse or promote products or services of Licensee, or any third party.
8. By copying, installing or otherwise using Python 3.3.3rc2, Licensee agrees to be bound by the terms and conditions of this License Agreement.

BEOPEN.COM LICENSE AGREEMENT FOR PYTHON 2.0

BEOPEN PYTHON OPEN SOURCE LICENSE AGREEMENT
VERSION 1

1. This LICENSE AGREEMENT is between BeOpen.com (“BeOpen”), having an office at 160 Saratoga Avenue, Santa Clara, CA 95051, and the Individual or Organization (“Licensee”) accessing and otherwise using this software in source or binary form and its associated documentation (“the Software”).
2. Subject to the terms and conditions of this BeOpen Python License Agreement, BeOpen hereby grants Licensee a non-exclusive, royalty-free, world-wide license to reproduce, analyze, test, perform and/or display publicly, prepare derivative works, distribute, and otherwise use the Software alone or in any derivative version, provided, however, that the BeOpen Python License is retained in the Software, alone or in any derivative
version prepared by Licensee.

3. BeOpen is making the Software available to Licensee on an “AS IS” basis. BEOPEN MAKES NO REPRESENTATIONS OR WARRANTIES, EXPRESS OR IMPLIED. BY WAY OF EXAMPLE, BUT NOT LIMITATION, BEOPEN MAKES NO AND DISCLAIMS ANY REPRESENTATION OR WARRANTY OF MERCHANTABILITY OR FITNESS FOR ANY PARTICULAR PURPOSE OR THAT THE USE OF THE SOFTWARE WILL NOT INFRINGE ANY THIRD PARTY RIGHTS.

4. BEOPEN SHALL NOT BE LIABLE TO LICENSEE OR ANY OTHER USERS OF THE SOFTWARE FOR ANY INCIDENTAL, SPECIAL, OR CONSEQUENTIAL DAMAGES OR LOSS AS A RESULT OF USING, MODIFYING OR DISTRIBUTING THE SOFTWARE, OR ANY DERIVATIVE THEREOF, EVEN IF ADVISED OF THE POSSIBILITY THEREOF.

5. This License Agreement will automatically terminate upon a material breach of its terms and conditions.

6. This License Agreement shall be governed by and interpreted in all respects by the law of the State of California, excluding conflict of law provisions. Nothing in this License Agreement shall be deemed to create any relationship of agency, partnership, or joint venture between BeOpen and Licensee. This License Agreement does not grant permission to use BeOpen trademarks or trade names in a trademark sense to endorse or promote products or services of Licensee, or any third party. As an exception, the “BeOpen Python” logos available at http://www.pythonlabs.com/logos.html may be used according to the permissions granted on that web page.

7. By copying, installing or otherwise using the software, Licensee agrees to be bound by the terms and conditions of this License Agreement.

CNRI LICENSE AGREEMENT FOR PYTHON 1.6.1
1. This LICENSE AGREEMENT is between the Corporation for National Research Initiatives, having an office at 1895 Preston White Drive, Reston, VA 20191 (“CNRI”), and the Individual or Organization (“Licensee”) accessing and otherwise using Python 1.6.1 software in source or binary form and its associated documentation.

2. Subject to the terms and conditions of this License Agreement, CNRI hereby grants Licensee a nonexclusive, royalty-free, worldwide license to reproduce, analyze, test, perform and/or display publicly, prepare derivative works, distribute, and otherwise use Python 1.6.1 alone or in any derivative version, provided, however, that CNRI's License Agreement and CNRI's notice of copyright, i.e., “Copyright © 1995-2001 Corporation for National Research Initiatives; All Rights Reserved” are retained in Python 1.6.1 alone or in any derivative version prepared by Licensee. Alternately, in lieu of CNRI's License Agreement, Licensee may substitute the following text (omitting the quotes): “Python 1.6.1 is made available subject to the terms and conditions in CNRI's License Agreement. This Agreement together with Python 1.6.1 may be located on the Internet using the following unique, persistent identifier (known as a handle): 1895.22/1013. This Agreement may also be obtained from a proxy server on the Internet using the following URL: http://hdl.handle.net/1895.22/1013.”

3. In the event Licensee prepares a derivative work that is based on or incorporates Python 1.6.1 or any part thereof, and wants to make the derivative work available to others as provided herein, then Licensee hereby agrees to include in any such work a brief summary of the changes made to Python 1.6.1.

4. CNRI is making Python 1.6.1 available to Licensee on an “AS IS” basis. CNRI MAKES NO REPRESENTATIONS OR WARRANTIES, EXPRESS OR IMPLIED. BY WAY OF EXAMPLE, BUT NOT LIMITATION, CNRI MAKES NO AND DISCLAIMS ANY REPRESENTATION OR WARRANTY OF MERCHANTABILITY
OR FITNESS FOR ANY PARTICULAR PURPOSE OR THAT THE USE OF PYTHON 1.6.1 WILL NOT INFRINGE ANY THIRD PARTY RIGHTS.

5. CNRI SHALL NOT BE LIABLE TO LICENSEE OR ANY OTHER USERS OF PYTHON 1.6.1 FOR ANY INCIDENTAL, SPECIAL, OR CONSEQUENTIAL DAMAGES OR LOSS AS A RESULT OF MODIFYING, DISTRIBUTING, OR OTHERWISE USING PYTHON 1.6.1, OR ANY DERIVATIVE THEREOF, EVEN IF ADVISED OF THE POSSIBILITY THEREOF.

6. This License Agreement will automatically terminate upon a material breach of its terms and conditions.

7. This License Agreement shall be governed by the federal intellectual property law of the United States, including without limitation the federal copyright law, and, to the extent such U.S. federal law does not apply, by the law of the Commonwealth of Virginia, excluding Virginia’s conflict of law provisions. Notwithstanding the foregoing, with regard to derivative works based on Python 1.6.1 that incorporate non-separable material that was previously distributed under the GNU General Public License (GPL), the law of the Commonwealth of Virginia shall govern this License Agreement only as to issues arising under or with respect to Paragraphs 4, 5, and 7 of this License Agreement. Nothing in this License Agreement shall be deemed to create any relationship of agency, partnership, or joint venture between CNRI and Licensee. This License Agreement does not grant permission to use CNRI trademarks or trade name in a trademark sense to endorse or promote products or services of Licensee, or any third party.

8. By clicking on the “ACCEPT” button where indicated, or by copying, installing or otherwise using Python 1.6.1, Licensee agrees to be bound by the terms and conditions of this License Agreement.

ACCEPT
CWI LICENSE AGREEMENT FOR PYTHON 0.9.0 THROUGH 1.2

Licenses and Acknowledgements for Incorporated Software

This section is an incomplete, but growing list of licenses and acknowledgements for third-party software incorporated in the Python distribution.

Mersenne Twister

The _random module includes code based on a download from http://www.math.sci.hiroshima-u.ac.jp/~m-mat/MT/MT2002/emt19937ar.html. The following are the verbatim comments from the original code:

A C-program for MT19937, with initialization improved 2002/1/26.
Coded by Takuji Nishimura and Makoto Matsumoto.

Before using, initialize the state by using init_genrand(seed) or init_by_array(init_key, key_length).

Copyright (C) 1997 - 2002, Makoto Matsumoto and Takuji Nishimura.
All rights reserved.

Redistribution and use in source and binary forms, with or without modification, are permitted provided that the following are met:

1. Redistributions of source code must retain the above copyright notice, this list of conditions and the following disclaimer.

2. Redistributions in binary form must reproduce the above copyright notice, this list of conditions and the following disclaimer in the documentation and/or other materials provided with the distribution.
3. The names of its contributors may not be used to endorse or promote products derived from this software without specific prior written permission.

THIS SOFTWARE IS PROVIDED BY THE COPYRIGHT HOLDERS AND "AS IS" AND ANY EXPRESS OR IMPLIED WARRANTIES, INCLUDING, BUT NOT LIMITED TO, THE IMPLIED WARRANTIES OF MERCHANTABILITY AND FITNESS FOR A PARTICULAR PURPOSE ARE DISCLAIMED. IN NO EVENT SHALL THE COPYRIGHT HOLDERS OR CONTRIBUTORS BE LIABLE FOR ANY DIRECT, INDIRECT, INCIDENTAL, SPECIAL, EXEMPLARY, OR CONSEQUENTIAL DAMAGES (INCLUDING, BUT NOT LIMITED TO, PROCUREMENT OF SUBSTITUTE GOODS OR SERVICES; LOSS OF USE, DATA, OR PROFITS; OR BUSINESS INTERRUPTION) HOWEVER CAUSED AND ON ANY THEORY OF LIABILITY, WHETHER IN CONTRACT, STRICT LIABILITY, OR TORT (INCLUDING NEGLIGENCE OR OTHERWISE) ARISING IN ANY WAY OUT OF THE USE OF THIS SOFTWARE, EVEN IF ADVISED OF THE POSSIBILITY OF SUCH DAMAGE.

Any feedback is very welcome.

**UUencode and UUdecode functions**

The *uu* module contains the following notice:

> Copyright 1994 by Lance Ellinghouse
> Cathedral City, California Republic, United States of America.
> All Rights Reserved
> Permission to use, copy, modify, and distribute this software and documentation for any purpose and without fee is hereby granted, provided that the above copyright notice appear in all copies and that both that copyright notice and this permission notice appear in supporting documentation, and that the name of Lance Ellinghouse not be used in advertising or publicity pertaining to distribution of the software without specific, written prior permission.

LANCE ELLINGHOUSE DISCLAIMS ALL WARRANTIES WITH REGARD TO THIS SOFTWARE, INCLUDING ALL IMPLIED WARRANTIES OF MERCHANTABILITY AND FITNESS. IN NO EVENT SHALL LANCE ELLINGHOUSE CENTRUM BE LIABLE FOR ANY SPECIAL, INDIRECT OR CONSEQUENTIAL DAMAGES OR ANY DAMAGES WHATSOEVER RESULTING FROM LOSS OF USE, DATA OR PROFITS, WHETHER IN AN ACTION OF CONTRACT, NEGLIGENCE OR OTHER TORTIOUS ACTION, ARISING OUT OF OR IN CONNECTION WITH THE USE OR PERFORMANCE OF THIS SOFTWARE.

Modified by Jack Jansen, CWI, July 1995:
- Use *binascii* module to do the actual line-by-line conversion between ascii and binary. This results in a 1000-fold speedup. The C version is still 5 times faster, though.
- Arguments more compliant with Python standard

**XML Remote Procedure Calls**

The *xmlrpc.client* module contains the following notice:
The XML-RPC client interface is

What’s New in Python

The “What’s New in Python” series of essays takes tours through the most important changes between major Python versions. They are a “must read” for anyone wishing to stay up-to-date after a new release.

- What’s New In Python 3.3
  - Summary – Release highlights
  - PEP 405: Virtual Environments
  - PEP 420: Implicit Namespace Packages
  - PEP 3118: New memoryview implementation and buffer protocol documentation
  - PEP 393: Flexible String Representation
  - PEP 397: Python Launcher for Windows
  - PEP 3151: Reworking the OS and IO exception hierarchy
  - PEP 380: Syntax for Delegating to a Subgenerator
  - PEP 409: Suppressing exception context
  - PEP 414: Explicit Unicode literals
  - PEP 3155: Qualified name for classes and functions
  - PEP 412: Key-Sharing Dictionary
  - PEP 362: Function Signature Object
  - PEP 421: Adding sys.implementation
  - Using importlib as the Implementation of Import
- Other Language Changes
- A Finer-Grained Import Lock
- Builtin functions and types
- New Modules
- Improved Modules
- Optimizations
- Build and C API Changes
- Deprecated
- Porting to Python 3.3

- What’s New In Python 3.2
- PEP 384: Defining a Stable ABI
- PEP 389: Argparse Command Line Parsing Module
- PEP 391: Dictionary Based Configuration for Logging
- PEP 3148: The concurrent.futures module
- PEP 3147: PYC Repository Directories
- PEP 3149: ABI Version Tagged .so Files
- PEP 3333: Python Web Server Gateway Interface v1.0.1
- Other Language Changes
- New, Improved, and Deprecated Modules
- Multi-threading
- Optimizations
- Unicode
- Codecs
- Documentation
- IDLE
- Code Repository
- Build and C API Changes
- Porting to Python 3.2

**What’s New In Python 3.1**
- PEP 372: Ordered Dictionaries
- PEP 378: FormatSpecifier for Thousands Separator
- Other Language Changes
- New, Improved, and Deprecated Modules
- Optimizations
- IDLE
- Build and C API Changes
- Porting to Python 3.1

**What’s New In Python 3.0**
- Common Stumbling Blocks
- Overview Of Syntax Changes
- Changes Already Present In Python 2.6
- Library Changes
- **PEP 3101**: A New Approach To String Formatting
- Changes To Exceptions
- Miscellaneous Other Changes
- Build and C API Changes
- Performance
- Porting To Python 3.0

**What's New in Python 2.7**
- The Future for Python 2.x
- Python 3.1 Features
  - PEP 372: Adding an Ordered Dictionary to collections
  - PEP 378: Format Specifier for Thousands Separator
  - PEP 389: The argparse Module for Parsing Command Lines
  - PEP 391: Dictionary-Based Configuration For Logging
  - PEP 3106: Dictionary Views
  - PEP 3137: The memoryview Object
- Other Language Changes
- New and Improved Modules
- Build and C API Changes
- Other Changes and Fixes
- Porting to Python 2.7
- Acknowledgements

**What's New in Python 2.6**
- Python 3.0
- Changes to the Development Process
  - PEP 343: The ‘with’ statement
  - PEP 366: Explicit Relative Imports From a Main Module
  - PEP 370: Per-user site-packages Directory
  - PEP 371: The multiprocessing Package
  - PEP 3101: Advanced String Formatting
  - PEP 3105: print As a Function
  - PEP 3110: Exception-Handling Changes
  - PEP 3112: Byte Literals
  - PEP 3116: New I/O Library
  - PEP 3118: Revised Buffer Protocol
  - PEP 3119: Abstract Base Classes
  - PEP 3127: Integer Literal Support and Syntax
- PEP 3129: Class Decorators
- PEP 3141: A Type Hierarchy for Numbers
- Other Language Changes
- New and Improved Modules
- Deprecations and Removals
- Build and C API Changes
- Porting to Python 2.6
- Acknowledgements

- **What's New in Python 2.5**
  - PEP 308: Conditional Expressions
  - PEP 309: Partial Function Application
  - PEP 314: Metadata for Python Software Packages v1.1
  - PEP 328: Absolute and Relative Imports
  - PEP 338: Executing Modules as Scripts
  - PEP 341: Unified try/except/finally
  - PEP 342: New Generator Features
  - PEP 343: The 'with' statement

The Python Tutorial

Python is an easy to learn, powerful programming language. It has efficient high-level data structures and a simple but effective approach to object-oriented programming. Python’s elegant syntax and dynamic typing, together with its interpreted nature, make it an ideal language for scripting and rapid application development in many areas on most platforms.

The Python interpreter and the extensive standard library are freely available in source or binary form for all major platforms from the Python Web site, http://www.python.org/, and may be freely distributed. The same site also contains distributions of and pointers to many free third party Python modules, programs and tools, and additional documentation.

The Python interpreter is easily extended with new functions and data types implemented in C or C++ (or other languages callable from C). Python is also suitable as an extension language for customizable applications.

This tutorial introduces the reader informally to the basic concepts and features of the Python language and system. It helps to have a Python interpreter handy for hands-on experience, but all examples are self-contained, so the tutorial can be read off-line as well.

For a description of standard objects and modules, see *The Python Standard Library*. *The Python Language Reference* gives a more formal definition of the language. To write extensions in C or C++, read *Extending and Embedding the Python Interpreter* and *Python/C API Reference Manual*. There are also several books covering Python in depth.
This tutorial does not attempt to be comprehensive and cover every single feature, or even every commonly used feature. Instead, it introduces many of Python’s most noteworthy features, and will give you a good idea of the language’s flavor and style. After reading it, you will be able to read and write Python modules and programs, and you will be ready to learn more about the various Python library modules described in *The Python Standard Library*.

The *Glossary* is also worth going through.

- 1. Whetting Your Appetite
- 2. Using the Python Interpreter
  - 2.1. Invoking the Interpreter
    - 2.1.1. Argument Passing
    - 2.1.2. Interactive Mode

14. Floating Point Arithmetic: Issues and Limitations
   14.1. Representation Error
The Python Standard Library

While *The Python Language Reference* describes the exact syntax and semantics of the Python language, this library reference manual describes the standard library that is distributed with Python. It also describes some of the optional components that are commonly included in Python distributions.

Python’s standard library is very extensive, offering a wide range of facilities as indicated by the long table of contents listed below. The library contains built-in modules (written in C) that provide access to system functionality such as file I/O that would otherwise be inaccessible to Python programmers, as well as modules written in Python that provide standardized solutions for many problems that occur in everyday programming. Some of these modules are explicitly designed to encourage and enhance the portability of Python programs by abstracting away platform-specifics into platform-neutral APIs.

The Python installers for the Windows platform usually includes the entire standard library and often also include many additional components. For Unix-like operating systems Python is normally provided as a collection of packages, so it may be necessary to use the packaging tools provided with the operating system to obtain some or all of the optional components.

In addition to the standard library, there is a growing collection of several thousand components (from individual programs and modules to packages and entire application development frameworks), available from the Python Package Index.

