        self.stdoffset = timedelta(hours=hours)
        self.reprname = reprname
        self.stdname = stdname
        self.dstname = dstname

    def __repr__(self):
        return self.reprname

    def tzname(self, dt):
        if self.dst(dt):
            return self.dstname
        else:
            return self.stdname
def utcoffset(self, dt):
    return self.stdoffset + self.dst(dt)

def dst(self, dt):
    if dt is None or dt.tzinfo is None:
        # An exception may be sensible here, in
        # It depends on how you want to treat the
        # fromutc() implementation (called by the
        # implementation) passes a datetime with
        return ZERO
    assert dt.tzinfo is self

    # Find start and end times for US DST. For years before 1967,
    # ZERO for no DST.
    if 2006 < dt.year:
        dststart, dstend = DSTSTART_2007, DSTEND_2007
    elif 1986 < dt.year < 2007:
    elif 1966 < dt.year < 1987:
    else:
        return ZERO

    start = first_sunday_on_or_after(dststart.replace(tzinfo=None))
    end = first_sunday_on_or_after(dstend.replace(tzinfo=None))

    # Can't compare naive to aware objects, so strip the
    # dt first.
    if start <= dt.replace(tzinfo=None) < end:
        return HOUR
    else:
        return ZERO

Eastern = USTimeZone(-5, "Eastern", "EST", "EDT")
Central = USTimeZone(-6, "Central", "CST", "CDT")
Mountain = USTimeZone(-7, "Mountain", "MST", "MDT")
Note that there are unavoidable subtleties twice per year in a tzinfo subclass accounting for both standard and daylight time, at the DST transition points. For concreteness, consider US Eastern (UTC -0500), where EDT begins the minute after 1:59 (EST) on the second Sunday in March, and ends the minute after 1:59 (EDT) on the first Sunday in November:

|-------|------|------|------|------|------|------|

When DST starts (the “start” line), the local wall clock leaps from 1:59 to 3:00. A wall time of the form 2:MM doesn’t really make sense on that day, so astimezone(Eastern) won’t deliver a result with hour == 2 on the day DST begins. In order for astimezone() to make this guarantee, the tzinfo.dst() method must consider times in the “missing hour” (2:MM for Eastern) to be in daylight time.

When DST ends (the “end” line), there’s a potentially worse problem: there’s an hour that can’t be spelled unambiguously in local wall time: the last hour of daylight time. In Eastern, that’s times of the form 5:MM UTC on the day daylight time ends. The local wall clock leaps from 1:59 (daylight time) back to 1:00 (standard time) again. Local times of the form 1:MM are ambiguous. astimezone() mimics the local clock’s behavior by mapping two adjacent UTC hours into the same local hour then. In the Eastern example, UTC times of the form 5:MM
and 6:MM both map to 1:MM when converted to Eastern. In order for `astimezone()` to make this guarantee, the `tzinfo.dst()` method must consider times in the “repeated hour” to be in standard time. This is easily arranged, as in the example, by expressing DST switch times in the time zone’s standard local time.

Applications that can’t bear such ambiguities should avoid using hybrid `tzinfo` subclasses; there are no ambiguities when using `timezone`, or any other fixed-offset `tzinfo` subclass (such as a class representing only EST (fixed offset -5 hours), or only EDT (fixed offset -4 hours)).

**See also:**

**pytz**

The standard library has no `tzinfo` instances except for UTC, but there exists a third-party library which brings the *IANA timezone database* (also known as the Olson database) to Python: `pytz`.

`pytz` contains up-to-date information and its usage is recommended.

**IANA timezone database**

The Time Zone Database (often called tz or zoneinfo) contains code and data that represent the history of local time for many representative locations around the globe. It is updated periodically to reflect changes made by political bodies to time zone boundaries, UTC offsets, and daylight-saving rules.
8.1.7. **timezone** Objects

The **timezone** class is a subclass of **tzinfo**, each instance of which represents a timezone defined by a fixed offset from UTC. Note that objects of this class cannot be used to represent timezone information in the locations where different offsets are used in different days of the year or where historical changes have been made to civil time.

```python
class datetime.timezone(offset[, name])
```

The `offset` argument must be specified as a **timedelta** object representing the difference between the local time and UTC. It must be strictly between `-timedelta(hours=24)` and `timedelta(hours=24)` and represent a whole number of minutes, otherwise `ValueError` is raised.

The `name` argument is optional. If specified it must be a string that is used as the value returned by the `tzname(dt)` method. Otherwise, `tzname(dt)` returns a string ‘UTC±HH:MM’, where s is the sign of `offset`, HH and MM are two digits of `offset.hours` and `offset.minutes` respectively.

**timezone.utcoffset(dt)**

Return the fixed value specified when the **timezone** instance is constructed. The `dt` argument is ignored. The return value is a **timedelta** instance equal to the difference between the local time and UTC.

**timezone.tzname(dt)**

Return the fixed value specified when the **timezone** instance is constructed or a string ‘UTC±HH:MM’, where s is the sign of `offset`,
HH and MM are two digits of `offset.hours` and `offset.minutes` respectively.

timezone. `dst(dt)`
Always returns None.

timezone. `fromutc(dt)`
Return `dt + offset`. The `dt` argument must be an aware `datetime` instance, with `tzinfo` set to `self`.

Class attributes:

timezone. `utc`
The UTC timezone, `timezone(timedelta(0))`. 
8.1.8. strftime() and strptime()

Behavior

date, datetime, and time objects all support a strftime(format) method, to create a string representing the time under the control of an explicit format string. Broadly speaking, d.strftime(fmt) acts like the time module's time.strftime(fmt, d.timetuple()) although not all objects support a timetuple() method.

Conversely, the datetime.strptime() class method creates a datetime object from a string representing a date and time and a corresponding format string. datetime.strptime(date_string, format) is equivalent to datetime(* (time.strptime(date_string, format)[0:6])).

For time objects, the format codes for year, month, and day should not be used, as time objects have no such values. If they're used anyway, 1900 is substituted for the year, and 1 for the month and day.

For date objects, the format codes for hours, minutes, seconds, and microseconds should not be used, as date objects have no such values. If they're used anyway, 0 is substituted for them.

The full set of format codes supported varies across platforms, because Python calls the platform C library's strftime() function, and platform variations are common. To see the full set of format codes supported on your platform, consult the strftime(3) documentation.

The following is a list of all the format codes that the C standard (1989
version) requires, and these work on all platforms with a standard C implementation. Note that the 1999 version of the C standard added additional format codes.

</tr>
<tr>
<td>%%</td>
<td>A literal '%' character.</td>
<td>%</td>
</tr>
</tbody>
</table>

Notes:

1. Because the format depends on the current locale, care should be taken when making assumptions about the output value. Field orderings will vary (for example, “month/day/year” versus “day/month/year”), and the output may contain Unicode
characters encoded using the locale’s default encoding (for example, if the current locale is js_JP, the default encoding could be any one of eucJP, SJIS, or utf-8; use `locale.getlocale()` to determine the current locale’s encoding).

2. The `strptime()` method can parse years in the full [1, 9999] range, but years < 1000 must be zero-filled to 4-digit width.

   *Changed in version 3.2:* In previous versions, `strftime()` method was restricted to years >= 1900.

   *Changed in version 3.3:* In version 3.2, `strftime()` method was restricted to years >= 1000.

3. When used with the `strptime()` method, the `%p` directive only affects the output hour field if the `%I` directive is used to parse the hour.

4. Unlike the `time` module, the `datetime` module does not support leap seconds.

5. When used with the `strptime()` method, the `%f` directive accepts from one to six digits and zero pads on the right. `%f` is an extension to the set of format characters in the C standard (but implemented separately in datetime objects, and therefore always available).

6. For a naive object, the `%z` and `%Z` format codes are replaced by empty strings.

   For an aware object:
%Z

utcoffset() is transformed into a 5-character string of the form +HHMM or -HHMM, where HH is a 2-digit string giving the number of UTC offset hours, and MM is a 2-digit string giving the number of UTC offset minutes. For example, if utcoffset() returns `timedelta(hours=-3, minutes=-30)`, %Z is replaced with the string '-0330'.

%Z

If tzname() returns None, %Z is replaced by an empty string. Otherwise %Z is replaced by the returned value, which must be a string.

*Changed in version 3.2:* When the %z directive is provided to the strftime() method, an aware `datetime` object will be produced. The `tzinfo` of the result will be set to a `timezone` instance.

7. When used with the strftime() method, %U and %W are only used in calculations when the day of the week and the year are specified.

**Footnotes**

[1] If, that is, we ignore the effects of Relativity
8.2. calendar — General calendar-related functions

Source code: Lib/calendar.py

This module allows you to output calendars like the Unix `cal` program, and provides additional useful functions related to the calendar. By default, these calendars have Monday as the first day of the week, and Sunday as the last (the European convention). Use `setfirstweekday()` to set the first day of the week to Sunday (6) or to any other weekday. Parameters that specify dates are given as integers. For related functionality, see also the `datetime` and `time` modules.

Most of these functions and classes rely on the `datetime` module which uses an idealized calendar, the current Gregorian calendar extended in both directions. This matches the definition of the “proleptic Gregorian” calendar in Dershowitz and Reingold’s book “Calendrical Calculations”, where it’s the base calendar for all computations.

```python
class calendar.Calendar(firstweekday=0)
```

Creates a `Calendar` object. `firstweekday` is an integer specifying the first day of the week. 0 is Monday (the default), 6 is Sunday.

A `Calendar` object provides several methods that can be used for preparing the calendar data for formatting. This class doesn’t do any formatting itself. This is the job of subclasses.

`Calendar` instances have the following methods:
**iterweekdays()**

Return an iterator for the week day numbers that will be used for one week. The first value from the iterator will be the same as the value of the `firstweekday` property.

**itermonthdates**(year, month)

Return an iterator for the month `month` (1-12) in the year `year`. This iterator will return all days (as `datetime.date` objects) for the month and all days before the start of the month or after the end of the month that are required to get a complete week.

**itermonthdays2**(year, month)

Return an iterator for the month `month` in the year `year` similar to `itermonthdates()`. Days returned will be tuples consisting of a day number and a week day number.

**itermonthdays**(year, month)

Return an iterator for the month `month` in the year `year` similar to `itermonthdates()`. Days returned will simply be day numbers.

**monthdatescalendar**(year, month)

Return a list of the weeks in the month `month` of the `year` as full weeks. Weeks are lists of seven `datetime.date` objects.

**monthdays2calendar**(year, month)

Return a list of the weeks in the month `month` of the `year` as full weeks. Weeks are lists of seven tuples of day numbers and weekday numbers.

**monthdayscalendar**(year, month)

Return a list of the weeks in the month `month` of the `year` as full
weeks. Weeks are lists of seven day numbers.

**yeardatescalendar**(year, width=3)

Return the data for the specified year ready for formatting. The return value is a list of month rows. Each month row contains up to width months (defaulting to 3). Each month contains between 4 and 6 weeks and each week contains 1–7 days. Days are `datetime.date` objects.

**yeardays2calendar**(year, width=3)

Return the data for the specified year ready for formatting (similar to `yeardatescalendar()`). Entries in the week lists are tuples of day numbers and weekday numbers. Day numbers outside this month are zero.

**yeardayscalendar**(year, width=3)

Return the data for the specified year ready for formatting (similar to `yeardatescalendar()`). Entries in the week lists are day numbers. Day numbers outside this month are zero.

**class** calendar. **TextCalendar**(firstweekday=0)

This class can be used to generate plain text calendars.

**TextCalendar** instances have the following methods:

**formatmonth**(theyear, themonth, w=0, l=0)

Return a month’s calendar in a multi-line string. If w is provided, it specifies the width of the date columns, which are centered. If l is given, it specifies the number of lines that each week will use. Depends on the first weekday as specified in the constructor or set by the `setfirstweekday()` method.

**prmmonth**(theyear, themonth, w=0, l=0)
Print a month’s calendar as returned by `formatmonth()`.

`formatyear(theyear, w=2, l=1, c=6, m=3)`
Return a \( m \)-column calendar for an entire year as a multi-line string. Optional parameters \( w \), \( l \), and \( c \) are for date column width, lines per week, and number of spaces between month columns, respectively. Depends on the first weekday as specified in the constructor or set by the `setfirstweekday()` method. The earliest year for which a calendar can be generated is platform-dependent.

`pryear(theyear, w=2, l=1, c=6, m=3)`
Print the calendar for an entire year as returned by `formatyear()`.

_class calendar_. **HTMLCalendar**(firstweekday=0)
This class can be used to generate HTML calendars.

**HTMLCalendar** instances have the following methods:

`formatmonth(theyear, themonth, withyear=True)`
Return a month's calendar as an HTML table. If `withyear` is true the year will be included in the header, otherwise just the month name will be used.

`formatyear(theyear, width=3)`
Return a year’s calendar as an HTML table. `width` (defaulting to 3) specifies the number of months per row.

`formatyearpage(theyear, width=3, css='calendar.css', encoding=None)`
Return a year’s calendar as a complete HTML page. `width` (defaulting to 3) specifies the number of months per row. `css` is
the name for the cascading style sheet to be used. None can be passed if no style sheet should be used. encoding specifies the encoding to be used for the output (defaulting to the system default encoding).

```python
class calendar.LocaleTextCalendar(firstweekday=0, locale=None)
```

This subclass of TextCalendar can be passed a locale name in the constructor and will return month and weekday names in the specified locale. If this locale includes an encoding all strings containing month and weekday names will be returned as unicode.

```python
class calendar.LocaleHTMLCalendar(firstweekday=0, locale=None)
```

This subclass of HTMLCalendar can be passed a locale name in the constructor and will return month and weekday names in the specified locale. If this locale includes an encoding all strings containing month and weekday names will be returned as unicode.

**Note:** The formatweekday() and formatmonthname() methods of these two classes temporarily change the current locale to the given locale. Because the current locale is a process-wide setting, they are not thread-safe.

For simple text calendars this module provides the following functions.

```python
calendar.setfirstweekday(weekday)
```

Sets the weekday (0 is Monday, 6 is Sunday) to start each week. The values MONDAY, TUESDAY, WEDNESDAY, THURSDAY, FRIDAY, SATURDAY, and SUNDAY are provided for convenience. For example, to set the first weekday to Sunday:
import calendar

calendar.setfirstweekday(calendar.SUNDAY)

calendar.firstweekday()
    Returns the current setting for the weekday to start each week.

calendar.isleap(year)
    Returns True if year is a leap year, otherwise False.

calendar.leapdays(y1, y2)
    Returns the number of leap years in the range from y1 to y2 (exclusive), where y1 and y2 are years.

    This function works for ranges spanning a century change.

calendar.weekday(year, month, day)
    Returns the day of the week (0 is Monday) for year (1970—...), month (1–12), day (1–31).

calendar.weekheader(n)
    Return a header containing abbreviated weekday names. n specifies the width in characters for one weekday.

calendar.monthrange(year, month)
    Returns weekday of first day of the month and number of days in month, for the specified year and month.

calendar.monthcalendar(year, month)
    Returns a matrix representing a month’s calendar. Each row represents a week; days outside of the month are represented by zeros. Each week begins with Monday unless set by setfirstweekday().
calendar.prmonth(theyear, themonth, w=0, l=0)

Prints a month’s calendar as returned by month().

calendar.month(theyear, themonth, w=0, l=0)

Returns a month’s calendar in a multi-line string using the formatmonth() of the TextCalendar class.

calendar.prcal(year, w=0, l=0, c=6, m=3)

Prints the calendar for an entire year as returned by calendar().

calendar.calendar(year, w=2, l=1, c=6, m=3)

Returns a 3-column calendar for an entire year as a multi-line string using the formatyear() of the TextCalendar class.

calendar.timegm(tuple)

An unrelated but handy function that takes a time tuple such as returned by the gmtime() function in the time module, and returns the corresponding Unix timestamp value, assuming an epoch of 1970, and the POSIX encoding. In fact, time.gmtime() and timegm() are each others’ inverse.

The calendar module exports the following data attributes:

calendar.day_name

An array that represents the days of the week in the current locale.

calendar.day_abbr

An array that represents the abbreviated days of the week in the current locale.

calendar.month_name

An array that represents the months of the year in the current locale.
locale. This follows normal convention of January being month number 1, so it has a length of 13 and `month_name[0]` is the empty string.

**calendar.month_abbr**

An array that represents the abbreviated months of the year in the current locale. This follows normal convention of January being month number 1, so it has a length of 13 and `month_abbr[0]` is the empty string.

*Changed in version 3.3:* Moved `Collections Abstract Base Classes` to
the `collections.abc` module. For backwards compatibility, they continue to be visible in this module as well.
8.3.1. **ChainMap** objects

*New in version 3.3.*

A **ChainMap** class is provided for quickly linking a number of mappings so they can be treated as a single unit. It is often much faster than creating a new dictionary and running multiple `update()` calls.

The class can be used to simulate nested scopes and is useful in templating.

```python
class collections.ChainMap(*maps)
```

A **ChainMap** groups multiple dicts or other mappings together to create a single, updateable view. If no `maps` are specified, a single empty dictionary is provided so that a new chain always has at least one mapping.

The underlying mappings are stored in a list. That list is public and can accessed or updated using the `maps` attribute. There is no other state.

Lookups search the underlying mappings successively until a key is found. In contrast, writes, updates, and deletions only operate on the first mapping.

A **ChainMap** incorporates the underlying mappings by reference. So, if one of the underlying mappings gets updated, those changes will be reflected in **ChainMap**.

All of the usual dictionary methods are supported. In addition, there is a `maps` attribute, a method for creating new subcontexts, and a
property for accessing all but the first mapping:

maps
A user updateable list of mappings. The list is ordered from first-searched to last-searched. It is the only stored state and can be modified to change which mappings are searched. The list should always contain at least one mapping.

new_child()
Returns a new ChainMap containing a new dict followed by all of the maps in the current instance. A call to d.new_child() is equivalent to: ChainMap({}, *d.maps). This method is used for creating subcontexts that can be updated without altering values in any of the parent mappings.

parents
Property returning a new ChainMap containing all of the maps in the current instance except the first one. This is useful for skipping the first map in the search. Use cases are similar to those for the nonlocal keyword used in nested scopes. The use cases also parallel those for the built-in super() function. A reference to d.parents is equivalent to: ChainMap(*d.maps[1:]).

See also:
- The MultiContext class in the Enthought CodeTools package has options to support writing to any mapping in the chain.
- Django’s Context class for templating is a read-only chain of mappings. It also features pushing and popping of contexts similar to the new_child() method and the parents()
property.
- The **Nested Contexts recipe** has options to control whether writes and other mutations apply only to the first mapping or to any mapping in the chain.
- A greatly simplified read-only version of Chainmap.

### 8.3.1.1. ChainMap Examples and Recipes

This section shows various approaches to working with chained maps.

Example of simulating Python’s internal lookup chain:

```python
import builtins
pylookup = ChainMap(locals(), globals(), vars(builtins))
```

Example of letting user specified command-line arguments take precedence over environment variables which in turn take precedence over default values:

```python
import os, argparse
defaults = {'color': 'red', 'user': 'guest'}
parser = argparse.ArgumentParser()
parsed = parser.parse_args()
parsed.add_argument('-u', '--user')
parsed.add_argument('-c', '--color')
namespace = parser.parse_args()
command_line_args = {k:v for k, v in vars(namespace)}
combined = ChainMap(command_line_args, os.environ, defaults)
print(combined['color'])
print(combined['user'])
```
Example patterns for using the `ChainMap` class to simulate nested contexts:

```python
C = ChainMap()  # Create root context
d = C.new_child()  # Create nested child context
e = C.new_child()  # Child of C, independent from C

C.maps[0]  # Current context dictionary -- like Python's locals()
C.maps[-1]  # Root context -- like Python's globals()
C.parents  # Enclosing context chain -- like Python's nonlocals

d['x']  # Get first key in the chain of contexts
C['x'] = 1  # Set value in current context
C.delitem('x')  # Delete from current context
list(C['x'])  # All nested values
k in d  # Check all nested values
len(d)  # Number of nested values
d.items()  # All nested items
dict(d)  # Flatten into a regular dictionary
```

The `ChainMap` class only makes updates (writes and deletions) to the first mapping in the chain while lookups will search the full chain. However, if deep writes and deletions are desired, it is easy to make a subclass that updates keys found deeper in the chain:

```python
class DeepChainMap(ChainMap):
    'Variant of ChainMap that allows direct updates to inner scopes'

    def __setitem__(self, key, value):
        for mapping in self.maps:
            if key in mapping:
                mapping[key] = value
        return self.maps[0][key] = value

    def __delitem__(self, key):
```

for mapping in self.maps:
    if key in mapping:
        del mapping[key]
    return
raise KeyError(key)

>>> d = DeepChainMap({'zebra': 'black'}, {'elephant': 'gray'})
>>> d['lion'] = 'orange'  # update an existing key
>>> d['snake'] = 'red'    # new keys get added to the topmost dict
>>> del d['elephant']    # remove an existing key
DeepChainMap({'zebra': 'black', 'snake': 'red'}, {})
8.3.2. **Counter** objects

A counter tool is provided to support convenient and rapid tallies. For example:

```python
>>> # Tally occurrences of words in a list
>>> cnt = Counter()
>>> for word in ['red', 'blue', 'red', 'green', 'blue', ...
...     cnt[word] += 1
>>> cnt
Counter({'blue': 3, 'red': 2, 'green': 1})

>>> # Find the ten most common words in Hamlet
>>> import re
>>> words = re.findall(r'\w+', open('hamlet.txt').read())
>>> Counter(words).most_common(10)
[('the', 1143), ('and', 966), ('to', 762), ('of', 661), ('you', 554), ('a', 546), ('my', 514), ('hamlet', 471), ('in', 451), ('is', 447)]
```

**class collections.Counter([iterable-or-mapping])**

A **Counter** is a **dict** subclass for counting hashable objects. It is an unordered collection where elements are stored as dictionary keys and their counts are stored as dictionary values. Counts are allowed to be any integer value including zero or negative counts. The **Counter** class is similar to bags or multisets in other languages.

Elements are counted from an **iterable** or initialized from another **mapping** (or counter):

```python
>>> c = Counter() # a new, empty counter
>>> c = Counter('gallahad') # a new counter from an iterable
```
Counter objects have a dictionary interface except that they return a zero count for missing items instead of raising a `KeyError`:

```python
>>> c = Counter({'red': 4, 'blue': 2})  # a new counter from a mapping
>>> c = Counter(cats=4, dogs=8)  # a new counter from keyword args
```

Setting a count to zero does not remove an element from a counter. Use `del` to remove it entirely:

```python
>>> c['eggs', 'ham']
>>> c['bacon']
0
```

```
New in version 3.1.

Counter objects support three methods beyond those available for all dictionaries:

**elements()**

Return an iterator over elements repeating each as many times as its count. Elements are returned in arbitrary order. If an element’s count is less than one, `elements()` will ignore it.

```python
>>> c = Counter(a=4, b=2, c=0, d=-2)
>>> list(c.elements())
['a', 'a', 'a', 'a', 'b', 'b']
```

**most_common([n])**

Return a list of the `n` most common elements and their counts
from the most common to the least. If \( n \) is not specified, \texttt{most\_common()} returns all elements in the counter. Elements with equal counts are ordered arbitrarily:

```python
>>> Counter('abracadabra').most_common(3)
[('a', 5), ('r', 2), ('b', 2)]
```

\texttt{subtract([iterable-or-mapping])}

Elements are subtracted from an \textit{iterable} or from another \textit{mapping} (or counter). Like \texttt{dict.update()} but subtracts counts instead of replacing them. Both inputs and outputs may be zero or negative.

```python
>>> c = Counter(a=4, b=2, c=0, d=-2)
>>> d = Counter(a=1, b=2, c=3, d=4)
>>> c.subtract(d)
>>> c
Counter({'a': 3, 'b': 0, 'c': -3, 'd': -6})
```

\textit{New in version 3.2.}

The usual dictionary methods are available for \texttt{Counter} objects except for two which work differently for counters.

\texttt{fromkeys(iterable)}

This class method is not implemented for \texttt{Counter} objects.

\texttt{update([iterable-or-mapping])}

Elements are counted from an \textit{iterable} or added-in from another \textit{mapping} (or counter). Like \texttt{dict.update()} but adds counts instead of replacing them. Also, the \textit{iterable} is expected to be a sequence of elements, not a sequence of (key, value) pairs.
Common patterns for working with `Counter` objects:

```python
sum(c.values())  # total of all counts
```
```
c.clear()  # reset all counts
```
```
list(c)  # list unique elements
```
```
set(c)  # convert to a set
```
```
dict(c)  # convert to a regular dictionary
```
```
c.items()  # convert to a list of (elem, cnt) pairs
```
```
Counter(dict(list_of_pairs))  # convert from a list of (elem, cnt) pairs
```
```
c.most_common()[:n-1:-1]  # n least common elements
```
```
+c  # remove zero and negative counts
```
```
```
Several mathematical operations are provided for combining `Counter` objects to produce multisets (counters that have counts greater than zero). Addition and subtraction combine counters by adding or subtracting the counts of corresponding elements. Intersection and union return the minimum and maximum of corresponding counts. Each operation can accept inputs with signed counts, but the output will exclude results with counts of zero or less.