- 1. Introduction
2. Built-in Functions
3. Built-in Constants
   3.1. Constants added by the site module
4. Built-in Types
   4.1. Truth Value Testing
   4.2. Boolean Operations — and, or, not
   4.3. Comparisons
   4.4. Numeric Types — int, float, complex
   4.5. Iterator Types
   4.6. Sequence Types — list, tuple, range
   4.7. Text Sequence Type — str
   4.8. Binary Sequence Types — bytes, bytearray, memoryview
   4.9. Set Types — set, frozenset
   4.10. Mapping Types — dict
   4.11. Context Manager Types
   4.12. Other Built-in Types
   4.13. Special Attributes
5. Built-in Exceptions
   5.1. Base classes
   5.2. Concrete exceptions
   5.3. Warnings
   5.4. Exception hierarchy
6. Text Processing Services
   6.1. string — Common string operations
   6.2. re — Regular expression operations
   6.3. difflib — Helpers for computing deltas
   6.4. textwrap — Text wrapping and filling
   6.5. unicodedata — Unicode Database
   6.6. stringprep — Internet String Preparation
   6.7. readline — GNU readline interface
   6.8. rlcompleter — Completion function for GNU readline
7. Binary Data Services
7.1. struct — Interpret bytes as packed binary data
7.2. codecs — Codec registry and base classes

8. Data Types
8.1. datetime — Basic date and time types
8.2. calendar — General calendar-related functions
8.3. collections — Container datatypes
8.4. collections.abc — Abstract Base Classes for Containers
8.5. heapq — Heap queue algorithm
8.6. bisect — Array bisection algorithm
8.7. array — Efficient arrays of numeric values
8.8. weakref — Weak references
8.9. types — Dynamic type creation and names for built-in types
8.10. copy — Shallow and deep copy operations
8.11. pprint — Data pretty printer
8.12. reprlib — Alternate repr() implementation

9. Numeric and Mathematical Modules
9.1. numbers — Numeric abstract base classes
9.2. math — Mathematical functions
9.3. cmath — Mathematical functions for complex numbers
9.4. decimal — Decimal fixed point and floating point arithmetic
9.5. fractions — Rational numbers
9.6. random — Generate pseudo-random numbers

10. Functional Programming Modules
10.1. itertools — Functions creating iterators for efficient looping
10.2. functools — Higher-order functions and operations on callable objects
10.3. operator — Standard operators as functions

11. File and Directory Access
○ 11.1. os.path — Common pathname manipulations
○ 11.2. fileinput — Iterate over lines from multiple input streams
○ 11.3. stat — Interpreting stat() results
○ 11.4. filecmp — File and Directory Comparisons
○ 11.5. tempfile — Generate temporary files and directories
○ 11.6. glob — Unix style pathname pattern expansion
○ 11.7. fnmatch — Unix filename pattern matching
○ 11.8. linecache — Random access to text lines
○ 11.9. shutil — High-level file operations
○ 11.10. macpath — Mac OS 9 path manipulation functions

• 12. Data Persistence
  ○ 12.1. pickle — Python object serialization
  ○ 12.2. copyreg — Register pickle support functions
  ○ 12.3. shelve — Python object persistence
  ○ 12.4. marshal — Internal Python object serialization
  ○ 12.5. dbm — Interfaces to Unix “databases”
  ○ 12.6. sqlite3 — DB-API 2.0 interface for SQLite databases

• 13. Data Compression and Archiving
  ○ 13.1. zlib — Compression compatible with gzip
  ○ 13.2. gzip — Support for gzip files
  ○ 13.3. bz2 — Support for bzip2 compression
  ○ 13.4. lzma — Compression using the LZMA algorithm
  ○ 13.5. zipfile — Work with ZIP archives
  ○ 13.6. tarfile — Read and write tar archive files

• 14. File Formats
  ○ 14.1. csv — CSV File Reading and Writing
  ○ 14.2. configparser — Configuration file parser
  ○ 14.3. netrc — netrc file processing
  ○ 14.4. xdrlib — Encode and decode XDR data
  ○ 14.5. plistlib — Generate and parse Mac OS X .plist files
15. Cryptographic Services
   • 15.1. hashlib — Secure hashes and message digests
   • 15.2. hmac — Keyed-Hashing for Message Authentication

16. Generic Operating System Services
   • 16.1. os — Miscellaneous operating system interfaces
   • 16.2. io — Core tools for working with streams
   • 16.3. time — Time access and conversions
   • 16.4. argparse — Parser for command-line options, arguments and sub-commands
   • 16.5. optparse — Parser for command line options
   • 16.6. getopt — C-style parser for command line options
   • 16.7. logging — Logging facility for Python
   • 16.8. logging.config — Logging configuration
   • 16.9. logging.handlers — Logging handlers
   • 16.10. getpass — Portable password input
   • 16.11. curses — Terminal handling for character-cell displays
   • 16.12. curses.textpad — Text input widget for curses programs
   • 16.13. curses.ascii — Utilities for ASCII characters
   • 16.14. curses.panel — A panel stack extension for curses
   • 16.15. platform — Access to underlying platform’s identifying data
   • 16.16. errno — Standard errno system symbols
   • 16.17. ctypes — A foreign function library for Python

17. Concurrent Execution
   • 17.1. threading — Thread-based parallelism
   • 17.2. multiprocessing — Process-based parallelism
   • 17.3. The concurrent package
   • 17.4. concurrent.futures — Launching parallel tasks
   • 17.5. subprocess — Subprocess management
   • 17.6. sched — Event scheduler
- 17.7. queue — A synchronized queue class
- 17.8. select — Waiting for I/O completion
- 17.9. dummy_threading — Drop-in replacement for the threading module
- 17.10. _thread — Low-level threading API
- 17.11. _dummy_thread — Drop-in replacement for the _thread module

- 18. Interprocess Communication and Networking
  - 18.1. socket — Low-level networking interface
  - 18.2. ssl — TLS/SSL wrapper for socket objects
  - 18.3. asyncore — Asynchronous socket handler
  - 18.4. asynchat — Asynchronous socket command/response handler
  - 18.5. signal — Set handlers for asynchronous events
  - 18.6. mmap — Memory-mapped file support

- 19. Internet Data Handling
  - 19.1. email — An email and MIME handling package
  - 19.2. json — JSON encoder and decoder
  - 19.3. mailcap — Mailcap file handling
  - 19.4. mailbox — Manipulate mailboxes in various formats
  - 19.5. mimetypes — Map filenames to MIME types
  - 19.6. base64 — RFC 3548: Base16, Base32, Base64 Data Encodings
  - 19.7. binhex — Encode and decode binhex4 files
  - 19.8. binascii — Convert between binary and ASCII
  - 19.9. quopri — Encode and decode MIME quoted-printable data
  - 19.10. uu — Encode and decode uuencode files

- 20. Structured Markup Processing Tools
  - 20.1. html — HyperText Markup Language support
  - 20.2. html.parser — Simple HTML and XHTML parser
  - 20.3. html.entities — Definitions of HTML general
20.4. XML Processing Modules
20.5. XML vulnerabilities
20.6. xml.etree.ElementTree — The ElementTree XML API
20.7. xml.dom — The Document Object Model API
20.8. xml.dom.minidom — Minimal DOM implementation
20.9. xml.dom.pulldom — Support for building partial DOM trees
20.10. xml.sax — Support for SAX2 parsers
20.11. xml.sax.handler — Base classes for SAX handlers
20.12. xml.sax.saxutils — SAX Utilities
20.13. xml.sax.xmlreader — Interface for XML parsers

21. Internet Protocols and Support
21.1. webbrowser — Convenient Web-browser controller
21.2. cgi — Common Gateway Interface support
21.3. cgitb — Traceback manager for CGI scripts
21.4. wsgiref — WSGI Utilities and Reference Implementation
21.5. urllib — URL handling modules
21.6. urllib.request — Extensible library for opening URLs
21.7. urllib.response — Response classes used by urllib
21.8. urllib.parse — Parse URLs into components
21.9. urllib.error — Exception classes raised by urllib.request
21.10. urllib.robotparser — Parser for robots.txt
21.11. http — HTTP modules
- 21.13. ftplib — FTP protocol client
- 21.14. poplib — POP3 protocol client
- 21.15. imaplib — IMAP4 protocol client
- 21.16. nntplib — NNTP protocol client
- 21.17. smtplib — SMTP protocol client
- 21.18. smtpd — SMTP Server
- 21.19. telnetlib — Telnet client
- 21.20. uuid — UUID objects according to RFC 4122
- 21.21. socketserver — A framework for network servers
- 21.22. http.server — HTTP servers
- 21.23. http.cookies — HTTP state management
- 21.24. http.cookiejar — Cookie handling for HTTP clients
- 21.25. xmlrpc — XMLRPC server and client modules
- 21.26. xmlrpc.client — XML-RPC client access
- 21.27. xmlrpc.server — Basic XML-RPC servers
- 21.28. ipaddress — IPv4/IPv6 manipulation library

- 22. Multimedia Services
  - 22.1. audioop — Manipulate raw audio data
  - 22.2. aifc — Read and write AIFF and AIFC files
  - 22.3. sunau — Read and write Sun AU files
  - 22.4. wave — Read and write WAV files
  - 22.5. chunk — Read IFF chunked data
  - 22.6. colorsys — Conversions between color systems
  - 22.7. imghdr — Determine the type of an image
  - 22.8. sndhdr — Determine type of sound file
  - 22.9. ossaudiodev — Access to OSS-compatible audio devices

- 23. Internationalization
  - 23.1. gettext — Multilingual internationalization services
  - 23.2. locale — Internationalization services

- 24. Program Frameworks
24.1. turtle — Turtle graphics
24.2. cmd — Support for line-oriented command interpreters
24.3. shlex — Simple lexical analysis

25. Graphical User Interfaces with Tk
25.1. tkinter — Python interface to Tcl/Tk
25.2. tkinter.ttk — Tk themed widgets
25.3. tkinter.tix — Extension widgets for Tk
25.4. tkinter.scrolledtext — Scrolled Text Widget
25.5. IDLE
25.6. Other Graphical User Interface Packages

26. Development Tools
26.1. pydoc — Documentation generator and online help system
26.2. doctest — Test interactive Python examples
26.3. unittest — Unit testing framework
26.4. unittest.mock — mock object library
26.5. unittest.mock — getting started
26.6. 2to3 - Automated Python 2 to 3 code translation
26.7. test — Regression tests package for Python
26.8. test.support — Utilities for the Python test suite
26.9. venv — Creation of virtual environments

27. Debugging and Profiling
27.1. bdb — Debugger framework
27.2. faulthandler — Dump the Python traceback
27.3. pdb — The Python Debugger
27.4. The Python Profilers
27.5. timeit — Measure execution time of small code snippets
27.6. trace — Trace or track Python statement execution

28. Python Runtime Services
28.1. sys — System-specific parameters and functions
28.2. sysconfig — Provide access to Python’s
configuration information

- 28.3. builtins — Built-in objects
- 28.4. __main__ — Top-level script environment
- 28.5. warnings — Warning control
- 28.6. contextlib — Utilities for with-statement contexts
- 28.7. abc — Abstract Base Classes
- 28.8. atexit — Exit handlers
- 28.9. traceback — Print or retrieve a stack traceback
- 28.10. __future__ — Future statement definitions
- 28.11. gc — Garbage Collector interface
- 28.12. inspect — Inspect live objects
- 28.13. site — Site-specific configuration hook
- 28.14. fpectl — Floating point exception control
- 28.15. distutils — Building and installing Python modules

- 29. Custom Python Interpreters
  - 29.1. code — Interpreter base classes
  - 29.2. codeop — Compile Python code

- 30. Importing Modules
  - 30.1. imp — Access the import internals
  - 30.2. zipimport — Import modules from Zip archives
  - 30.3. pkgutil — Package extension utility
  - 30.4. modulefinder — Find modules used by a script
  - 30.5. runpy — Locating and executing Python modules
  - 30.6. importlib — An implementation of import

- 31. Python Language Services
  - 31.1. parser — Access Python parse trees
  - 31.2. ast — Abstract Syntax Trees
  - 31.3. symtable — Access to the compiler's symbol tables
  - 31.4. symbol — Constants used with Python parse trees
  - 31.5. token — Constants used with Python parse trees
  - 31.6. keyword — Testing for Python keywords
  - 31.7. tokenize — Tokenizer for Python source
31.8. tabnanny — Detection of ambiguous indentation
31.9. pyc1br — Python class browser support
31.10. py_compile — Compile Python source files
31.11. compileall — Byte-compile Python libraries
31.12. dis — Disassembler for Python bytecode
31.13. pickletools — Tools for pickle developers

• 32. Miscellaneous Services
  32.1. formatter — Generic output formatting

• 33. MS Windows Specific Services
  33.1. msilib — Read and write Microsoft Installer files
  33.2. msvcr — Useful routines from the MS VC++ runtime
  33.3. winreg — Windows registry access
  33.4. winsound — Sound-playing interface for Windows

• 34. Unix Specific Services
  34.1. posix — The most common POSIX system calls
  34.2. pwd — The password database
  34.3. spwd — The shadow password database
  34.4. grp — The group database
  34.5. crypt — Function to check Unix passwords
  34.6. termios — POSIX style tty control
  34.7. tty — Terminal control functions
  34.8. pty — Pseudo-terminal utilities
  34.9. fcntl — The fcntl and ioctl system calls
  34.10. pipes — Interface to shell pipelines
  34.11. resource — Resource usage information
  34.12. nis — Interface to Sun’s NIS (Yellow Pages)
  34.13. syslog — Unix syslog library routines

• 35. Undocumented Modules
  35.1. Platform specific modules
The Python Language Reference

This reference manual describes the syntax and “core semantics” of the language. It is terse, but attempts to be exact and complete. The semantics of non-essential built-in object types and of the built-in functions and modules are described in The Python Standard Library. For an informal introduction to the language, see The Python Tutorial. For C or C++ programmers, two additional manuals exist: Extending and Embedding the Python Interpreter describes the high-level picture of how to write a Python extension module, and the Python/C API Reference Manual describes the interfaces available to C/C++ programmers in detail.

Python HOWTOs

Python HOWTOs are documents that cover a single, specific topic, and attempt to cover it fairly completely. Modelled on the Linux Documentation Project’s HOWTO collection, this collection is an effort to foster documentation that’s more detailed than the Python Library Reference.

Currently, the HOWTOs are:

- Porting Python 2 Code to Python 3
- Porting Extension Modules to Python 3
- Curses Programming with Python
- Descriptor HowTo Guide
- Functional Programming HOWTO
- Logging HOWTO
- Logging Cookbook
- Regular Expression HOWTO
- Socket Programming HOWTO
- Sorting HOW TO
- Unicode HOWTO
- HOWTO Fetch Internet Resources Using The urllib Package
- HOWTO Use Python in the web
- Argparse Tutorial
- An introduction to the ipaddress module
Extending and Embedding the Python Interpreter

This document describes how to write modules in C or C++ to extend the Python interpreter with new modules. Those modules can not only define new functions but also new object types and their methods. The document also describes how to embed the Python interpreter in another application, for use as an extension language. Finally, it shows how to compile and link extension modules so that they can be loaded dynamically (at run time) into the interpreter, if the underlying operating system supports this feature.

This document assumes basic knowledge about Python. For an informal introduction to the language, see *The Python Tutorial*. *The Python Language Reference* gives a more formal definition of the language. *The Python Standard Library* documents the existing object types, functions and modules (both built-in and written in Python) that give the language its wide application range.

For a detailed description of the whole Python/C API, see the separate *Python/C API Reference Manual*.

Installing Python Modules

Author: Greg Ward

Abstract

This document describes the Python Distribution Utilities (“Distutils”) from the end-user’s point-of-view, describing how to extend the capabilities of a standard Python installation by building and installing third-party Python modules and extensions.
Introduction

Although Python’s extensive standard library covers many programming needs, there often comes a time when you need to add some new functionality to your Python installation in the form of third-party modules. This might be necessary to support your own programming, or to support an application that you want to use and that happens to be written in Python.

In the past, there has been little support for adding third-party modules to an existing Python installation. With the introduction of the Python Distribution Utilities (Distutils for short) in Python 2.0, this changed.

This document is aimed primarily at the people who need to install third-party Python modules: end-users and system administrators who just need to get some Python application running, and existing Python programmers who want to add some new goodies to their toolbox. You don’t need to know Python to read this document; there will be some brief forays into using Python’s interactive mode to explore your installation, but that’s it. If you’re looking for information on how to distribute your own Python modules so that others may use them, see the Distributing Python Modules manual.

Best case: trivial installation

In the best case, someone will have prepared a special version of the module distribution you want to install that is targeted specifically at your platform and is installed just like any other software on your platform. For example, the module developer might make an executable installer available for Windows users, an RPM package for users of RPM-based Linux systems (Red Hat, SuSE, Mandrake, and
many others), a Debian package for users of Debian-based Linux systems, and so forth.

In that case, you would download the installer appropriate to your platform and do the obvious thing with it: run it if it's an executable installer, `rpm --install` it if it's an RPM, etc. You don’t need to run Python or a setup script, you don’t need to compile anything—you might not even need to read any instructions (although it's always a good idea to do so anyway).

Of course, things will not always be that easy. You might be interested in a module distribution that doesn’t have an easy-to-use installer for your platform. In that case, you’ll have to start with the source distribution released by the module's author/maintainer. Installing from a source distribution is not too hard, as long as the modules are packaged in the standard way. The bulk of this document is about building and installing modules from standard source distributions.

The new standard: Distutils

If you download a module source distribution, you can tell pretty quickly if it was packaged and distributed in the standard way, i.e. using the Distutils. First, the distribution’s name and version number will be featured prominently in the name of the downloaded archive, e.g. `foo-1.0.tar.gz` or `widget-0.9.7.zip`. Next, the archive will unpack into a similarly-named directory: `foo-1.0` or `widget-0.9.7`. Additionally, the distribution will contain a setup script `setup.py`, and a file named `README.txt` or possibly just `README`, which should explain that building and installing the module distribution is a simple matter of running one command from a terminal:
**python setup.py install**

For Windows, this command should be run from a command prompt window (*Start ➤ Accessories*):

**setup.py install**

If all these things are true, then you already know how to build and install the modules you’ve just downloaded: Run the command above. Unless you need to install things in a non-standard way or customize the build process, you don’t really need this manual. Or rather, the above command is everything you need to get out of this manual.
Standard Build and Install

As described in section *The new standard: Distutils*, building and installing a module distribution using the Distutils is usually one simple command to run from a terminal:

```
python setup.py install
```

Platform variations

You should always run the setup command from the distribution root directory, i.e. the top-level subdirectory that the module source distribution unpacks into. For example, if you’ve just downloaded a module source distribution `foo-1.0.tar.gz` onto a Unix system, the normal thing to do is:

```
gunzip -c foo-1.0.tar.gz | tar xf -  # unpacks into directory foo-1.0
cd foo-1.0
python setup.py install
```

On Windows, you’d probably download `foo-1.0.zip`. If you downloaded the archive file to `C:\Temp`, then it would unpack into `C:\Temp\foo-1.0`; you can use either a archive manipulator with a graphical user interface (such as WinZip) or a command-line tool (such as `unzip` or `pkunzip`) to unpack the archive. Then, open a command prompt window and run:

```
cd c:\Temp\foo-1.0
python setup.py install
```
Splitting the job up

Running `setup.py install` builds and installs all modules in one run. If you prefer to work incrementally—especially useful if you want to customize the build process, or if things are going wrong—you can use the setup script to do one thing at a time. This is particularly helpful when the build and install will be done by different users—for example, you might want to build a module distribution and hand it off to a system administrator for installation (or do it yourself, with super-user privileges).

For example, you can build everything in one step, and then install everything in a second step, by invoking the setup script twice:

```
python setup.py build
python setup.py install
```

If you do this, you will notice that running the `install` command first runs the `build` command, which—in this case—quickly notices that it has nothing to do, since everything in the `build` directory is up-to-date.

You may not need this ability to break things down often if all you do is install modules downloaded off the ‘net, but it’s very handy for more advanced tasks. If you get into distributing your own Python modules and extensions, you’ll run lots of individual Distutils commands on their own.

How building works

As implied above, the `build` command is responsible for putting the files to install into a `build directory`. By default, this is `build` under the
distribution root; if you're excessively concerned with speed, or want to keep the source tree pristine, you can change the build directory with the --build-base option. For example:

```
python setup.py build --build-base=/path/to/pybuild/
```

(Or you could do this permanently with a directive in your system or personal Distutils configuration file; see section Distutils Configuration Files.) Normally, this isn't necessary.

The default layout for the build tree is as follows:

```
--- build/ --- lib/
or
--- build/ --- lib.<plat>/
    temp.<plat>/
```

where `<plat>` expands to a brief description of the current OS/hardware platform and Python version. The first form, with just a `lib` directory, is used for “pure module distributions”—that is, module distributions that include only pure Python modules. If a module distribution contains any extensions (modules written in C/C++), then the second form, with two `<plat>` directories, is used. In that case, the `temp.plat` directory holds temporary files generated by the compile/link process that don’t actually get installed. In either case, the `lib` (or `lib.plat`) directory contains all Python modules (pure Python and extensions) that will be installed.

In the future, more directories will be added to handle Python scripts, documentation, binary executables, and whatever else is needed to handle the job of installing Python modules and applications.
How installation works

After the **build** command runs (whether you run it explicitly, or the **install** command does it for you), the work of the **install** command is relatively simple: all it has to do is copy everything under `build/lib` (or `build/libplat`) to your chosen installation directory.

If you don’t choose an installation directory—i.e., if you just run `setup.py install`—then the **install** command installs to the standard location for third-party Python modules. This location varies by platform and by how you built-installed Python itself. On Unix (and Mac OS X, which is also Unix-based), it also depends on whether the module distribution being installed is pure Python or contains extensions (“non-pure”):

<table>
<thead>
<tr>
<th>Platform</th>
<th>Standard installation location</th>
<th>Default</th>
</tr>
</thead>
<tbody>
<tr>
<td>Unix (pure)</td>
<td><strong>prefix/lib/pythonX.Y/site-packages</strong></td>
<td><code>/usr/local/lib/packages</code></td>
</tr>
<tr>
<td>Unix (non-pure)</td>
<td><strong>exec-prefix/lib/pythonX.Y/site-packages</strong></td>
<td><code>/usr/local/lib/packages</code></td>
</tr>
<tr>
<td>Windows</td>
<td><strong>prefix\Lib\site-packages</strong></td>
<td>C:\PythonXY\Lib</td>
</tr>
</tbody>
</table>

Notes:

1. Most Linux distributions include Python as a standard part of the system, so `prefix` and `exec-prefix` are usually both `/usr` on Linux. If you build Python yourself on Linux (or any Unix-like system), the default `prefix` and `exec-prefix` are `/usr/local`.
2. The default installation directory on Windows was `C:\Program Files\Python` under Python 1.6a1, 1.5.2, and earlier.
prefix and exec-prefix stand for the directories that Python is installed to, and where it finds its libraries at run-time. They are always the same under Windows, and very often the same under Unix and Mac OS X. You can find out what your Python installation uses for prefix and exec-prefix by running Python in interactive mode and typing a few simple commands. Under Unix, just type python at the shell prompt. Under Windows, choose Start ➤ Programs ➤ Python X.Y ➤ Python (command line). Once the interpreter is started, you type Python code at the prompt. For example, on my Linux system, I type the three Python statements shown below, and get the output as shown, to find out my prefix and exec-prefix:

```
Python 2.4 (#26, Aug 7 2004, 17:19:02)
Type "help", "copyright", "credits" or "license" for more information.
>>> import sys
>>> sys.prefix
'/usr'
>>> sys.exec_prefix
'/usr'
```

A few other placeholders are used in this document: X.Y stands for the version of Python, for example 3.2; abiflags will be replaced by the value of sys.abiflags or the empty string for platforms which don’t define ABI flags; distname will be replaced by the name of the module distribution being installed. Dots and capitalization are important in the paths; for example, a value that uses python3.2 on UNIX will typically use Python32 on Windows.

If you don’t want to install modules to the standard location, or if you don’t have permission to write there, then you need to read about alternate installations in section Alternate Installation. If you want to customize your installation directories more heavily, see section
Custom Installation on custom installations.
Alternate Installation

Often, it is necessary or desirable to install modules to a location other than the standard location for third-party Python modules. For example, on a Unix system you might not have permission to write to the standard third-party module directory. Or you might wish to try out a module before making it a standard part of your local Python installation. This is especially true when upgrading a distribution already present: you want to make sure your existing base of scripts still works with the new version before actually upgrading.

The Distutils `install` command is designed to make installing module distributions to an alternate location simple and painless. The basic idea is that you supply a base directory for the installation, and the `install` command picks a set of directories (called an *installation scheme*) under this base directory in which to install files. The details differ across platforms, so read whichever of the following sections applies to you.

Note that the various alternate installation schemes are mutually exclusive: you can pass `--user`, or `--home`, or `--prefix` and `--exec-prefix`, or `--install-base` and `--install-platbase`, but you can’t mix from these groups.

Alternate installation: the user scheme

This scheme is designed to be the most convenient solution for users that don’t have write permission to the global site-packages directory or don’t want to install into it. It is enabled with a simple option:

```
python setup.py install --user
```
Files will be installed into subdirectories of `site.USER_BASE` (written as `userbase` hereafter). This scheme installs pure Python modules and extension modules in the same location (also known as `site.USER_SITE`). Here are the values for UNIX, including Mac OS X:

<table>
<thead>
<tr>
<th>Type of file</th>
<th>Installation directory</th>
</tr>
</thead>
<tbody>
<tr>
<td>modules</td>
<td>userbase/lib/pythonX.Y/site-packages</td>
</tr>
<tr>
<td>scripts</td>
<td>userbase/bin</td>
</tr>
<tr>
<td>data</td>
<td>userbase</td>
</tr>
<tr>
<td>C headers</td>
<td>userbase/include/pythonX.Y/abiflags/distname</td>
</tr>
</tbody>
</table>

And here are the values used on Windows:

<table>
<thead>
<tr>
<th>Type of file</th>
<th>Installation directory</th>
</tr>
</thead>
<tbody>
<tr>
<td>modules</td>
<td>userbase\PythonXY\site-packages</td>
</tr>
<tr>
<td>scripts</td>
<td>userbase\Scripts</td>
</tr>
<tr>
<td>data</td>
<td>userbase</td>
</tr>
<tr>
<td>C headers</td>
<td>userbase\PythonXY\Include\distname</td>
</tr>
</tbody>
</table>

The advantage of using this scheme compared to the other ones described below is that the user site-packages directory is under normal conditions always included in `sys.path` (see `site` for more information), which means that there is no additional step to perform after running the `setup.py` script to finalize the installation.

The `build_ext` command also has a `--user` option to add `userbase\include` to the compiler search path for header files and
Alternate installation: the home scheme

The idea behind the “home scheme” is that you build and maintain a personal stash of Python modules. This scheme’s name is derived from the idea of a “home” directory on Unix, since it’s not unusual for a Unix user to make their home directory have a layout similar to `/usr/` or `/usr/local/`. This scheme can be used by anyone, regardless of the operating system they are installing for.

Installing a new module distribution is as simple as

```
python setup.py install --home=<dir>
```

where you can supply any directory you like for the `--home` option. On Unix, lazy typists can just type a tilde (`~`); the `install` command will expand this to your home directory:

```
python setup.py install --home=~
```

To make Python find the distributions installed with this scheme, you may have to `modify Python's search path` or edit `sitecustomize` (see `site`) to call `site.addsitedir()` or edit `sys.path`.

The `--home` option defines the installation base directory. Files are installed to the following directories under the installation base as follows:

<table>
<thead>
<tr>
<th>Type of file</th>
<th>Installation directory</th>
</tr>
</thead>
<tbody>
<tr>
<td>modules</td>
<td><code>home/lib/python</code></td>
</tr>
<tr>
<td></td>
<td></td>
</tr>
<tr>
<td>------------------</td>
<td>-------------</td>
</tr>
<tr>
<td>scripts</td>
<td>home/bin</td>
</tr>
<tr>
<td>data</td>
<td>home</td>
</tr>
<tr>
<td>C headers</td>
<td>home/include/python/distname</td>
</tr>
</tbody>
</table>

(Mentally replace slashes with backslashes if you’re on Windows.)

Alternate installation: Unix (the prefix scheme)

The “prefix scheme” is useful when you wish to use one Python installation to perform the build/install (i.e., to run the setup script), but install modules into the third-party module directory of a different Python installation (or something that looks like a different Python installation). If this sounds a trifle unusual, it is—that’s why the user and home schemes come before. However, there are at least two known cases where the prefix scheme will be useful.

First, consider that many Linux distributions put Python in /usr, rather than the more traditional /usr/local. This is entirely appropriate, since in those cases Python is part of “the system” rather than a local add-on. However, if you are installing Python modules from source, you probably want them to go in /usr/local/lib/python2.X rather than /usr/lib/python2.X. This can be done with

```
/usr/bin/python setup.py install --prefix=/usr/local
```

Another possibility is a network filesystem where the name used to write to a remote directory is different from the name used to read it: for example, the Python interpreter accessed as /usr/local/bin/python might search for modules in /usr/local/lib/python2.X, but those modules would have to be
installed to, say, /mnt/@server/export/lib/python2.X. This could be done with

```
/usr/local/bin/python setup.py install --prefix=/mnt
```

In either case, the --prefix option defines the installation base, and the --exec-prefix option defines the platform-specific installation base, which is used for platform-specific files. (Currently, this just means non-pure module distributions, but could be expanded to C libraries, binary executables, etc.) If --exec-prefix is not supplied, it defaults to --prefix. Files are installed as follows:

<table>
<thead>
<tr>
<th>Type of file</th>
<th>Installation directory</th>
</tr>
</thead>
<tbody>
<tr>
<td>Python modules</td>
<td><code>prefix/lib/pythonX.Y/site-packages</code></td>
</tr>
<tr>
<td>extension modules</td>
<td><code>exec-prefix/lib/pythonX.Y/site-packages</code></td>
</tr>
<tr>
<td>scripts</td>
<td><code>prefix/bin</code></td>
</tr>
<tr>
<td>data</td>
<td><code>prefix</code></td>
</tr>
<tr>
<td>C headers</td>
<td><code>prefix/include/pythonX.Yabiflags/distname</code></td>
</tr>
</tbody>
</table>

There is no requirement that --prefix or --exec-prefix actually point to an alternate Python installation; if the directories listed above do not already exist, they are created at installation time.

Incidentally, the real reason the prefix scheme is important is simply that a standard Unix installation uses the prefix scheme, but with --prefix and --exec-prefix supplied by Python itself as `sys.prefix` and `sys.exec_prefix`. Thus, you might think you'll never use the prefix
scheme, but every time you run `python setup.py install` without any other options, you’re using it.

Note that installing extensions to an alternate Python installation has no effect on how those extensions are built: in particular, the Python header files (`Python.h` and friends) installed with the Python interpreter used to run the setup script will be used in compiling extensions. It is your responsibility to ensure that the interpreter used to run extensions installed in this way is compatible with the interpreter used to build them. The best way to do this is to ensure that the two interpreters are the same version of Python (possibly different builds, or possibly copies of the same build). (Of course, if your `--prefix` and `--exec-prefix` don’t even point to an alternate Python installation, this is immaterial.)

**Alternate installation: Windows (the prefix scheme)**

Windows has no concept of a user’s home directory, and since the standard Python installation under Windows is simpler than under Unix, the `--prefix` option has traditionally been used to install additional packages in separate locations on Windows.

```
python setup.py install --prefix="\Temp\Python"
```

to install modules to the `\Temp\Python` directory on the current drive.

The installation base is defined by the `--prefix` option; the `--exec-prefix` option is not supported under Windows, which means that pure Python modules and extension modules are installed into the same location. Files are installed as follows:
<table>
<thead>
<tr>
<th>Type of file</th>
<th>Installation directory</th>
</tr>
</thead>
<tbody>
<tr>
<td>modules</td>
<td><code>prefix\Lib\site-packages</code></td>
</tr>
<tr>
<td>scripts</td>
<td><code>prefix\Scripts</code></td>
</tr>
<tr>
<td>data</td>
<td><code>prefix</code></td>
</tr>
<tr>
<td>C headers</td>
<td><code>prefix\Include\distname</code></td>
</tr>
</tbody>
</table>
Custom Installation

Sometimes, the alternate installation schemes described in section *Alternate Installation* just don’t do what you want. You might want to tweak just one or two directories while keeping everything under the same base directory, or you might want to completely redefine the installation scheme. In either case, you’re creating a *custom installation scheme*.

To create a custom installation scheme, you start with one of the alternate schemes and override some of the installation directories used for the various types of files, using these options:

<table>
<thead>
<tr>
<th>Type of file</th>
<th>Override option</th>
</tr>
</thead>
<tbody>
<tr>
<td>Python modules</td>
<td>--install-purelib</td>
</tr>

These override options can be relative, absolute, or explicitly defined in terms of one of the installation base directories. (There are two installation base directories, and they are normally the same—they only differ when you use the Unix “prefix scheme” and supply different `--prefix` and `--exec-prefix` options; using `--install-lib`
will override values computed or given for `--install-purelib` and `--install-platlib`, and is recommended for schemes that don’t make a difference between Python and extension modules.)

For example, say you’re installing a module distribution to your home directory under Unix—but you want scripts to go in `~/scripts` rather than `~/bin`. As you might expect, you can override this directory with the `--install-scripts` option; in this case, it makes most sense to supply a relative path, which will be interpreted relative to the installation base directory (your home directory, in this case):

```
python setup.py install --home=~ --install-scripts=scripts
```

Another Unix example: suppose your Python installation was built and installed with a prefix of `/usr/local/python`, so under a standard installation scripts will wind up in `/usr/local/python/bin`. If you want them in `/usr/local/bin` instead, you would supply this absolute directory for the `--install-scripts` option:

```
python setup.py install --install-scripts=/usr/local/bin
```

(This performs an installation using the “prefix scheme,” where the prefix is whatever your Python interpreter was installed with—`/usr/local/python` in this case.)

If you maintain Python on Windows, you might want third-party modules to live in a subdirectory of `prefix`, rather than right in `prefix` itself. This is almost as easy as customizing the script installation directory —you just have to remember that there are two types of modules to worry about, Python and extension modules, which can conveniently be both controlled by one option:
python setup.py install --install-lib=Site

The specified installation directory is relative to prefix. Of course, you also have to ensure that this directory is in Python’s module search path, such as by putting a .pth file in a site directory (see site). See section Modifying Python’s Search Path to find out how to modify Python’s search path.

If you want to define an entire installation scheme, you just have to supply all of the installation directory options. The recommended way to do this is to supply relative paths; for example, if you want to maintain all Python module-related files under python in your home directory, and you want a separate directory for each platform that you use your home directory from, you might define the following installation scheme:

python setup.py install --home=~ \
   --install-purelib=python/lib \
   --install-platlib=python/lib \
   --install-scripts=python/scripts \
   --install-data=python/data

or, equivalently,

python setup.py install --home=~/python \
   --install-purelib=lib \
   --install-platlib='lib.$PLAT' \
   --install-scripts=scripts \
   --install-data=data

$PLAT is not (necessarily) an environment variable—it will be expanded by the Distutils as it parses your command line options, just
as it does when parsing your configuration file(s).

Obviously, specifying the entire installation scheme every time you install a new module distribution would be very tedious. Thus, you can put these options into your Distutils config file (see section Distutils Configuration Files):

```
[install]
install-base=$HOME
install-purelib=python/lib
install-platlib=python/lib.$PLAT
install-scripts=python/scripts
install-data=python/data
```

or, equivalently,

```
[install]
install-base=$HOME/python
install-purelib=lib
install-platlib=lib.$PLAT
install-scripts=scripts
install-data=data
```

Note that these two are not equivalent if you supply a different installation base directory when you run the setup script. For example,

```
python setup.py install --install-base=/tmp
```

would install pure modules to `/tmp/python/lib` in the first case, and to `/tmp/lib` in the second case. (For the second case, you probably want to supply an installation base of `/tmp/python`.)