```python
>>> c = Counter(a=3, b=1)
>>> d = Counter(a=1, b=2)
>>> c + d  # add two counters together
Counter({'a': 4, 'b': 3})
```
```
>>> c - d  # subtract (keeping only positive counts)
Counter({'a': 2})
```
```
>>> c & d  # intersection: min counts
Counter({'a': 1, 'b': 1})
```
```
>>> c | d  # union: max(c[x], d[x])
Counter({'a': 3, 'b': 2})
```
```
Unary addition and substraction are shortcuts for adding an empty counter or subtracting from an empty counter.
```
>>> c = Counter(a=2, b=-4)
>>> +c
Counter({'a': 2})
>>> -c
Counter({'b': 4})

New in version 3.3: Added support for unary plus, unary minus, and in-place multiset operations.

**Note:** Counters were primarily designed to work with positive integers to represent running counts; however, care was taken to not unnecessarily preclude use cases needing other types or negative values. To help with those use cases, this section documents the minimum range and type restrictions.

- The `Counter` class itself is a dictionary subclass with no restrictions on its keys and values. The values are intended to be numbers representing counts, but you *could* store anything in the value field.
- The `most_common()` method requires only that the values be orderable.
- For in-place operations such as `c[key] += 1`, the value type need only support addition and subtraction. So fractions, floats, and decimals would work and negative values are supported. The same is also true for `update()` and `subtract()` which allow negative and zero values for both inputs and outputs.
- The multiset methods are designed only for use cases with positive values. The inputs may be negative or zero, but only outputs with positive values are created. There are no type restrictions, but the value type needs to support addition, subtraction, and comparison.
- The `elements()` method requires integer counts. It ignores zero and negative counts.

    ```python
    map(Counter, combinations_with_replacement('ABC', 2)) –>
    > AA AB AC BB BC CC
    ```
8.3.3. **deque objects**

```python
class collections.deque([iterable[, maxlen]])
```

Returns a new deque object initialized left-to-right (using `append()`) with data from `iterable`. If `iterable` is not specified, the new deque is empty.

Deques are a generalization of stacks and queues (the name is pronounced “deck” and is short for “double-ended queue”). Deques support thread-safe, memory efficient appends and pops from either side of the deque with approximately the same O(1) performance in either direction.

Though `list` objects support similar operations, they are optimized for fast fixed-length operations and incur O(n) memory movement costs for `pop(0)` and `insert(0, v)` operations which change both the size and position of the underlying data representation.

If `maxlen` is not specified or is `None`, deques may grow to an arbitrary length. Otherwise, the deque is bounded to the specified maximum length. Once a bounded length deque is full, when new items are added, a corresponding number of items are discarded from the opposite end. Bounded length deques provide functionality similar to the `tail` filter in Unix. They are also useful for tracking transactions and other pools of data where only the most recent activity is of interest.

Deque objects support the following methods:

```python
append(x)
```
Add $x$ to the right side of the deque.

**appendleft**($x$)
Add $x$ to the left side of the deque.

**clear**()
Remove all elements from the deque leaving it with length 0.

**count**($x$)
Count the number of deque elements equal to $x$.

*New in version 3.2.*

**extend**(*iterable*)
Extend the right side of the deque by appending elements from the iterable argument.

**extendleft**(*iterable*)
Extend the left side of the deque by appending elements from *iterable*. Note, the series of left appends results in reversing the order of elements in the iterable argument.

**pop**()
Remove and return an element from the right side of the deque. If no elements are present, raises an **IndexError**.

**popleft**()
Remove and return an element from the left side of the deque. If no elements are present, raises an **IndexError**.

**remove**(*value*)
Removed the first occurrence of *value*. If not found, raises a **ValueError**.
reverse()
Reverse the elements of the deque in-place and then return None.

New in version 3.2.

rotate(n)
Rotate the deque n steps to the right. If n is negative, rotate to the left. Rotating one step to the right is equivalent to:
\[ d.appendleft(d.pop()) \]

Deque objects also provide one read-only attribute:

maxlen
Maximum size of a deque or None if unbounded.

New in version 3.1.

In addition to the above, deques support iteration, pickling, \texttt{len(d)}, \texttt{reversed(d)}, \texttt{copy.copy(d)}, \texttt{copy.deepcopy(d)}, membership testing with the \texttt{in} operator, and subscript references such as \texttt{d[-1]}. Indexed access is \(O(1)\) at both ends but slows to \(O(n)\) in the middle. For fast random access, use lists instead.

Example:

```python
>>> from collections import deque
>>> d = deque('ghi') # make a new deque
>>> for elem in d: # iterate over
...   print(elem.upper())
G
H
I
```
>>> d.append('j')  # add a new entry to the deque
>>> d.appendleft('f')  # add a new entry to the left side of the deque
>>> d
deque(['f', 'g', 'h', 'i', 'j'])

>>> d.pop()  # return and remove the rightmost item
'j'

>>> d.popleft()  # return and remove the leftmost item
'f'

>>> list(d)  # list the contents of the deque
['g', 'h', 'i']

>>> d[0]  # peek at leftmost item
'g'

>>> d[-1]  # peek at rightmost item
'i'

>>> list(reversed(d))  # list the contents of the deque in reverse
['i', 'h', 'g']

>>> 'h' in d  # search the deque
True

>>> d.extend('jkl')  # add multiple elements at once

>>> d
deque(['g', 'h', 'i', 'j', 'k', 'l'])

>>> d.rotate(1)  # right rotation

>>> d
deque(['l', 'g', 'h', 'i', 'j', 'k'])

>>> d.rotate(-1)  # left rotation

>>> d
deque(['g', 'h', 'i', 'j', 'k', 'l'])

>>> deque(reversed(d))  # make a new deque in reverse order

Traceback (most recent call last):
  File "<pyshell#6>", line 1, in -toplevel-
  d.pop()

  File "<pyshell#6>", line 1, in -toplevel-
    d.pop()
8.3.3.1. deque Recipes

This section shows various approaches to working with deques.

Bounded length deques provide functionality similar to the `tail` filter in Unix:

```python
def tail(filename, n=10):
    'Return the last n lines of a file'
    with open(filename) as f:
        return deque(f, n)
```

Another approach to using deques is to maintain a sequence of recently added elements by appending to the right and popping to the left:

```python
def moving_average(iterable, n=3):
    # moving_average([40, 30, 50, 46, 39, 44]) --> 4
    # http://en.wikipedia.org/wiki/Moving_average
    it = iter(iterable)
    d = deque(itertools.islice(it, n-1))
    d.appendleft(0)
    s = sum(d)
    for elem in it:
        s += elem - d.popleft()
        d.append(elem)
        yield s / n
```
The `rotate()` method provides a way to implement *deque* slicing and deletion. For example, a pure Python implementation of `del d[n]` relies on the `rotate()` method to position elements to be popped:

```python
def delete_nth(d, n):
    d.rotate(-n)
    d.popleft()
    d.rotate(n)
```

To implement *deque* slicing, use a similar approach applying `rotate()` to bring a target element to the left side of the deque. Remove old entries with `popleft()`, add new entries with `extend()`, and then reverse the rotation. With minor variations on that approach, it is easy to implement Forth style stack manipulations such as `dup`, `drop`, `swap`, `over`, `pick`, `rot`, and `roll`.
8.3.4. defaultdict objects

```
class collections.defaultdict([default_factory[,...]])
```

Returns a new dictionary-like object. defaultdict is a subclass of the built-in dict class. It overrides one method and adds one writable instance variable. The remaining functionality is the same as for the dict class and is not documented here.

The first argument provides the initial value for the default_factory attribute; it defaults to None. All remaining arguments are treated the same as if they were passed to the dict constructor, including keyword arguments.

defaultdict objects support the following method in addition to the standard dict operations:

```
defaultdict.__missing__(key)
```

If the default_factory attribute is None, this raises a KeyError exception with the key as argument.

If default_factory is not None, it is called without arguments to provide a default value for the given key, this value is inserted in the dictionary for the key, and returned.

If calling default_factory raises an exception this exception is propagated unchanged.

This method is called by the __getitem__() method of the dict class when the requested key is not found; whatever it returns or raises is then returned or raised by __getitem__().
Note that \_\_missing\_\() is not called for any operations besides \_\_getitem\_\(\). This means that \texttt{get()} will, like normal dictionaries, return None as a default rather than using \texttt{default\_factory}.

\texttt{defaultdict} objects support the following instance variable:

\textbf{default\_factory}

This attribute is used by the \_\_missing\_\() method; it is initialized from the first argument to the constructor, if present, or to None, if absent.

\subsection*{8.3.4.1. defaultdict Examples}

Using \texttt{list} as the \texttt{default\_factory}, it is easy to group a sequence of key-value pairs into a dictionary of lists:

\begin{verbatim}
>>> s = [('yellow', 1), ('blue', 2), ('yellow', 3),
      >>> d = defaultdict(list)
      >>> for k, v in s:
        ...   d[k].append(v)
        ...
      >>> list(d.items())
    [('blue', [2, 4]), ('red', [1]), ('yellow', [1, 3])]
\end{verbatim}

When each key is encountered for the first time, it is not already in the mapping; so an entry is automatically created using the \texttt{default\_factory} function which returns an empty \texttt{list}. The \texttt{list.append()} operation then attaches the value to the new list. When keys are encountered again, the look-up proceeds normally (returning the list for that key) and the \texttt{list.append()} operation adds another value to the list. This technique is simpler and faster than
an equivalent technique using `dict.setdefault()`:

```python
>>> d = {}
>>> for k, v in s:
...     d.setdefault(k, []).append(v)
...
>>> list(d.items())
[['blue', [2, 4]], ['red', [1]], ['yellow', [1, 3]]]
```

Setting the `default_factory` to `int` makes the `defaultdict` useful for counting (like a bag or multiset in other languages):

```python
>>> s = 'mississippi'
>>> d = defaultdict(int)
>>> for k in s:
...     d[k] += 1
...
>>> list(d.items())
[('i', 4), ('p', 2), ('s', 4), ('m', 1)]
```

When a letter is first encountered, it is missing from the mapping, so the `default_factory` function calls `int()` to supply a default count of zero. The increment operation then builds up the count for each letter.

The function `int()` which always returns zero is just a special case of constant functions. A faster and more flexible way to create constant functions is to use a lambda function which can supply any constant value (not just zero):

```python
>>> def constant_factory(value):
...     return lambda: value
...
>>> d = defaultdict(constant_factory('<missing>'))
>>> d.update(name='John', action='ran')
```
Setting the `default_factory` to `set` makes the `defaultdict` useful for building a dictionary of sets:

```python
>>> s = [('red', 1), ('blue', 2), ('red', 3), ('blue', 4)]
>>> d = defaultdict(set)
>>> for k, v in s:
...     d[k].add(v)
... 
>>> list(d.items())
[('blue', {2, 4}), ('red', {1, 3})]
```
8.3.5. `namedtuple()` Factory Function for Tuples with Named Fields

Named tuples assign meaning to each position in a tuple and allow for more readable, self-documenting code. They can be used wherever regular tuples are used, and they add the ability to access fields by name instead of position index.

```python
collections.namedtuple(typename, field_names, verbose=False, rename=False)
```

Returns a new tuple subclass named `typename`. The new subclass is used to create tuple-like objects that have fields accessible by attribute lookup as well as being indexable and iterable. Instances of the subclass also have a helpful docstring (with typename and field_names) and a helpful `__repr__()` method which lists the tuple contents in a `name=value` format.

The `field_names` are a single string with each fieldname separated by whitespace and/or commas, for example `'x y'` or `'x, y'`. Alternatively, `field_names` can be a sequence of strings such as `['x', 'y']`.

Any valid Python identifier may be used for a fieldname except for names starting with an underscore. Valid identifiers consist of letters, digits, and underscores but do not start with a digit or underscore and cannot be a keyword such as `class`, `for`, `return`, `global`, `pass`, or `raise`.

If `rename` is true, invalid fieldnames are automatically replaced with positional names. For example, `['abc', 'def', 'ghi', 'abc']` is converted to `['abc', '_1', 'ghi', '_3']`. 
eliminating the keyword `def` and the duplicate fieldname `abc`.

If `verbose` is true, the class definition is printed after it is built. This option is outdated; instead, it is simpler to print the `_source` attribute.

Named tuple instances do not have per-instance dictionaries, so they are lightweight and require no more memory than regular tuples.

*Changed in version 3.1*: Added support for `rename`.

```python
>>> # Basic example
>>> Point = namedtuple('Point', ['x', 'y'])
>>> p = Point(11, y=22)        # instantiate with positional arguments
>>> p[0] + p[1]               # indexable like the plain tuple (11, 22)
33
>>> x, y = p                  # unpack like a regular tuple
>>> x, y
(11, 22)
>>> p.x + p.y                # fields also accessible by name
33
>>> p                      # readable __repr__ with values
Point(x=11, y=22)
```

Named tuples are especially useful for assigning field names to result tuples returned by the `csv` or `sqlite3` modules:

```python
EmployeeRecord = namedtuple('EmployeeRecord', 'name, age, title, department, paygrade')

import csv
for emp in map(EmployeeRecord._make, csv.reader(open(...))):
    print(emp.name, emp.title)

import sqlite3
```
conn = sqlite3.connect('/companydata')
cursor = conn.cursor()
cursor.execute('SELECT name, age, title, department, paygrade FROM employees')
for emp in map(EmployeeRecord._make, cursor.fetchall):
    print(emp.name, emp.title)

In addition to the methods inherited from tuples, named tuples support three additional methods and two attributes. To prevent conflicts with field names, the method and attribute names start with an underscore.

```
classmethod somenamedtuple._make(iterable)
```

Class method that makes a new instance from an existing sequence or iterable.

```
>>> t = [11, 22]
>>> Point._make(t)
Point(x=11, y=22)
```

```
somenamedtuple._asdict()
```

Return a new OrderedDict which maps field names to their corresponding values. Note, this method is no longer needed now that the same effect can be achieved by using the built-in vars() function:

```
>>> vars(p)
OrderedDict([('x', 11), ('y', 22)])
```

*Changed in version 3.1:* Returns an OrderedDict instead of a regular dict.

```
somenamedtuple._replace(kwargs)
```

Return a new instance of the named tuple replacing specified fields with new values:
>>> p = Point(x=11, y=22)
>>> p._replace(x=33)
Point(x=33, y=22)

>>> for partnum, record in inventory.items():
...     inventory[partnum] = record._replace(price=somenamedtuple._source)

somenamedtuple._source
A string with the pure Python source code used to create the
typed tuple class. The source makes the typed tuple self-
documenting. It can be printed, executed using exec(), or saved
to a file and imported.

New in version 3.3.

somenamedtuple._fields
Tuple of strings listing the field names. Useful for introspection and
for creating new named tuple types from existing named tuples.

>>> p._fields
('x', 'y')

>>> Color = namedtuple('Color', 'red green blue')
>>> Pixel = namedtuple('Pixel', Point._fields + Color._fields)
>>> Pixel(11, 22, 128, 255, 0)
Pixel(x=11, y=22, red=128, green=255, blue=0)

To retrieve a field whose name is stored in a string, use the
getattr() function:

>>> getattr(p, 'x')
11
To convert a dictionary to a named tuple, use the double-star-operator (as described in *Unpacking Argument Lists*):

```python
>>> d = {'x': 11, 'y': 22}
>>> Point(**d)
Point(x=11, y=22)
```

Since a named tuple is a regular Python class, it is easy to add or change functionality with a subclass. Here is how to add a calculated field and a fixed-width print format:

```python
>>> class Point(namedtuple('Point', 'x y')):
    __slots__ = ()
    @property
    def hypot(self):
        return (self.x ** 2 + self.y ** 2) ** 0.5
    def __str__(self):
        return 'Point: x=%6.3f  y=%6.3f  hypot=%6.3f'

>>> for p in Point(3, 4), Point(14, 5/7):
    print(p)
Point:  x= 3.000  y= 4.000  hypot= 5.000
Point:  x=14.000  y= 0.714  hypot=14.018
```

The subclass shown above sets `__slots__` to an empty tuple. This helps keep memory requirements low by preventing the creation of instance dictionaries.

Subclassing is not useful for adding new, stored fields. Instead, simply create a new named tuple type from the `_fields` attribute:

```python
>>> Point3D = namedtuple('Point3D', Point._fields + ['z'])
```
Default values can be implemented by using \_replace() to customize a prototype instance:

```python
>>> Account = namedtuple('Account', 'owner balance transaction_count')
>>> default_account = Account('<owner name>', 0.0, 0)
>>> johns_account = default_account._replace(owner='John')
>>> janes_account = default_account._replace(owner='Jane')
```

Enumerated constants can be implemented with named tuples, but it is simpler and more efficient to use a simple class declaration:

```python
>>> Status = namedtuple('Status', 'open pending closed')
>>> Status.open, Status.pending, Status.closed = (0, 1, 2)
>>> class Status:
...     open, pending, closed = range(3)
```

See also:

- [Named tuple recipe](#) adapted for Python 2.4.
- Recipe for named tuple abstract base class with a metaclass mix-in by Jan Kaliszewski. Besides providing an abstract base class for named tuples, it also supports an alternate metaclass-based constructor that is convenient for use cases where named tuples are being subclassed.
8.3.6. **OrderedDict** objects

Ordered dictionaries are just like regular dictionaries but they remember the order that items were inserted. When iterating over an ordered dictionary, the items are returned in the order their keys were first added.

```python
class collections.OrderedDict([items])
```

Return an instance of a dict subclass, supporting the usual `dict` methods. An `OrderedDict` is a dict that remembers the order that keys were first inserted. If a new entry overwrites an existing entry, the original insertion position is left unchanged. Deleting an entry and reinserting it will move it to the end.

*New in version 3.1.*

**popitem**(last=True)

The `popitem()` method for ordered dictionaries returns and removes a (key, value) pair. The pairs are returned in LIFO order if `last` is true or FIFO order if false.

**move_to_end**(key, last=True)

Move an existing key to either end of an ordered dictionary. The item is moved to the right end if `last` is true (the default) or to the beginning if `last` is false. Raises `KeyError` if the key does not exist:

```python
>>> d = OrderedDict.fromkeys('abcde')
>>> d.move_to_end('b')
>>> ''.join(d.keys())
'acdeb'
>>> d.move_to_end('b', last=False)
```
In addition to the usual mapping methods, ordered dictionaries also support reverse iteration using `reversed()`.

Equality tests between `OrderedDict` objects are order-sensitive and are implemented as `list(od1.items())==list(od2.items())`. Equality tests between `OrderedDict` objects and other `Mapping` objects are order-insensitive like regular dictionaries. This allows `OrderedDict` objects to be substituted anywhere a regular dictionary is used.

The `OrderedDict` constructor and update() method both accept keyword arguments, but their order is lost because Python’s function call semantics pass-in keyword arguments using a regular unordered dictionary.

See also: Equivalent `OrderedDict` recipe that runs on Python 2.4 or later.

8.3.6.1. `OrderedDict` Examples and Recipes

Since an ordered dictionary remembers its insertion order, it can be used in conjunction with sorting to make a sorted dictionary:

```python
>>> # regular unsorted dictionary
>>> d = {'banana': 3, 'apple': 4, 'pear': 1, 'orange': 2}

>>> # dictionary sorted by key
>>> OrderedDict(sorted(d.items(), key=lambda t: t[0]))
```
OrderedDict([('apple', 4), ('banana', 3), ('orange', 2), ('pear', 1)])

>>> # dictionary sorted by value
>>> OrderedDict(sorted(d.items(), key=lambda t: t[1])
OrderedDict([('pear', 1), ('orange', 2), ('banana', 3), ('apple', 4)])

>>> # dictionary sorted by length of the key string
>>> OrderedDict(sorted(d.items(), key=lambda t: len(t[0])))
OrderedDict([('banana', 3), ('apple', 4), ('orange', 2), ('pear', 1)])

The new sorted dictionaries maintain their sort order when entries are deleted. But when new keys are added, the keys are appended to the end and the sort is not maintained.

It is also straight-forward to create an ordered dictionary variant that remembers the order the keys were last inserted. If a new entry overwrites an existing entry, the original insertion position is changed and moved to the end:

class LastUpdatedOrderedDict(OrderedDict):
    'Store items in the order the keys were last added'
    def __setitem__(self, key, value):
        if key in self:
            del self[key]
        OrderedDict.__setitem__(self, key, value)

An ordered dictionary can be combined with the Counter class so that the counter remembers the order elements are first encountered:

class OrderedCounter(Counter, LastUpdatedOrderedDict):
    'Counter that remembers the order elements are first encountered'
    def __repr__(self):
return '%s(%r)' % (self.__class__.__name__,

def __reduce__(self):
    return self.__class__, (OrderedDict(self),)
8.3.7. *UserDict* objects

The class, *UserDict* acts as a wrapper around dictionary objects. The need for this class has been partially supplanted by the ability to subclass directly from *dict*; however, this class can be easier to work with because the underlying dictionary is accessible as an attribute.

```python
class collections.UserDict([initialdata])
```

Class that simulates a dictionary. The instance’s contents are kept in a regular dictionary, which is accessible via the *data* attribute of *UserDict* instances. If *initialdata* is provided, *data* is initialized with its contents; note that a reference to *initialdata* will not be kept, allowing it be used for other purposes.

In addition to supporting the methods and operations of mappings, *UserDict* instances provide the following attribute:

*data*

A real dictionary used to store the contents of the *UserDict* class.
8.3.8. **UserList** objects

This class acts as a wrapper around list objects. It is a useful base class for your own list-like classes which can inherit from them and override existing methods or add new ones. In this way, one can add new behaviors to lists.

The need for this class has been partially supplanted by the ability to subclass directly from `list`; however, this class can be easier to work with because the underlying list is accessible as an attribute.

```python
class collections.UserList(list)
```

Class that simulates a list. The instance's contents are kept in a regular list, which is accessible via the `data` attribute of `UserList` instances. The instance's contents are initially set to a copy of `list`, defaulting to the empty list `[]`. `list` can be any iterable, for example a real Python list or a `UserList` object.

In addition to supporting the methods and operations of mutable sequences, `UserList` instances provide the following attribute:

```
data
```

A real `list` object used to store the contents of the `UserList` class.

**Subclassing requirements:** Subclasses of `UserList` are expect to offer a constructor which can be called with either no arguments or one argument. List operations which return a new sequence attempt to create an instance of the actual implementation class. To do so, it assumes that the constructor can be called with a single parameter, which is a sequence object used as a data source.
If a derived class does not wish to comply with this requirement, all of the special methods supported by this class will need to be overridden; please consult the sources for information about the methods which need to be provided in that case.
8.3.9. **UserString** objects

The class, **UserString** acts as a wrapper around string objects. The need for this class has been partially supplanted by the ability to subclass directly from **str**; however, this class can be easier to work with because the underlying string is accessible as an attribute.

```python
class collections.UserString([sequence])
```

Class that simulates a string or a Unicode string object. The instance's content is kept in a regular string object, which is accessible via the data attribute of **UserString** instances. The instance's contents are initially set to a copy of *sequence*. The *sequence* can be an instance of **bytes**, **str**, **UserString** (or a subclass) or an arbitrary sequence which can be converted into a string using the built-in **str()** function.
8.4. collections.abc —
Abstract Base Classes for Containers

New in version 3.3: Formerly, this module was part of the collections module.

Source code: Lib/collections/abc.py

This module provides abstract base classes that can be used to test whether a class provides a particular interface; for example, whether it is hashable or whether it is a mapping.
### 8.4.1. Collections Abstract Base Classes

The collections module offers the following *ABCs*:

<table>
<thead>
<tr>
<th>ABC</th>
<th>Inherits from</th>
<th>Abstract Methods</th>
<th>Mixin M</th>
</tr>
</thead>
<tbody>

</table>
class collections.abc.Container
class collections.abc.Hashable
class collections.abc.Sized
class collections.abc.Callable

ABCs for classes that provide respectively the methods __contains__(), __hash__(), __len__(), and __call__().

class collections.abc.Iterable

ABC for classes that provide the __iter__() method. See also the definition of iterable.

class collections.abc.Iterator

ABC for classes that provide the __iter__() and __next__() methods. See also the definition of iterator.

class collections.abc.Sequence
class collections.abc.MutableSequence

ABCs for read-only and mutable sequences.

class collections.abc.Set
class collections.abc.MutableSet

ABCs for read-only and mutable sets.

class collections.abc.Mapping
class collections.abc.MutableMapping

ABCs for read-only and mutable mappings.

class collections.abc.MappingView
class collections.abc.ItemsView
class collections.abc.KeysView
class collections.abc.ValuesView

ABCs for mapping, items, keys, and values views.
These ABCs allow us to ask classes or instances if they provide particular functionality, for example:

```python
def __init__(self, iterable):
    self.elements = lst = []
    for value in iterable:
        if value not in lst:
            lst.append(value)

def __and__(self):
    return iter(self.elements)
```

Several of the ABCs are also useful as mixins that make it easier to develop classes supporting container APIs. For example, to write a class supporting the full `Set` API, it only necessary to supply the three underlying abstract methods: `__contains__()`, `__iter__()`, and `__len__()`. The ABC supplies the remaining methods such as `__and__()` and `isdisjoint()`:

```python
class ListBasedSet(collections.abc.Set):
    """Alternate set implementation favoring space and not requiring the set elements to be hashable."
    def __init__(self, iterable):
        self.elements = lst = []
        for value in iterable:
            if value not in lst:
                lst.append(value)
    def __iter__(self):
        return iter(self.elements)
    def __contains__(self, value):
        return value in self.elements
    def __len__(self):
        return len(self.elements)
```

s1 = ListBasedSet('abcdef')
s2 = ListBasedSet('defghi')
overlap = s1 & s2  # The __and__() method

```

Notes on using `Set` and `MutableSet` as a mixin:
1. Since some set operations create new sets, the default mixin methods need a way to create new instances from an iterable. The class constructor is assumed to have a signature in the form `ClassName(iterable)`. That assumption is factored-out to an internal classmethod called `_from_iterable()` which calls `cls(iterable)` to produce a new set. If the `Set` mixin is being used in a class with a different constructor signature, you will need to override `_from_iterable()` with a classmethod that can construct new instances from an iterable argument.