You probably noticed the use of `$HOME` and `$PLAT` in the sample configuration file input. These are Distutils configuration variables,
which bear a strong resemblance to environment variables. In fact, you can use environment variables in config files on platforms that have such a notion but the Distutils additionally define a few extra variables that may not be in your environment, such as $PLAT$. (And of course, on systems that don’t have environment variables, such as Mac OS 9, the configuration variables supplied by the Distutils are the only ones you can use.) See section *Distutils Configuration Files* for details.

**Note:** When a *virtual environment* is activated, any options that change the installation path will be ignored from all distutils configuration files to prevent inadvertently installing projects outside of the virtual environment.

**Modifying Python’s Search Path**

When the Python interpreter executes an *import* statement, it searches for both Python code and extension modules along a search path. A default value for the path is configured into the Python binary when the interpreter is built. You can determine the path by importing the *sys* module and printing the value of *sys.path*.

```
$ python
[GCC 2.96 20000731 (Red Hat Linux 7.3 2.96-112)] on linux2
Type "help", "copyright", "credits" or "license" for more information.
>>> import sys
>>> sys.path
```
The null string in `sys.path` represents the current working directory.

The expected convention for locally installed packages is to put them in the `.../site-packages/` directory, but you may want to install Python modules into some arbitrary directory. For example, your site may have a convention of keeping all software related to the web server under `/www`. Add-on Python modules might then belong in `/www/python`, and in order to import them, this directory must be added to `sys.path`. There are several different ways to add the directory.

The most convenient way is to add a path configuration file to a directory that's already on Python's path, usually to the `.../site-packages/` directory. Path configuration files have an extension of `.pth`, and each line must contain a single path that will be appended to `sys.path`. (Because the new paths are appended to `sys.path`, modules in the added directories will not override standard modules. This means you can't use this mechanism for installing fixed versions of standard modules.)

Paths can be absolute or relative, in which case they're relative to the directory containing the `.pth` file. See the documentation of the `site` module for more information.

A slightly less convenient way is to edit the `site.py` file in Python's standard library, and modify `sys.path`. `site.py` is automatically imported when the Python interpreter is executed, unless the `-S` switch is supplied to suppress this behaviour. So you could simply edit `site.py` and add two lines to it:

```python
import sys
sys.path.append('/www/python/')
```
However, if you reinstall the same major version of Python (perhaps when upgrading from 2.2 to 2.2.2, for example) `site.py` will be overwritten by the stock version. You’d have to remember that it was modified and save a copy before doing the installation.

There are two environment variables that can modify `sys.path`. `PYTHONHOME` sets an alternate value for the prefix of the Python installation. For example, if `PYTHONHOME` is set to `/www/python`, the search path will be set to `['', '/www/python/lib/pythonX.Y/', '/www/python/lib/pythonX.Y/plat-linux2', ...]`.

The `PYTHONPATH` variable can be set to a list of paths that will be added to the beginning of `sys.path`. For example, if `PYTHONPATH` is set to `/www/python:/opt/py`, the search path will begin with `['/www/python', '/opt/py']`. (Note that directories must exist in order to be added to `sys.path`; the `site` module removes paths that don’t exist.)

Finally, `sys.path` is just a regular Python list, so any Python application can modify it by adding or removing entries.
Distutils Configuration Files

As mentioned above, you can use Distutils configuration files to record personal or site preferences for any Distutils options. That is, any option to any command can be stored in one of two or three (depending on your platform) configuration files, which will be consulted before the command-line is parsed. This means that configuration files will override default values, and the command-line will in turn override configuration files. Furthermore, if multiple configuration files apply, values from “earlier” files are overridden by “later” files.

Location and names of config files

The names and locations of the configuration files vary slightly across platforms. On Unix and Mac OS X, the three configuration files (in the order they are processed) are:

<table>
<thead>
<tr>
<th>Type of file</th>
<th>Location and filename</th>
</tr>
</thead>
<tbody>
<tr>
<td>system</td>
<td>prefix/lib/pythonver/distutils/distutils.cfg</td>
</tr>
<tr>
<td>personal</td>
<td>$HOME/.pydistutils.cfg</td>
</tr>
<tr>
<td>local</td>
<td>setup.cfg</td>
</tr>
</tbody>
</table>

And on Windows, the configuration files are:

<table>
<thead>
<tr>
<th>Type of file</th>
<th>Location and filename</th>
<th>Notes</th>
</tr>
</thead>
<tbody>
<tr>
<td>system</td>
<td>prefix\Lib\distutils\distutils.cfg</td>
<td>(4)</td>
</tr>
<tr>
<td>personal</td>
<td>%HOME%\pydistutils.cfg</td>
<td>(5)</td>
</tr>
</tbody>
</table>
On all platforms, the “personal” file can be temporarily disabled by passing the `--no-user-cfg` option.

**Notes:**

1. Strictly speaking, the system-wide configuration file lives in the directory where the Distutils are installed; under Python 1.6 and later on Unix, this is as shown. For Python 1.5.2, the Distutils will normally be installed to `prefix/lib/python1.5/site-packages/distutils`, so the system configuration file should be put there under Python 1.5.2.

2. On Unix, if the `HOME` environment variable is not defined, the user's home directory will be determined with the `getpwuid()` function from the standard `pwd` module. This is done by the `os.path.expanduser()` function used by Distutils.

3. I.e., in the current directory (usually the location of the setup script).

4. (See also note (1).) Under Python 1.6 and later, Python's default "installation prefix" is `C:\Python`, so the system configuration file is normally `C:\Python\Lib\distutils\distutils.cfg`. Under Python 1.5.2, the default prefix was `C:\Program Files\Python`, and the Distutils were not part of the standard library—so the system configuration file would be `C:\Program Files\Python\distutils\distutils.cfg` in a standard Python 1.5.2 installation under Windows.

5. On Windows, if the `HOME` environment variable is not defined, `USERPROFILE` then `HOMEDRIVE` and `HOMEPATH` will be tried. This is done by the `os.path.expanduser()` function used by Distutils.

**Syntax of config files**
The Distutils configuration files all have the same syntax. The config files are grouped into sections. There is one section for each Distutils command, plus a global section for global options that affect every command. Each section consists of one option per line, specified as option=value.

For example, the following is a complete config file that just forces all commands to run quietly by default:

```
[global]
verbose=0
```

If this is installed as the system config file, it will affect all processing of any Python module distribution by any user on the current system. If it is installed as your personal config file (on systems that support them), it will affect only module distributions processed by you. And if it is used as the setup.cfg for a particular module distribution, it affects only that distribution.

You could override the default “build base” directory and make the build* commands always forcibly rebuild all files with the following:

```
[build]
build-base=blib
force=1
```

which corresponds to the command-line arguments

```
python setup.py build --build-base=blib --force
```

except that including the build command on the command-line means that command will be run. Including a particular command in config files has no such implication; it only means that if the command is run,
the options in the config file will apply. (Or if other commands that derive values from it are run, they will use the values in the config file.)

You can find out the complete list of options for any command using the --help option, e.g.:

```
python setup.py build --help
```

and you can find out the complete list of global options by using --help without a command:

```
python setup.py --help
```

See also the “Reference” section of the “Distributing Python Modules” manual.
Building Extensions: Tips and Tricks

Whenever possible, the Distutils try to use the configuration information made available by the Python interpreter used to run the `setup.py` script. For example, the same compiler and linker flags used to compile Python will also be used for compiling extensions. Usually this will work well, but in complicated situations this might be inappropriate. This section discusses how to override the usual Distutils behaviour.

**Tweaking compiler/linker flags**

Compiling a Python extension written in C or C++ will sometimes require specifying custom flags for the compiler and linker in order to use a particular library or produce a special kind of object code. This is especially true if the extension hasn’t been tested on your platform, or if you’re trying to cross-compile Python.

In the most general case, the extension author might have foreseen that compiling the extensions would be complicated, and provided a `Setup` file for you to edit. This will likely only be done if the module distribution contains many separate extension modules, or if they often require elaborate sets of compiler flags in order to work.

A `Setup` file, if present, is parsed in order to get a list of extensions to build. Each line in a `Setup` describes a single module. Lines have the following structure:

```plaintext
module ... [sourcefile ...] [cpparg ...] [library ...
```

Let's examine each of the fields in turn.
• **module** is the name of the extension module to be built, and should be a valid Python identifier. You can’t just change this in order to rename a module (edits to the source code would also be needed), so this should be left alone.

• **sourcefile** is anything that’s likely to be a source code file, at least judging by the filename. Filenames ending in `.c` are assumed to be written in C, filenames ending in `.C`, `.cc`, and `.cpp` are assumed to be C++, and filenames ending in `.m` or `.mm` are assumed to be in Objective C.

• **cpparg** is an argument for the C preprocessor, and is anything starting with `-I`, `-D`, `-U` or `-C`.

• **library** is anything ending in `.a` or beginning with `-l` or `-L`.

If a particular platform requires a special library on your platform, you can add it by editing the Setup file and running `python setup.py build`. For example, if the module defined by the line

```bash
foo foomodule.c
```

must be linked with the math library `libm.a` on your platform, simply add `-lm` to the line:

```bash
foo foomodule.c -lm
```

Arbitrary switches intended for the compiler or the linker can be supplied with the `-Xcompiler arg` and `-Xlinker arg` options:

```bash
foo foomodule.c -Xcompiler -o32 -Xlinker -shared -lm
```

The next option after `-Xcompiler` and `-Xlinker` will be appended to the proper command line, so in the above example the compiler will be passed the `-o32` option, and the linker will be passed `-shared`. If a compiler option requires an argument, you’ll have to supply multiple -
Compiler flags can also be supplied through setting the CFLAGS environment variable. If set, the contents of CFLAGS will be added to the compiler flags specified in the Setup file.

Using non-Microsoft compilers on Windows

Borland/CodeGear C++

This subsection describes the necessary steps to use Distutils with the Borland C++ compiler version 5.5. First you have to know that Borland’s object file format (OMF) is different from the format used by the Python version you can download from the Python or ActiveState Web site. (Python is built with Microsoft Visual C++, which uses COFF as the object file format.) For this reason you have to convert Python’s library python25.lib into the Borland format. You can do this as follows:

```
coff2omf python25.lib python25_bcpp.lib
```

The coff2omf program comes with the Borland compiler. The file python25.lib is in the Libs directory of your Python installation. If your extension uses other libraries (zlib, ...) you have to convert them too.

The converted files have to reside in the same directories as the normal libraries.

How does Distutils manage to use these libraries with their changed names? If the extension needs a library (eg. foo) Distutils checks first
if it finds a library with suffix _bcpp (eg. foo_bcpp.lib) and then uses this library. In the case it doesn't find such a special library it uses the default name (foo.lib.) [1]

To let Distutils compile your extension with Borland C++ you now have to type:

```
python setup.py build --compiler=bcpp
```

If you want to use the Borland C++ compiler as the default, you could specify this in your personal or system-wide configuration file for Distutils (see section Distutils Configuration Files.)

See also:

**C++Builder Compiler**

Information about the free C++ compiler from Borland, including links to the download pages.

**Creating Python Extensions Using Borland’s Free Compiler**

Document describing how to use Borland's free command-line C++ compiler to build Python.

**GNU C / Cygwin / MinGW**

This section describes the necessary steps to use Distutils with the GNU C/C++ compilers in their Cygwin and MinGW distributions. [2] For a Python interpreter that was built with Cygwin, everything should work without any of these following steps.

Not all extensions can be built with MinGW or Cygwin, but many can. Extensions most likely to not work are those that use C++ or depend on Microsoft Visual C extensions.
To let Distutils compile your extension with Cygwin you have to type:

```
python setup.py build --compiler=cygwin
```

and for Cygwin in no-cygwin mode [3] or for MinGW type:

```
python setup.py build --compiler=mingw32
```

If you want to use any of these options/compilers as default, you should consider writing it in your personal or system-wide configuration file for Distutils (see section Distutils Configuration Files.)

**Older Versions of Python and MinGW**

The following instructions only apply if you’re using a version of Python inferior to 2.4.1 with a MinGW inferior to 3.0.0 (with binutils-2.13.90-20030111-1).

These compilers require some special libraries. This task is more complex than for Borland’s C++, because there is no program to convert the library. First you have to create a list of symbols which the Python DLL exports. (You can find a good program for this task at http://sourceforge.net/projects/mingw/files/MinGW/Extension/pexports/)

```
pexports python25.dll >python25.def
```

The location of an installed `python25.dll` will depend on the installation options and the version and language of Windows. In a “just for me” installation, it will appear in the root of the installation directory. In a shared installation, it will be located in the system directory.

Then you can create from these information an import library for gcc.
The resulting library has to be placed in the same directory as python25.lib. (Should be the libs directory under your Python installation directory.)

If your extension uses other libraries (zlib,...) you might have to convert them too. The converted files have to reside in the same directories as the normal libraries do.

See also:

Building Python modules on MS Windows platform with MinGW
Information about building the required libraries for the MinGW environment.

Footnotes

[1] This also means you could replace all existing COFF-libraries with OMF-libraries of the same name.

[3] Then you have no POSIX emulation available, but you also don't need cygwin1.dll.
Distributing Python Modules

Authors: Greg Ward, Anthony Baxter
Email: distutils-sig@python.org

This document describes the Python Distribution Utilities (“Distutils”) from the module developer’s point of view, describing how to use the Distutils to make Python modules and extensions easily available to a wider audience with very little overhead for build/release/install mechanics.

- 1. An Introduction to Distutils
  - 1.1. Concepts & Terminology
  - 1.2. A Simple Example
  - 1.3. General Python terminology

10.15. distutils.debug — Distutils debug mode
10.16. distutils.errors — Distutils exceptions
10.17. distutils.fancy_getopt — Wrapper around the standard getopt module
10.18. distutils.filelist — The FileList class
10.19. distutils.log — Simple PEP 282-style logging
10.20. distutils.spawn — Spawn a sub-process
10.21. distutils.sysconfig — System configuration information
10.22. distutils.text_file — The TextFile class
10.23. distutils.version — Version number classes
10.24. distutils.cmd — Abstract base class for Distutils commands
10.25. Creating a new Distutils command
10.26. distutils.command — Individual Distutils commands
10.27. distutils.command.bdist — Build a binary installer
10.28. distutils.command.bdist_packager — Abstract base class for packagers
10.29. distutils.command.bdist_dumb — Build a “dumb” installer
10.30. distutils.command.bdist_msi — Build a Microsoft Installer binary package
10.31. distutils.command.bdist_rpm — Build a binary distribution as a Redhat RPM and SRPM
10.32. distutils.command.bdist_wininst — Build a Windows installer
10.33. distutils.command.sdist — Build a source distribution
10.34. distutils.command.build — Build all files of a
- 10.35. distutils.command.build_clib — Build any C libraries in a package
- 10.36. distutils.command.build_ext — Build any extensions in a package
- 10.37. distutils.command.build_py — Build the .py/.pyc files of a package
- 10.38. distutils.command.build_scripts — Build the scripts of a package
- 10.39. distutils.command.clean — Clean a package build area
- 10.40. distutils.command.config — Perform package configuration
- 10.41. distutils.command.install — Install a package
- 10.42. distutils.command.install_data — Install data files from a package
- 10.43. distutils.command.install_headers — Install C/C++ header files from a package
- 10.44. distutils.command.install_lib — Install library files from a package
- 10.45. distutils.command.install_scripts — Install script files from a package
- 10.46. distutils.command.register — Register a module with the Python Package Index
- 10.47. distutils.command.check — Check the metadata of a package

The Python Tutorial

1. Whetting Your Appetite

2. Using the Python Interpreter
   - 2.1. Invoking the Interpreter
     - 2.1.1. Argument Passing
     - 2.1.2. Interactive Mode
   - 2.2. The Interpreter and Its Environment
     - 2.2.1. Error Handling
     - 2.2.2. Executable Python Scripts
     - 2.2.3. Source Code Encoding
     - 2.2.4. The Interactive Startup File
     - 2.2.5. The Customization Modules

3. An Informal Introduction to Python
   - 3.1. Using Python as a Calculator
     - 3.1.1. Numbers
     - 3.1.2. Strings
     - 3.1.3. Lists
   - 3.2. First Steps Towards Programming

4. More Control Flow Tools
   - 4.1. if Statements
   - 4.2. for Statements
   - 4.3. The range() Function
   - 4.4. break and continue Statements, and else Clauses on Loops
   - 4.5. pass Statements
4.6. Defining Functions
4.7. More on Defining Functions
  4.7.1. Default Argument Values
  4.7.2. Keyword Arguments
  4.7.3. Arbitrary Argument Lists
  4.7.4. Unpacking Argument Lists
  4.7.5. Lambda Expressions
  4.7.6. Documentation Strings
  4.7.7. Function Annotations
4.8. Intermezzo: Coding Style

5. Data Structures
  5.1. More on Lists
    5.1.1. Using Lists as Stacks
    5.1.2. Using Lists as Queues
    5.1.3. List Comprehensions
    5.1.4. Nested List Comprehensions
  5.2. The del statement
  5.3. Tuples and Sequences
  5.4. Sets
  5.5. Dictionaries
  5.6. Looping Techniques
  5.7. More on Conditions
  5.8. Comparing Sequences and Other Types

6. Modules
  6.1. More on Modules
    6.1.1. Executing modules as scripts
    6.1.2. The Module Search Path
    6.1.3. “Compiled” Python files
  6.2. Standard Modules
  6.3. The dir() Function
  6.4. Packages
    6.4.1. Importing * From a Package
    6.4.2. Intra-package References
    6.4.3. Packages in Multiple Directories
7. Input and Output
   7.1. Fancier Output Formatting
      7.1.1. Old string formatting
   7.2. Reading and Writing Files
      7.2.1. Methods of File Objects
      7.2.2. The pickle Module
8. Errors and Exceptions
   8.1. Syntax Errors
   8.2. Exceptions
   8.3. Handling Exceptions
   8.4. Raising Exceptions
   8.5. User-defined Exceptions
   8.6. Defining Clean-up Actions
   8.7. Predefined Clean-up Actions
9. Classes
   9.1. A Word About Names and Objects
   9.2. Python Scopes and Namespaces
      9.2.1. Scopes and Namespaces Example
   9.3. A First Look at Classes
      9.3.1. Class Definition Syntax
      9.3.2. Class Objects
      9.3.3. Instance Objects
      9.3.4. Method Objects
   9.4. Random Remarks
   9.5. Inheritance
      9.5.1. Multiple Inheritance
   9.6. Private Variables
   9.7. Odds and Ends
   9.8. Exceptions Are Classes Too
   9.9. Iterators
   9.10. Generators
   9.11. Generator Expressions
10. Brief Tour of the Standard Library
    10.1. Operating System Interface
• 10.2. File Wildcards
• 10.3. Command Line Arguments
• 10.4. Error Output Redirection and Program Termination
• 10.5. String Pattern Matching
• 10.6. Mathematics
• 10.7. Internet Access
• 10.8. Dates and Times
• 10.9. Data Compression
• 10.10. Performance Measurement
• 10.11. Quality Control
• 10.12. Batteries Included
• 11. Brief Tour of the Standard Library – Part II
  • 11.1. Output Formatting
  • 11.2. Templating
  • 11.3. Working with Binary Data Record Layouts
  • 11.4. Multi-threading
  • 11.5. Logging
  • 11.6. Weak References
  • 11.7. Tools for Working with Lists
  • 11.8. Decimal Floating Point Arithmetic
• 12. What Now?
• 13. Interactive Input Editing and History Substitution
  • 13.1. Line Editing
  • 13.2. History Substitution
  • 13.3. Key Bindings
  • 13.4. Alternatives to the Interactive Interpreter
• 14. Floating Point Arithmetic: Issues and Limitations
  • 14.1. Representation Error

• Python Setup and Usage
  • 1. Command line and environment
    • 1.1. Command line
      • 1.1.1. Interface options
      • 1.1.2. Generic options
      • 1.1.3. Miscellaneous options
1.1.4. Options you shouldn’t use

1.2. Environment variables
  1.2.1. Debug-mode variables

2. Using Python on Unix platforms
  2.1. Getting and installing the latest version of Python
    2.1.1. On Linux
    2.1.2. On FreeBSD and OpenBSD
    2.1.3. On OpenSolaris
  2.2. Building Python
  2.3. Python-related paths and files
  2.4. Miscellaneous
  2.5. Editors

3. Using Python on Windows
  3.1. Installing Python
  3.2. Alternative bundles
  3.3. Configuring Python
    3.3.1. Excursus: Setting environment variables
    3.3.2. Finding the Python executable
    3.3.3. Finding modules
    3.3.4. Executing scripts
    3.3.5. Executing scripts without the Python launcher
  3.4. Python Launcher for Windows
    3.4.1. Getting started
      3.4.1.1. From the command-line
      3.4.1.2. From a script
      3.4.1.3. From file associations
    3.4.2. Shebang Lines
    3.4.3. Arguments in shebang lines
    3.4.4. Customization
      3.4.4.1. Customization via INI files
      3.4.4.2. Customizing default Python versions
    3.4.5. Diagnostics
  3.5. Additional modules
    3.5.1. PyWin32
- 3.5.2. Py2exe
- 3.5.3. WConio
- 3.6. Compiling Python on Windows
- 3.7. Other resources
- 4. Using Python on a Macintosh
  - 4.1. Getting and Installing MacPython
    - 4.1.1. How to run a Python script
    - 4.1.2. Running scripts with a GUI
    - 4.1.3. Configuration
  - 4.2. The IDE
  - 4.3. Installing Additional Python Packages
  - 4.4. GUI Programming on the Mac
  - 4.5. Distributing Python Applications on the Mac
  - 4.6. Other Resources
- 5. Additional Tools and Scripts
  - 5.1. pyenv - Creating virtual environments
- The Python Language Reference
  - 1. Introduction
    - 1.1. Alternate Implementations
    - 1.2. Notation
  - 2. Lexical analysis
    - 2.1. Line structure
      - 2.1.1. Logical lines
      - 2.1.2. Physical lines
      - 2.1.3. Comments
      - 2.1.4. Encoding declarations
      - 2.1.5. Explicit line joining
      - 2.1.6. Implicit line joining
      - 2.1.7. Blank lines
      - 2.1.8. Indentation
      - 2.1.9. Whitespace between tokens
    - 2.2. Other tokens
    - 2.3. Identifiers and keywords
      - 2.3.1. Keywords
- 2.3.2. Reserved classes of identifiers
- 2.4. Literals
  - 2.4.1. String and Bytes literals
  - 2.4.2. String literal concatenation
  - 2.4.3. Numeric literals
  - 2.4.4. Integer literals
  - 2.4.5. Floating point literals
  - 2.4.6. Imaginary literals
- 2.5. Operators
- 2.6. Delimiters
- 3. Data model
  - 3.1. Objects, values and types
  - 3.2. The standard type hierarchy
  - 3.3. Special method names
    - 3.3.1. Basic customization
    - 3.3.2. Customizing attribute access
      - 3.3.2.1. Implementing Descriptors
      - 3.3.2.2. Invoking Descriptors
      - 3.3.2.3. __slots__
        - 3.3.2.3.1. Notes on using __slots__
    - 3.3.3. Customizing class creation
      - 3.3.3.1. Determining the appropriate metaclass
      - 3.3.3.2. Preparing the class namespace
      - 3.3.3.3. Executing the class body
      - 3.3.3.4. Creating the class object
      - 3.3.3.5. Metaclass example
    - 3.3.4. Customizing instance and subclass checks
    - 3.3.5. Emulating callable objects
    - 3.3.6. Emulating container types
    - 3.3.7. Emulating numeric types
    - 3.3.8. With Statement Context Managers
    - 3.3.9. Special method lookup
- 4. Execution model
  - 4.1. Naming and binding
4.1.1. Interaction with dynamic features

4.2. Exceptions

5. The import system

5.1. importlib

5.2. Packages

5.2.1. Regular packages

5.2.2. Namespace packages

5.3. Searching

5.3.1. The module cache

5.3.2. Finders and loaders

5.3.3. Import hooks

5.3.4. The meta path

5.4. Loaders

5.4.1. Module reprs

5.4.2. module.__path__

5.5. The Path Based Finder

5.5.1. Path entry finders

5.5.2. Path entry finder protocol

5.6. Replacing the standard import system

5.7. Open issues

5.8. References

6. Expressions

6.1. Arithmetic conversions

6.2. Atoms

6.2.1. Identifiers (Names)

6.2.2. Literals

6.2.3. Parenthesized forms

6.2.4. Displays for lists, sets and dictionaries

6.2.5. List displays

6.2.6. Set displays

6.2.7. Dictionary displays

6.2.8. Generator expressions

6.2.9. Yield expressions

6.2.9.1. Generator-iterator methods
6.2.9.2. Examples

6.3. Primaries
   - 6.3.1. Attribute references
   - 6.3.2. Subscriptions
   - 6.3.3. Slicings
   - 6.3.4. Calls

6.4. The power operator

6.5. Unary arithmetic and bitwise operations

6.6. Binary arithmetic operations

6.7. Shifting operations

6.8. Binary bitwise operations

6.9. Comparisons

6.10. Boolean operations

6.11. Conditional expressions

6.12. Lambdas

6.13. Expression lists

6.15. Operator precedence

7. Simple statements
   - 7.1. Expression statements
   - 7.2. Assignment statements
     - 7.2.1. Augmented assignment statements
   - 7.3. The assert statement
   - 7.4. The pass statement
   - 7.5. The del statement
   - 7.6. The return statement
   - 7.7. The yield statement
   - 7.8. The raise statement
   - 7.9. The break statement
   - 7.10. The continue statement
   - 7.11. The import statement
     - 7.11.1. Future statements
   - 7.12. The global statement
7.13. The nonlocal statement

8. Compound statements
   8.1. The if statement
   8.2. The while statement
   8.3. The for statement
   8.4. The try statement
   8.5. The with statement
   8.6. Function definitions
   8.7. Class definitions

9. Top-level components
   9.1. Complete Python programs
   9.2. File input
   9.3. Interactive input
   9.4. Expression input

10. Full Grammar specification

The Python Standard Library
   1. Introduction
   2. Built-in Functions
   3. Built-in Constants
      3.1. Constants added by the site module
   4. Built-in Types
      4.1. Truth Value Testing
      4.2. Boolean Operations — and, or, not
      4.3. Comparisons
      4.4. Numeric Types — int, float, complex
         4.4.1. Bitwise Operations on Integer Types
         4.4.2. Additional Methods on Integer Types
         4.4.3. Additional Methods on Float
         4.4.4. Hashing of numeric types
      4.5. Iterator Types
         4.5.1. Generator Types
      4.6. Sequence Types — list, tuple, range
         4.6.1. Common Sequence Operations
- 4.6.2. Immutable Sequence Types
- 4.6.3. Mutable Sequence Types
- 4.6.4. Lists
- 4.6.5. Tuples
- 4.6.6. Ranges
- 4.7. Text Sequence Type — str
  - 4.7.1. String Methods
  - 4.7.2. printf-style String Formatting
- 4.8. Binary Sequence Types — bytes, bytearray, memoryview
  - 4.8.1. Bytes
  - 4.8.2. Bytearray Objects
  - 4.8.3. Bytes and Bytearray Operations
  - 4.8.4. Memory Views
- 4.9. Set Types — set, frozenset
- 4.10. Mapping Types — dict
  - 4.10.1. Dictionary view objects
- 4.11. Context Manager Types
- 4.12. Other Built-in Types
  - 4.12.1. Modules
  - 4.12.2. Classes and Class Instances
  - 4.12.3. Functions
  - 4.12.4. Methods
  - 4.12.5. Code Objects
  - 4.12.6. Type Objects
  - 4.12.7. The Null Object
  - 4.12.8. The Ellipsis Object
  - 4.12.9. The NotImplemented Object
  - 4.12.10. Boolean Values
  - 4.12.11. Internal Objects
- 4.13. Special Attributes
- 5. Built-in Exceptions
  - 5.1. Base classes
  - 5.2. Concrete exceptions
5.2.1. OS exceptions
5.3. Warnings
5.4. Exception hierarchy

6. Text Processing Services

6.1. string — Common string operations
   6.1.1. String constants
   6.1.2. String Formatting
   6.1.3. Format String Syntax
      6.1.3.1. Format Specification Mini-Language
      6.1.3.2. Format examples
   6.1.4. Template strings
   6.1.5. Helper functions

6.2. re — Regular expression operations
   6.2.1. Regular Expression Syntax
   6.2.2. Module Contents
   6.2.3. Regular Expression Objects
   6.2.4. Match Objects
   6.2.5. Regular Expression Examples
      6.2.5.1. Checking for a Pair
      6.2.5.2. Simulating scanf()
      6.2.5.3. search() vs. match()
      6.2.5.4. Making a Phonebook
      6.2.5.5. Text Munging
      6.2.5.6. Finding all Adverbs
      6.2.5.7. Finding all Adverbs and their Positions
      6.2.5.8. Raw String Notation
      6.2.5.9. Writing a Tokenizer

6.3. difflib — Helpers for computing deltas
   6.3.1. SequenceMatcher Objects
   6.3.2. SequenceMatcher Examples
   6.3.3. Differ Objects
   6.3.4. Differ Example
   6.3.5. A command-line interface to difflib

6.4. textwrap — Text wrapping and filling
- 6.5. unicodedata — Unicode Database
- 6.6. stringprep — Internet String Preparation
- 6.7. readline — GNU readline interface
  - 6.7.1. Example
- 6.8. rlcompleter — Completion function for GNU readline
  - 6.8.1. Completer Objects

7. Binary Data Services
- 7.1. struct — Interpret bytes as packed binary data
  - 7.1.1. Functions and Exceptions
  - 7.1.2. Format Strings
    - 7.1.2.1. Byte Order, Size, and Alignment
    - 7.1.2.2. Format Characters
    - 7.1.2.3. Examples
  - 7.1.3. Classes
- 7.2. codecs — Codec registry and base classes
  - 7.2.1. Codec Base Classes
    - 7.2.1.1. Codec Objects
    - 7.2.1.2. IncrementalEncoder Objects
    - 7.2.1.3. IncrementalDecoder Objects
    - 7.2.1.4. StreamWriter Objects
    - 7.2.1.5. StreamReader Objects
    - 7.2.1.6. StreamReaderWriter Objects
    - 7.2.1.7. StreamRecode Objects
  - 7.2.2. Encodings and Unicode
  - 7.2.3. Standard Encodings
  - 7.2.4. Python Specific Encodings
  - 7.2.5. encodings.idna — Internationalized Domain Names in Applications
  - 7.2.6. encodings.mbcst — Windows ANSI codepage
  - 7.2.7. encodings.utf_8_sig — UTF-8 codec with BOM signature
8. Data Types

- 8.1. datetime — Basic date and time types
  - 8.1.1. Available Types
  - 8.1.2. timedelta Objects
  - 8.1.3. date Objects
  - 8.1.4. datetime Objects
  - 8.1.5. time Objects
  - 8.1.6. tzinfo Objects
  - 8.1.7. timezone Objects
  - 8.1.8. strftime() and strptime() Behavior

- 8.2. calendar — General calendar-related functions

- 8.3. collections — Container datatypes
  - 8.3.1. ChainMap objects
    - 8.3.1.1. ChainMap Examples and Recipes
  - 8.3.2. Counter objects
  - 8.3.3. deque objects
    - 8.3.3.1. deque Recipes
  - 8.3.4. defaultdict objects
    - 8.3.4.1. defaultdict Examples
  - 8.3.5. namedtuple() Factory Function for Tuples with Named Fields
  - 8.3.6. OrderedDict objects
    - 8.3.6.1. OrderedDict Examples and Recipes
  - 8.3.7. UserDict objects
  - 8.3.8. UserList objects
  - 8.3.9. UserString objects

- 8.4. collections.abc — Abstract Base Classes for Containers
  - 8.4.1. Collections Abstract Base Classes

- 8.5. heapq — Heap queue algorithm
  - 8.5.1. Basic Examples
  - 8.5.2. Priority Queue Implementation Notes
- 8.5.3. Theory
- 8.6. bisect — Array bisection algorithm
  - 8.6.1. Searching Sorted Lists
  - 8.6.2. Other Examples
- 8.7. array — Efficient arrays of numeric values
- 8.8. weakref — Weak references
  - 8.8.1. Weak Reference Objects
  - 8.8.2. Example
- 8.9. types — Dynamic type creation and names for built-in types
  - 8.9.1. Dynamic Type Creation
  - 8.9.2. Standard Interpreter Types
- 8.10. copy — Shallow and deep copy operations
- 8.11. pprint — Data pretty printer
  - 8.11.1. PrettyPrinter Objects
  - 8.11.2. Example
- 8.12. reprlib — Alternate repr() implementation
  - 8.12.1. Repr Objects
  - 8.12.2. Subclassing Repr Objects

9. Numeric and Mathematical Modules
- 9.1. numbers — Numeric abstract base classes
  - 9.1.1. The numeric tower
  - 9.1.2. Notes for type implementors
    - 9.1.2.1. Adding More Numeric ABCs
    - 9.1.2.2. Implementing the arithmetic operations
- 9.2. math — Mathematical functions
  - 9.2.1. Number-theoretic and representation functions
  - 9.2.2. Power and logarithmic functions
  - 9.2.3. Trigonometric functions
  - 9.2.4. Angular conversion
  - 9.2.5. Hyperbolic functions
  - 9.2.6. Special functions
• 9.2.7. Constants
• 9.3. `cmath` — Mathematical functions for complex numbers
  • 9.3.1. Conversions to and from polar coordinates
  • 9.3.2. Power and logarithmic functions
  • 9.3.3. Trigonometric functions
  • 9.3.4. Hyperbolic functions
  • 9.3.5. Classification functions
  • 9.3.6. Constants
• 9.4. `decimal` — Decimal fixed point and floating point arithmetic
  • 9.4.1. Quick-start Tutorial
  • 9.4.2. Decimal objects
    • 9.4.2.1. Logical operands
  • 9.4.3. Context objects
  • 9.4.4. Constants
  • 9.4.5. Rounding modes
  • 9.4.6. Signals
  • 9.4.7. Floating Point Notes
    • 9.4.7.1. Mitigating round-off error with increased precision
    • 9.4.7.2. Special values
  • 9.4.8. Working with threads
  • 9.4.9. Recipes
  • 9.4.10. Decimal FAQ
• 9.5. `fractions` — Rational numbers
• 9.6. `random` — Generate pseudo-random numbers
  • 9.6.1. Notes on Reproducibility
  • 9.6.2. Examples and Recipes
• 10. Functional Programming Modules
  • 10.1. `itertools` — Functions creating iterators for efficient looping
    • 10.1.1. Itertool functions
    • 10.1.2. Itertools Recipes
10.2. functools — Higher-order functions and operations on callable objects
   ■ 10.2.1. partial Objects

10.3. operator — Standard operators as functions
   ■ 10.3.1. Mapping Operators to Functions
   ■ 10.3.2. Inplace Operators

11. File and Directory Access
   ■ 11.1. os.path — Common pathname manipulations
   ■ 11.2. fileinput — Iterate over lines from multiple input streams
   ■ 11.3. stat — Interpreting stat() results
   ■ 11.4. filecmp — File and Directory Comparisons
     ■ 11.4.1. The dircmp class
   ■ 11.5. tempfile — Generate temporary files and directories
     ■ 11.5.1. Examples
   ■ 11.6. glob — Unix style pathname pattern expansion
   ■ 11.7. fnmatch — Unix filename pattern matching
   ■ 11.8. linecache — Random access to text lines
   ■ 11.9. shutil — High-level file operations
     ■ 11.9.1. Directory and files operations
       ■ 11.9.1.1. copytree example
     ■ 11.9.2. Archiving operations
       ■ 11.9.2.1. Archiving example
     ■ 11.9.3. Querying the size of the output terminal
   ■ 11.10. macpath — Mac OS 9 path manipulation functions