2. To override the comparisons (presumably for speed, as the semantics are fixed), redefine `__le__()` and then the other operations will automatically follow suit.

3. The `Set` mixin provides a `_hash()` method to compute a hash value for the set; however, `__hash__()` is not defined because not all sets are hashable or immutable. To add set hashability using mixins, inherit from both `Set()` and `Hashable()`, then define `__hash__ = Set._hash`.

See also:

- **OrderedSet recipe** for an example built on `MutableSet`.
- For more about ABCs, see the `abc` module and [PEP 3119](https://www.python.org/dev/peps/pep-0319/).
This module provides an implementation of the heap queue algorithm, also known as the priority queue algorithm.

Heaps are binary trees for which every parent node has a value less than or equal to any of its children. This implementation uses arrays for which \( \text{heap}[k] \leq \text{heap}[2*k+1] \) and \( \text{heap}[k] \leq \text{heap}[2*k+2] \) for all \( k \), counting elements from zero. For the sake of comparison, non-existing elements are considered to be infinite. The interesting property of a heap is that its smallest element is always the root, \( \text{heap}[0] \).

The API below differs from textbook heap algorithms in two aspects: (a) We use zero-based indexing. This makes the relationship between the index for a node and the indexes for its children slightly less obvious, but is more suitable since Python uses zero-based indexing. (b) Our \text{pop} \ method returns the smallest item, not the largest (called a “min heap” in textbooks; a “max heap” is more common in texts because of its suitability for in-place sorting).

These two make it possible to view the heap as a regular Python list without surprises: \( \text{heap}[0] \) is the smallest item, and \text{heap.sort()} maintains the heap invariant!

To create a heap, use a list initialized to [], or you can transform a populated list into a heap via function \text{heapify()}.
The following functions are provided:

heapq. **heappush**(heap, item)

Push the value item onto the heap, maintaining the heap invariant.

heapq. **heappop**(heap)

Pop and return the smallest item from the heap, maintaining the heap invariant. If the heap is empty, `IndexError` is raised.

heapq. **heappushpop**(heap, item)

Push item on the heap, then pop and return the smallest item from the heap. The combined action runs more efficiently than `heappush()` followed by a separate call to `heappop()`.

heapq. **heapify**(x)

Transform list x into a heap, in-place, in linear time.

heapq. **heappreplace**(heap, item)

Pop and return the smallest item from the heap, and also push the new item. The heap size doesn’t change. If the heap is empty, `IndexError` is raised.

This one step operation is more efficient than a `heappop()` followed by `heappush()` and can be more appropriate when using a fixed-size heap. The pop/push combination always returns an element from the heap and replaces it with item.

The value returned may be larger than the item added. If that isn’t desired, consider using `heappushpop()` instead. Its push/pop combination returns the smaller of the two values, leaving the larger value on the heap.

The module also offers three general purpose functions based on
heaps.

heapq. **merge(***iterables*)**

Merge multiple sorted inputs into a single sorted output (for example, merge timestamped entries from multiple log files). Returns an *iterator* over the sorted values.

Similar to `sorted(itertools.chain(*iterables))` but returns an iterable, does not pull the data into memory all at once, and assumes that each of the input streams is already sorted (smallest to largest).

heapq. **nlargest(**n, iterable, key=None*)**

Return a list with the *n* largest elements from the dataset defined by *iterable*. *key*, if provided, specifies a function of one argument that is used to extract a comparison key from each element in the iterable: `key=str.lower` Equivalent to: `sorted(iterable, key=key, reverse=True)[:n]`

heapq. **nsmallest(**n, iterable, key=None*)**

Return a list with the *n* smallest elements from the dataset defined by *iterable*. *key*, if provided, specifies a function of one argument that is used to extract a comparison key from each element in the iterable: `key=str.lower` Equivalent to: `sorted(iterable, key=key)[:n]`

The latter two functions perform best for smaller values of *n*. For larger values, it is more efficient to use the `sorted()` function. Also, when *n==1*, it is more efficient to use the built-in `min()` and `max()` functions.
8.5.1. Basic Examples

A heapsort can be implemented by pushing all values onto a heap and then popping off the smallest values one at a time:

```python
def heapsort(iterable):
    'Equivalent to sorted(iterable)'
    h = []
    for value in iterable:
        heappush(h, value)
    return [heappop(h) for i in range(len(h))]

>>> heapsort([1, 3, 5, 7, 9, 2, 4, 6, 8, 0])
[0, 1, 2, 3, 4, 5, 6, 7, 8, 9]
```

Heap elements can be tuples. This is useful for assigning comparison values (such as task priorities) alongside the main record being tracked:

```python
>>> h = []
>>> heappush(h, (5, 'write code'))
>>> heappush(h, (7, 'release product'))
>>> heappush(h, (1, 'write spec'))
>>> heappush(h, (3, 'create tests'))
>>> heappop(h)
(1, 'write spec')
```
8.5.2. Priority Queue Implementation

Notes

A priority queue is common use for a heap, and it presents several implementation challenges:

- Sort stability: how do you get two tasks with equal priorities to be returned in the order they were originally added?
- Tuple comparison breaks for (priority, task) pairs if the priorities are equal and the tasks do not have a default comparison order.
- If the priority of a task changes, how do you move it to a new position in the heap?
- Or if a pending task needs to be deleted, how do you find it and remove it from the queue?

A solution to the first two challenges is to store entries as 3-element list including the priority, an entry count, and the task. The entry count serves as a tie-breaker so that two tasks with the same priority are returned in the order they were added. And since no two entry counts are the same, the tuple comparison will never attempt to directly compare two tasks.

The remaining challenges revolve around finding a pending task and making changes to its priority or removing it entirely. Finding a task can be done with a dictionary pointing to an entry in the queue.

Removing the entry or changing its priority is more difficult because it would break the heap structure invariants. So, a possible solution is to mark the entry as removed and add a new entry with the revised priority:

```
pq = []  # list of entries arranged in a heap
entry_finder = {}  # mapping of tasks to entries
```
REMOVED = '<removed-task>' # placeholder for a counter
counter = itertools.count() # unique sequence counter

def add_task(task, priority=0):
    'Add a new task or update the priority of an existing task.'
    if task in entry_finder:
        remove_task(task)
    count = next(counter)
    entry = [priority, count, task]
    entry_finder[task] = entry
    heappush(pq, entry)

def remove_task(task):
    'Mark an existing task as REMOVED. Raise KeyError if not found.'
    entry = entry_finder.pop(task)
    entry[-1] = REMOVED

def pop_task():
    'Remove and return the lowest priority task. Raise KeyError if empty.'
    while pq:
        priority, count, task = heappop(pq)
        if task is not REMOVED:
            del entry_finder[task]
            return task
    raise KeyError('pop from an empty priority queue')
8.5.3. Theory

Heaps are arrays for which $a[k] \leq a[2k+1]$ and $a[k] \leq a[2k+2]$ for all $k$, counting elements from 0. For the sake of comparison, non-existing elements are considered to be infinite. The interesting property of a heap is that $a[0]$ is always its smallest element.

The strange invariant above is meant to be an efficient memory representation for a tournament. The numbers below are $k$, not $a[k]:$

In the tree above, each cell $k$ is topping $2k+1$ and $2k+2$. In an usual binary tournament we see in sports, each cell is the winner over the two cells it tops, and we can trace the winner down the tree to see all opponents s/he had. However, in many computer applications of such tournaments, we do not need to trace the history of a winner. To be more memory efficient, when a winner is promoted, we try to replace it by something else at a lower level, and the rule becomes that a cell and the two cells it tops contain three different items, but the top cell “wins” over the two topped cells.

If this heap invariant is protected at all time, index 0 is clearly the
overall winner. The simplest algorithmic way to remove it and find the "next" winner is to move some loser (let’s say cell 30 in the diagram above) into the 0 position, and then percolate this new 0 down the tree, exchanging values, until the invariant is re-established. This is clearly logarithmic on the total number of items in the tree. By iterating over all items, you get an $O(n \log n)$ sort.

A nice feature of this sort is that you can efficiently insert new items while the sort is going on, provided that the inserted items are not “better” than the last 0’th element you extracted. This is especially useful in simulation contexts, where the tree holds all incoming events, and the “win” condition means the smallest scheduled time. When an event schedules other events for execution, they are scheduled into the future, so they can easily go into the heap. So, a heap is a good structure for implementing schedulers (this is what I used for my MIDI sequencer :-).

Various structures for implementing schedulers have been extensively studied, and heaps are good for this, as they are reasonably speedy, the speed is almost constant, and the worst case is not much different than the average case. However, there are other representations which are more efficient overall, yet the worst cases might be terrible.

Heaps are also very useful in big disk sorts. You most probably all know that a big sort implies producing “runs” (which are pre-sorted sequences, which size is usually related to the amount of CPU memory), followed by a merging passes for these runs, which merging is often very cleverly organised [1]. It is very important that the initial sort produces the longest runs possible. Tournaments are a good way to that. If, using all the memory available to hold a tournament, you replace and percolate items that happen to fit the current run, you’ll produce runs which are twice the size of the memory for random input, and much better for input fuzzily ordered.
Moreover, if you output the 0'th item on disk and get an input which may not fit in the current tournament (because the value “wins” over the last output value), it cannot fit in the heap, so the size of the heap decreases. The freed memory could be cleverly reused immediately for progressively building a second heap, which grows at exactly the same rate the first heap is melting. When the first heap completely vanishes, you switch heaps and start a new run. Clever and quite effective!

In a word, heaps are useful memory structures to know. I use them in a few applications, and I think it is good to keep a ‘heap’ module around. :-)

**Footnotes**

The disk balancing algorithms which are current, nowadays, are more annoying than clever, and this is a consequence of the seeking capabilities of the disks. On devices which cannot seek, like big tape drives, the story was quite different, and one had to be very clever to ensure (far in advance) that each tape movement will be the most effective possible (that is, will best participate at “progressing” the merge). Some tapes were even able to read backwards, and this was also used to avoid the rewinding time. Believe me, real good tape sorts were quite spectacular to watch! From all times, sorting has always been a Great Art! :-)
8.6. **bisect** — Array bisection algorithm

**Source code:** Lib/bisect.py

This module provides support for maintaining a list in sorted order without having to sort the list after each insertion. For long lists of items with expensive comparison operations, this can be an improvement over the more common approach. The module is called **bisect** because it uses a basic bisection algorithm to do its work. The source code may be most useful as a working example of the algorithm (the boundary conditions are already right!).

The following functions are provided:

**bisect.bisect_left** *(a, x, lo=0, hi=len(a))*

Locate the insertion point for `x` in `a` to maintain sorted order. The parameters `lo` and `hi` may be used to specify a subset of the list which should be considered; by default the entire list is used. If `x` is already present in `a`, the insertion point will be before (to the left of) any existing entries. The return value is suitable for use as the first parameter to `list.insert()` assuming that `a` is already sorted.

The returned insertion point `i` partitions the array `a` into two halves so that `all(val < x for val in a[lo:i])` for the left side and `all(val >= x for val in a[i:hi])` for the right side.

**bisect.bisect_right** *(a, x, lo=0, hi=len(a))*

Similarly to `bisect_left()`, but returns an insertion point which
comes after (to the right of) any existing entries of $x$ in $a$.

The returned insertion point $i$ partitions the array $a$ into two halves so that all($val \leq x$ for $val$ in $a[lo:i]$) for the left side and all($val > x$ for $val$ in $a[i:hi]$) for the right side.

$\text{bisect.}\text{insort}\_\text{left}(a, x, lo=0, hi=len(a))$

Insert $x$ in $a$ in sorted order. This is equivalent to $a.insert(\text{bisect.}\text{bisect}\_\text{left}(a, x, lo, hi), x)$ assuming that $a$ is already sorted. Keep in mind that the $O(\log n)$ search is dominated by the slow $O(n)$ insertion step.

$\text{bisect.}\text{insort}\_\text{right}(a, x, lo=0, hi=len(a))$

$\text{bisect.}\text{insort}(a, x, lo=0, hi=len(a))$

Similar to $\text{insort}\_\text{left}()$, but inserting $x$ in $a$ after any existing entries of $x$.

**See also:** SortedCollection recipe that uses bisect to build a full-featured collection class with straight-forward search methods and support for a key-function. The keys are precomputed to save unnecessary calls to the key function during searches.
8.6.1. Searching Sorted Lists

The above `bisect()` functions are useful for finding insertion points but can be tricky or awkward to use for common searching tasks. The following five functions show how to transform them into the standard lookups for sorted lists:

```python
def index(a, x):
    'Locate the leftmost value exactly equal to x'
    i = bisect_left(a, x)
    if i != len(a) and a[i] == x:
        return i
    raise ValueError

def find_lt(a, x):
    'Find rightmost value less than x'
    i = bisect_left(a, x)
    if i:
        return a[i-1]
    raise ValueError

def find_le(a, x):
    'Find rightmost value less than or equal to x'
    i = bisect_right(a, x)
    if i:
        return a[i-1]
    raise ValueError

def find_gt(a, x):
    'Find leftmost value greater than x'
    i = bisect_right(a, x)
    if i != len(a):
        return a[i]
    raise ValueError
```
def find_ge(a, x):
    'Find leftmost item greater than or equal to x'
    i = bisect_left(a, x)
    if i != len(a):
        return a[i]
    raise ValueError
8.6.2. Other Examples

The `bisect()` function can be useful for numeric table lookups. This example uses `bisect()` to look up a letter grade for an exam score (say) based on a set of ordered numeric breakpoints: 90 and up is an ‘A’, 80 to 89 is a ‘B’, and so on:

```python
>>> def grade(score, breakpoints=[60, 70, 80, 90], grades=['F', 'D', 'C', 'B', 'A']):
...    i = bisect(breakpoints, score)
...    return grades[i]
...
>>> [grade(score) for score in [33, 99, 77, 70, 89]]
['F', 'A', 'C', 'C', 'B', 'A', 'A']
```

Unlike the `sorted()` function, it does not make sense for the `bisect()` functions to have `key` or `reversed` arguments because that would lead to an inefficient design (successive calls to bisect functions would not “remember” all of the previous key lookups).

Instead, it is better to search a list of precomputed keys to find the index of the record in question:

```python
>>> data = [('red', 5), ('blue', 1), ('yellow', 8),
          ('green', 3), ('black', 0), ('blue', 1), ('red', 5), ('yellow', 8)]
>>> data.sort(key=lambda r: r[1])
>>> keys = [r[1] for r in data] # precompute
>>> data[bisect_left(keys, 0)]
('black', 0)
>>> data[bisect_left(keys, 1)]
('blue', 1)
>>> data[bisect_left(keys, 5)]
('red', 5)
>>> data[bisect_left(keys, 8)]
('yellow', 8)
```
8.7. `array` — Efficient arrays of numeric values

This module defines an object type which can compactly represent an array of basic values: characters, integers, floating point numbers. Arrays are sequence types and behave very much like lists, except that the type of objects stored in them is constrained. The type is specified at object creation time by using a `type code`, which is a single character. The following type codes are defined:

<table>
<thead>
<tr>
<th>Type code</th>
<th>C Type</th>
<th>Python Type</th>
<th>Minimum size in bytes</th>
<th>Notes</th>
</tr>
</thead>
<tbody>
<tr>
<td>'b'</td>
<td>signed char</td>
<td>int</td>
<td>1</td>
<td></td>
</tr>
<tr>
<td>'B'</td>
<td>unsigned char</td>
<td>int</td>
<td>1</td>
<td></td>
</tr>
<tr>
<td>'u'</td>
<td>Py_UNICODE</td>
<td>Unicode character</td>
<td>2</td>
<td>(1)</td>
</tr>
<tr>
<td>'h'</td>
<td>signed short</td>
<td>int</td>
<td>2</td>
<td></td>
</tr>
<tr>
<td>'H'</td>
<td>unsigned short</td>
<td>int</td>
<td>2</td>
<td></td>
</tr>
<tr>
<td>'i'</td>
<td>signed int</td>
<td>int</td>
<td>2</td>
<td></td>
</tr>
<tr>
<td>'I'</td>
<td>unsigned int</td>
<td>int</td>
<td>2</td>
<td></td>
</tr>
<tr>
<td>'l'</td>
<td>signed long</td>
<td>int</td>
<td>4</td>
<td></td>
</tr>
<tr>
<td>'L'</td>
<td>unsigned long</td>
<td>int</td>
<td>4</td>
<td></td>
</tr>
<tr>
<td>'q'</td>
<td>signed long long</td>
<td>int</td>
<td>8</td>
<td>(2)</td>
</tr>
<tr>
<td>'Q'</td>
<td>unsigned long long</td>
<td>int</td>
<td>8</td>
<td>(2)</td>
</tr>
<tr>
<td>'f'</td>
<td>float</td>
<td>float</td>
<td>4</td>
<td></td>
</tr>
</tbody>
</table>
Notes:

1. The \texttt{u} type code corresponds to Python's obsolete unicode character (\texttt{Py_UNICODE} which is wchar\_t). Depending on the platform, it can be 16 bits or 32 bits.

\texttt{u} will be removed together with the rest of the \texttt{Py_UNICODE} API.

\textbf{Deprecated since version 3.3, will be removed in version 4.0.}

2. The \texttt{q} and \texttt{Q} type codes are available only if the platform C compiler used to build Python supports C \texttt{long long}, or, on Windows, \texttt{__int64}.

\textit{New in version 3.3.}

The actual representation of values is determined by the machine architecture (strictly speaking, by the C implementation). The actual size can be accessed through the \texttt{itemsize} attribute.

The module defines the following type:

\texttt{class array.array(typecode[, initializer])}

A new array whose items are restricted by \texttt{typecode}, and initialized from the optional \texttt{initializer} value, which must be a list, a \texttt{bytes-like object}, or iterable over elements of the appropriate type.

If given a list or string, the initializer is passed to the new array's \texttt{fromlist()}, \texttt{frombytes()}, or \texttt{fromunicode()} method (see below) to add initial items to the array. Otherwise, the iterable
initializer is passed to the `extend()` method.

**array.** `typecodes`

A string with all available type codes.

Array objects support the ordinary sequence operations of indexing, slicing, concatenation, and multiplication. When using slice assignment, the assigned value must be an array object with the same type code; in all other cases, `TypeError` is raised. Array objects also implement the buffer interface, and may be used wherever *bytes-like objects* are supported.

The following data items and methods are also supported:

**array.** `typecode`

The typecode character used to create the array.

**array.** `itemsize`

The length in bytes of one array item in the internal representation.

**array.** `append(x)`

Append a new item with value `x` to the end of the array.

**array.** `buffer_info()`

Return a tuple `(address, length)` giving the current memory address and the length in elements of the buffer used to hold array's contents. The size of the memory buffer in bytes can be computed as `array.buffer_info()[1] * array.itemsize`. This is occasionally useful when working with low-level (and inherently unsafe) I/O interfaces that require memory addresses, such as certain `ioctl()` operations. The returned numbers are valid as long as the array exists and no length-changing operations are applied to it.
Note: When using array objects from code written in C or C++ (the only way to effectively make use of this information), it makes more sense to use the buffer interface supported by array objects. This method is maintained for backward compatibility and should be avoided in new code. The buffer interface is documented in *Buffer Protocol*.

array. **byteswap()**

“Byteswap” all items of the array. This is only supported for values which are 1, 2, 4, or 8 bytes in size; for other types of values, `RuntimeError` is raised. It is useful when reading data from a file written on a machine with a different byte order.

array. **count(x)**

Return the number of occurrences of `x` in the array.

array. **extend(iterable)**

Append items from `iterable` to the end of the array. If `iterable` is another array, it must have exactly the same type code; if not, `TypeError` will be raised. If `iterable` is not an array, it must be iterable and its elements must be the right type to be appended to the array.

array. **frombytes(s)**

Appends items from the string, interpreting the string as an array of machine values (as if it had been read from a file using the `fromfile()` method).

*New in version 3.2:* `fromstring()` is renamed to `frombytes()` for clarity.

array. **fromfile(f, n)**
Read \( n \) items (as machine values) from the \( \text{file object} \ f \) and append them to the end of the array. If less than \( n \) items are available, \( \text{EOFError} \) is raised, but the items that were available are still inserted into the array. \( f \) must be a real built-in file object; something else with a \( \text{read()} \) method won’t do.

\[
\text{array.} \ \text{fromlist}(\text{list})
\]
Append items from the list. This is equivalent to \( \text{for} \ \text{x} \ \text{in} \ \text{list}: \ \text{a.append(x)} \) except that if there is a type error, the array is unchanged.

\[
\text{array.} \ \text{fromstring}()
\]
Deprecated alias for \( \text{frombytes}() \).

\[
\text{array.} \ \text{fromunicode}(\text{s})
\]
Extends this array with data from the given unicode string. The array must be a type \( 'u' \) array; otherwise a \( \text{ValueError} \) is raised. Use \( \text{array.frombytes(unicodestring.encode(enc))} \) to append Unicode data to an array of some other type.

\[
\text{array.} \ \text{index}(\text{x})
\]
Return the smallest \( i \) such that \( i \) is the index of the first occurrence of \( x \) in the array.

\[
\text{array.} \ \text{insert}(i, \text{x})
\]
Insert a new item with value \( x \) in the array before position \( i \). Negative values are treated as being relative to the end of the array.

\[
\text{array.} \ \text{pop}([i])
\]
Removes the item with the index \( i \) from the array and returns it.
The optional argument defaults to `-1`, so that by default the last item is removed and returned.

array. **remove**(x)
Remove the first occurrence of `x` from the array.

array. **reverse**()
Reverse the order of the items in the array.

array. **tobytes**()
Convert the array to an array of machine values and return the bytes representation (the same sequence of bytes that would be written to a file by the `tofile()` method.)

*New in version 3.2:* `tostring()` is renamed to `tobytes()` for clarity.

array. **tofile**(f)
Write all items (as machine values) to the *file object* `f`.

array. **tolist**()
Convert the array to an ordinary list with the same items.

array. **tostring**()
Deprecated alias for `tobytes()`.

array. **tounicode**()
Convert the array to a unicode string. The array must be a type `'u'` array; otherwise a `ValueError` is raised. Use `array.tobytes().decode(enc)` to obtain a unicode string from an array of some other type.

When an array object is printed or converted to a string, it is
represented as \texttt{array(typecode, initializer)}. The \texttt{initializer} is omitted if the array is empty, otherwise it is a string if the \texttt{typecode} is 'u', otherwise it is a list of numbers. The string is guaranteed to be able to be converted back to an array with the same type and value using \texttt{eval()}, so long as the \texttt{array()} function has been imported using \texttt{from array import array}. Examples:

\begin{verbatim}
array('l')
array('u', 'hello \u2641')
array('l', [1, 2, 3, 4, 5])
array('d', [1.0, 2.0, 3.14])
\end{verbatim}

8.8. weakref — Weak references

Source code: Lib/weakref.py

The weakref module allows the Python programmer to create *weak references* to objects.

In the following, the term *referent* means the object which is referred to by a weak reference.

A weak reference to an object is not enough to keep the object alive: when the only remaining references to a referent are weak references, *garbage collection* is free to destroy the referent and reuse its memory for something else. However, until the object is actually destroyed the weak reference may return the object even if there are no strong references to it.

A primary use for weak references is to implement caches or mappings holding large objects, where it’s desired that a large object not be kept alive solely because it appears in a cache or mapping.

For example, if you have a number of large binary image objects, you may wish to associate a name with each. If you used a Python dictionary to map names to images, or images to names, the image objects would remain alive just because they appeared as values or keys in the dictionaries. The WeakKeyDictionary and WeakValueDictionary classes supplied by the weakref module are an alternative, using weak references to construct mappings that don’t keep objects alive solely because they appear in the mapping objects. If, for example, an image object is a value in a WeakValueDictionary, then when the last remaining references to
that image object are the weak references held by weak mappings, garbage collection can reclaim the object, and its corresponding entries in weak mappings are simply deleted.

**WeakKeyDictionary** and **WeakValueDictionary** use weak references in their implementation, setting up callback functions on the weak references that notify the weak dictionaries when a key or value has been reclaimed by garbage collection. **WeakSet** implements the **set** interface, but keeps weak references to its elements, just like a **WeakKeyDictionary** does.

Most programs should find that using one of these weak container types is all they need – it’s not usually necessary to create your own weak references directly. The low-level machinery used by the weak dictionary implementations is exposed by the **weakref** module for the benefit of advanced uses.

Not all objects can be weakly referenced; those objects which can include class instances, functions written in Python (but not in C), instance methods, sets, frozensets, some **file objects**, **generators**, type objects, sockets, arrays, deques, regular expression pattern objects, and code objects.