12. Data Persistence
   ■ 12.1. pickle — Python object serialization
     ■ 12.1.1. Relationship to other Python modules
     ■ 12.1.2. Data stream format
     ■ 12.1.3. Module Interface
     ■ 12.1.4. What can be pickled and unpickled?
- 12.1.5. Pickling Class Instances
  - 12.1.5.1. Persistence of External Objects
  - 12.1.5.2. Dispatch Tables
  - 12.1.5.3. Handling Stateful Objects
- 12.1.6. Restricting Globals
- 12.1.7. Examples
- 12.2. `copyreg` — Register pickle support functions
  - 12.2.1. Example
- 12.3. `shelve` — Python object persistence
  - 12.3.1. Restrictions
  - 12.3.2. Example
- 12.4. `marshal` — Internal Python object serialization
- 12.5. `dbm` — Interfaces to Unix “databases”
  - 12.5.1. `dbm.gnu` — GNU’s reinterpretation of `dbm`
  - 12.5.2. `dbm.ndbm` — Interface based on `ndbm`
  - 12.5.3. `dbm.dumb` — Portable DBM implementation
- 12.6. `sqlite3` — DB-API 2.0 interface for SQLite databases
  - 12.6.1. Module functions and constants
  - 12.6.2. Connection Objects
  - 12.6.3. Cursor Objects
  - 12.6.4. Row Objects
  - 12.6.5. SQLite and Python types
    - 12.6.5.1. Introduction
    - 12.6.5.2. Using adapters to store additional Python types in SQLite databases
      - 12.6.5.2.1. Letting your object adapt itself
      - 12.6.5.2.2. Registering an adapter callable
    - 12.6.5.3. Converting SQLite values to custom Python types
    - 12.6.5.4. Default adapters and converters
  - 12.6.6. Controlling Transactions
  - 12.6.7. Using `sqlite3` efficiently
12.6.7.1. Using shortcut methods
12.6.7.2. Accessing columns by name instead of by index
12.6.7.3. Using the connection as a context manager
12.6.8. Common issues
12.6.8.1. Multithreading

13. Data Compression and Archiving
   13.1. zlib — Compression compatible with gzip
   13.2. gzip — Support for gzip files
      13.2.1. Examples of usage
   13.3. bz2 — Support for bzip2 compression
      13.3.1. (De)compression of files
      13.3.2. Incremental (de)compression
      13.3.3. One-shot (de)compression
   13.4. lzma — Compression using the LZMA algorithm
      13.4.1. Reading and writing compressed files
      13.4.2. Compressing and decompressing data in memory
      13.4.3. Miscellaneous
      13.4.4. Specifying custom filter chains
      13.4.5. Examples
   13.5. zipfile — Work with ZIP archives
      13.5.1. ZipFile Objects
      13.5.2. PyZipFile Objects
      13.5.3. ZipInfo Objects
   13.6. tarfile — Read and write tar archive files
      13.6.1. TarFile Objects
      13.6.2. TarInfo Objects
      13.6.3. Examples
      13.6.4. Supported tar formats
      13.6.5. Unicode issues

14. File Formats
   14.1. csv — CSV File Reading and Writing
- 14.1.1. Module Contents
- 14.1.2. Dialects and Formatting Parameters
- 14.1.3. Reader Objects
- 14.1.4. Writer Objects
- 14.1.5. Examples
- 14.2. configparser — Configuration file parser
  - 14.2.1. Quick Start
  - 14.2.2. Supported Datatypes
  - 14.2.3. Fallback Values
  - 14.2.4. Supported INI File Structure
  - 14.2.5. Interpolation of values
  - 14.2.6. Mapping Protocol Access
  - 14.2.7. Customizing Parser Behaviour
  - 14.2.8. Legacy API Examples
  - 14.2.9. ConfigParser Objects
  - 14.2.10. RawConfigParser Objects
  - 14.2.11. Exceptions
- 14.3. netrc — netrc file processing
  - 14.3.1. netrc Objects
- 14.4. xdrlib — Encode and decode XDR data
  - 14.4.1. Packer Objects
  - 14.4.2. Unpacker Objects
  - 14.4.3. Exceptions
- 14.5. plistlib — Generate and parse Mac OS X .plist files
  - 14.5.1. Examples
- 15. Cryptographic Services
  - 15.1. hashlib — Secure hashes and message digestes
  - 15.2. hmac — Keyed-Hashing for Message Authentication
- 16. Generic Operating System Services
  - 16.1. os — Miscellaneous operating system interfaces
    - 16.1.1. File Names, Command Line Arguments, and Environment Variables
- 16.1.2. Process Parameters
- 16.1.3. File Object Creation
- 16.1.4. File Descriptor Operations
  - 16.1.4.1. open() flag constants
  - 16.1.4.2. Querying the size of a terminal
- 16.1.5. Files and Directories
  - 16.1.5.1. Linux extended attributes
- 16.1.6. Process Management
- 16.1.7. Interface to the scheduler
- 16.1.8. Miscellaneous System Information
- 16.1.9. Miscellaneous Functions
- 16.2. io — Core tools for working with streams
  - 16.2.1. Overview
    - 16.2.1.1. Text I/O
    - 16.2.1.2. Binary I/O
    - 16.2.1.3. Raw I/O
  - 16.2.2. High-level Module Interface
    - 16.2.2.1. In-memory streams
  - 16.2.3. Class hierarchy
    - 16.2.3.1. I/O Base Classes
    - 16.2.3.2. Raw File I/O
    - 16.2.3.3. Buffered Streams
    - 16.2.3.4. Text I/O
  - 16.2.4. Performance
    - 16.2.4.1. Binary I/O
    - 16.2.4.2. Text I/O
    - 16.2.4.3. Multi-threading
    - 16.2.4.4. Reentrancy
- 16.3. time — Time access and conversions
- 16.4. argparse — Parser for command-line options, arguments and sub-commands
  - 16.4.1. Example
    - 16.4.1.1. Creating a parser
    - 16.4.1.2. Adding arguments
- 16.4.1.3. Parsing arguments
- 16.4.2. ArgumentParser objects
  - 16.4.2.1. prog
  - 16.4.2.2. usage
  - 16.4.2.3. description
  - 16.4.2.4. epilog
  - 16.4.2.5. parents
  - 16.4.2.6. formatter_class
  - 16.4.2.7. prefix_chars
  - 16.4.2.8. fromfile_prefix_chars
  - 16.4.2.9. argument_default
  - 16.4.2.10. conflict_handler
  - 16.4.2.11. add_help
- 16.4.3. The add_argument() method
  - 16.4.3.1. name or flags
  - 16.4.3.2. action
  - 16.4.3.3. nargs
  - 16.4.3.4. const
  - 16.4.3.5. default
  - 16.4.3.6. type
  - 16.4.3.7. choices
  - 16.4.3.8. required
  - 16.4.3.9. help
  - 16.4.3.10. metavar
  - 16.4.3.11. dest
- 16.4.4. The parse_args() method
  - 16.4.4.1. Option value syntax
  - 16.4.4.2. Invalid arguments
  - 16.4.4.3. Arguments containing -
  - 16.4.4.4. Argument abbreviations
  - 16.4.4.5. Beyond sys.argv
  - 16.4.4.6. The Namespace object
- 16.4.5. Other utilities
  - 16.4.5.1. Sub-commands
16.4.5.2. FileType objects
16.4.5.3. Argument groups
16.4.5.4. Mutual exclusion
16.4.5.5. Parser defaults
16.4.5.6. Printing help
16.4.5.7. Partial parsing
16.4.5.8. Customizing file parsing
16.4.5.9. Exiting methods
16.4.6. Upgrading optparse code
16.5. optparse — Parser for command line options
   16.5.1. Background
      16.5.1.1. Terminology
      16.5.1.2. What are options for?
      16.5.1.3. What are positional arguments for?
   16.5.2. Tutorial
      16.5.2.1. Understanding option actions
      16.5.2.2. The store action
      16.5.2.3. Handling boolean (flag) options
      16.5.2.4. Other actions
      16.5.2.5. Default values
      16.5.2.6. Generating help
         16.5.2.6.1. Grouping Options
      16.5.2.7. Printing a version string
      16.5.2.8. How optparse handles errors
      16.5.2.9. Putting it all together
   16.5.3. Reference Guide
      16.5.3.1. Creating the parser
      16.5.3.2. Populating the parser
      16.5.3.3. Defining options
      16.5.3.4. Option attributes
      16.5.3.5. Standard option actions
      16.5.3.6. Standard option types
      16.5.3.7. Parsing arguments
      16.5.3.8. Querying and manipulating your
option parser
- 16.5.3.9. Conflicts between options
- 16.5.3.10. Cleanup
- 16.5.3.11. Other methods
- 16.5.4. Option Callbacks
  - 16.5.4.1. Defining a callback option
  - 16.5.4.2. How callbacks are called
  - 16.5.4.3. Raising errors in a callback
  - 16.5.4.4. Callback example 1: trivial callback
  - 16.5.4.5. Callback example 2: check option order
  - 16.5.4.6. Callback example 3: check option order (generalized)
  - 16.5.4.7. Callback example 4: check arbitrary condition
  - 16.5.4.8. Callback example 5: fixed arguments
  - 16.5.4.9. Callback example 6: variable arguments
- 16.5.5. Extending optparse
  - 16.5.5.1. Adding new types
  - 16.5.5.2. Adding new actions
- 16.6. getopt — C-style parser for command line options
- 16.7. logging — Logging facility for Python
  - 16.7.1. Logger Objects
  - 16.7.2. Handler Objects
  - 16.7.3. Formatter Objects
  - 16.7.4. Filter Objects
  - 16.7.5. LogRecord Objects
  - 16.7.6. LogRecord attributes
  - 16.7.7. LoggerAdapter Objects
  - 16.7.8. Thread Safety
  - 16.7.9. Module-Level Functions
  - 16.7.10. Module-Level Attributes
16.7.11. Integration with the warnings module

16.8. logging.config — Logging configuration
   16.8.1. Configuration functions
   16.8.2. Configuration dictionary schema
      16.8.2.1. Dictionary Schema Details
      16.8.2.2. Incremental Configuration
      16.8.2.3. Object connections
      16.8.2.4. User-defined objects
      16.8.2.5. Access to external objects
      16.8.2.6. Access to internal objects
      16.8.2.7. Import resolution and custom importers
   16.8.3. Configuration file format

16.9. logging.handlers — Logging handlers
   16.9.1. StreamHandler
   16.9.2. FileHandler
   16.9.3. NullHandler
   16.9.4. WatchedFileHandler
   16.9.5. BaseRotatingHandler
   16.9.6. RotatingFileHandler
   16.9.7. TimedRotatingFileHandler
   16.9.8. SocketHandler
   16.9.9. DatagramHandler
   16.9.10. SysLogHandler
   16.9.11. NTEventLogHandler
   16.9.12. SMTPHandler
   16.9.13. MemoryHandler
   16.9.14. HTTPHandler
   16.9.15. QueueHandler
   16.9.16. QueueListener

16.10. getpass — Portable password input

16.11. curses — Terminal handling for character-cell displays
   16.11.1. Functions
- 16.11.2. Window Objects
- 16.11.3. Constants
- 16.12. `curses.textpad` — Text input widget for curses programs
  - 16.12.1. Textbox objects
- 16.13. `curses.ascii` — Utilities for ASCII characters
- 16.14. `curses.panel` — A panel stack extension for curses
  - 16.14.1. Functions
  - 16.14.2. Panel Objects
- 16.15. `platform` — Access to underlying platform's identifying data
  - 16.15.1. Cross Platform
  - 16.15.2. Java Platform
  - 16.15.3. Windows Platform
    - 16.15.3.1. Win95/98 specific
  - 16.15.4. Mac OS Platform
  - 16.15.5. Unix Platforms
- 16.16. `errno` — Standard errno system symbols
- 16.17. `ctypes` — A foreign function library for Python
  - 16.17.1. ctypes tutorial
    - 16.17.1.1. Loading dynamic link libraries
    - 16.17.1.2. Accessing functions from loaded dlls
    - 16.17.1.3. Calling functions
    - 16.17.1.4. Fundamental data types
    - 16.17.1.5. Calling functions, continued
    - 16.17.1.6. Calling functions with your own custom data types
    - 16.17.1.7. Specifying the required argument types (function prototypes)
    - 16.17.1.8. Return types
    - 16.17.1.9. Passing pointers (or: passing parameters by reference)
    - 16.17.1.10. Structures and unions
- 16.17.1.11. Structure/union alignment and byte order
- 16.17.1.12. Bit fields in structures and unions
- 16.17.1.13. Arrays
- 16.17.1.14. Pointers
- 16.17.1.15. Type conversions
- 16.17.1.16. Incomplete Types
- 16.17.1.17. Callback functions
- 16.17.1.18. Accessing values exported from dlls
- 16.17.1.19. Surprises
- 16.17.1.20. Variable-sized data types

- 16.17.2. ctypes reference
  - 16.17.2.1. Finding shared libraries
  - 16.17.2.2. Loading shared libraries
  - 16.17.2.3. Foreign functions
  - 16.17.2.4. Function prototypes
  - 16.17.2.5. Utility functions
  - 16.17.2.6. Data types
  - 16.17.2.7. Fundamental data types
  - 16.17.2.8. Structured data types
  - 16.17.2.9. Arrays and pointers

- 17. Concurrent Execution
  - 17.1. threading — Thread-based parallelism
    - 17.1.1. Thread-Local Data
    - 17.1.2. Thread Objects
    - 17.1.3. Lock Objects
    - 17.1.4. RLock Objects
    - 17.1.5. Condition Objects
    - 17.1.6. Semaphore Objects
      - 17.1.6.1. Semaphore Example
    - 17.1.7. Event Objects
    - 17.1.8. Timer Objects
    - 17.1.9. Barrier Objects
    - 17.1.10. Using locks, conditions, and semaphores in
17.2. multiprocessing — Process-based parallelism

- 17.2.1. Introduction
  - 17.2.1.1. The Process class
  - 17.2.1.2. Exchanging objects between processes
  - 17.2.1.3. Synchronization between processes
  - 17.2.1.4. Sharing state between processes
  - 17.2.1.5. Using a pool of workers

- 17.2.2. Reference
  - 17.2.2.1. Process and exceptions
  - 17.2.2.2. Pipes and Queues
  - 17.2.2.3. Miscellaneous
  - 17.2.2.4. Connection Objects
  - 17.2.2.5. Synchronization primitives
  - 17.2.2.6. Shared ctypes Objects
    - 17.2.2.6.1. The multiprocessing.sharedctypes module
  - 17.2.2.7. Managers
    - 17.2.2.7.1. Namespace objects
    - 17.2.2.7.2. Customized managers
    - 17.2.2.7.3. Using a remote manager
  - 17.2.2.8. Proxy Objects
    - 17.2.2.8.1. Cleanup
  - 17.2.2.9. Process Pools
  - 17.2.2.10. Listeners and Clients
    - 17.2.2.10.1. Address Formats
  - 17.2.2.11. Authentication keys
  - 17.2.2.12. Logging
  - 17.2.2.13. The multiprocessing.dummy module

- 17.2.3. Programming guidelines
  - 17.2.3.1. All platforms
17.2.3.2. Windows

17.2.4. Examples

17.3. The concurrent package

17.4. `concurrent.futures` — Launching parallel tasks

- 17.4.1. Executor Objects
- 17.4.2. ThreadPoolExecutor
  - 17.4.2.1. ThreadPoolExecutor Example
- 17.4.3. ProcessPoolExecutor
  - 17.4.3.1. ProcessPoolExecutor Example
- 17.4.4. Future Objects
- 17.4.5. Module Functions
- 17.4.6. Exception classes

17.5. `subprocess` — Subprocess management

- 17.5.1. Using the subprocess Module
  - 17.5.1.1. Frequently Used Arguments
  - 17.5.1.2. Popen Constructor
  - 17.5.1.3. Exceptions
  - 17.5.1.4. Security
- 17.5.2. Popen Objects
- 17.5.3. Windows Popen Helpers
  - 17.5.3.1. Constants
- 17.5.4. Replacing Older Functions with the subprocess Module
  - 17.5.4.1. Replacing `/bin/sh` shell backquote
  - 17.5.4.2. Replacing shell pipeline
  - 17.5.4.3. Replacing os.system()
  - 17.5.4.4. Replacing the os.spawn family
  - 17.5.4.5. Replacing os.popen(), os.popen2(), os.popen3()
  - 17.5.4.6. Replacing functions from the popen2 module
- 17.5.5. Legacy Shell Invocation Functions
17.5.6. Notes
  17.5.6.1. Converting an argument sequence to a string on Windows
17.6. sched — Event scheduler
  17.6.1. Scheduler Objects
17.7. queue — A synchronized queue class
  17.7.1. Queue Objects
17.8. select — Waiting for I/O completion
  17.8.1. /dev/poll Polling Objects
  17.8.2. Edge and Level Trigger Polling (epoll) Objects
  17.8.3. Polling Objects
  17.8.4. Kqueue Objects
  17.8.5. Kevent Objects
17.9. dummy_threading — Drop-in replacement for the threading module
17.10. _thread — Low-level threading API
17.11. _dummy_thread — Drop-in replacement for the _thread module
18. Interprocess Communication and Networking
  18.1. socket — Low-level networking interface
    18.1.1. Socket families
    18.1.2. Module contents
    18.1.3. Socket Objects
    18.1.4. Notes on socket timeouts
      18.1.4.1. Timeouts and the connect method
      18.1.4.2. Timeouts and the accept method
    18.1.5. Example
  18.2. ssl — TLS/SSL wrapper for socket objects
    18.2.1. Functions, Constants, and Exceptions
      18.2.1.1. Socket creation
      18.2.1.2. Random generation
      18.2.1.3. Certificate handling
18.2.1.4. Constants
18.2.2. SSL Sockets
18.2.3. SSL Contexts
18.2.4. Certificates
  18.2.4.1. Certificate chains
  18.2.4.2. CA certificates
  18.2.4.3. Combined key and certificate
  18.2.4.4. Self-signed certificates
18.2.5. Examples
  18.2.5.1. Testing for SSL support
  18.2.5.2. Client-side operation
  18.2.5.3. Server-side operation
18.2.6. Notes on non-blocking sockets
18.2.7. Security considerations
  18.2.7.1. Verifying certificates
  18.2.7.2. Protocol versions
  18.2.7.3. Cipher selection
18.3. asyncore — Asynchronous socket handler
  18.3.1. asyncore Example basic HTTP client
  18.3.2. asyncore Example basic echo server
18.4. asynchat — Asynchronous socket command/response handler
  18.4.1. asynchat - Auxiliary Classes
  18.4.2. asynchat Example
18.5. signal — Set handlers for asynchronous events
  18.5.1. General rules
    18.5.1.1. Execution of Python signal handlers
    18.5.1.2. Signals and threads
  18.5.2. Module contents
  18.5.3. Example
18.6. mmap — Memory-mapped file support
19. Internet Data Handling
  19.1. email — An email and MIME handling package
    19.1.1. email.message: Representing an email
19.1.2. email.parser: Parsing email messages
   - 19.1.2.1. FeedParser API
   - 19.1.2.2. Parser class API
   - 19.1.2.3. Additional notes