*Changed in version 3.2:* Added support for thread.lock, threading.Lock, and code objects.

Several built-in types such as **list** and **dict** do not directly support weak references but can add support through subclassing:

```python
class Dict(dict):
    pass

obj = Dict(red=1, green=2, blue=3)  # this object is weak referenceable
```
Other built-in types such as `tuple` and `int` do not support weak references even when subclassed (This is an implementation detail and may be different across various Python implementations.).

Extension types can easily be made to support weak references; see *Weak Reference Support*.

```python
class weakref.ref(object[, callback])
```

Return a weak reference to `object`. The original object can be retrieved by calling the reference object if the referent is still alive; if the referent is no longer alive, calling the reference object will cause `None` to be returned. If `callback` is provided and not `None`, and the returned weakref object is still alive, the callback will be called when the object is about to be finalized; the weak reference object will be passed as the only parameter to the callback; the referent will no longer be available.

It is allowable for many weak references to be constructed for the same object. Callbacks registered for each weak reference will be called from the most recently registered callback to the oldest registered callback.

Exceptions raised by the callback will be noted on the standard error output, but cannot be propagated; they are handled in exactly the same way as exceptions raised from an object’s `__del__()` method.

Weak references are *hashable* if the `object` is hashable. They will maintain their hash value even after the `object` was deleted. If `hash()` is called the first time only after the `object` was deleted, the call will raise `TypeError`. 
Weak references support tests for equality, but not ordering. If the referents are still alive, two references have the same equality relationship as their referents (regardless of the `callback`). If either referent has been deleted, the references are equal only if the reference objects are the same object.

This is a subclassable type rather than a factory function.

`weakref.proxy(object[, callback])`

Return a proxy to `object` which uses a weak reference. This supports use of the proxy in most contexts instead of requiring the explicit dereferencing used with weak reference objects. The returned object will have a type of either `ProxyType` or `CallableProxyType`, depending on whether `object` is callable. Proxy objects are not `hashable` regardless of the referent; this avoids a number of problems related to their fundamentally mutable nature, and prevent their use as dictionary keys. `callback` is the same as the parameter of the same name to the `ref()` function.

`weakref.getweakrefcount(object)`

Return the number of weak references and proxies which refer to `object`.

`weakref.getweakrefs(object)`

Return a list of all weak reference and proxy objects which refer to `object`.

`class weakref.WeakKeyDictionary([dict])`

Mapping class that references keys weakly. Entries in the dictionary will be discarded when there is no longer a strong reference to the key. This can be used to associate additional data
with an object owned by other parts of an application without adding attributes to those objects. This can be especially useful with objects that override attribute accesses.

**Note:** Caution: Because a `WeakKeyDictionary` is built on top of a Python dictionary, it must not change size when iterating over it. This can be difficult to ensure for a `WeakKeyDictionary` because actions performed by the program during iteration may cause items in the dictionary to vanish “by magic” (as a side effect of garbage collection).

`WeakKeyDictionary` objects have the following additional methods. These expose the internal references directly. The references are not guaranteed to be “live” at the time they are used, so the result of calling the references needs to be checked before being used. This can be used to avoid creating references that will cause the garbage collector to keep the keys around longer than needed.

`WeakKeyDictionary.keyrefs()`

Return an iterable of the weak references to the keys.

class `weakref.WeakValueDictionary([dict])`

Mapping class that references values weakly. Entries in the dictionary will be discarded when no strong reference to the value exists any more.

**Note:** Caution: Because a `WeakValueDictionary` is built on top of a Python dictionary, it must not change size when iterating over it. This can be difficult to ensure for a `WeakValueDictionary` because actions performed by the program during iteration may cause items in the dictionary to
vanish “by magic” (as a side effect of garbage collection).

**WeakValueDictionary** objects have the following additional methods. These method have the same issues as the and keyrefs() method of **WeakKeyDictionary** objects.

**WeakValueDictionary**. **valuerefs()**

Return an iterable of the weak references to the values.

**class weakref. WeakSet([elements])**

Set class that keeps weak references to its elements. An element will be discarded when no strong reference to it exists any more.

**weakref. ReferenceType**

The type object for weak references objects.

**weakref. ProxyType**

The type object for proxies of objects which are not callable.

**weakref. CallableProxyType**

The type object for proxies of callable objects.

**weakref. ProxyTypes**

Sequence containing all the type objects for proxies. This can make it simpler to test if an object is a proxy without being dependent on naming both proxy types.

**exception weakref. ReferenceError**

Exception raised when a proxy object is used but the underlying object has been collected. This is the same as the standard **ReferenceError** exception.

**See also:**
**PEP 0205 - Weak References**

The proposal and rationale for this feature, including links to earlier implementations and information about similar features in other languages.
8.8.1. Weak Reference Objects

Weak reference objects have no attributes or methods, but do allow the referent to be obtained, if it still exists, by calling it:

```python
>>> import weakref
>>> class Object:
    ...    pass
    ...
>>> o = Object()
>>> r = weakref.ref(o)
>>> o2 = r()
>>> o is o2
True
```

If the referent no longer exists, calling the reference object returns `None`:

```python
>>> del o, o2
>>> print(r())
None
```

Testing that a weak reference object is still live should be done using the expression `ref() is not None`. Normally, application code that needs to use a reference object should follow this pattern:

```python
# r is a weak reference object
o = r()
if o is None:
    # referent has been garbage collected
    print("Object has been deallocated; can't frobnish")
else:
    print("Object is still live!")
o.do_something_useful()
```
Using a separate test for “liveness” creates race conditions in threaded applications; another thread can cause a weak reference to become invalidated before the weak reference is called; the idiom shown above is safe in threaded applications as well as single-threaded applications.

Specialized versions of \texttt{ref} objects can be created through subclassing. This is used in the implementation of the \texttt{WeakValueDictionary} to reduce the memory overhead for each entry in the mapping. This may be most useful to associate additional information with a reference, but could also be used to insert additional processing on calls to retrieve the referent.

This example shows how a subclass of \texttt{ref} can be used to store additional information about an object and affect the value that's returned when the referent is accessed:

```python
import weakref

class ExtendedRef(weakref.ref):
    def __init__(self, ob, callback=None, **annotations):
        super(ExtendedRef, self).__init__(ob, callback)
        self.__counter = 0
        for k, v in annotations.items():
            setattr(self, k, v)

    def __call__(self):
        """Return a pair containing the referent and the number of times the reference has been called."
        ob = super(ExtendedRef, self).__call__()
        if ob is not None:
            self.__counter += 1
```
ob = (ob, self.__counter)

return ob
8.8.2. Example

This simple example shows how an application can use objects IDs to retrieve objects that it has seen before. The IDs of the objects can then be used in other data structures without forcing the objects to remain alive, but the objects can still be retrieved by ID if they do.

```python
import weakref

_id2obj_dict = weakref.WeakValueDictionary()

def remember(obj):
    oid = id(obj)
    _id2obj_dict[oid] = obj
    return oid

def id2obj(oid):
    return _id2obj_dict[oid]
```

8. Data Types
8.9. **types** — Dynamic type creation and names for built-in types

**Source code:** Lib/types.py

This module defines utility function to assist in dynamic creation of new types.

It also defines names for some object types that are used by the standard Python interpreter, but not exposed as builtins like `int` or `str` are.
8.9.1. Dynamic Type Creation

types.new_class(name, bases=(), kwds=None, exec_body=None)

Creates a class object dynamically using the appropriate metaclass.

The first three arguments are the components that make up a class definition header: the class name, the base classes (in order), the keyword arguments (such as metaclass).

The exec_body argument is a callback that is used to populate the freshly created class namespace. It should accept the class namespace as its sole argument and update the namespace directly with the class contents. If no callback is provided, it has the same effect as passing in lambda ns: ns.

New in version 3.3.

types.prepare_class(name, bases=(), kwds=None)

Calculates the appropriate metaclass and creates the class namespace.

The arguments are the components that make up a class definition header: the class name, the base classes (in order) and the keyword arguments (such as metaclass).

The return value is a 3-tuple: metaclass, namespace, kwds

metaclass is the appropriate metaclass, namespace is the prepared class namespace and kwds is an updated copy of the passed in kwds argument with any 'metaclass' entry removed.
If no *kwds* argument is passed in, this will be an empty dict.

*New in version 3.3.*

**See also:**

*Customizing class creation*
  Full details of the class creation process supported by these functions

**PEP 3115 - Metaclasses in Python 3000**
  Introduced the __prepare__ namespace hook
8.9.2. Standard Interpreter Types

This module provides names for many of the types that are required to implement a Python interpreter. It deliberately avoids including some of the types that arise only incidentally during processing such as the listiterator type.

Typical use of these names is for `isinstance()` or `issubclass()` checks.

Standard names are defined for the following types:

- **types.FunctionType**
- **types.LambdaType**
  - The type of user-defined functions and functions created by `lambda` expressions.

- **types.GeneratorType**
  - The type of `generator`-iterator objects, produced by calling a generator function.

- **types.CodeType**
  - The type for code objects such as returned by `compile()`.

- **types.MethodType**
  - The type of methods of user-defined class instances.

- **types.BuiltinFunctionType**
- **types.BuiltinMethodType**
  - The type of built-in functions like `len()` or `sys.exit()`, and methods of built-in classes. (Here, the term “built-in” means “written in C”.)
types. **ModuleType**
The type of modules.

types. **TracebackType**
The type of traceback objects such as found in `sys.exc_info()` [2].

types. **FrameType**
The type of frame objects such as found in `tb.tb_frame` if `tb` is a traceback object.

types. **GetSetDescriptorType**
The type of objects defined in extension modules with `PyGetSetDef`, such as `FrameType.f_locals` or `array.array.typecode`. This type is used as descriptor for object attributes; it has the same purpose as the `property` type, but for classes defined in extension modules.

types. **MemberDescriptorType**
The type of objects defined in extension modules with `PyMemberDef`, such as `datetime.timedelta.days`. This type is used as descriptor for simple C data members which use standard conversion functions; it has the same purpose as the `property` type, but for classes defined in extension modules.

**CPython implementation detail:** In other implementations of Python, this type may be identical to `GetSetDescriptorType`.

**class** types. **MappingProxyType**(mapping)
Read-only proxy of a mapping. It provides a dynamic view on the mapping's entries, which means that when the mapping changes, the view reflects these changes.
New in version 3.3.

**key in proxy**
Return True if the underlying mapping has a key `key`, else False.

**proxy[key]**
Return the item of the underlying mapping with key `key`. Raises a `KeyError` if `key` is not in the underlying mapping.

**iter(proxy)**
Return an iterator over the keys of the underlying mapping. This is a shortcut for `iter(proxy.keys())`.

**len(proxy)**
Return the number of items in the underlying mapping.

**copy()**
Return a shallow copy of the underlying mapping.

**get(key[, default])**
Return the value for `key` if `key` is in the underlying mapping, else `default`. If `default` is not given, it defaults to None, so that this method never raises a `KeyError`.

**items()**
Return a new view of the underlying mapping’s items `((key, value)` pairs).

**keys()**
Return a new view of the underlying mapping’s keys.

**values()**
Return a new view of the underlying mapping's values.

class types. SimpleNamespace

A simple object subclass that provides attribute access to its namespace, as well as a meaningful repr.

Unlike object, with SimpleNamespace you can add and remove attributes. If a SimpleNamespace object is initialized with keyword arguments, those are directly added to the underlying namespace.

The type is roughly equivalent to the following code:

```python
class SimpleNamespace:
    def __init__(self, **kwarsgs):
        self.__dict__.update(kwarsgs)
    def __repr__(self):
        keys = sorted(self.__dict__)
        items = ("{}={!r}".format(k, self.__dict_
        return "{}({})".format(type(self).__name__
```

SimpleNamespace may be useful as a replacement for class NS: pass. However, for a structured record type use namedtuple() instead.

New in version 3.3.
8.10. **copy** — Shallow and deep copy operations

Assignment statements in Python do not copy objects, they create bindings between a target and an object. For collections that are mutable or contain mutable items, a copy is sometimes needed so one can change one copy without changing the other. This module provides generic shallow and deep copy operations (explained below).

Interface summary:

```python
copy.copy(x)
```
Return a shallow copy of `x`.

```python
copy.deepcopy(x)
```
Return a deep copy of `x`.

```python
exception copy.error
```
Raised for module specific errors.

The difference between shallow and deep copying is only relevant for compound objects (objects that contain other objects, like lists or class instances):

- A **shallow copy** constructs a new compound object and then (to the extent possible) inserts *references* into it to the objects found in the original.
- A **deep copy** constructs a new compound object and then, recursively, inserts *copies* into it of the objects found in the original.

Two problems often exist with deep copy operations that don’t exist
with shallow copy operations:

- Recursive objects (compound objects that, directly or indirectly, contain a reference to themselves) may cause a recursive loop.
- Because deep copy copies *everything* it may copy too much, e.g., administrative data structures that should be shared even between copies.

The `deepcopy()` function avoids these problems by:

- keeping a “memo” dictionary of objects already copied during the current copying pass; and
- letting user-defined classes override the copying operation or the set of components copied.

This module does not copy types like module, method, stack trace, stack frame, file, socket, window, array, or any similar types. It does “copy” functions and classes (shallow and deeply), by returning the original object unchanged; this is compatible with the way these are treated by the `pickle` module.

Shallow copies of dictionaries can be made using `dict.copy()`, and of lists by assigning a slice of the entire list, for example, `copied_list = original_list[:]`.

Classes can use the same interfaces to control copying that they use to control pickling. See the description of module `pickle` for information on these methods. In fact, `copy` module uses the registered pickle functions from `copyreg` module.

In order for a class to define its own copy implementation, it can define special methods `__copy__() and __deepcopy__()` . The former is called to implement the shallow copy operation; no additional arguments are passed. The latter is called to implement the deep copy
operation; it is passed one argument, the memo dictionary. If the
__deepcopy__() implementation needs to make a deep copy of a
component, it should call the deepcopy() function with the
component as first argument and the memo dictionary as second
argument.

Module pickle
Discussion of the special methods used to support object state
retrieval and restoration.
8.11. pprint — Data pretty printer

Source code: Lib/pprint.py

The pprint module provides a capability to “pretty-print” arbitrary Python data structures in a form which can be used as input to the interpreter. If the formatted structures include objects which are not fundamental Python types, the representation may not be loadable. This may be the case if objects such as files, sockets, classes, or instances are included, as well as many other built-in objects which are not representable as Python constants.

The formatted representation keeps objects on a single line if it can, and breaks them onto multiple lines if they don’t fit within the allowed width. Construct PrettyPrinter objects explicitly if you need to adjust the width constraint.

Dictionaries are sorted by key before the display is computed.

The pprint module defines one class:

class pprint.PrettyPrinter(indent=1, width=80, depth=None, stream=None)

Construct a PrettyPrinter instance. This constructor understands several keyword parameters. An output stream may be set using the stream keyword; the only method used on the stream object is the file protocol's write() method. If not specified, the PrettyPrinter adopts sys.stdout. Three additional parameters may be used to control the formatted representation. The keywords are indent, depth, and width. The
amount of indentation added for each recursive level is specified by \textit{indent}; the default is one. Other values can cause output to look a little odd, but can make nesting easier to spot. The number of levels which may be printed is controlled by \textit{depth}; if the data structure being printed is too deep, the next contained level is replaced by \ldots. By default, there is no constraint on the depth of the objects being formatted. The desired output width is constrained using the \textit{width} parameter; the default is 80 characters. If a structure cannot be formatted within the constrained width, a best effort will be made.

```python
>>> import pprint
>>> stuff = ['spam', 'eggs', 'lumberjack', 'knights', 'ni]
>>> stuff.insert(0, stuff[:])
>>> pp = pprint.PrettyPrinter(indent=4)
>>> pp.pprint(stuff)
['spam', 'eggs', 'lumberjack', 'knights', 'ni',
'spam',
'eggs',
'lumberjack',
'knights',
'ni']
```

The \texttt{PrettyPrinter} class supports several derivative functions:

\texttt{pprint.pformat(object, indent=1, width=80, depth=None)}

Return the formatted representation of \texttt{object} as a string. \texttt{indent}, \texttt{width} and \texttt{depth} will be passed to the \texttt{PrettyPrinter} constructor
as formatting parameters.

```python
>>> import pprint
>>> stuff = ['spam', 'eggs', 'lumberjack', 'knights']
>>> stuff.insert(0, stuff)
>>> pprint.pprint(stuff)
[<Recursion on list with id=...>,
 'spam',
 'eggs',
 'lumberjack',
 'knights',
 'ni']
```

**pprint.isreadable(object)**

Determine if the formatted representation of object is “readable,” or can be used to reconstruct the value using `eval()`. This always returns False for recursive objects.

```python
>>> pprint.isreadable(stuff)
False
```

**pprint.isrecursive(object)**
Determine if *object* requires a recursive representation.

One more support function is also defined:

**pprint.saferepr**(object)

Return a string representation of *object*, protected against recursive data structures. If the representation of *object* exposes a recursive entry, the recursive reference will be represented as `<Recursion on typename with id=number>`. The representation is not otherwise formatted.

```python
>>> pprint.saferepr(stuff)
'[[<Recursion on list with id=...>, 'spam', 'eggs', 'lumberjack'], 'knights', 'ni']
```
PrettyPrinter instances have the following methods:

PrettyPrinter.pformat(object)
Return the formatted representation of object. This takes into account the options passed to the PrettyPrinter constructor.

PrettyPrinter.pprint(object)
Print the formatted representation of object on the configured stream, followed by a newline.

The following methods provide the implementations for the corresponding functions of the same names. Using these methods on an instance is slightly more efficient since new PrettyPrinter objects don’t need to be created.

PrettyPrinter.isreadable(object)
Determine if the formatted representation of the object is “readable,” or can be used to reconstruct the value using eval(). Note that this returns False for recursive objects. If the depth parameter of the PrettyPrinter is set and the object is deeper than allowed, this returns False.

PrettyPrinter.isrecursive(object)
Determine if the object requires a recursive representation.

This method is provided as a hook to allow subclasses to modify the way objects are converted to strings. The default implementation uses the internals of the saferepr() implementation.

PrettyPrinter.format(object, context, maxlevels, level)
Returns three values: the formatted version of object as a string, a flag indicating whether the result is readable, and a flag indicating whether recursion was detected. The first argument is the object to be presented. The second is a dictionary which contains the id() of objects that are part of the current presentation context (direct and indirect containers for object that are affecting the presentation) as the keys; if an object needs to be presented which is already represented in context, the third return value should be True. Recursive calls to the format() method should add additional entries for containers to this dictionary. The third argument, maxlevels, gives the requested limit to recursion; this will be 0 if there is no requested limit. This argument should be passed unmodified to recursive calls. The fourth argument, level, gives the current level; recursive calls should be passed a value less than that of the current call.
8.11.2. Example

To demonstrate several uses of the `pprint()` function and its parameters, let's fetch information about a project from PyPI:

```python
>>> import json
>>> import pprint
>>> from urllib.request import urlopen

>>> with urlopen('http://pypi.python.org/pypi/configparser/json') as url:
    http_info = url.info()
    raw_data = url.read().decode(http_info.get_content_charset())

>>> project_info = json.loads(raw_data)

>>> result = {'headers': http_info.items(), 'body': project_info}
```

In its basic form, `pprint()` shows the whole object:

```python
>>> pprint.pprint(result)
{'body': {'info': {'_pypi_hidden': False,
                '_pypi_ordering': 12,
                'classifiers': ['Development Status :: 4 - Beta',
                                'Intended Audience :: Developers',
                                'License :: OSI Approved :: MIT License',
                                'Natural Language :: English',
                                'Operating System :: OS Independent',
                                'Programming Language :: Python',
                                'Programming Language :: Python :: 2',
                                'Programming Language :: Python :: 2.6',
                                'Programming Language :: Python :: 2.7',
                                'Topic :: Software Development :: Libraries',
                                'Topic :: Software Development :: Libraries :: Python Modules'],
              'download_url': 'UNKNOWN',
              'home_page': 'http://docs.python.org/py3k/library/configparser.html',
              'keywords': 'configparser ini parsing conf cfg configuration file',
              'license': 'MIT',
```

The result can be limited to a certain depth (ellipsis is used for deeper contents):

```python
>>> pprint.pprint(result, depth=3)
{'body': {'info': {'_pypi_hidden': False,
'_pypi_ordering': 12,
'classifiers': [...],
'download_url': 'UNKNOWN',
'home_page': 'http://docs.python.org/py3k/library/configparser.html',
'keywords': 'configparser ini parsing conf cfg configuration file',
'license': 'MIT',

'headers': [('Date', 'Sat, 14 May 2011 12:48:52 GMT'),
('Server', 'Apache/2.2.16 (Debian)'),
('Content-Disposition', 'inline'),
('Connection', 'close'),
('Transfer-Encoding', 'chunked'),
('Content-Type', 'application/json; charset=UTF-8')]}
```

Additionally, maximum width can be suggested. If a long object cannot be split, the specified width will be exceeded:

```python
>>> pprint.pprint(result['headers'], width=30)
[('Date', 'Sat, 14 May 2011 12:48:52 GMT'),
 ('Server', 'Apache/2.2.16 (Debian)'),
 ('Content-Disposition', 'inline'),
 ('Connection', 'close'),
 ('Transfer-Encoding', 'chunked'),
 ('Content-Type', 'application/json; charset=UTF-8')]
```
The `repllib` module provides a means for producing object representations with limits on the size of the resulting strings. This is used in the Python debugger and may be useful in other contexts as well.

This module provides a class, an instance, and a function:

```python
class repllib.Repr
    Class which provides formatting services useful in implementing functions similar to the built-in `repr()`; size limits for different object types are added to avoid the generation of representations which are excessively long.

repllib.aRepr
    This is an instance of `Repr` which is used to provide the `repr()` function described below. Changing the attributes of this object will affect the size limits used by `repr()` and the Python debugger.

repllib.repr(obj)
    This is the `repr()` method of `aRepr`. It returns a string similar to that returned by the built-in function of the same name, but with limits on most sizes.
```

In addition to size-limiting tools, the module also provides a decorator for detecting recursive calls to `__repr__()` and substituting a
placeholder string instead.

@reprlib.recursive_repr(fillvalue="...")

Decorator for __repr__() methods to detect recursive calls within the same thread. If a recursive call is made, the fillvalue is returned, otherwise, the usual __repr__() call is made. For example:

```python
>>> class MyList(list):
...     @recursive_repr()
...     def __repr__(self):
...         return '<' + '|' + ''.join(map(repr, self)) + '>
...

>>> m = MyList('abc')
>>> m.append(m)
>>> m.append('x')
>>> print(m)
<a'|'b'|'c'|...'|'x'>
```

New in version 3.2.
8.12.1. Repr Objects

Repr instances provide several attributes which can be used to provide size limits for the representations of different object types, and methods which format specific object types.

Repr. **maxlevel**

Depth limit on the creation of recursive representations. The default is 6.

Repr. **maxdict**
Repr. **maxlist**
Repr. **maxtuple**
Repr. **maxset**
Repr. **maxfrozenset**
Repr. **maxdeque**
Repr. **maxarray**

Limits on the number of entries represented for the named object type. The default is 4 for **maxdict**, 5 for **maxarray**, and 6 for the others.

Repr. **maxlong**

Maximum number of characters in the representation for an integer. Digits are dropped from the middle. The default is 40.

Repr. **maxstring**

Limit on the number of characters in the representation of the string. Note that the “normal” representation of the string is used as the character source: if escape sequences are needed in the representation, these may be mangled when the representation is shortened. The default is 30.
**Repr. maxother**

This limit is used to control the size of object types for which no specific formatting method is available on the `Repr` object. It is applied in a similar manner as `maxstring`. The default is 20.

**Repr. repr(obj)**

The equivalent to the built-in `repr()` that uses the formatting imposed by the instance.

**Repr. repr1(obj, level)**

Recursive implementation used by `repr()`. This uses the type of `obj` to determine which formatting method to call, passing it `obj` and `level`. The type-specific methods should call `repr1()` to perform recursive formatting, with `level - 1` for the value of `level` in the recursive call.

**Repr. repr_TYPE(obj, level)**

Formatting methods for specific types are implemented as methods with a name based on the type name. In the method name, `TYPE` is replaced by `string.join(string.split(type(obj).__name__, '_'))`. Dispatch to these methods is handled by `repr1()`. Type-specific methods which need to recursively format a value should call `self.repr1(subobj, level - 1)`.
8.12.2. Subclassing Repr Objects

The use of dynamic dispatching by `Repr.repr1()` allows subclasses of `Repr` to add support for additional built-in object types or to modify the handling of types already supported. This example shows how special support for file objects could be added:

```python
import reprlib
import sys

class MyRepr(reprlib.Repr):
    def repr_file(self, obj, level):
        if obj.name in ['<stdin>', '<stdout>', '<stderr'>:
            return obj.name
        else:
            return repr(obj)

aRepr = MyRepr()
print(aRepr.repr(sys.stdin))  # prints '<stdin>
```
9. Numeric and Mathematical Modules

The modules described in this chapter provide numeric and math-related functions and data types. The numbers module defines an abstract hierarchy of numeric types. The math and cmath modules contain various mathematical functions for floating-point and complex numbers. The decimal module supports exact representations of decimal numbers, using arbitrary precision arithmetic.