19.1.3. email.generator: Generating MIME documents

19.1.4. email.policy: Policy Objects

19.1.5. email.headerregistry: Custom Header Objects

19.1.6. email.mime: Creating email and MIME objects from scratch

19.1.7. email.header: Internationalized headers

19.1.8. email.charset: Representing character sets

19.1.9. email.encoders: Encoders

19.1.10. email.errors: Exception and Defect classes

19.1.11. email.utils: Miscellaneous utilities

19.1.12. email.iterators: Iterators

19.1.13. email: Examples

19.1.14. Package History

19.1.15. Differences from mimelib

19.2. json — JSON encoder and decoder
   - 19.2.1. Basic Usage
   - 19.2.2. Encoders and Decoders
   - 19.2.3. Standard Compliance
     - 19.2.3.1. Character Encodings
     - 19.2.3.2. Top-level Non-Object, Non-Array Values
     - 19.2.3.3. Infinite and NaN Number Values
     - 19.2.3.4. Repeated Names Within an Object

19.3. mailcap — Mailcap file handling
19.4. mailbox — Manipulate mailboxes in various formats
   - 19.4.1. Mailbox objects
     - 19.4.1.1. Maildir
     - 19.4.1.2. mbox
     - 19.4.1.3. MH
     - 19.4.1.4. Babyl
     - 19.4.1.5. MMDF
   - 19.4.2. Message objects
     - 19.4.2.1. MaildirMessage
     - 19.4.2.2. mboxMessage
     - 19.4.2.3. MHMessage
     - 19.4.2.4. BabylMessage
     - 19.4.2.5. MMDFMessage
   - 19.4.3. Exceptions
   - 19.4.4. Examples

19.5. mimetypes — Map filenames to MIME types
   - 19.5.1. MimeTypes Objects

19.6. base64 — RFC 3548: Base16, Base32, Base64 Data Encodings

19.7. binhex — Encode and decode binhex4 files
   - 19.7.1. Notes

19.8. binascii — Convert between binary and ASCII

19.9. quopri — Encode and decode MIME quoted-printable data

19.10. uu — Encode and decode uuencode files

20. Structured Markup Processing Tools
   - 20.1. html — HyperText Markup Language support
   - 20.2. html.parser — Simple HTML and XHTML parser
     - 20.2.1. Example HTML Parser Application
     - 20.2.2. HTMLParser Methods
20.2.3. Examples
20.3. html.entities — Definitions of HTML general entities
20.4. XML Processing Modules
20.5. XML vulnerabilities
  20.5.1. defused packages
20.6. xml.etree.ElementTree — The ElementTree XML API
  20.6.1. Tutorial
    20.6.1.1. XML tree and elements
    20.6.1.2. Parsing XML
    20.6.1.3. Finding interesting elements
    20.6.1.4. Modifying an XML File
    20.6.1.5. Building XML documents
    20.6.1.6. Additional resources
  20.6.2. XPath support
    20.6.2.1. Example
    20.6.2.2. Supported XPath syntax
  20.6.3. Reference
    20.6.3.1. Functions
    20.6.3.2. Element Objects
    20.6.3.3. ElementTree Objects
    20.6.3.4. QName Objects
    20.6.3.5. TreeBuilder Objects
    20.6.3.6. XMLParser Objects
    20.6.3.7. Exceptions
20.7. xml.dom — The Document Object Model API
  20.7.1. Module Contents
  20.7.2. Objects in the DOM
    20.7.2.1. DOMImplementation Objects
    20.7.2.2. Node Objects
    20.7.2.3. NodeList Objects
    20.7.2.4. DocumentType Objects
    20.7.2.5. Document Objects
- 20.7.2.6. Element Objects
- 20.7.2.7. Attr Objects
- 20.7.2.8. NamedNodeMap Objects
- 20.7.2.9. Comment Objects
- 20.7.2.10. Text and CDATASection Objects
- 20.7.2.11. ProcessingInstruction Objects
- 20.7.2.12. Exceptions
- 20.7.3. Conformance
  - 20.7.3.1. Type Mapping
  - 20.7.3.2. Accessor Methods
- 20.8. xml.dom.minidom — Minimal DOM implementation
  - 20.8.1. DOM Objects
  - 20.8.2. DOM Example
  - 20.8.3. minidom and the DOM standard
- 20.9. xml.dom.pulldom — Support for building partial DOM trees
  - 20.9.1. DOMEventStream Objects
- 20.10. xml.sax — Support for SAX2 parsers
  - 20.10.1. SAXException Objects
- 20.11. xml.sax.handler — Base classes for SAX handlers
  - 20.11.1. ContentHandler Objects
  - 20.11.2. DTDHandler Objects
  - 20.11.3. EntityResolver Objects
  - 20.11.4. ErrorHandler Objects
- 20.12. xml.sax.saxutils — SAX Utilities
- 20.13. xml.sax.xmlreader — Interface for XML parsers
  - 20.13.1. XMLReader Objects
  - 20.13.2. IncrementalParser Objects
  - 20.13.3. Locator Objects
  - 20.13.4. InputSource Objects
  - 20.13.5. The Attributes Interface
- 20.13.6. The AttributesNS Interface
  - 20.14.1. XMLParser Objects
  - 20.14.2. ExpatError Exceptions
  - 20.14.3. Example
  - 20.14.4. Content Model Descriptions
  - 20.14.5. Expat error constants

- 21. Internet Protocols and Support
  - 21.1. webbrowser — Convenient Web-browser controller
    - 21.1.1. Browser Controller Objects
  - 21.2. cgi — Common Gateway Interface support
    - 21.2.1. Introduction
    - 21.2.2. Using the cgi module
    - 21.2.3. Higher Level Interface
    - 21.2.4. Functions
    - 21.2.5. Caring about security
    - 21.2.6. Installing your CGI script on a Unix system
    - 21.2.7. Testing your CGI script
    - 21.2.8. Debugging CGI scripts
    - 21.2.9. Common problems and solutions
  - 21.3. cgitb — Traceback manager for CGI scripts
  - 21.4. wsgiref — WSGI Utilities and Reference Implementation
    - 21.4.1. wsgiref.util — WSGI environment utilities
    - 21.4.2. wsgiref.headers — WSGI response header tools
    - 21.4.3. wsgiref.simple_server — a simple WSGI HTTP server
    - 21.4.4. wsgiref.validate — WSGI conformance checker
- 21.4.5. `wsgiref.handlers` — server/gateway base classes
- 21.4.6. Examples
- 21.5. `urllib` — URL handling modules
- 21.6. `urllib.request` — Extensible library for opening URLs
  - 21.6.1. Request Objects
  - 21.6.2. OpenerDirector Objects
  - 21.6.3. BaseHandler Objects
  - 21.6.4. HTTPRedirectHandler Objects
  - 21.6.5. HTTPCookieProcessor Objects
  - 21.6.6. ProxyHandler Objects
  - 21.6.7. HTTPPasswordMgr Objects
  - 21.6.8. AbstractBasicAuthHandler Objects
  - 21.6.9. HTTPBasicAuthHandler Objects
  - 21.6.10. ProxyBasicAuthHandler Objects
  - 21.6.11. AbstractDigestAuthHandler Objects
  - 21.6.12. HTTPDigestAuthHandler Objects
  - 21.6.13. ProxyDigestAuthHandler Objects
  - 21.6.14. HTTPHandler Objects
  - 21.6.15. HTTPSHandler Objects
  - 21.6.16. FileHandler Objects
  - 21.6.17. FTPHandler Objects
  - 21.6.18. CacheFTPHandler Objects
  - 21.6.19. UnknownHandler Objects
  - 21.6.20. HTTPErrorProcessor Objects
  - 21.6.21. Examples
  - 21.6.22. Legacy interface
  - 21.6.23. `urllib.request` Restrictions
- 21.7. `urllib.response` — Response classes used by `urllib`
- 21.8. `urllib.parse` — Parse URLs into components
  - 21.8.1. URL Parsing
  - 21.8.2. Parsing ASCII Encoded Bytes
21.8.3. Structured Parse Results
21.8.4. URL Quoting
21.9. urllib.error — Exception classes raised by urllib.request
21.10. urllib.robotparser — Parser for robots.txt
21.11. http — HTTP modules
   21.12.1. HTTPConnection Objects
   21.12.2. HTTPResponse Objects
   21.12.3. Examples
   21.12.4. HTTPMessage Objects
21.13. ftplib — FTP protocol client
   21.13.1. FTP Objects
   21.13.2. FTP_TLS Objects
21.14. poplib — POP3 protocol client
   21.14.1. POP3 Objects
   21.14.2. POP3 Example
21.15. imaplib — IMAP4 protocol client
   21.15.1. IMAP4 Objects
   21.15.2. IMAP4 Example
21.16. nntplib — NNTP protocol client
   21.16.1. NNTP Objects
      21.16.1.1. Attributes
      21.16.1.2. Methods
   21.16.2. Utility functions
21.17. smtplib — SMTP protocol client
   21.17.1. SMTP Objects
   21.17.2. SMTP Example
21.18. smtpd — SMTP Server
   21.18.1. SMTPServer Objects
   21.18.2. DebuggingServer Objects
   21.18.3. PureProxy Objects
   21.18.4. MailmanProxy Objects
- 21.18.5. SMTPChannel Objects
- 21.19. telnetlib — Telnet client
  - 21.19.1. Telnet Objects
  - 21.19.2. Telnet Example
- 21.20. uuid — UUID objects according to RFC 4122
  - 21.20.1. Example
- 21.21. socketserver — A framework for network servers
  - 21.21.1. Server Creation Notes
  - 21.21.2. Server Objects
  - 21.21.3. RequestHandler Objects
  - 21.21.4. Examples
    - 21.21.4.1. socketserver.TCPServer Example
    - 21.21.4.2. socketserver.UDPServer Example
    - 21.21.4.3. Asynchronous Mixins
- 21.22. http.server — HTTP servers
- 21.23. http.cookies — HTTP state management
  - 21.23.1. Cookie Objects
  - 21.23.2. Morsel Objects
  - 21.23.3. Example
- 21.24. http.cookiejar — Cookie handling for HTTP clients
  - 21.24.2. FileCookieJar subclasses and co-operation with web browsers
  - 21.24.3. CookiePolicy Objects
  - 21.24.4. DefaultCookiePolicy Objects
  - 21.24.5. Cookie Objects
  - 21.24.6. Examples
- 21.25. xmlrpc — XMLRPC server and client modules
- 21.26. xmlrpc.client — XML-RPC client access
- 21.26.2. DateTime Objects
- 21.26.3. Binary Objects
- 21.26.4. Fault Objects
- 21.26.6. MultiCall Objects
- 21.26.7. Convenience Functions
- **21.27. xmlrpc.server — Basic XML-RPC servers**
  - 21.27.1. SimpleXMLRPCServer Objects
    - 21.27.1.1. SimpleXMLRPCServer Example
  - 21.27.2. CGIXHRPCRequestHandler
  - 21.27.3. Documenting XMLRPC server
  - 21.27.4. DocXMLRPCServer Objects
  - 21.27.5. DocCGIXMLRPCRequestHandler
- **21.28. ipaddress — IPv4/IPv6 manipulation library**
  - 21.28.1. Convenience factory functions
  - 21.28.2. IP Addresses
    - 21.28.2.1. Address objects
    - 21.28.2.2. Conversion to Strings and Integers
    - 21.28.2.3. Operators
      - 21.28.2.3.1. Comparison operators
      - 21.28.2.3.2. Arithmetic operators
  - 21.28.3. IP Network definitions
    - 21.28.3.1. Prefix, net mask and host mask
    - 21.28.3.2. Network objects
    - 21.28.3.3. Operators
      - 21.28.3.3.1. Logical operators
      - 21.28.3.3.2. Iteration
      - 21.28.3.3.3. Networks as containers of addresses
  - 21.28.4. Interface objects
  - 21.28.5. Other Module Level Functions
21.28.6. Custom Exceptions

22. Multimedia Services

- 22.1. audioop — Manipulate raw audio data
- 22.2. aifc — Read and write AIFF and AIFC files
- 22.3. sunau — Read and write Sun AU files
  - 22.3.1. AU_read Objects
  - 22.3.2. AU_write Objects
- 22.4. wave — Read and write WAV files
  - 22.4.1. Wave_read Objects
  - 22.4.2. Wave_write Objects
- 22.5. chunk — Read IFF chunked data
- 22.6. colorsys — Conversions between color systems
- 22.7. imghdr — Determine the type of an image
- 22.8. sndhdr — Determine type of sound file
- 22.9. ossaudiodev — Access to OSS-compatible audio devices
  - 22.9.1. Audio Device Objects
  - 22.9.2. Mixer Device Objects

23. Internationalization

- 23.1. gettext — Multilingual internationalization services
  - 23.1.1. GNU gettext API
  - 23.1.2. Class-based API
    - 23.1.2.1. The NullTranslations class
    - 23.1.2.2. The GNUTranslations class
    - 23.1.2.3. Solaris message catalog support
    - 23.1.2.4. The Catalog constructor
  - 23.1.3. Internationalizing your programs and modules
    - 23.1.3.1. Localizing your module
    - 23.1.3.2. Localizing your application
    - 23.1.3.3. Changing languages on the fly
    - 23.1.3.4. Deferred translations
23.1.4. Acknowledgements

23.2. locale — Internationalization services
- 23.2.1. Background, details, hints, tips and caveats
- 23.2.2. For extension writers and programs that embed Python
- 23.2.3. Access to message catalogs

24. Program Frameworks

- 24.1. turtle — Turtle graphics
  - 24.1.1. Introduction
  - 24.1.2. Overview of available Turtle and Screen methods
    - 24.1.2.1. Turtle methods
    - 24.1.2.2. Methods of TurtleScreen/Screen
  - 24.1.3. Methods of RawTurtle/Turtle and corresponding functions
    - 24.1.3.1. Turtle motion
    - 24.1.3.2. Tell Turtle’s state
    - 24.1.3.3. Settings for measurement
    - 24.1.3.4. Pen control
      - 24.1.3.4.1. Drawing state
      - 24.1.3.4.2. Color control
      - 24.1.3.4.3. Filling
      - 24.1.3.4.4. More drawing control
    - 24.1.3.5. Turtle state
      - 24.1.3.5.1. Visibility
      - 24.1.3.5.2. Appearance
    - 24.1.3.6. Using events
    - 24.1.3.7. Special Turtle methods
    - 24.1.3.8. Compound shapes
  - 24.1.4. Methods of TurtleScreen/Screen and corresponding functions
    - 24.1.4.1. Window control
    - 24.1.4.2. Animation control
    - 24.1.4.3. Using screen events
- 24.1.4.4. Input methods
- 24.1.4.5. Settings and special methods
- 24.1.4.6. Methods specific to Screen, not inherited from TurtleScreen
- 24.1.5. Public classes
- 24.1.6. Help and configuration
  - 24.1.6.1. How to use help
  - 24.1.6.2. Translation of docstrings into different languages
  - 24.1.6.3. How to configure Screen and Turtles
- 24.1.7. Demo scripts
- 24.1.8. Changes since Python 2.6
- 24.1.9. Changes since Python 3.0
- 24.2. cmd — Support for line-oriented command interpreters
  - 24.2.1. Cmd Objects
  - 24.2.2. Cmd Example
- 24.3. shlex — Simple lexical analysis
  - 24.3.1. shlex Objects
  - 24.3.2. Parsing Rules
- 25. Graphical User Interfaces with Tk
  - 25.1. tkinter — Python interface to Tcl/Tk
    - 25.1.1. Tkinter Modules
    - 25.1.2. Tkinter Life Preserver
      - 25.1.2.1. How To Use This Section
      - 25.1.2.2. A Simple Hello World Program
    - 25.1.3. A (Very) Quick Look at Tcl/Tk
    - 25.1.4. Mapping Basic Tk into Tkinter
    - 25.1.5. How Tk and Tkinter are Related
    - 25.1.6. Handy Reference
      - 25.1.6.1. Setting Options
      - 25.1.6.2. The Packer
      - 25.1.6.3. Packer Options
      - 25.1.6.4. Coupling Widget Variables
- 25.1.6.5. The Window Manager
- 25.1.6.6. Tk Option Data Types
- 25.1.6.7. Bindings and Events
- 25.1.6.8. The index Parameter
- 25.1.6.9. Images

- 25.2. `tkinter.ttk` — Tk themed widgets
  - 25.2.1. Using Ttk
  - 25.2.2. Ttk Widgets
  - 25.2.3. Widget
    - 25.2.3.1. Standard Options
    - 25.2.3.2. Scrollable Widget Options

    - 26.5.3.1. Mocking chained calls
    - 26.5.3.2. Partial mocking
    - 26.5.3.3. Mocking a Generator Method
    - 26.5.3.4. Applying the same patch to every test method
    - 26.5.3.5. Mocking Unbound Methods
    - 26.5.3.6. Checking multiple calls with mock
    - 26.5.3.7. Coping with mutable arguments
    - 26.5.3.8. Nesting Patches
    - 26.5.3.9. Mocking a dictionary with MagicMock
26.5.3.10. Mock subclasses and their attributes
26.5.3.11. Mocking imports with patch.dict
26.5.3.12. Tracking order of calls and less verbose call assertions
26.5.3.13. More complex argument matching

26.6. 2to3 - Automated Python 2 to 3 code translation
  26.6.1. Using 2to3
  26.6.2. Fixers
  26.6.3. lib2to3 - 2to3's library

26.7. test — Regression tests package for Python
  26.7.1. Writing Unit Tests for the test package
  26.7.2. Running tests using the command-line interface

26.8. test.support — Utilities for the Python test suite

26.9. venv — Creation of virtual environments
  26.9.1. Creating virtual environments
  26.9.2. API
  26.9.3. An example of extending EnvBuilder

27. Debugging and Profiling
  27.1. bdb — Debugger framework
  27.2. faulthandler — Dump the Python traceback
    27.2.1. Dump the traceback
    27.2.2. Fault handler state
    27.2.3. Dump the tracebacks after a timeout
    27.2.4. Dump the traceback on a user signal
    27.2.5. File descriptor issue
    27.2.6. Example
  27.3. pdb — The Python Debugger
    27.3.1. Debugger Commands
  27.4. The Python Profilers
    27.4.1. Introduction to the profilers
    27.4.2. Instant User’s Manual
27.4.3. profile and cProfile Module Reference
27.4.4. The Stats Class
27.4.5. What Is Deterministic Profiling?
27.4.6. Limitations
27.4.7. Calibration
27.4.8. Using a custom timer

27.5. timeit — Measure execution time of small code snippets
- 27.5.1. Basic Examples
- 27.5.2. Python Interface
- 27.5.3. Command-Line Interface
- 27.5.4. Examples

27.6. trace — Trace or track Python statement execution
- 27.6.1. Command-Line Usage
  - 27.6.1.1. Main options
  - 27.6.1.2. Modifiers
  - 27.6.1.3. Filters
- 27.6.2. Programmatic Interface

28. Python Runtime Services
- 28.1. sys — System-specific parameters and functions
- 28.2. sysconfig — Provide access to Python's configuration information
  - 28.2.1. Configuration variables
  - 28.2.2. Installation paths
  - 28.2.3. Other functions
  - 28.2.4. Using sysconfig as a script
- 28.3. builtins — Built-in objects
- 28.4. __main__ — Top-level script environment
- 28.5. warnings — Warning control
  - 28.5.1. Warning Categories
  - 28.5.2. The Warnings Filter
    - 28.5.2.1. Default Warning Filters
- 28.5.3. Temporarily Suppressing Warnings
- 28.5.4. Testing Warnings
- 28.5.5. Updating Code For New Versions of Python
- 28.5.6. Available Functions
- 28.5.7. Available Context Managers
- 28.6. `contextlib` — Utilities for with-statement contexts
  - 28.6.1. Utilities
  - 28.6.2. Examples and Recipes
    - 28.6.2.1. Supporting a variable number of context managers
    - 28.6.2.2. Simplifying support for single optional context managers
    - 28.6.2.3. Catching exceptions from `__enter__` methods
    - 28.6.2.4. Cleaning up in an `__enter__` implementation
    - 28.6.2.5. Replacing any use of try-finally and flag variables
    - 28.6.2.6. Using a context manager as a function decorator
- 28.7. `abc` — Abstract Base Classes
- 28.8. `atexit` — Exit handlers
  - 28.8.1. `atexit` Example
- 28.9. `traceback` — Print or retrieve a stack traceback
  - 28.9.1. Traceback Examples
- 28.10. `__future__` — Future statement definitions
- 28.11. `gc` — Garbage Collector interface
- 28.12. `inspect` — Inspect live objects
  - 28.12.1. Types and members
  - 28.12.2. Retrieving source code
  - 28.12.3. Introspecting callables with the Signature object
- 28.12.4. Classes and functions
- 28.12.5. The interpreter stack
- 28.12.6. Fetching attributes statically
- 28.13. site — Site-specific configuration hook
- 28.14. fpectl — Floating point exception control
  - 28.14.2. Limitations and other considerations
- 28.15. distutils — Building and installing Python modules
  - 29. Custom Python Interpreters
    - 29.1. code — Interpreter base classes
      - 29.1.1. Interactive Interpreter Objects
      - 29.1.2. Interactive Console Objects
    - 29.2. codeop — Compile Python code
  - 30. Importing Modules
    - 30.1. imp — Access the import internals
      - 30.1.1. Examples
    - 30.2. zipimport — Import modules from Zip archives
      - 30.2.1. zipimporter Objects
      - 30.2.2. Examples
    - 30.3. pkgutil — Package extension utility
    - 30.4. modulefinder — Find modules used by a script
      - 30.4.1. Example usage of ModuleFinder
    - 30.5. runpy — Locating and executing Python modules
    - 30.6. importlib – An implementation of import
      - 30.6.1. Introduction
      - 30.6.2. Functions
      - 30.6.3. importlib.abc – Abstract base classes related to import
      - 30.6.4. importlib.machinery – Importers and path hooks
      - 30.6.5. importlib.util – Utility code for
importers

31. Python Language Services

- 31.1. parser — Access Python parse trees
  - 31.1.1. Creating ST Objects
  - 31.1.2. Converting ST Objects
  - 31.1.3. Queries on ST Objects
  - 31.1.4. Exceptions and Error Handling
  - 31.1.5. ST Objects
  - 31.1.6. Example: Emulation of compile()

- 31.2. ast — Abstract Syntax Trees
  - 31.2.1. Node classes
  - 31.2.2. Abstract Grammar
  - 31.2.3. ast Helpers

- 31.3. symtable — Access to the compiler's symbol tables
  - 31.3.1. Generating Symbol Tables
  - 31.3.2. Examining Symbol Tables

- 31.4. symbol — Constants used with Python parse trees

- 31.5. token — Constants used with Python parse trees

- 31.6. keyword — Testing for Python keywords

- 31.7. tokenize — Tokenizer for Python source
  - 31.7.1. Tokenizing Input
  - 31.7.2. Command-Line Usage
  - 31.7.3. Examples

- 31.8. tabnanny — Detection of ambiguous indentation

- 31.9. pyc1br — Python class browser support
  - 31.9.1. Class Objects
  - 31.9.2. Function Objects

- 31.10. py_compile — Compile Python source files

- 31.11. compileall — Byte-compile Python libraries
  - 31.11.1. Command-line use
  - 31.11.2. Public functions
- 31.12. dis — Disassembler for Python bytecode
  - 31.12.1. Python Bytecode Instructions
- 31.13. pickletools — Tools for pickle developers
  - 31.13.1. Command line usage
    - 31.13.1.1. Command line options
  - 31.13.2. Programmatic Interface
- 32. Miscellaneous Services
  - 32.1. formatter — Generic output formatting
    - 32.1.1. The Formatter Interface
    - 32.1.2. Formatter Implementations
    - 32.1.3. The Writer Interface
    - 32.1.4. Writer Implementations
- 33. MS Windows Specific Services
  - 33.1. msilib — Read and write Microsoft Installer files
    - 33.1.1. Database Objects
    - 33.1.2. View Objects
    - 33.1.3. Summary Information Objects
    - 33.1.4. Record Objects
    - 33.1.5. Errors
    - 33.1.6. CAB Objects
    - 33.1.7. Directory Objects
    - 33.1.8. Features
    - 33.1.9. GUI classes
    - 33.1.10. Precomputed tables
  - 33.2. msvcrt — Useful routines from the MS VC++ runtime
    - 33.2.1. File Operations
    - 33.2.2. Console I/O
    - 33.2.3. Other Functions
  - 33.3. winreg — Windows registry access
    - 33.3.1. Functions
    - 33.3.2. Constants
      - 33.3.2.1. HKEY_* Constants
      - 33.3.2.2. Access Rights
33.3.2.2.1. 64-bit Specific
33.3.2.3. Value Types
33.3.3. Registry Handle Objects
33.4. winsound — Sound-playing interface for Windows

34. Unix Specific Services
34.1. posix — The most common POSIX system calls
   34.1.1. Large File Support
   34.1.2. Notable Module Contents
34.2. pwd — The password database
34.3. spwd — The shadow password database
34.4. grp — The group database
34.5. crypt — Function to check Unix passwords
   34.5.1. Hashing Methods
   34.5.2. Module Attributes
   34.5.3. Module Functions
   34.5.4. Examples
34.6. termios — POSIX style tty control
   34.6.1. Example
34.7. tty — Terminal control functions
34.8. pty — Pseudo-terminal utilities
   34.8.1. Example
34.9. fcntl — The fcntl and ioctl system calls
34.10. pipes — Interface to shell pipelines
   34.10.1. Template Objects
34.11. resource — Resource usage information
   34.11.1. Resource Limits
   34.11.2. Resource Usage
34.12. nis — Interface to Sun’s NIS (Yellow Pages)
34.13. syslog — Unix syslog library routines
   34.13.1. Examples
   34.13.1.1. Simple example

35. Undocumented Modules
35.1. Platform specific modules
• Extending and Embedding the Python Interpreter
  ○ 1. Extending Python with C or C++
    ▪ 1.1. A Simple Example
    ▪ 1.2. Intermezzo: Errors and Exceptions
    ▪ 1.3. Back to the Example
    ▪ 1.4. The Module’s Method Table and Initialization Function

9. Command Reference

9.1. Installing modules: the `install` command family

9.1.1. `install_data`

9.1.2. `install_scripts`

9.2. Creating a source distribution: the `sdist` command

10. API Reference

10.1. `distutils.core` — Core Distutils functionality

10.2. `distutils.ccompiler` — CCompiler base class

10.3. `distutils.unixccompiler` — Unix C Compiler

10.4. `distutils.msvccompiler` — Microsoft Compiler

10.5. `distutils.bcppcompiler` — Borland Compiler

10.6. `distutils.cygwincompiler` — Cygwin Compiler

10.7. `distutils.emxccompiler` — OS/2 EMX Compiler

10.8. `distutils.archive_util` — Archiving utilities

10.9. `distutils.dep_util` — Dependency checking

10.10. `distutils.dir_util` — Directory tree operations

10.11. `distutils.file_util` — Single file operations

10.12. `distutils.util` — Miscellaneous other utility functions

10.13. `distutils.dist` — The Distribution class

10.14. `distutils.extension` — The Extension class

10.15. `distutils.debug` — Distutils debug mode

10.16. `distutils.errors` — Distutils exceptions

10.17. `distutils.fancy_getopt` — Wrapper around the standard getopt module

10.18. `distutils.filelist` — The FileList class

10.19. `distutils.log` — Simple PEP 282-style
logging

- 10.20. distutils.spawn — Spawn a sub-process
- 10.21. distutils.sysconfig — System configuration information
- 10.22. distutils.text_file — The TextFile class
- 10.23. distutils.version — Version number classes
- 10.24. distutils.cmd — Abstract base class for Distutils commands
- 10.25. Creating a new Distutils command
- 10.26. distutils.command — Individual Distutils commands
- 10.27. distutils.command.bdist — Build a binary installer
- 10.28. distutils.command.bdist_packager — Abstract base class for packagers
- 10.29. distutils.command.bdist_dumb — Build a “dumb” installer
- 10.30. distutils.command.bdist_msi — Build a Microsoft Installer binary package
- 10.31. distutils.command.bdist_rpm — Build a binary distribution as a Redhat RPM and SRPM
- 10.32. distutils.command.bdist_wininst — Build a Windows installer
- 10.33. distutils.command.sdist — Build a source distribution
- 10.34. distutils.command.build — Build all files of a package
- 10.35. distutils.command.build_clib — Build any C libraries in a package
- 10.36. distutils.command.build_ext — Build any extensions in a package
- 10.37. distutils.command.build_py — Build the
.py/.pyc files of a package

- 10.38. `distutils.command.build_scripts` — Build the scripts of a package
- 10.39. `distutils.command.clean` — Clean a package build area
- 10.40. `distutils.command.config` — Perform package configuration
- 10.41. `distutils.command.install` — Install a package
- 10.42. `distutils.command.install_data` — Install data files from a package
- 10.43. `distutils.command.install_headers` — Install C/C++ header files from a package
- 10.44. `distutils.command.install_lib` — Install library files from a package
- 10.45. `distutils.command.install_scripts` — Install script files from a package
- 10.46. `distutils.command.register` — Register a module with the Python Package Index
- 10.47. `distutils.command.check` — Check the meta-data of a package

- Installing Python Modules
  - Introduction
    - Best case: trivial installation
    - The new standard: Distutils
  - Standard Build and Install
    - Platform variations
    - Splitting the job up
    - How building works
    - How installation works
  - Alternate Installation
    - Alternate installation: the user scheme
    - Alternate installation: the home scheme
- Alternate installation: Unix (the prefix scheme)
- Alternate installation: Windows (the prefix scheme)

- Custom Installation
  - Modifying Python’s Search Path

- Distutils Configuration Files
  - Location and names of config files
  - Syntax of config files

- Building Extensions: Tips and Tricks
  - Tweaking compiler/linker flags
  - Using non-Microsoft compilers on Windows
    - Borland/CodeGear C++
    - GNU C / Cygwin / MinGW
      - Older Versions of Python and MinGW

- Python HOWTOs
  - Porting Python 2 Code to Python 3
    - Choosing a Strategy
      - Universal Bits of Advice
    - Python 3 and 3to2
    - Python 2 and 2to3
      - Support Python 2.7
      - Try to Support Python 2.6 and Newer Only
        - from __future__ import print_function
        - from __future__ import unicode_literals
        - Bytes literals
      - Supporting Python 2.5 and Newer Only
        - from __future__ import absolute_import
        - Mark all Unicode strings with a u prefix
      - Handle Common “Gotchas”
        - from __future__ import division
        - Specify when opening a file as binary
        - Text files
Subclass object

Deal With the Bytes/String Dichotomy
  - Mark Up Python 2 String Literals
  - Decide what APIs Will Accept
  - Bytes / Unicode Comparison

Indexing bytes objects
- __str__() / __unicode__()

Don't Index on Exceptions
- Don't use __getslice__ & Friends

Updating doctests
- Update map for imbalanced input sequences

Eliminate -3 Warnings

Run 2to3
- Manually
- During Installation

Verify & Test
- Python 2/3 Compatible Source
  - Follow The Steps for Using 2to3
  - Use six
  - Capturing the Currently Raised Exception

    • Performance
    • Sequences (Tuples/Lists)
    • Dictionaries
    • Objects
    • Modules
  • Design and History FAQ
    • Why does Python use indentation for grouping of statements?
    • Why am I getting strange results with simple arithmetic operations?
    • Why are floating-point calculations so inaccurate?
    • Why are Python strings immutable?
    • Why must ‘self’ be used explicitly in method definitions and calls?
    • Why can’t I use an assignment in an expression?
    • Why does Python use methods for some functionality (e.g. list.index()) but functions for other (e.g. len(list))?
- Why is `join()` a string method instead of a list or tuple method?
- How fast are exceptions?
- Why isn’t there a switch or case statement in Python?
- Can’t you emulate threads in the interpreter instead of relying on an OS-specific thread implementation?
- Why can’t lambda expressions contain statements?
- Can Python be compiled to machine code, C or some other language?
- How does Python manage memory?
- Why doesn’t CPython use a more traditional garbage collection scheme?
- Why isn’t all memory freed when CPython exits?
- Why are there separate tuple and list data types?
- How are lists implemented?
- How are dictionaries implemented?
- Why must dictionary keys be immutable?
- Why doesn’t list.sort() return the sorted list?
- How do you specify and enforce an interface spec in Python?
- Why are default values shared between objects?
- Why is there no goto?
- Why can’t raw strings (r-strings) end with a backslash?
- Why doesn’t Python have a “with” statement for attribute assignments?
- Why are colons required for the if/while/def/class statements?
- Why does Python allow commas at the end of lists and tuples?

from the image, the natural text appears to be a list of Python objects and operators, along with some notes on their usage and attributes. The text includes:

- **Objects**:
  - range
  - sequence, [1], [2], [3], [4], [5], [6], [7], [8]
  - set, [1], [2], [3]
  - set type
  - slice
  - socket
  - string, [1], [2]
  - traceback, [1], [2], [3], [4]
  - tuple, [1], [2], [3], [4], [5], [6]
  - type, [1], [2]
  - user-defined function, [1], [2]
  - user-defined method

- **Operators**:
  - object (UnicodeError attribute)
  - object() (built-in function)
  - object.__slots__ (built-in variable)
  - object_filenames()
    (distutils.ccompiler.CCompiler method)
  - objects
    - comparing
    - flattening
    - marshalling
    - persistent
    - pickling
    - serializing
    - obufcount()
      (ossaudiodev.oss_audio_device method)
    - obuffree()
      (ossaudiodev.oss_audio_device method)
    - oct() (built-in function)
    - octal
      - literals
    - octal literal
    - octdigits (in module string)

- **Comparison and Inclusion**:
  - and, [1], [2]
  - comparison
  - in, [1], [2]
  - is, [1]
  - is not, [1]
  - not, [1]
  - not in, [1], [2]
  - or, [1], [2]
  - overloading
  - precedence
  - ternary
    operator (2to3 fixer)
    (module)