The following modules are documented in this chapter:

- **9.1. numbers — Numeric abstract base classes**
  - 9.1.1. The numeric tower
  - 9.1.2. Notes for type implementors
    - 9.1.2.1. Adding More Numeric ABCs
    - 9.1.2.2. Implementing the arithmetic operations
- **9.2. math — Mathematical functions**
  - 9.2.1. Number-theoretic and representation functions
  - 9.2.2. Power and logarithmic functions
  - 9.2.3. Trigonometric functions
  - 9.2.4. Angular conversion
  - 9.2.5. Hyperbolic functions
  - 9.2.6. Special functions
  - 9.2.7. Constants
- **9.3. cmath — Mathematical functions for complex numbers**
  - 9.3.1. Conversions to and from polar coordinates
  - 9.3.2. Power and logarithmic functions
  - 9.3.3. Trigonometric functions
  - 9.3.4. Hyperbolic functions
  - 9.3.5. Classification functions
- 9.3.6. Constants
- 9.4. decimal — Decimal fixed point and floating point arithmetic
  - 9.4.1. Quick-start Tutorial
  - 9.4.2. Decimal objects
    - 9.4.2.1. Logical operands
  - 9.4.3. Context objects
  - 9.4.4. Constants
  - 9.4.5. Rounding modes
  - 9.4.6. Signals
  - 9.4.7. Floating Point Notes
    - 9.4.7.1. Mitigating round-off error with increased precision
    - 9.4.7.2. Special values
  - 9.4.8. Working with threads
  - 9.4.9. Recipes
  - 9.4.10. Decimal FAQ
- 9.5. fractions — Rational numbers
- 9.6. random — Generate pseudo-random numbers
  - 9.6.1. Notes on Reproducibility
  - 9.6.2. Examples and Recipes
9.1. **numbers** — Numeric abstract base classes

The **numbers** module ([PEP 3141](https://www.python.org/dev/peps/pep-3141/)) defines a hierarchy of numeric abstract base classes which progressively define more operations. None of the types defined in this module can be instantiated.

```python
class numbers.Number
    The root of the numeric hierarchy. If you just want to check if an argument `x` is a number, without caring what kind, use `isinstance(x, Number)`.```
9.1.1. The numeric tower

class numbers. Complex
Subclasses of this type describe complex numbers and include the operations that work on the built-in complex type. These are: conversions to complex and bool, real, imag, +, -, *, /, abs(), conjugate(), ==, and !=. All except - and != are abstract.

real
Abstract. Retrieves the real component of this number.

imag
Abstract. Retrieves the imaginary component of this number.

conjugate()
Abstract. Returns the complex conjugate. For example, (1+3j).conjugate() == (1-3j).

class numbers. Real
To Complex, Real adds the operations that work on real numbers.

In short, those are: a conversion to float, math.trunc(), round(), math.floor(), math.ceil(), divmod(), //, %, <, <=, >, and >=.

Real also provides defaults for complex(), real, imag, and conjugate().

class numbers. Rational
Subtypes Real and adds numerator and denominator
properties, which should be in lowest terms. With these, it provides a default for `float()`.

**numerator**
Abstract.

**denominator**
Abstract.

class numbers. **Integral**
Subtypes **Rational** and adds a conversion to `int`. Provides defaults for `float()`, **numerator**, and **denominator**. Adds abstract methods for `**` and bit-string operations: `<<, >>, &, ^, |, ~`.
9.1.2. Notes for type implementors

Implementors should be careful to make equal numbers equal and hash them to the same values. This may be subtle if there are two different extensions of the real numbers. For example, `fractions.Fraction` implements `hash()` as follows:

```python
def __hash__(self):
    if self.denominator == 1:
        # Get integers right.
        return hash(self.numerator)
    # Expensive check, but definitely correct.
    if self == float(self):
        return hash(float(self))
    else:
        # Use tuple's hash to avoid a high collision rate on simple fractions.
        return hash((self.numerator, self.denominator))
```

9.1.2.1. Adding More Numeric ABCs

There are, of course, more possible ABCs for numbers, and this would be a poor hierarchy if it precluded the possibility of adding those. You can add `MyFoo` between `Complex` and `Real` with:

```python
class MyFoo(Complex): ...
MyFoo.register(Real)
```

9.1.2.2. Implementing the arithmetic operations

We want to implement the arithmetic operations so that mixed-mode
operations either call an implementation whose author knew about the
types of both arguments, or convert both to the nearest built in type
and do the operation there. For subtypes of Integral, this means
that \texttt{\_\_add\_\_()} and \texttt{\_\_radd\_\_()} should be defined as:

\begin{verbatim}
class MyIntegral(Integral):
    def \_\_add\_\_(self, other):
        if isinstance(other, MyIntegral):
            return do_my_adding_stuff(self, other)
        elif isinstance(other, OtherTypeIKnowAbout):
            return do_my_other_adding_stuff(self, other)
        else:
            return NotImplemented
    def \_\_radd\_\_(self, other):
        if isinstance(other, MyIntegral):
            return do_my_adding_stuff(other, self)
        elif isinstance(other, OtherTypeIKnowAbout):
            return do_my_other_adding_stuff(other, self)
        elif isinstance(other, Integral):
            return int(other) + int(self)
        elif isinstance(other, Real):
            return float(other) + float(self)
        elif isinstance(other, Complex):
            return complex(other) + complex(self)
        else:
            return NotImplemented
\end{verbatim}

There are 5 different cases for a mixed-type operation on subclasses
of \texttt{Complex}. I'll refer to all of the above code that doesn't refer to
\texttt{MyIntegral} and \texttt{OtherTypeIKnowAbout} as “boilerplate”. \texttt{a}
will be
an instance of \texttt{A}, which is a subtype of \texttt{Complex} (a : A <: Complex), and \texttt{b} : B <: Complex. I'll consider a + b:
1. If \texttt{A} defines an \texttt{__add__()} which accepts \texttt{b}, all is well.
2. If \texttt{A} falls back to the boilerplate code, and it were to return a value from \texttt{__add__()}, we'd miss the possibility that \texttt{B} defines a more intelligent \texttt{__radd__()}, so the boilerplate should return \texttt{NotImplemented} from \texttt{__add__()}. (Or \texttt{A} may not implement \texttt{__add__()} at all.)
3. Then \texttt{B}'s \texttt{__radd__()} gets a chance. If it accepts \texttt{a}, all is well.
4. If it falls back to the boilerplate, there are no more possible methods to try, so this is where the default implementation should live.
5. If \texttt{B <: A}, Python tries \texttt{B.__radd__} before \texttt{A.__add__}. This is ok, because it was implemented with knowledge of \texttt{A}, so it can handle those instances before delegating to \texttt{Complex}.

If \texttt{A <: Complex} and \texttt{B <: Real} without sharing any other knowledge, then the appropriate shared operation is the one involving the built in \texttt{complex}, and both \texttt{__radd__()}s land there, so \texttt{a+b == b+a}.

Because most of the operations on any given type will be very similar, it can be useful to define a helper function which generates the forward and reverse instances of any given operator. For example, \texttt{fractions.Fraction} uses:

```python
def _operator_fallbacks(monomorphic_operator, fallback_operator):
    def forward(a, b):
        if isinstance(b, (int, Fraction)):
            return monomorphic_operator(a, b)
        elif isinstance(b, float):
            return fallback_operator(float(a), b)
        elif isinstance(b, complex):
            return fallback_operator(complex(a), b)
```

else:
    return NotImplemented
forward.__name__ = '__' + fallback_operator.__name__
forward.__doc__ = monomorphic_operator.__doc__

def reverse(b, a):
    if isinstance(a, Rational):
        # Includes ints.
        return monomorphic_operator(a, b)
    elif isinstance(a, numbers.Real):
        return fallback_operator(float(a), float(b))
    elif isinstance(a, numbers.Complex):
        return fallback_operator(complex(a), complex(b))
    else:
        return NotImplemented
reverse.__name__ = '__r' + fallback_operator.__name__
reverse.__doc__ = monomorphic_operator.__doc__

return forward, reverse

def __add__(a, b):
    """a + b""
    return Fraction(a.numerator * b.denominator +
        b.numerator * a.denominator,
        a.denominator * b.denominator)

__add__, __radd__ = _operator_fallbacks(_add, operator)

# ...
9.2. math — Mathematical functions

This module is always available. It provides access to the mathematical functions defined by the C standard.

These functions cannot be used with complex numbers; use the functions of the same name from the cmath module if you require support for complex numbers. The distinction between functions which support complex numbers and those which don’t is made since most users do not want to learn quite as much mathematics as required to understand complex numbers. Receiving an exception instead of a complex result allows earlier detection of the unexpected complex number used as a parameter, so that the programmer can determine how and why it was generated in the first place.

The following functions are provided by this module. Except when explicitly noted otherwise, all return values are floats.
9.2.1. Number-theoretic and representation functions

math. **ceil**($x$)

Return the ceiling of $x$, the smallest integer greater than or equal to $x$. If $x$ is not a float, delegates to $x.__ceil__()$, which should return an Integral value.

math. **copysign**($x$, $y$)

Return $x$ with the sign of $y$. On a platform that supports signed zeros, copysign(1.0, -0.0) returns -1.0.

math. **fabs**($x$)

Return the absolute value of $x$.

math. **factorial**($x$)

Return $x$ factorial. Raises ValueError if $x$ is not integral or is negative.

math. **floor**($x$)

Return the floor of $x$, the largest integer less than or equal to $x$. If $x$ is not a float, delegates to $x.__floor__()$, which should return an Integral value.

math. **fmod**($x$, $y$)

Return $\text{fmod}(x, y)$, as defined by the platform C library. Note that the Python expression $x \% y$ may not return the same result. The intent of the C standard is that $\text{fmod}(x, y)$ be exactly (mathematically; to infinite precision) equal to $x - n*y$ for some integer $n$ such that the result has the same sign as $x$ and
magnitude less than $\text{abs}(y)$. Python's $x \% y$ returns a result with the sign of $y$ instead, and may not be exactly computable for float arguments. For example, $\text{fmod}(-1e-100, 1e100)$ is $-1e-100$, but the result of Python's $-1e-100 \% 1e100$ is $1e100-1e-100$, which cannot be represented exactly as a float, and rounds to the surprising $1e100$. For this reason, function $\text{fmod()}$ is generally preferred when working with floats, while Python's $x \% y$ is preferred when working with integers.

**math.\text{frexp}(x)**

Return the mantissa and exponent of $x$ as the pair $(m, e)$. $m$ is a float and $e$ is an integer such that $x == m \times 2^{e}$ exactly. If $x$ is zero, returns $(0.0, 0)$, otherwise $0.5 \leq \text{abs}(m) < 1$. This is used to “pick apart” the internal representation of a float in a portable way.

**math.\text{fsum}(\text{iterable})**

Return an accurate floating point sum of values in the iterable. Avoids loss of precision by tracking multiple intermediate partial sums:

```
>>> sum([.1, .1, .1, .1, .1, .1, .1, .1, .1])
0.9999999999999999
>>> fsum([.1, .1, .1, .1, .1, .1, .1, .1, .1])
1.0
```

The algorithm's accuracy depends on IEEE-754 arithmetic guarantees and the typical case where the rounding mode is half-even. On some non-Windows builds, the underlying C library uses extended precision addition and may occasionally double-round an intermediate sum causing it to be off in its least significant bit.
For further discussion and two alternative approaches, see the ASPN cookbook recipes for accurate floating point summation.

math.\texttt{isfinite}(x)

Return True if \( x \) is neither an infinity nor a NaN, and False otherwise. (Note that \( 0.0 \) is considered finite.)

\textit{New in version 3.2.}

math.\texttt{isinf}(x)

Return True if \( x \) is a positive or negative infinity, and False otherwise.

math.\texttt{isnan}(x)

Return True if \( x \) is a NaN (not a number), and False otherwise.

math.\texttt{ldexp}(x, i)

Return \( x \times (2**i) \). This is essentially the inverse of function \texttt{frexp()}.

math.\texttt{modf}(x)

Return the fractional and integer parts of \( x \). Both results carry the sign of \( x \) and are floats.

math.\texttt{trunc}(x)

Return the \texttt{Real} value \( x \) truncated to an \texttt{Integral} (usually an integer). Delegates to \( x.\_\_\texttt{trunc}\_\_() \).

Note that \texttt{frexp()} and \texttt{modf()} have a different call/return pattern than their C equivalents: they take a single argument and return a pair of values, rather than returning their second return value through an ‘output parameter’ (there is no such thing in Python).
For the `ceil()`, `floor()`, and `modf()` functions, note that all floating-point numbers of sufficiently large magnitude are exact integers. Python floats typically carry no more than 53 bits of precision (the same as the platform C double type), in which case any float \( x \) with \( \text{abs}(x) \geq 2^{52} \) necessarily has no fractional bits.
9.2.2. Power and logarithmic functions

math.\texttt{exp}(x)

Return \(e^x\).

math.\texttt{expm1}(x)

Return \(e^x - 1\). For small floats \(x\), the subtraction in \(\text{exp}(x) - 1\) can result in a significant loss of precision; the \texttt{expm1()} function provides a way to compute this quantity to full precision:

\begin{verbatim}
>>> from math import exp, expm1
>>> exp(1e-5) - 1  # gives result accurate to 11 places
1.000005000069649e-05
>>> expm1(1e-5)    # result accurate to full precision
1.0000050000166668e-05
\end{verbatim}

New in version 3.2.

math.\texttt{log}(x[, base])

With one argument, return the natural logarithm of \(x\) (to base \(e\)).

With two arguments, return the logarithm of \(x\) to the given \(base\), calculated as \(\log(x)/\log(base)\).

math.\texttt{log1p}(x)

Return the natural logarithm of \(1+x\) (base \(e\)). The result is calculated in a way which is accurate for \(x\) near zero.

math.\texttt{log2}(x)

Return the base-2 logarithm of \(x\). This is usually more accurate than \(\log(x, 2)\).
New in version 3.3.

See also: `int.bit_length()` returns the number of bits necessary to represent an integer in binary, excluding the sign and leading zeros.

**math.log10(x)**

Return the base-10 logarithm of x. This is usually more accurate than `log(x, 10)`.

**math.pow(x, y)**

Return x raised to the power y. Exceptional cases follow Annex 'F' of the C99 standard as far as possible. In particular, `pow(1.0, x)` and `pow(x, 0.0)` always return 1.0, even when x is a zero or a NaN. If both x and y are finite, x is negative, and y is not an integer then `pow(x, y)` is undefined, and raises `ValueError`.

Unlike the built-in `**` operator, `math.pow()` converts both its arguments to type `float`. Use `**` or the built-in `pow()` function for computing exact integer powers.

**math.sqrt(x)**

Return the square root of x.
9.2.3. Trigonometric functions

math.**acos**(*x*)

Return the arc cosine of *x*, in radians.

math.**asin**(*x*)

Return the arc sine of *x*, in radians.

math.**atan**(*x*)

Return the arc tangent of *x*, in radians.

math.**atan2**(*y*, *x*)

Return \( \text{atan}(y / x) \), in radians. The result is between \(-\pi\) and \(\pi\). The vector in the plane from the origin to point \((x, y)\) makes this angle with the positive X axis. The point of **atan2()** is that the signs of both inputs are known to it, so it can compute the correct quadrant for the angle. For example, **atan(1)** and **atan2(1, 1)** are both \(\pi/4\), but **atan2(-1, -1)** is \(-3\pi/4\).

math.**cos**(*x*)

Return the cosine of *x* radians.

math.**hypot**(*x*, *y*)

Return the Euclidean norm, \(\sqrt{x^2 + y^2}\). This is the length of the vector from the origin to point \((x, y)\).

math.**sin**(*x*)

Return the sine of *x* radians.

math.**tan**(*x*)

Return the tangent of *x* radians.
9.2.4. Angular conversion

\texttt{math.degrees(x)}
\begin{itemize}
  \item Converts angle \( x \) from radians to degrees.
\end{itemize}

\texttt{math.radians(x)}
\begin{itemize}
  \item Converts angle \( x \) from degrees to radians.
\end{itemize}
9.2.5. Hyperbolic functions

Hyperbolic functions are analogs of trigonometric functions that are based on hyperbolas instead of circles.

\[ \text{math.} \text{acosh}(x) \]
Return the inverse hyperbolic cosine of \( x \).

\[ \text{math.} \text{asinh}(x) \]
Return the inverse hyperbolic sine of \( x \).

\[ \text{math.} \text{atanh}(x) \]
Return the inverse hyperbolic tangent of \( x \).

\[ \text{math.} \text{cosh}(x) \]
Return the hyperbolic cosine of \( x \).

\[ \text{math.} \text{sinh}(x) \]
Return the hyperbolic sine of \( x \).

\[ \text{math.} \text{tanh}(x) \]
Return the hyperbolic tangent of \( x \).
9.2.6. Special functions

**math.\texttt{erf}(x)**

Return the error function at \( x \).

The \texttt{erf()} function can be used to compute traditional statistical functions such as the cumulative standard normal distribution:

```python
def phi(x):
    'Cumulative distribution function for the standard normal distribution'
    return (1.0 + \texttt{erf}(x / \texttt{sqrt}(2.0))) / 2.0
```

*New in version 3.2.*

**math.\texttt{erfc}(x)**

Return the complementary error function at \( x \). The complementary error function is defined as \( 1.0 - \texttt{erf}(x) \). It is used for large values of \( x \) where a subtraction from one would cause a loss of significance.

*New in version 3.2.*

**math.\texttt{gamma}(x)**

Return the Gamma function at \( x \).

*New in version 3.2.*

**math.\texttt{lgamma}(x)**

Return the natural logarithm of the absolute value of the Gamma function at \( x \).

*New in version 3.2.*
9.2.7. Constants

math.pi

The mathematical constant $\pi = 3.141592...$, to available precision.

math.e

The mathematical constant $e = 2.718281...$, to available precision.

**CPython implementation detail:** The `math` module consists mostly of thin wrappers around the platform C math library functions. Behavior in exceptional cases follows Annex F of the C99 standard where appropriate. The current implementation will raise `ValueError` for invalid operations like `sqrt(-1.0)` or `log(0.0)` (where C99 Annex F recommends signaling invalid operation or divide-by-zero), and `OverflowError` for results that overflow (for example, `exp(1000.0)`). A NaN will not be returned from any of the functions above unless one or more of the input arguments was a NaN; in that case, most functions will return a NaN, but (again following C99 Annex F) there are some exceptions to this rule, for example `pow(float('nan'), 0.0)` or `hypot(float('nan'), float('inf'))`. Note that Python makes no effort to distinguish signaling NaNs from quiet NaNs, and behavior for signaling NaNs remains unspecified. Typical behavior is to treat all NaNs as though they were quiet.

**See also:**

**Module cmath**

Complex number versions of many of these functions.
9.3. **cmath** — Mathematical functions for complex numbers

This module is always available. It provides access to mathematical functions for complex numbers. The functions in this module accept integers, floating-point numbers or complex numbers as arguments. They will also accept any Python object that has either a `__complex__()` or a `__float__()` method: these methods are used to convert the object to a complex or floating-point number, respectively, and the function is then applied to the result of the conversion.

**Note:** On platforms with hardware and system-level support for signed zeros, functions involving branch cuts are continuous on both sides of the branch cut: the sign of the zero distinguishes one side of the branch cut from the other. On platforms that do not support signed zeros the continuity is as specified below.
9.3.1. Conversions to and from polar coordinates

A Python complex number \( z \) is stored internally using *rectangular* or *Cartesian* coordinates. It is completely determined by its *real part* \( z.\text{real} \) and its *imaginary part* \( z.\text{imag} \). In other words:

\[
z \equiv z.\text{real} + z.\text{imag} \times 1j
\]

*Polar coordinates* give an alternative way to represent a complex number. In polar coordinates, a complex number \( z \) is defined by the modulus \( r \) and the phase angle \( \phi \). The modulus \( r \) is the distance from \( z \) to the origin, while the phase \( \phi \) is the counterclockwise angle, measured in radians, from the positive \( x \)-axis to the line segment that joins the origin to \( z \).

The following functions can be used to convert from the native rectangular coordinates to polar coordinates and back.

`cmath.phase(x)`

Return the phase of \( x \) (also known as the *argument* of \( x \)), as a float. \( \text{phase}(x) \) is equivalent to `math.atan2(x.\text{imag}, x.\text{real})`. The result lies in the range \([-\pi, \pi]\), and the branch cut for this operation lies along the negative real axis, continuous from above. On systems with support for signed zeros (which includes most systems in current use), this means that the sign of the result is the same as the sign of \( x.\text{imag} \), even when \( x.\text{imag} \) is zero:

```python
>>> phase(complex(-1.0, 0.0))
3.141592653589793
>>> phase(complex(-1.0, -0.0))
-3.141592653589793
```
Note: The modulus (absolute value) of a complex number $x$ can be computed using the built-in `abs()` function. There is no separate `cmath` module function for this operation.

cmath.\texttt{polar}(x)

Return the representation of $x$ in polar coordinates. Returns a pair $(r, \phi)$ where $r$ is the modulus of $x$ and $\phi$ is the phase of $x$. `polar(x)` is equivalent to `(abs(x), \text{phase}(x))`.

cmath.\texttt{rect}(r, \phi)

Return the complex number $x$ with polar coordinates $r$ and $\phi$. Equivalent to $r \times (\text{math.cos}(\phi) + \text{math.sin}(\phi)*1j)$.
9.3.2. Power and logarithmic functions

cmath. \texttt{exp}(x)
Return the exponential value $e^{**x}$.

cmath. \texttt{log}(x[, base])
Returns the logarithm of $x$ to the given $base$. If the $base$ is not specified, returns the natural logarithm of $x$. There is one branch cut, from 0 along the negative real axis to $-\infty$, continuous from above.

cmath. \texttt{log10}(x)
Return the base-10 logarithm of $x$. This has the same branch cut as \texttt{log}().

cmath. \texttt{sqrt}(x)
Return the square root of $x$. This has the same branch cut as \texttt{log}().
9.3.3. Trigonometric functions

cmath.**acos**(*x*)

Return the arc cosine of *x*. There are two branch cuts: One extends right from 1 along the real axis to ∞, continuous from below. The other extends left from -1 along the real axis to -∞, continuous from above.

cmath.**asin**(*x*)

Return the arc sine of *x*. This has the same branch cuts as **acos()**.

cmath.**atan**(*x*)

Return the arc tangent of *x*. There are two branch cuts: One extends from 1j along the imaginary axis to ∞j, continuous from the right. The other extends from -1j along the imaginary axis to -∞j, continuous from the left.

cmath.**cos**(*x*)

Return the cosine of *x*.

cmath.**sin**(*x*)

Return the sine of *x*.

cmath.**tan**(*x*)

Return the tangent of *x*. 
9.3.4. Hyperbolic functions

cmath.\texttt{acosh}(x)

Return the hyperbolic arc cosine of \( x \). There is one branch cut, extending left from 1 along the real axis to \(-\infty\), continuous from above.

cmath.\texttt{asinh}(x)

Return the hyperbolic arc sine of \( x \). There are two branch cuts: One extends from \( 1j \) along the imaginary axis to \( \infty j \), continuous from the right. The other extends from \( -1j \) along the imaginary axis to \( -\infty j \), continuous from the left.

cmath.\texttt{atanh}(x)

Return the hyperbolic arc tangent of \( x \). There are two branch cuts: One extends from \( 1 \) along the real axis to \( \infty \), continuous from below. The other extends from \( -1 \) along the real axis to \( -\infty \), continuous from above.

cmath.\texttt{cosh}(x)

Return the hyperbolic cosine of \( x \).

cmath.\texttt{sinh}(x)

Return the hyperbolic sine of \( x \).

cmath.\texttt{tanh}(x)

Return the hyperbolic tangent of \( x \).
9.3.5. Classification functions

cmath.\texttt{isfinite}(x)
    Return True if both the real and imaginary parts of $x$ are finite, and False otherwise.

    \textit{New in version 3.2.}

cmath.\texttt{isinf}(x)
    Return True if either the real or the imaginary part of $x$ is an infinity, and False otherwise.

cmath.\texttt{isnan}(x)
    Return True if either the real or the imaginary part of $x$ is a NaN, and False otherwise.
9.3.6. Constants

cmath.pi

The mathematical constant π, as a float.

cmath.e

The mathematical constant e, as a float.

Note that the selection of functions is similar, but not identical, to that in module math. The reason for having two modules is that some users aren’t interested in complex numbers, and perhaps don’t even know what they are. They would rather have math.sqrt(-1) raise an exception than return a complex number. Also note that the functions defined in cmath always return a complex number, even if the answer can be expressed as a real number (in which case the complex number has an imaginary part of zero).

A note on branch cuts: They are curves along which the given function fails to be continuous. They are a necessary feature of many complex functions. It is assumed that if you need to compute with complex functions, you will understand about branch cuts. Consult almost any (not too elementary) book on complex variables for enlightenment. For information of the proper choice of branch cuts for numerical purposes, a good reference should be the following:

9.4. **decimal** — Decimal fixed point and floating point arithmetic

The **decimal** module provides support for fast correctly-rounded decimal floating point arithmetic. It offers several advantages over the **float** datatype:

- Decimal “is based on a floating-point model which was designed with people in mind, and necessarily has a paramount guiding principle – computers must provide an arithmetic that works in the same way as the arithmetic that people learn at school.” – excerpt from the decimal arithmetic specification.

- Decimal numbers can be represented exactly. In contrast, numbers like 1.1 and 2.2 do not have exact representations in binary floating point. End users typically would not expect 1.1 + 2.2 to display as 3.3000000000000003 as it does with binary floating point.

- The exactness carries over into arithmetic. In decimal floating point, 0.1 + 0.1 + 0.1 - 0.3 is exactly equal to zero. In binary floating point, the result is 5.5511151231257827e-017. While near to zero, the differences prevent reliable equality testing and differences can accumulate. For this reason, decimal is preferred in accounting applications which have strict equality invariants.

- The decimal module incorporates a notion of significant places so that 1.30 + 1.20 is 2.50. The trailing zero is kept to indicate significance. This is the customary presentation for monetary
applications. For multiplication, the “schoolbook” approach uses all the figures in the multiplicands. For instance, $1.3 \times 1.2$ gives 1.56 while $1.30 \times 1.20$ gives 1.5600.

- Unlike hardware based binary floating point, the decimal module has a user alterable precision (defaulting to 28 places) which can be as large as needed for a given problem:

```python
>>> from decimal import *
>>> getcontext().prec = 6
>>> Decimal(1) / Decimal(7)
Decimal('0.142857')
>>> getcontext().prec = 28
>>> Decimal(1) / Decimal(7)
Decimal('0.1428571428571428571428571429')
```

- Both binary and decimal floating point are implemented in terms of published standards. While the built-in float type exposes only a modest portion of its capabilities, the decimal module exposes all required parts of the standard. When needed, the programmer has full control over rounding and signal handling. This includes an option to enforce exact arithmetic by using exceptions to block any inexact operations.

- The decimal module was designed to support “without prejudice, both exact unrounded decimal arithmetic (sometimes called fixed-point arithmetic) and rounded floating-point arithmetic.” – excerpt from the decimal arithmetic specification.

The module design is centered around three concepts: the decimal number, the context for arithmetic, and signals.

A decimal number is immutable. It has a sign, coefficient digits, and an exponent. To preserve significance, the coefficient digits do not
truncate trailing zeros. Decimals also include special values such as Infinity, -Infinity, and NaN. The standard also differentiates -0 from +0.

The context for arithmetic is an environment specifying precision, rounding rules, limits on exponents, flags indicating the results of operations, and trap enablers which determine whether signals are treated as exceptions. Rounding options include ROUND_CEILING, ROUND_DOWN, ROUND_FLOOR, ROUND_HALF_DOWN, ROUND_HALF_EVEN, ROUND_HALF_UP, ROUND_UP, and ROUND_05UP.

Signals are groups of exceptional conditions arising during the course of computation. Depending on the needs of the application, signals may be ignored, considered as informational, or treated as exceptions. The signals in the decimal module are: Clamped, InvalidOperation, DivisionByZero, Inexact, Rounded, Subnormal, Overflow, Underflow and FloatOperation.

For each signal there is a flag and a trap enabler. When a signal is encountered, its flag is set to one, then, if the trap enabler is set to one, an exception is raised. Flags are sticky, so the user needs to reset them before monitoring a calculation.

See also:

9.4.1. Quick-start Tutorial

The usual start to using decimals is importing the module, viewing the current context with `getcontext()` and, if necessary, setting new values for precision, rounding, or enabled traps:

```python
>>> from decimal import *
>>> getcontext()
Context(prec=28, rounding=ROUND_HALF_EVEN, Emin=-999999, Emax=999999, capitals=1, clamp=0, flags=[], traps=[Overflow, DivisionByZero, InvalidOperation])
```

Decimal instances can be constructed from integers, strings, floats, or tuples. Construction from an integer or a float performs an exact conversion of the value of that integer or float. Decimal numbers include special values such as NaN which stands for “Not a number”, positive and negative Infinity, and -0:

```python
>>> getcontext().prec = 28 # Set a new precision
>>> getcontext().prec = 7
```

```python
>>> Decimal(10)
Decimal('10')
>>> Decimal('3.14')
Decimal('3.14')
>>> Decimal(3.14)
Decimal('3.14')
>>> Decimal((0, (3, 1, 4), -2))
Decimal('3.14')
>>> Decimal(str(2.0 ** 0.5))
Decimal('1.4142135623730951')
>>> Decimal(2) ** Decimal('0.5')
Decimal('1.414213562373095048801688724')
```
If the **FloatOperation** signal is trapped, accidental mixing of decimals and floats in constructors or ordering comparisons raises an exception:

```python
>>> c = getcontext()
>>> c.traps[FloatOperation] = True
>>> Decimal(3.14)
Traceback (most recent call last):
  File "<stdin>"", line 1, in <module>
decimal.FloatOperation: [<class 'decimal.FloatOperation'>]
>>> Decimal('3.5') < 3.7
Traceback (most recent call last):
  File "<stdin>"", line 1, in <module>
decimal.FloatOperation: [<class 'decimal.FloatOperation'>]
>>> Decimal('3.5') == 3.5
True
```

**New in version 3.3.**

The significance of a new Decimal is determined solely by the number of digits input. Context precision and rounding only come into play during arithmetic operations.

```python
>>> getcontext().prec = 6
>>> Decimal('3.0')
Decimal('3.0')
>>> Decimal('3.1415926535')
Decimal('3.1415926535')
>>> Decimal('3.1415926535') + Decimal('2.7182818285')
```
Decimal('5.85987')

>>> getcontext().rounding = ROUND_UP
>>> Decimal('3.1415926535') + Decimal('2.7182818285')
Decimal('5.85988')

If the internal limits of the C version are exceeded, constructing a decimal raises InvalidOperation:

>>> Decimal("1e9999999999999999999")
Traceback (most recent call last):
  File "<stdin>", line 1, in <module>
decimal.InvalidOperation: [<class 'decimal.InvalidOperation'>]

Changed in version 3.3.

Decimals interact well with much of the rest of Python. Here is a small decimal floating point flying circus:

```python
>>> data = list(map(Decimal, '1.34 1.87 3.45 2.35 1.00 0.03 9.25'))
>>> max(data)
Decimal('9.25')
>>> min(data)
Decimal('0.03')
>>> sorted(data)
[Decimal('0.03'), Decimal('1.00'), Decimal('1.34'), Decimal('1.87'), Decimal('2.35'), Decimal('3.45'), Decimal('9.25')]
>>> sum(data)
Decimal('19.29')
>>> a,b,c = data[:3]
>>> str(a)
'1.34'
>>> float(a)
1.34
>>> round(a, 1)
Decimal('1.3')
```

And some mathematical functions are also available to Decimal:

```python
>>> getcontext().prec = 28
>>> Decimal(2).sqrt()
Decimal('1.414213562373095048801688724')
>>> Decimal(1).exp()
Decimal('2.718281828459045235360287471')
>>> Decimal('10').ln()
Decimal('2.302585092994045684017991455')
>>> Decimal('10').log10()
Decimal('1')
```

The quantize() method rounds a number to a fixed exponent. This method is useful for monetary applications that often round results to a fixed number of places:

```python
>>> Decimal('7.325').quantize(Decimal('.01'), rounding=ROUND_HALF_UP)
Decimal('7.32')
>>> Decimal('7.325').quantize(Decimal('1.'), rounding=ROUND_HALF_UP)
Decimal('8')
```

As shown above, the `getcontext()` function accesses the current context and allows the settings to be changed. This approach meets the needs of most applications.
For more advanced work, it may be useful to create alternate contexts using the `Context()` constructor. To make an alternate active, use the `setcontext()` function.

In accordance with the standard, the `Decimal` module provides two ready-to-use standard contexts, `BasicContext` and `ExtendedContext`. The former is especially useful for debugging because many of the traps are enabled:

```python
>>> myothercontext = Context(prec=60, rounding=ROUND_HALF_DOWN)
>>> setcontext(myothercontext)
>>> Decimal(1) / Decimal(7)
Decimal('0.142857142857142857142857142857142857142857142857142857142857')

>>> ExtendedContext
Context(prec=9, rounding=ROUND_HALF_EVEN, Emin=-999999, Emax=999999,
capitals=1, clamp=0, flags=[], traps=[])
>>> setcontext(ExtendedContext)
>>> Decimal(1) / Decimal(7)
Decimal('0.142857143')
>>> Decimal(42) / Decimal(0)
Decimal('Infinity')

>>> setcontext(BasicContext)
>>> Decimal(42) / Decimal(0)
Traceback (most recent call last):
  File "<pyshell#143>", line 1, in -toplevel-
    Decimal(42) / Decimal(0)
DivisionByZero: x / 0
```

Contexts also have signal flags for monitoring exceptional conditions encountered during computations. The flags remain set until explicitly cleared, so it is best to clear the flags before each set of monitored computations by using the `clear_flags()` method.
The flags entry shows that the rational approximation to Pi was rounded (digits beyond the context precision were thrown away) and that the result is inexact (some of the discarded digits were non-zero).

Individual traps are set using the dictionary in the traps field of a context:

```
>>> setcontext(ExtendedContext)
>>> Decimal(1) / Decimal(0)
Decimal('Infinity')
>>> getcontext().traps[DivisionByZero] = 1
>>> Decimal(1) / Decimal(0)
Traceback (most recent call last):
  File "<pyshell#112>", line 1, in -toplevel-
    Decimal(1) / Decimal(0)
DivisionByZero: x / 0
```

Most programs adjust the current context only once, at the beginning of the program. And, in many applications, data is converted to Decimal with a single cast inside a loop. With context set and decimals created, the bulk of the program manipulates the data no differently than with other Python numeric types.
9.4.2. Decimal objects

class decimal.**Decimal**(value="0", context=None)

Construct a new **Decimal** object based from `value`.

`value` can be an integer, string, tuple, **float**, or another **Decimal** object. If no `value` is given, returns **Decimal('0')**. If `value` is a string, it should conform to the decimal numeric string syntax after leading and trailing whitespace characters are removed:

```
sign ::= '+' | '-'
digit ::= '0' | '1' | '2' | '3' | '4' |
indicator ::= 'e' | 'E'
digits ::= digit [digit]...
decimal-part ::= digits '.' [digits] | ['.'] digits
exponent-part ::= indicator [sign] digits
infinity ::= 'Infinity' | 'Inf'
nan ::= 'NaN' [digits] | 'sNaN' [digits]
numeric-value ::= decimal-part [exponent-part]
numeric-string ::= [sign] numeric-value | [sign]
```

Other Unicode decimal digits are also permitted where `digit` appears above. These include decimal digits from various other alphabets (for example, Arabic-Indic and Devanāgarī digits) along with the fullwidth digits \uff10 through \uff19.

If `value` is a **tuple**, it should have three components, a sign (0 for positive or 1 for negative), a **tuple** of digits, and an integer exponent. For example, `Decimal((0, (1, 4, 1, 4), -3))` returns **Decimal('1.414')**.

If `value` is a **float**, the binary floating point value is losslessly
converted to its exact decimal equivalent. This conversion can often require 53 or more digits of precision. For example, `Decimal(float('1.1'))` converts to `Decimal('1.100000000000000088817841970012523233890533447265625')`

The context precision does not affect how many digits are stored. That is determined exclusively by the number of digits in value. For example, `Decimal('3.00000')` records all five zeros even if the context precision is only three.

The purpose of the context argument is determining what to do if value is a malformed string. If the context traps `InvalidOperation`, an exception is raised; otherwise, the constructor returns a new Decimal with the value of NaN.

Once constructed, `Decimal` objects are immutable.

*Changed in version 3.2:* The argument to the constructor is now permitted to be a `float` instance.

*Changed in version 3.3:* `float` arguments raise an exception if the `FloatOperation` trap is set. By default the trap is off.

Decimal floating point objects share many properties with the other built-in numeric types such as `float` and `int`. All of the usual math operations and special methods apply. Likewise, decimal objects can be copied, pickled, printed, used as dictionary keys, used as set elements, compared, sorted, and coerced to another type (such as `float` or `int`).

There are some small differences between arithmetic on Decimal objects and arithmetic on integers and floats. When the remainder operator `%` is applied to Decimal objects, the sign of the result is
the sign of the dividend rather than the sign of the divisor:

```python
>>> (-7) % 4
1
>>> Decimal(-7) % Decimal(4)
Decimal('-3')
```

The integer division operator `//` behaves analogously, returning the integer part of the true quotient (truncating towards zero) rather than its floor, so as to preserve the usual identity \( x = (x \div y) \times y + x \% y \):

```python
>>> -7 // 4
-2
>>> Decimal(-7) // Decimal(4)
Decimal('-1')
```

The `%` and `//` operators implement the remainder and divide-integer operations (respectively) as described in the specification.

Decimal objects cannot generally be combined with floats or instances of `fractions.Fraction` in arithmetic operations: an attempt to add a `Decimal` to a `float`, for example, will raise a `TypeError`. However, it is possible to use Python's comparison operators to compare a `Decimal` instance \( x \) with another number \( y \). This avoids confusing results when doing equality comparisons between numbers of different types.

*Changed in version 3.2:* Mixed-type comparisons between `Decimal` instances and other numeric types are now fully supported.
In addition to the standard numeric properties, decimal floating point objects also have a number of specialized methods:

**adjusted()**
Return the adjusted exponent after shifting out the coefficient's rightmost digits until only the lead digit remains: `Decimal('321e+5').adjusted()` returns seven. Used for determining the position of the most significant digit with respect to the decimal point.

**as_tuple()**
Return a *named tuple* representation of the number: `DecimalTuple(sign, digits, exponent)`.

**canonical()**
Return the canonical encoding of the argument. Currently, the encoding of a *Decimal* instance is always canonical, so this operation returns its argument unchanged.

**compare**(other, context=None)
Compare the values of two Decimal instances. `compare()` returns a Decimal instance, and if either operand is a NaN then the result is a NaN:

```python
a or b is a NaN ==> Decimal('NaN')
a < b ==> Decimal('-1')
a == b ==> Decimal('0')
a > b ==> Decimal('1')
```

**compare_signal**(other, context=None)
This operation is identical to the `compare()` method, except that all NaNS signal. That is, if neither operand is a signaling
NaN then any quiet NaN operand is treated as though it were a signaling NaN.

**compare_total**(other, context=None)

Compare two operands using their abstract representation rather than their numerical value. Similar to the **compare()** method, but the result gives a total ordering on **Decimal** instances. Two **Decimal** instances with the same numeric value but different representations compare unequal in this ordering:

```python
>>> Decimal('12.0').compare_total(Decimal('12'))
Decimal('-1')
```

Quiet and signaling NaNSs are also included in the total ordering. The result of this function is **Decimal('0')** if both operands have the same representation, **Decimal('-1')** if the first operand is lower in the total order than the second, and **Decimal('1')** if the first operand is higher in the total order than the second operand. See the specification for details of the total order.

This operation is unaffected by context and is quiet: no flags are changed and no rounding is performed. As an exception, the C version may raise InvalidOperation if the second operand cannot be converted exactly.

**compare_total_mag**(other, context=None)

Compare two operands using their abstract representation rather than their value as in **compare_total()**, but ignoring the sign of each operand. **x.compare_total_mag(y)** is equivalent to
x.copy_abs().compare_total(y.copy_abs()).

This operation is unaffected by context and is quiet: no flags are changed and no rounding is performed. As an exception, the C version may raise InvalidOperation if the second operand cannot be converted exactly.

**conjugate()**

Just returns self, this method is only to comply with the Decimal Specification.

**copy_abs()**

Return the absolute value of the argument. This operation is unaffected by the context and is quiet: no flags are changed and no rounding is performed.

**copy_negate()**

Return the negation of the argument. This operation is unaffected by the context and is quiet: no flags are changed and no rounding is performed.

**copy_sign(other, context=None)**

Return a copy of the first operand with the sign set to be the same as the sign of the second operand. For example:

```python
>>> Decimal('2.3').copy_sign(Decimal('-1.5'))
Decimal('-2.3')
```

This operation is unaffected by context and is quiet: no flags are changed and no rounding is performed. As an exception, the C version may raise InvalidOperation if the second operand cannot be converted exactly.
exp\(\text{context}={\text{None}}\)

Return the value of the (natural) exponential function \(e^{**x}\) at the given number. The result is correctly rounded using the \text{ROUND_HALF_EVEN} rounding mode.

```python
>>> Decimal(1).exp()
Decimal('2.718281828459045235360287471')
>>> Decimal(321).exp()
Decimal('2.561702493119680037517373933E+139')
```

from\_float\(f\)

Classmethod that converts a float to a decimal number, exactly.

Note \text{Decimal.from\_float(0.1)} is not the same as \text{Decimal('0.1')}.
Since 0.1 is not exactly representable in binary floating point, the value is stored as the nearest representable value which is \(0x1.99999999999999999p-4\). That equivalent value in decimal is \(0.10000000000000000555111512312578270211815834045410\)

\textbf{Note:} From Python 3.2 onwards, a \texttt{Decimal} instance can also be constructed directly from a \texttt{float}.

```python
>>> Decimal.from_float(0.1)
Decimal('0.10000000000000000555111512312578270211815834045410')
>>> Decimal.from_float(float('nan'))
Decimal('NaN')
>>> Decimal.from_float(float('inf'))
Decimal('Infinity')
>>> Decimal.from_float(float('-inf'))
Decimal('-Infinity')
```

\textit{New in version 3.1.}
**fma**(other, third, context=None)

Fused multiply-add. Return self*other+third with no rounding of the intermediate product self*other.

```python
>>> Decimal(2).fma(3, 5)
Decimal('11')
```

**is_canonical()**

Return True if the argument is canonical and False otherwise. Currently, a Decimal instance is always canonical, so this operation always returns True.

**is_finite()**

Return True if the argument is a finite number, and False if the argument is an infinity or a NaN.

**is_infinite()**

Return True if the argument is either positive or negative infinity and False otherwise.

**is_nan()**

Return True if the argument is a (quiet or signaling) NaN and False otherwise.

**is_normal**(context=None)

Return True if the argument is a normal finite number. Return False if the argument is zero, subnormal, infinite or a NaN.

**is_qnan()**

Return True if the argument is a quiet NaN, and False otherwise.
is_signed()
    Return True if the argument has a negative sign and False otherwise. Note that zeros and NaNs can both carry signs.

is_snan()
    Return True if the argument is a signaling NaN and False otherwise.

is_subnormal(context=None)
    Return True if the argument is subnormal, and False otherwise.

is_zero()
    Return True if the argument is a (positive or negative) zero and False otherwise.

ln(context=None)
    Return the natural (base e) logarithm of the operand. The result is correctly rounded using the ROUND_HALF_EVEN rounding mode.

log10(context=None)
    Return the base ten logarithm of the operand. The result is correctly rounded using the ROUND_HALF_EVEN rounding mode.

logb(context=None)
    For a nonzero number, return the adjusted exponent of its operand as a Decimal instance. If the operand is a zero then Decimal('-Infinity') is returned and the DivisionByZero flag is raised. If the operand is an infinity then Decimal('Infinity') is returned.
**logical_and**(other, context=None)

*logical_and()* is a logical operation which takes two *logical operands* (see *Logical operands*). The result is the digit-wise and of the two operands.

**logical_invert**(context=None)

*logical_invert()* is a logical operation. The result is the digit-wise inversion of the operand.

**logical_or**(other, context=None)

*logical_or()* is a logical operation which takes two *logical operands* (see *Logical operands*). The result is the digit-wise or of the two operands.

**logical_xor**(other, context=None)

*logical_xor()* is a logical operation which takes two *logical operands* (see *Logical operands*). The result is the digit-wise exclusive or of the two operands.

**max**(other, context=None)

Like *max(self, other)* except that the context rounding rule is applied before returning and that NaN values are either signaled or ignored (depending on the context and whether they are signaling or quiet).

**max_mag**(other, context=None)

Similar to the *max()* method, but the comparison is done using the absolute values of the operands.

**min**(other, context=None)

Like *min(self, other)* except that the context rounding rule is applied before returning and that NaN values are either
signaled or ignored (depending on the context and whether they are signaling or quiet).

**min_mag**(*other, context=None*)

Similar to the **min()** method, but the comparison is done using the absolute values of the operands.

**next_minus**(*context=None*)

Return the largest number representable in the given context (or in the current thread's context if no context is given) that is smaller than the given operand.

**next_plus**(*context=None*)

Return the smallest number representable in the given context (or in the current thread's context if no context is given) that is larger than the given operand.

**next_toward**(*other, context=None*)

If the two operands are unequal, return the number closest to the first operand in the direction of the second operand. If both operands are numerically equal, return a copy of the first operand with the sign set to be the same as the sign of the second operand.

**normalize**(*context=None*)

Normalize the number by stripping the rightmost trailing zeros and converting any result equal to **Decimal('0')** to **Decimal('0e0')**. Used for producing canonical values for attributes of an equivalence class. For example, **Decimal('32.100')** and **Decimal('0.321000e+2')** both normalize to the equivalent value **Decimal('32.1').**
**number_class**(context=None)

Return a string describing the class of the operand. The returned value is one of the following ten strings:

- "-Infinity", indicating that the operand is negative infinity.
- "-Normal", indicating that the operand is a negative normal number.
- "-Subnormal", indicating that the operand is negative and subnormal.
- "-Zero", indicating that the operand is a negative zero.
- "+Zero", indicating that the operand is a positive zero.
- "+Subnormal", indicating that the operand is positive and subnormal.
- "+Normal", indicating that the operand is a positive normal number.
- "+Infinity", indicating that the operand is positive infinity.
- "NaN", indicating that the operand is a quiet NaN (Not a Number).
- "sNaN", indicating that the operand is a signaling NaN.

**quantize**(exp, rounding=None, context=None, watchexp=True)

Return a value equal to the first operand after rounding and having the exponent of the second operand.

```python
>>> Decimal('1.41421356').quantize(Decimal('1.000'))
Decimal('1.414')
```

Unlike other operations, if the length of the coefficient after the quantize operation would be greater than precision, then an `InvalidOperation` is signaled. This guarantees that, unless
there is an error condition, the quantized exponent is always equal to that of the right-hand operand.

Also unlike other operations, quantize never signals Underflow, even if the result is subnormal and inexact.

If the exponent of the second operand is larger than that of the first then rounding may be necessary. In this case, the rounding mode is determined by the rounding argument if given, else by the given context argument; if neither argument is given the rounding mode of the current thread's context is used.

If watchexp is set (default), then an error is returned whenever the resulting exponent is greater than Emax or less than Etiny.

*Deprecated since version 3.3: watchexp is an implementation detail from the pure Python version and is not present in the C version. It will be removed in version 3.4, where it defaults to True.*

**radix()**

Return Decimal(10), the radix (base) in which the Decimal class does all its arithmetic. Included for compatibility with the specification.

**remainder_near**(other, context=None)

Return the remainder from dividing self by other. This differs from self % other in that the sign of the remainder is chosen so as to minimize its absolute value. More precisely, the return value is self - n * other where n is the integer nearest to the exact value of self / other, and if two
integers are equally near then the even one is chosen.

If the result is zero then its sign will be the sign of self.

>>> Decimal(18).remainder_near(Decimal(10))
Decimal('-2')
>>> Decimal(25).remainder_near(Decimal(10))
Decimal('5')
>>> Decimal(35).remainder_near(Decimal(10))
Decimal('-5')

**rotate**(other, context=None)

Return the result of rotating the digits of the first operand by an amount specified by the second operand. The second operand must be an integer in the range -precision through precision. The absolute value of the second operand gives the number of places to rotate. If the second operand is positive then rotation is to the left; otherwise rotation is to the right. The coefficient of the first operand is padded on the left with zeros to length precision if necessary. The sign and exponent of the first operand are unchanged.

**same_quantum**(other, context=None)

Test whether self and other have the same exponent or whether both are NaN.

This operation is unaffected by context and is quiet: no flags are changed and no rounding is performed. As an exception, the C version may raise InvalidOperation if the second operand cannot be converted exactly.

**scaleb**(other, context=None)

Return the first operand with exponent adjusted by the second.
Equivalently, return the first operand multiplied by $10^{\text{other}}$. The second operand must be an integer.

**shift**(*other*, *context=None*)
Return the result of shifting the digits of the first operand by an amount specified by the second operand. The second operand must be an integer in the range -precision through precision. The absolute value of the second operand gives the number of places to shift. If the second operand is positive then the shift is to the left; otherwise the shift is to the right. Digits shifted into the coefficient are zeros. The sign and exponent of the first operand are unchanged.

**sqrt**(*context=None*)
Return the square root of the argument to full precision.

**to_eng_string**(*context=None*)
Convert to an engineering-type string. Engineering notation has an exponent which is a multiple of 3, so there are up to 3 digits left of the decimal place. For example, converts `Decimal('123E+1')` to `Decimal('1.23E+3')`

**to_integral**(*rounding=None*, *context=None*)
Identical to the `to_integral_value()` method. The `to_integral` name has been kept for compatibility with older versions.

**to_integral_exact**(*rounding=None*, *context=None*)
Round to the nearest integer, signaling `Inexact` or `Rounded` as appropriate if rounding occurs. The rounding mode is
determined by the rounding parameter if given, else by the given context. If neither parameter is given then the rounding mode of the current context is used.

**to_integral_value**(rounding=None, context=None)
Round to the nearest integer without signaling Inexact or Rounded. If given, applies rounding; otherwise, uses the rounding method in either the supplied context or the current context.

### 9.4.2.1. Logical operands

The logical_and(), logical_invert(), logical_or(), and logical_xor() methods expect their arguments to be logical operands. A logical operand is a Decimal instance whose exponent and sign are both zero, and whose digits are all either 0 or 1.
9.4.3. Context objects

Contexts are environments for arithmetic operations. They govern precision, set rules for rounding, determine which signals are treated as exceptions, and limit the range for exponents.

Each thread has its own current context which is accessed or changed using the `getcontext()` and `setcontext()` functions:

```python
decimal.getcontext()
    Return the current context for the active thread.

decimal.setcontext(c)
    Set the current context for the active thread to c.
```

You can also use the `with` statement and the `localcontext()` function to temporarily change the active context.

```python
decimal.localcontext(ctx=None)
    Return a context manager that will set the current context for the active thread to a copy of ctx on entry to the with-statement and restore the previous context when exiting the with-statement. If no context is specified, a copy of the current context is used.
```

For example, the following code sets the current decimal precision to 42 places, performs a calculation, and then automatically restores the previous context:

```python
from decimal import localcontext

with localcontext() as ctx:
    ctx.prec = 42  # Perform a high precision calculation
    s = calculate_something()
```
New contexts can also be created using the Context constructor described below. In addition, the module provides three pre-made contexts:

**class decimal.BasicContext**

This is a standard context defined by the General Decimal Arithmetic Specification. Precision is set to nine. Rounding is set to **ROUND_HALF_UP**. All flags are cleared. All traps are enabled (treated as exceptions) except **Inexact**, **Rounded**, and **Subnormal**.

Because many of the traps are enabled, this context is useful for debugging.

**class decimal.ExtendedContext**

This is a standard context defined by the General Decimal Arithmetic Specification. Precision is set to nine. Rounding is set to **ROUND_HALF_EVEN**. All flags are cleared. No traps are enabled (so that exceptions are not raised during computations).

Because the traps are disabled, this context is useful for applications that prefer to have result value of NaN or Infinity instead of raising exceptions. This allows an application to complete a run in the presence of conditions that would otherwise halt the program.

**class decimal.DefaultContext**

This context is used by the Context constructor as a prototype for new contexts. Changing a field (such a precision) has the effect of changing the default for new contexts created by the Context.
constructor.

This context is most useful in multi-threaded environments. Changing one of the fields before threads are started has the effect of setting system-wide defaults. Changing the fields after threads have started is not recommended as it would require thread synchronization to prevent race conditions.

In single threaded environments, it is preferable to not use this context at all. Instead, simply create contexts explicitly as described below.

The default values are \( \text{prec=28} \), \( \text{rounding=ROUND_HALF_EVEN} \), and enabled traps for \( \text{Overflow, InvalidOperation} \), and \( \text{DivisionByZero} \).

In addition to the three supplied contexts, new contexts can be created with the \texttt{Context} constructor.

\begin{verbatim}

class decimal.Context(\textit{prec=\texttt{None}, rounding=\texttt{None}, Emin=\texttt{None}, Emax=\texttt{None}, capitals=\texttt{None}, clamp=\texttt{None}, flags=\texttt{None}, traps=\texttt{None}})

Creates a new context. If a field is not specified or is \texttt{None}, the default values are copied from the \texttt{DefaultContext}. If the \texttt{flags} field is not specified or is \texttt{None}, all flags are cleared.

\textit{prec} is an integer in the range \([1, \texttt{MAX_PREC}]\) that sets the precision for arithmetic operations in the context.

The \textit{rounding} option is one of the constants listed in the section \texttt{Rounding Modes}.

The \textit{traps} and \texttt{flags} fields list any signals to be set. Generally, new contexts should only set traps and leave the flags clear.
\end{verbatim}
The $E_{\text{min}}$ and $E_{\text{max}}$ fields are integers specifying the outer limits allowable for exponents. $E_{\text{min}}$ must be in the range $[\text{MIN}_{\text{EMIN}}, 0]$, $E_{\text{max}}$ in the range $[0, \text{MAX}_{\text{EMAX}}]$.

The $\text{capitals}$ field is either 0 or 1 (the default). If set to 1, exponents are printed with a capital E; otherwise, a lowercase e is used: `Decimal('6.02e+23')`.

The $\text{clamp}$ field is either 0 (the default) or 1. If set to 1, the exponent $e$ of a `Decimal` instance representable in this context is strictly limited to the range $E_{\text{min}} - \text{prec} + 1 \leq e \leq E_{\text{max}} - \text{prec} + 1$. If $\text{clamp}$ is 0 then a weaker condition holds: the adjusted exponent of the `Decimal` instance is at most $E_{\text{max}}$. When $\text{clamp}$ is 1, a large normal number will, where possible, have its exponent reduced and a corresponding number of zeros added to its coefficient, in order to fit the exponent constraints; this preserves the value of the number but loses information about significant trailing zeros. For example:

```python
>>> Context(prec=6, Emax=999, clamp=1).create_decimal('1.23000E+999')
Decimal('1.23000E+999')
```

A $\text{clamp}$ value of 1 allows compatibility with the fixed-width decimal interchange formats specified in IEEE 754.

The `Context` class defines several general purpose methods as well as a large number of methods for doing arithmetic directly in a given context. In addition, for each of the `Decimal` methods described above (with the exception of the `adjusted()` and `as_tuple()` methods) there is a corresponding `Context` method. For example, for a `Context` instance $C$ and `Decimal`
instance \(x\), \(C.exp(x)\) is equivalent to \(x.exp(context=C)\). Each \texttt{Context} method accepts a Python integer (an instance of \texttt{int}) anywhere that a Decimal instance is accepted.

\textbf{clear\_flags()}

Resets all of the flags to 0.

\textbf{clear\_traps()}

Resets all of the traps to 0.

\textit{New in version 3.3.}

\textbf{copy()}

Return a duplicate of the context.

\textbf{copy\_decimal(num)}

Return a copy of the Decimal instance \(num\).

\textbf{create\_decimal(num)}

Creates a new Decimal instance from \(num\) but using \texttt{self} as context. Unlike the \texttt{Decimal} constructor, the context precision, rounding method, flags, and traps are applied to the conversion.

This is useful because constants are often given to a greater precision than is needed by the application. Another benefit is that rounding immediately eliminates unintended effects from digits beyond the current precision. In the following example, using unrounded inputs means that adding zero to a sum can change the result:

```python
>>> getcontext().prec = 3
>>> Decimal('3.4445') + Decimal('1.0023')
Decimal('4.45')
```
Decimal('3.4445') + Decimal(0) + Decimal('1.0023')
Decimal('4.44')
This method implements the to-number operation of the IBM specification. If the argument is a string, no leading or trailing whitespace is permitted.

**create_decimal_from_float**(f)
Creates a new Decimal instance from a float f but rounding using *self* as the context. Unlike the `Decimal.from_float()` class method, the context precision, rounding method, flags, and traps are applied to the conversion.

```python
>>> context = Context(prec=5, rounding=ROUND_DOWN)
>>> context.create_decimal_from_float(math.pi)
Decimal('3.1415')
>>> context = Context(prec=5, traps=[Inexact])
>>> context.create_decimal_from_float(math.pi)
Traceback (most recent call last):
  ...  
decimal.Inexact: None
```

*New in version 3.1.*

**Etiny()**
Returns a value equal to $E_{\text{min}} - \text{prec} + 1$ which is the minimum exponent value for subnormal results. When underflow occurs, the exponent is set to *Etiny*.

**Etop()**
Returns a value equal to $E_{\text{max}} - \text{prec} + 1$.

The usual approach to working with decimals is to create `Decimal`
instances and then apply arithmetic operations which take place within the current context for the active thread. An alternative approach is to use context methods for calculating within a specific context. The methods are similar to those for the `Decimal` class and are only briefly recounted here.

**abs**(*x*)
- Returns the absolute value of *x*.

**add**(*x, y*)
- Return the sum of *x* and *y*.

**canonical**(*x*)
- Returns the same Decimal object *x*.

**compare**(*x, y*)
- Compares *x* and *y* numerically.

**compare_signal**(*x, y*)
- Compares the values of the two operands numerically.

**compare_total**(*x, y*)
- Compares two operands using their abstract representation.

**compare_total_mag**(*x, y*)
- Compares two operands using their abstract representation, ignoring sign.

**copy_abs**(*x*)
- Returns a copy of *x* with the sign set to 0.

**copy_negate**(*x*)
- Returns a copy of *x* with the sign inverted.
copy_sign\( (x, y) \)
Copies the sign from \( y \) to \( x \).

divide\( (x, y) \)
Return \( x \) divided by \( y \).

divide_int\( (x, y) \)
Return \( x \) divided by \( y \), truncated to an integer.

divmod\( (x, y) \)
Divides two numbers and returns the integer part of the result.

exp\( (x) \)
Returns \( e \times x \).

fma\( (x, y, z) \)
Returns \( x \) multiplied by \( y \), plus \( z \).

is_canonical\( (x) \)
Returns True if \( x \) is canonical; otherwise returns False.

is_finite\( (x) \)
Returns True if \( x \) is finite; otherwise returns False.

is_infinite\( (x) \)
Returns True if \( x \) is infinite; otherwise returns False.

is_nan\( (x) \)
Returns True if \( x \) is a qNaN or sNaN; otherwise returns False.

is_normal\( (x) \)
Returns True if \( x \) is a normal number; otherwise returns False.
is_qnan(x)
Returns True if x is a quiet NaN; otherwise returns False.

is_signed(x)
Returns True if x is negative; otherwise returns False.

is_snan(x)
Returns True if x is a signaling NaN; otherwise returns False.

is_subnormal(x)
Returns True if x is subnormal; otherwise returns False.

is_zero(x)
Returns True if x is a zero; otherwise returns False.

ln(x)
Returns the natural (base e) logarithm of x.

log10(x)
Returns the base 10 logarithm of x.

logb(x)
Returns the exponent of the magnitude of the operand's MSD.

logical_and(x, y)
Applies the logical operation and between each operand's digits.

logical_invert(x)
Invert all the digits in x.

logical_or(x, y)
Applies the logical operation or between each operand's digits.
logical_xor($x, y$)
Applies the logical operation xor between each operand's digits.

max($x, y$)
Compares two values numerically and returns the maximum.

max_mag($x, y$)
Compares the values numerically with their sign ignored.

min($x, y$)
Compares two values numerically and returns the minimum.

min_mag($x, y$)
Compares the values numerically with their sign ignored.

minus($x$)
Minus corresponds to the unary prefix minus operator in Python.

multiply($x, y$)
Return the product of $x$ and $y$.

next_minus($x$)
Returns the largest representable number smaller than $x$.

next_plus($x$)
Returns the smallest representable number larger than $x$.

next_toward($x, y$)
Returns the number closest to $x$, in direction towards $y$.

normalize($x$)
Reduces $x$ to its simplest form.
number_class(x)
Returns an indication of the class of x.

plus(x)
Plus corresponds to the unary prefix plus operator in Python. This operation applies the context precision and rounding, so it is not an identity operation.

power(x, y, modulo=None)
Return x to the power of y, reduced modulo modulo if given.

With two arguments, compute x**y. If x is negative then y must be integral. The result will be inexact unless y is integral and the result is finite and can be expressed exactly in ‘precision’ digits. The rounding mode of the context is used. Results are always correctly-rounded in the Python version.

*Changed in version 3.3:* The C module computes power() in terms of the correctly-rounded exp() and ln() functions. The result is well-defined but only “almost always correctly-rounded”.

With three arguments, compute (x**y) % modulo. For the three argument form, the following restrictions on the arguments hold:

- all three arguments must be integral
- y must be nonnegative
- at least one of x or y must be nonzero
- modulo must be nonzero and have at most ‘precision’ digits

The value resulting from Context.power(x, y, modulo) is
equal to the value that would be obtained by computing
\((x^{**}y) \%\) modulo with unbounded precision, but is
computed more efficiently. The exponent of the result is zero,
regardless of the exponents of \(x, y\) and modulo. The result is
always exact.

quantize\((x, y)\)

Returns a value equal to \(x\) (rounded), having the exponent of \(y\).

radix()

Just returns 10, as this is Decimal, :)

remainder\((x, y)\)

Returns the remainder from integer division.

The sign of the result, if non-zero, is the same as that of the
original dividend.

remainder\_near\((x, y)\)

Returns \(x - y \times n\), where \(n\) is the integer nearest the exact
value of \(x / y\) (if the result is 0 then its sign will be the sign of
\(x\)).

rotate\((x, y)\)

Returns a rotated copy of \(x, y\) times.

same\_quantum\((x, y)\)

Returns True if the two operands have the same exponent.

scaleb\((x, y)\)

Returns the first operand after adding the second value its exp.

shift\((x, y)\)
Returns a shifted copy of $x$, $y$ times.

$\text{sqrt}(x)$
Square root of a non-negative number to context precision.

$\text{subtract}(x, y)$
Return the difference between $x$ and $y$.

$\text{to\_eng\_string}(x)$
Converts a number to a string, using scientific notation.

$\text{to\_integral\_exact}(x)$
Rounds to an integer.

$\text{to\_sci\_string}(x)$
Converts a number to a string using scientific notation.
9.4.4. Constants

The constants in this section are only relevant for the C module. They are also included in the pure Python version for compatibility.

<table>
<thead>
<tr>
<th>Constant</th>
<th>32-bit</th>
<th>64-bit</th>
</tr>
</thead>
<tbody>
<tr>
<td><code>decimal.MAX_PREC</code></td>
<td>4250000000</td>

<td>-849999999</td>
<td>-1999999999999999999</td>
</tr>
</tbody>
</table>

`decimal.HAVE_THREADS`

The default value is True. If Python is compiled without threads, the C version automatically disables the expensive thread local context machinery. In this case, the value is False.
9.4.5. Rounding modes

decimal. **ROUND_CEILING**
    Round towards Infinity.

decimal. **ROUND_DOWN**
    Round towards zero.

decimal. **ROUND_FLOOR**
    Round towards -Infinity.

decimal. **ROUND_HALF_DOWN**
    Round to nearest with ties going towards zero.

decimal. **ROUND_HALF_EVEN**
    Round to nearest with ties going to nearest even integer.

decimal. **ROUND_HALF_UP**
    Round to nearest with ties going away from zero.

decimal. **ROUND_UP**
    Round away from zero.

decimal. **ROUND_05UP**
    Round away from zero if last digit after rounding towards zero would have been 0 or 5; otherwise round towards zero.
9.4.6. Signals

Signals represent conditions that arise during computation. Each corresponds to one context flag and one context trap enabler.

The context flag is set whenever the condition is encountered. After the computation, flags may be checked for informational purposes (for instance, to determine whether a computation was exact). After checking the flags, be sure to clear all flags before starting the next computation.

If the context's trap enabler is set for the signal, then the condition causes a Python exception to be raised. For example, if the DivisionByZero trap is set, then a DivisionByZero exception is raised upon encountering the condition.

class decimal.Clamped
    Altered an exponent to fit representation constraints.

    Typically, clamping occurs when an exponent falls outside the context's Emin and Emax limits. If possible, the exponent is reduced to fit by adding zeros to the coefficient.

class decimal.DecimalException
    Base class for other signals and a subclass of ArithmeticError.

class decimal.DivisionByZero
    Signals the division of a non-infinite number by zero.

    Can occur with division, modulo division, or when raising a number to a negative power. If this signal is not trapped, returns Infinity
or -Infinity with the sign determined by the inputs to the calculation.

*class* decimal. **Inexact**

Indicates that rounding occurred and the result is not exact.

Signals when non-zero digits were discarded during rounding. The rounded result is returned. The signal flag or trap is used to detect when results are inexact.

*class* decimal. **InvalidOperation**

An invalid operation was performed.

Indicates that an operation was requested that does not make sense. If not trapped, returns NaN. Possible causes include:

- Infinity - Infinity
- 0 * Infinity
- Infinity / Infinity
- x % 0
- Infinity % x
- sqrt(-x) and \( x > 0 \)
- 0 ** 0
- x ** (non-integer)
- x ** Infinity

*class* decimal. **Overflow**

Numerical overflow.

Indicates the exponent is larger than Emax after rounding has occurred. If not trapped, the result depends on the rounding mode, either pulling inward to the largest representable finite number or rounding outward to Infinity. In either case, **Inexact** and **Rounded** are also signaled.
class decimal. **Rounded**

Rounding occurred though possibly no information was lost.

Signaled whenever rounding discards digits; even if those digits are zero (such as rounding 5.00 to 5.0). If not trapped, returns the result unchanged. This signal is used to detect loss of significant digits.

class decimal. **Subnormal**

Exponent was lower than Emin prior to rounding.

Occurs when an operation result is subnormal (the exponent is too small). If not trapped, returns the result unchanged.

class decimal. **Underflow**

Numerical underflow with result rounded to zero.

Occurs when a subnormal result is pushed to zero by rounding. **Inexact** and **Subnormal** are also signaled.

class decimal. **FloatOperation**

Enable stricter semantics for mixing floats and Decimals.

If the signal is not trapped (default), mixing floats and Decimals is permitted in the **Decimal** constructor, **create_decimal()** and all comparison operators. Both conversion and comparisons are exact. Any occurrence of a mixed operation is silently recorded by setting **FloatOperation** in the context flags. Explicit conversions with **from_float()** or **create_decimal_from_float()** do not set the flag.

Otherwise (the signal is trapped), only equality comparisons and explicit conversions are silent. All other mixed operations raise
**FloatOperation.**

The following table summarizes the hierarchy of signals:

<table>
<thead>
<tr>
<th>exceptions.ArithmeticError(exceptions.Exception)</th>
</tr>
</thead>
<tbody>
<tr>
<td>DecimalException</td>
</tr>
<tr>
<td>Clamped</td>
</tr>
<tr>
<td>DivisionByZero(DecimalException, exceptions.)</td>
</tr>
<tr>
<td>Inexact</td>

<tr>
<td>Overflow(Inexact, Rounded)</td>
</tr>
<tr>
<td>Underflow(Inexact, Rounded, Subnormal)</td>
</tr>
<tr>
<td>InvalidOperation</td>
</tr>
<tr>
<td>Rounded</td>
</tr>
<tr>
<td>Subnormal</td>
</tr>
<tr>
<td>FloatOperation(DecimalException, exceptions.)</td>
</tr>
</tbody>
</table>
9.4.7. Floating Point Notes

9.4.7.1. Mitigating round-off error with increased precision

The use of decimal floating point eliminates decimal representation error (making it possible to represent 0.1 exactly); however, some operations can still incur round-off error when non-zero digits exceed the fixed precision.

The effects of round-off error can be amplified by the addition or subtraction of nearly offsetting quantities resulting in loss of significance. Knuth provides two instructive examples where rounded floating point arithmetic with insufficient precision causes the breakdown of the associative and distributive properties of addition:

```python
# Examples from Seminumerical Algorithms, Section 4.
>>> from decimal import Decimal, getcontext
>>> getcontext().prec = 8

>>> u, v, w = Decimal(1111113), Decimal(-1111111),
>>> (u + v) + w
Decimal('9.511111')
>>> u + (v + w)
Decimal('10')

>>> u, v, w = Decimal(20000), Decimal(-6), Decimal('6.0000003'),
>>> (u*v) + (u*w)
Decimal('0.01')
>>> u * (v+w)
Decimal('0.0060000')
```

The `decimal` module makes it possible to restore the identities by
expanding the precision sufficiently to avoid loss of significance:

```python
>>> getcontext().prec = 20
>>> u, v, w = Decimal('11111113'), Decimal('-11111111'),
>>> (u + v) + w
Decimal('9.51111111')
>>> u + (v + w)
Decimal('9.51111111')
>>> u, v, w = Decimal('20000'), Decimal('-6'), Decimal('6.0000003')
>>> (u*v) + (u*w)
Decimal('0.0060000')
>>> u * (v+w)
Decimal('0.0060000')
```

### 9.4.7.2. Special values

The number system for the `decimal` module provides special values including NaN, sNaN, -Infinity, Infinity, and two zeros, +0 and -0.

Infinities can be constructed directly with: `Decimal('Infinity')`. Also, they can arise from dividing by zero when the `DivisionByZero` signal is not trapped. Likewise, when the `Overflow` signal is not trapped, infinity can result from rounding beyond the limits of the largest representable number.

The infinities are signed (affine) and can be used in arithmetic operations where they get treated as very large, indeterminate numbers. For instance, adding a constant to infinity gives another infinite result.

Some operations are indeterminate and return NaN, or if the
**InvalidOperation** signal is trapped, raise an exception. For example, $0/0$ returns NaN which means “not a number”. This variety of NaN is quiet and, once created, will flow through other computations always resulting in another NaN. This behavior can be useful for a series of computations that occasionally have missing inputs — it allows the calculation to proceed while flagging specific results as invalid.

A variant is sNaN which signals rather than remaining quiet after every operation. This is a useful return value when an invalid result needs to interrupt a calculation for special handling.

The behavior of Python's comparison operators can be a little surprising where a NaN is involved. A test for equality where one of the operands is a quiet or signaling NaN always returns **False** (even when doing `Decimal('NaN')==Decimal('NaN')`), while a test for inequality always returns **True**. An attempt to compare two Decimals using any of the `<`, `<=`, `>` or `>=` operators will raise the **InvalidOperation** signal if either operand is a NaN, and return **False** if this signal is not trapped. Note that the General Decimal Arithmetic specification does not specify the behavior of direct comparisons; these rules for comparisons involving a NaN were taken from the IEEE 854 standard (see Table 3 in section 5.7). To ensure strict standards-compliance, use the `compare()` and `compare-signal()` methods instead.

The signed zeros can result from calculations that underflow. They keep the sign that would have resulted if the calculation had been carried out to greater precision. Since their magnitude is zero, both positive and negative zeros are treated as equal and their sign is informational.
In addition to the two signed zeros which are distinct yet equal, there are various representations of zero with differing precisions yet equivalent in value. This takes a bit of getting used to. For an eye accustomed to normalized floating point representations, it is not immediately obvious that the following calculation returns a value equal to zero:

```python
>>> 1 / Decimal('Infinity')
Decimal('0E-1000026')
```
9.4.8. Working with threads

The `getcontext()` function accesses a different `Context` object for each thread. Having separate thread contexts means that threads may make changes (such as `getcontext().prec=10`) without interfering with other threads.

Likewise, the `setcontext()` function automatically assigns its target to the current thread.

If `setcontext()` has not been called before `getcontext()`, then `getcontext()` will automatically create a new context for use in the current thread.

The new context is copied from a prototype context called `DefaultContext`. To control the defaults so that each thread will use the same values throughout the application, directly modify the `DefaultContext` object. This should be done before any threads are started so that there won’t be a race condition between threads calling `getcontext()`. For example:

```python
# Set applicationwide defaults for all threads about to be launched
DefaultContext.prec = 12
DefaultContext.rounding = ROUND_DOWN
DefaultContext.traps = ExtendedContext.traps.copy()
DefaultContext.traps[InvalidOperation] = 1
setcontext(DefaultContext)

# Afterwards, the threads can be started
t1.start()
t2.start()
t3.start()
...
```
9.4.9. Recipes

Here are a few recipes that serve as utility functions and that demonstrate ways to work with the \texttt{Decimal} class:

```python
def moneyfmt(value, places=2, curr='', sep=',', dp='.', pos='', neg='-', trailneg=''):    
    """Convert Decimal to a money formatted string."

    places: required number of places after the decimal point
    curr: optional currency symbol before the sign
    sep: optional grouping separator (comma, period, space, or blank)
    dp: decimal point indicator (comma or period)
    pos: optional sign for positive numbers: '+'
    neg: optional sign for negative numbers: '-'
    trailneg: optional trailing minus indicator: '-'

    >>> d = Decimal('-1234567.8901')
    >>> moneyfmt(d, curr='$')
    '-$1,234,567.89'
    >>> moneyfmt(d, places=0, sep='.', dp='', neg='', pos='', trailneg='-')
    '1.234.568-'
    >>> moneyfmt(d, curr='$', neg='(', trailneg=')')
    '($1,234,567.89)'
    >>> moneyfmt(Decimal(123456789), sep=' ')
    '123 456 789.00'
    >>> moneyfmt(Decimal('-0.02'), neg='<', trailneg='>')
    '<0.02>'

    """

    q = Decimal(10) ** -places  # 2 places --> ' 0.01'
    sign, digits, exp = value.quantize(q).as_tuple()
    result = []
    digits = list(map(str, digits))
build, next = result.append, digits.pop
if sign:
    build(trailneg)
for i in range(places):
    build(next() if digits else '0')
if places:
    build(dp)
if not digits:
    build('0')
i = 0
while digits:
    build(next())
i += 1
    if i == 3 and digits:
        i = 0
        build(sep)
built(curr)
built(neg if sign else pos)
return ''.join(reversed(result))

def pi():
    """Compute Pi to the current precision."

    >>> print(pi())
    3.141592653589793238462643383

    """
getcontext().prec += 2  # extra digits for intermediate values
three = Decimal(3)       # substitute "three=3.0"
lasts, t, s, n, na, d, da = 0, three, 3, 1, 0, 0
while s != lasts:
    lasts = s
    n, na = n+na, na+8
    d, da = d+da, da+32
    t = (t * n) / d
    s += t
getcontext().prec -= 2
def exp(x):
    """Return e raised to the power of x. Result type matches input type.
    """

    >>> print(exp(Decimal(1)))
    2.718281828459045235360287471
    >>> print(exp(Decimal(2)))
    7.389056098930650227230427461
    >>> print(exp(2.0))
    7.38905609893

i, lasts, s, fact, num, sign = 0, 0, 1, 1, 1, 1
while s != lasts:
    lasts = s
    i += 2
    fact *= i * (i-1)
    num *= x * x
    sign *= -1
    s += num / fact * sign
getcontext().prec -= 2
return +s

def sin(x):
    """Return the sine of x as measured in radians.
    The Taylor series approximation works best for a small value of x.
    For larger values, first compute x = x % (2 * pi)
    >>> print(sin(Decimal('0.5')))
    0.4794255386042030002732879352
    >>> print(sin(0.5))
    0.479425538604
    >>> print(sin(0.5+0j))
    (0.479425538604+0j)
    """
getcontext().prec += 2
i, lasts, s, fact, num, sign = 1, 0, x, 1, x, 1
while s != lasts:
    lasts = s
    i += 2
    fact *= i * (i-1)
    num *= x * x
    sign *= -1
s += num / fact * sign
getcontext().prec -= 2
return +s
9.4.10. Decimal FAQ

Q. It is cumbersome to type `decimal.Decimal('1234.5')`. Is there a way to minimize typing when using the interactive interpreter?

A. Some users abbreviate the constructor to just a single letter:

```python
>>> D = decimal.Decimal
>>> D('1.23') + D('3.45')
Decimal('4.68')
```

Q. In a fixed-point application with two decimal places, some inputs have many places and need to be rounded. Others are not supposed to have excess digits and need to be validated. What methods should be used?

A. The `quantize()` method rounds to a fixed number of decimal places. If the `Inexact` trap is set, it is also useful for validation:

```python
>>> TWOPLACES = Decimal(10) ** -2  # same as Decimal('0.01')

>>> # Round to two places
>>> Decimal('3.214').quantize(TWOPLACES)
Decimal('3.21')

>>> # Validate that a number does not exceed two places
>>> Decimal('3.21').quantize(TWOPLACES, context=Context)
Decimal('3.21')

>>> Decimal('3.214').quantize(TWOPLACES, context=Context)
Traceback (most recent call last):
...
Q. Once I have valid two place inputs, how do I maintain that invariant throughout an application?

A. Some operations like addition, subtraction, and multiplication by an integer will automatically preserve fixed point. Others operations, like division and non-integer multiplication, will change the number of decimal places and need to be followed-up with a quantize() step:

```python
>>> a = Decimal('102.72')  # Initial fixed-point value
>>> b = Decimal('3.17')
>>> a + b  # Addition preserves fixed-point
Decimal('105.89')
>>> a - b
Decimal('99.55')
>>> a * 42  # So does integer multiplication
Decimal('4314.24')
>>> (a * b).quantize(TWOPLACES)  # Must quantize non-integer multiplication
Decimal('325.62')
>>> (b / a).quantize(TWOPLACES)  # And quantize division
Decimal('0.03')
```

In developing fixed-point applications, it is convenient to define functions to handle the quantize() step:

```python
>>> def mul(x, y, fp=TWOPLACES):
...     return (x * y).quantize(fp)
>>> def div(x, y, fp=TWOPLACES):
...     return (x / y).quantize(fp)
```

```python
>>> mul(a, b)  # Automatically preserves fixed-point
Decimal('325.62')
>>> div(b, a)
```
Q. There are many ways to express the same value. The numbers 200, 200.000, 2E2, and 02E+4 all have the same value at various precisions. Is there a way to transform them to a single recognizable canonical value?

A. The normalize() method maps all equivalent values to a single representative:

```python
>>> values = map(Decimal, '200 200.000 2E2 .02E+4'.split)
>>> [v.normalize() for v in values]
[Decimal('2E+2'), Decimal('2E+2'), Decimal('2E+2'), Decimal('2E+2')]
```

Q. Some decimal values always print with exponential notation. Is there a way to get a non-exponential representation?

A. For some values, exponential notation is the only way to express the number of significant places in the coefficient. For example, expressing 5.0E+3 as 5000 keeps the value constant but cannot show the original’s two-place significance.

If an application does not care about tracking significance, it is easy to remove the exponent and trailing zeroes, losing significance, but keeping the value unchanged:

```python
>>> def remove_exponent(d):
...     return d.quantize(Decimal(1)) if d == d.to_integral

>>> remove_exponent(Decimal('5E+3'))
Decimal('5000')
```
Q. Is there a way to convert a regular float to a **Decimal**?

A. Yes, any binary floating point number can be exactly expressed as a Decimal though an exact conversion may take more precision than intuition would suggest:

```python
>>> Decimal(math.pi)
Decimal('3.141592653589793115997963468544185161590576171875')
```

Q. Within a complex calculation, how can I make sure that I haven't gotten a spurious result because of insufficient precision or rounding anomalies.

A. The decimal module makes it easy to test results. A best practice is to re-run calculations using greater precision and with various rounding modes. Widely differing results indicate insufficient precision, rounding mode issues, ill-conditioned inputs, or a numerically unstable algorithm.

Q. I noticed that context precision is applied to the results of operations but not to the inputs. Is there anything to watch out for when mixing values of different precisions?

A. Yes. The principle is that all values are considered to be exact and so is the arithmetic on those values. Only the results are rounded. The advantage for inputs is that “what you type is what you get”. A disadvantage is that the results can look odd if you forget that the inputs haven’t been rounded:

```python
>>> getcontext().prec = 3
>>> Decimal('3.104') + Decimal('2.104')
Decimal('5.21')
>>> Decimal('3.104') + Decimal('0.000') + Decimal('2
```
The solution is either to increase precision or to force rounding of inputs using the unary plus operation:

```python
>>> getcontext().prec = 3
>>> +Decimal('1.23456789')  # unary plus triggers rounding
Decimal('1.23')
```

Alternatively, inputs can be rounded upon creation using the `Context.create_decimal()` method:

```python
>>> Context(prec=5, rounding=ROUND_DOWN).create_decimal('1.2345')
Decimal('1.2345')
```
9.5. fractions — Rational numbers

Source code: Lib/fractions.py

The fractions module provides support for rational number arithmetic.

A Fraction instance can be constructed from a pair of integers, from another rational number, or from a string.

class fractions.Fraction(numerator=0, denominator=1)
class fractions.Fraction(other_fraction)
class fractions.Fraction(float)
class fractions.Fraction(decimal)
class fractions.Fraction(string)

The first version requires that numerator and denominator are instances of numbers.Rational and returns a new Fraction instance with value numerator/denominator. If denominator is 0, it raises a ZeroDivisionError. The second version requires that other_fraction is an instance of numbers.Rational and returns a Fraction instance with the same value. The next two versions accept either a float or a decimal.Decimal instance, and return a Fraction instance with exactly the same value. Note that due to the usual issues with binary floating-point (see Floating Point Arithmetic: Issues and Limitations), the argument to Fraction(1.1) is not exactly equal to 11/10, and so Fraction(1.1) does not return Fraction(11, 10) as one might expect. (But see the documentation for the
limit_denominator() method below.) The last version of the constructor expects a string or unicode instance. The usual form for this instance is:

```
[sign] numerator ["/'"] denominator
```

where the optional `sign` may be either `'+'` or `'-'` and `numerator` and `denominator` (if present) are strings of decimal digits. In addition, any string that represents a finite value and is accepted by the `float` constructor is also accepted by the `Fraction` constructor. In either form the input string may also have leading and/or trailing whitespace. Here are some examples:

```python
>>> from fractions import Fraction
>>> Fraction(16, -10)
Fraction(-8, 5)
>>> Fraction(123)
Fraction(123, 1)
>>> Fraction()
Fraction(0, 1)
>>> Fraction('3/7')
Fraction(3, 7)
>>> Fraction(' -3/7 ')
Fraction(-3, 7)
>>> Fraction('1.414213 \t\n')
Fraction(1414213, 1000000)
>>> Fraction('- .125 ')
Fraction(-1, 8)
>>> Fraction('7e-6')
Fraction(7, 10000000)
>>> Fraction(2.25)
Fraction(9, 4)
>>> Fraction(1.1)
Fraction(2476979795053773, 2251799813685248)
>>> from decimal import Decimal
```
The `Fraction` class inherits from the abstract base class `numbers.Rational`, and implements all of the methods and operations from that class. `Fraction` instances are hashable, and should be treated as immutable. In addition, `Fraction` has the following properties and methods:

*Changed in version 3.2:* The `Fraction` constructor now accepts `float` and `decimal.Decimal` instances.

**numerator**
Numerator of the Fraction in lowest term.

**denominator**
Denominator of the Fraction in lowest term.

**from_float(flt)**
This class method constructs a `Fraction` representing the exact value of `flt`, which must be a `float`. Beware that `Fraction.from_float(0.3)` is not the same value as `Fraction(3, 10)`.

**from_decimal(dec)**
This class method constructs a `Fraction` representing the exact value of `dec`, which must be a `decimal.Decimal` instance.
Note: From Python 3.2 onwards, you can also construct a `Fraction` instance directly from a `decimal.Decimal` instance.

**limit_denominator**(max_denominator=1000000)

Finds and returns the closest `Fraction` to `self` that has denominator at most `max_denominator`. This method is useful for finding rational approximations to a given floating-point number:

```python
>>> from fractions import Fraction
>>> Fraction('3.1415926535897932').limit_denominator()
Fraction(355, 113)
```

or for recovering a rational number that's represented as a float:

```python
>>> from math import pi, cos
>>> Fraction(cos(pi/3))
Fraction(4503599627370497, 9007199254740992)
>>> Fraction(cos(pi/3)).limit_denominator()
Fraction(1, 2)
>>> Fraction(1.1).limit_denominator()
Fraction(11, 10)
```

**__floor__()**

Returns the greatest `int` \(\leq \text{self}\). This method can also be accessed through the `math.floor()` function:

```python
>>> from math import floor
>>> floor(Fraction(355, 113))
3
```

**__ceil__()**
Returns the least \texttt{int} \geq \texttt{self}. This method can also be accessed through the \texttt{math.ceil()} function.

\begin{verbatim}
__round__()
__round__(ndigits)
\end{verbatim}

The first version returns the nearest \texttt{int} to \texttt{self}, rounding half to even. The second version rounds \texttt{self} to the nearest multiple of \texttt{Fraction(1, 10**ndigits)} (logically, if \texttt{ndigits} is negative), again rounding half toward even. This method can also be accessed through the \texttt{round()} function.

\texttt{fractions.gcd(a, b)}

Return the greatest common divisor of the integers \texttt{a} and \texttt{b}. If either \texttt{a} or \texttt{b} is nonzero, then the absolute value of \texttt{gcd(a, b)} is the largest integer that divides both \texttt{a} and \texttt{b}. \texttt{gcd(a, b)} has the same sign as \texttt{b} if \texttt{b} is nonzero; otherwise it takes the sign of \texttt{a}. \texttt{gcd(0, 0)} returns \texttt{0}.

\textbf{See also:}

\textbf{Module numbers}

The abstract base classes making up the numeric tower.
This module implements pseudo-random number generators for various distributions.

For integers, there is uniform selection from a range. For sequences, there is uniform selection of a random element, a function to generate a random permutation of a list in-place, and a function for random sampling without replacement.

On the real line, there are functions to compute uniform, normal (Gaussian), lognormal, negative exponential, gamma, and beta distributions. For generating distributions of angles, the von Mises distribution is available.

Almost all module functions depend on the basic function `random()`, which generates a random float uniformly in the semi-open range [0.0, 1.0). Python uses the Mersenne Twister as the core generator. It produces 53-bit precision floats and has a period of $2^{19937}-1$. The underlying implementation in C is both fast and threadsafe. The Mersenne Twister is one of the most extensively tested random number generators in existence. However, being completely deterministic, it is not suitable for all purposes, and is completely unsuitable for cryptographic purposes.

The functions supplied by this module are actually bound methods of a hidden instance of the `random.Random` class. You can instantiate
your own instances of Random to get generators that don’t share state.

Class Random can also be subclassed if you want to use a different basic generator of your own devising: in that case, override the random(), seed(), getstate(), and setstate() methods. Optionally, a new generator can supply a getrandbits() method — this allows randrange() to produce selections over an arbitrarily large range.

The random module also provides the SystemRandom class which uses the system function os.urandom() to generate random numbers from sources provided by the operating system.

**Warning:** The pseudo-random generators of this module should not be used for security purposes. Use os.urandom() or SystemRandom if you require a cryptographically secure pseudo-random number generator.

Bookkeeping functions:

```python
random.seed(a=None, version=2)
```

Initialize the random number generator.

If a is omitted or None, the current system time is used. If randomness sources are provided by the operating system, they are used instead of the system time (see the os.urandom() function for details on availability).

If a is an int, it is used directly.

With version 2 (the default), a str, bytes, or bytearray object
gets converted to an int and all of its bits are used. With version 1, the hash() of a is used instead.

*Changed in version 3.2:* Moved to the version 2 scheme which uses all of the bits in a string seed.

**random.getstate()**

Return an object capturing the current internal state of the generator. This object can be passed to setstate() to restore the state.

**random.setstate(state)**

state should have been obtained from a previous call to getstate(), and setstate() restores the internal state of the generator to what it was at the time getstate() was called.

**random.getrandbits(k)**

Returns a Python integer with k random bits. This method is supplied with the MersenneTwister generator and some other generators may also provide it as an optional part of the API. When available, getrandbits() enables randrange() to handle arbitrarily large ranges.

Functions for integers:

**random.randrange(stop)**

**random.randrange(start, stop[, step])**

Return a randomly selected element from range(start, stop, step). This is equivalent to choice(range(start, stop, step)), but doesn’t actually build a range object.

The positional argument pattern matches that of range().
Keyword arguments should not be used because the function may use them in unexpected ways.

*Changed in version 3.2:* `randrange()` is more sophisticated about producing equally distributed values. Formerly it used a style like `int(random()*n)` which could produce slightly uneven distributions.

```python
random.randint(a, b)
```

Return a random integer $N$ such that $a \leq N \leq b$. Alias for `randrange(a, b+1)`.

Functions for sequences:

```python
random.choice(seq)
```

Return a random element from the non-empty sequence `seq`. If `seq` is empty, raises `IndexError`.

```python
random.shuffle(x[, random])
```

Shuffle the sequence `x` in place. The optional argument `random` is a 0-argument function returning a random float in $[0.0, 1.0)$; by default, this is the function `random()`.

Note that for even rather small `len(x)`, the total number of permutations of `x` is larger than the period of most random number generators; this implies that most permutations of a long sequence can never be generated.

```python
random.sample(population, k)
```

Return a $k$ length list of unique elements chosen from the population sequence or set. Used for random sampling without replacement.
Returns a new list containing elements from the population while leaving the original population unchanged. The resulting list is in selection order so that all sub-slices will also be valid random samples. This allows raffle winners (the sample) to be partitioned into grand prize and second place winners (the subslices).

Members of the population need not be *hashable* or unique. If the population contains repeats, then each occurrence is a possible selection in the sample.

To choose a sample from a range of integers, use an `range()` object as an argument. This is especially fast and space efficient for sampling from a large population:

```
sample(range(10000000), 60).
```

If the sample size is larger than the population size, a `ValueError` is raised.

The following functions generate specific real-valued distributions. Function parameters are named after the corresponding variables in the distribution’s equation, as used in common mathematical practice; most of these equations can be found in any statistics text.

`random.random()`

Return the next random floating point number in the range `[0.0, 1.0)`.

`random.uniform(a, b)`

Return a random floating point number `N` such that `a <= N <= b` for `a <= b` and `b <= N <= a` for `b < a`.

The end-point value `b` may or may not be included in the range depending on floating-point rounding in the equation `a + (b-a)`
random.triangular(low, high, mode)
Return a random floating point number \( N \) such that \( \text{low} \leq N \leq \text{high} \) and with the specified \( \text{mode} \) between those bounds. The \( \text{low} \) and \( \text{high} \) bounds default to zero and one. The \( \text{mode} \) argument defaults to the midpoint between the bounds, giving a symmetric distribution.

random.betavariate(alpha, beta)
Beta distribution. Conditions on the parameters are \( \alpha > 0 \) and \( \beta > 0 \). Returned values range between 0 and 1.

random.expovariate(lambd)
Exponential distribution. \( \lambda \) is 1.0 divided by the desired mean. It should be nonzero. (The parameter would be called “\( \lambda \)”, but that is a reserved word in Python.) Returned values range from 0 to positive infinity if \( \lambda \) is positive, and from negative infinity to 0 if \( \lambda \) is negative.

random.gammavariate(alpha, beta)
Gamma distribution. (\textit{Not} the gamma function!) Conditions on the parameters are \( \alpha > 0 \) and \( \beta > 0 \).

The probability distribution function is:

\[
pdf(x) = \frac{x^{\alpha - 1} \exp(-x/\beta)}{\Gamma(\alpha) \beta^{\alpha}}
\]

random.gauss(mu, sigma)
Gaussian distribution. \( \mu \) is the mean, and \( \sigma \) is the standard
deviation. This is slightly faster than the `normalvariate()` function defined below.

```python
random.lognormvariate(mu, sigma)
```

Log normal distribution. If you take the natural logarithm of this distribution, you’ll get a normal distribution with mean `mu` and standard deviation `sigma`. `mu` can have any value, and `sigma` must be greater than zero.

```python
random.normalvariate(mu, sigma)
```

Normal distribution. `mu` is the mean, and `sigma` is the standard deviation.

```python
random.vonmisesvariate(mu, kappa)
```

`mu` is the mean angle, expressed in radians between 0 and 2*π, and `kappa` is the concentration parameter, which must be greater than or equal to zero. If `kappa` is equal to zero, this distribution reduces to a uniform random angle over the range 0 to 2*π.

```python
random.paretovariate(alpha)
```

Pareto distribution. `alpha` is the shape parameter.

```python
random.weibullvariate(alpha, beta)
```

Weibull distribution. `alpha` is the scale parameter and `beta` is the shape parameter.

Alternative Generator:

```python
class random.SystemRandom([seed])
```

Class that uses the `os.urandom()` function for generating random numbers from sources provided by the operating system. Not available on all systems. Does not rely on software state, and
sequences are not reproducible. Accordingly, the `seed()` method has no effect and is ignored. The `getstate()` and `setstate()` methods raise `NotImplementedError` if called.

**See also:** M. Matsumoto and T. Nishimura, “Mersenne Twister: A 623-dimensionally equidistributed uniform pseudorandom number generator”, ACM Transactions on Modeling and Computer Simulation Vol. 8, No. 1, January pp.3-30 1998.

Complementary-Multiply-with-Carry recipe for a compatible alternative random number generator with a long period and comparatively simple update operations.
9.6.1. Notes on Reproducibility

Sometimes it is useful to be able to reproduce the sequences given by a pseudo random number generator. By re-using a seed value, the same sequence should be reproducible from run to run as long as multiple threads are not running.

Most of the random module’s algorithms and seeding functions are subject to change across Python versions, but two aspects are guaranteed not to change:

- If a new seeding method is added, then a backward compatible seeder will be offered.
- The generator’s `random()` method will continue to produce the same sequence when the compatible seeder is given the same seed.
9.6.2. Examples and Recipes

Basic usage:

```python
>>> random.random()          # Random float 0.0 <= x < 1.0
0.37444887175646646

>>> random.uniform(1, 10)   # Random float 1.0 <= x < 10.0
1.1800146073117523

>>> random.randrange(10)    # Integer from 0 to 9
7

>>> random.randrange(0, 101, 2)  # Even integer from 0 to 100
26

>>> random.choice('abcdefghij')  # Single random element
'c'

>>> items = [1, 2, 3, 4, 5, 6, 7]
>>> random.shuffle(items)
>>> items
[7, 3, 2, 5, 6, 4, 1]

>>> random.sample([1, 2, 3, 4, 5], 3)  # Three samples without replacement
[4, 1, 5]
```

A common task is to make a `random.choice()` with weighted probabilities.

If the weights are small integer ratios, a simple technique is to build a sample population with repeats:

```python
>>> weighted_choices = [('Red', 3), ('Blue', 2), ('Yellow', 1)]
>>> random.choice(weighted_choices)
'Blue'
```
A more general approach is to arrange the weights in a cumulative distribution with `itertools.accumulate()`, and then locate the random value with `bisect.bisect()`:

```python
>>> choices, weights = zip(*weighted_choices)
>>> cumdist = list(itertools.accumulate(weights))
>>> x = random.random() * cumdist[-1]
>>> choices[bisect.bisect(cumdist, x)]
'Blue'
```
10. Functional Programming Modules

The modules described in this chapter provide functions and classes that support a functional programming style, and general operations on callables.

The following modules are documented in this chapter:

- **10.1. itertools — Functions creating iterators for efficient looping**
  - 10.1.1. Itertool functions
  - 10.1.2. Itertools Recipes
- **10.2. functools — Higher-order functions and operations on callable objects**
  - 10.2.1. partial Objects
- **10.3. operator — Standard operators as functions**
  - 10.3.1. Mapping Operators to Functions
  - 10.3.2. Inplace Operators
10.1. `itertools` — Functions creating iterators for efficient looping

This module implements a number of `iterator` building blocks inspired by constructs from APL, Haskell, and SML. Each has been recast in a form suitable for Python.

The module standardizes a core set of fast, memory efficient tools that are useful by themselves or in combination. Together, they form an “iterator algebra” making it possible to construct specialized tools succinctly and efficiently in pure Python.

For instance, SML provides a tabulation tool: `tabulate(f)` which produces a sequence `f(0), f(1), ...`. The same effect can be achieved in Python by combining `map()` and `count()` to form `map(f, count())`.

These tools and their built-in counterparts also work well with the high-speed functions in the `operator` module. For example, the multiplication operator can be mapped across two vectors to form an efficient dot-product: `sum(map(operator.mul, vector1, vector2))`.

Infinite Iterators:

<table>
<thead>

<td>p, r</td>
<td>r-length tuples, in sorted order, with repeated elements</td>
</tr>
</tbody>
</table>
product('ABCD', repeat=2)

permutations('ABCD', 2)

combinations('ABCD', 2)

combinations_with_replacement('ABCD', 2)
10.1.1. Itertool functions

The following module functions all construct and return iterators. Some provide streams of infinite length, so they should only be accessed by functions or loops that truncate the stream.

**itertools.accumulate(iterable[, func])**

Make an iterator that returns accumulated sums. Elements may be any addable type including `Decimal` or `Fraction`. If the optional `func` argument is supplied, it should be a function of two arguments and it will be used instead of addition.

Equivalent to:

```python
def accumulate(iterable, func=operator.add):
    'Return running totals'
    # accumulate([1,2,3,4,5]) --> 1 3 6 10 15
    # accumulate([1,2,3,4,5], operator.mul) --> 1
    it = iter(iterable)
    total = next(it)
    yield total
    for element in it:
        total = func(total, element)
        yield total
```

There are a number of uses for the `func` argument. It can be set to `min()` for a running minimum, `max()` for a running maximum, or `operator.mul()` for a running product. Amortization tables can be built by accumulating interest and applying payments. First-order recurrence relations can be modeled by supplying the initial value in the iterable and using only the accumulated total in `func` argument:
```python
>>> data = [3, 4, 6, 2, 1, 9, 0, 7, 5, 8]
>>> list(accumulate(data, operator.mul))  # running product
[3, 12, 72, 144, 144, 1296, 0, 0, 0, 0]
>>> list(accumulate(data, max))  # running maximum
[3, 4, 6, 6, 9, 9, 9, 9, 9, 9]
```

# Amortize a 5% loan of 1000 with 4 annual payments
```python
>>> cashflows = [1000, -90, -90, -90, -90]
>>> list(accumulate(cashflows, lambda bal, pmt: bal + pmt))
[1000, 960.0, 918.0, 873.9000000000001, 827.5950000000001]
```

# Chaotic recurrence relation http://en.wikipedia.org/wiki/Logistic_map
```python
>>> logistic_map = lambda x, _: r * x * (1 - x)
>>> r = 3.8
>>> x0 = 0.4
>>> inputs = repeat(x0, 36)  # only the initial value is used
>>> [format(x, '.2f') for x in accumulate(inputs, logistic_map)]
['0.40', '0.91', '0.30', '0.81', '0.60', '0.92', '0.88', '0.39', '0.90', '0.33', '0.84', '0.52', '0.93', '0.25', '0.71', '0.79', '0.63', '0.88', '0.83', '0.54', '0.95', '0.20', '0.60', '0.91', ...
```

See `functools.reduce()` for a similar function that returns only the final accumulated value.

New in version 3.2.

Changed in version 3.3: Added the optional `func` parameter.

**`itertools.chain(*iterables)`**

Make an iterator that returns elements from the first iterable until it is exhausted, then proceeds to the next iterable, until all of the iterables are exhausted. Used for treating consecutive sequences as a single sequence. Equivalent to:
def chain(*iterables):
    # chain('ABC', 'DEF') --> A B C D E F
    for it in iterables:
        for element in it:
            yield element

classmethod chain.from_iterable(iterable)
Alternate constructor for chain(). Gets chained inputs from a single iterable argument that is evaluated lazily. Roughly equivalent to:

def from_iterable(iterables):
    # chain.from_iterable(['ABC', 'DEF']) --> A B C D E F
    for it in iterables:
        for element in it:
            yield element

import itertools.combinations(iterable, r)
Return r length subsequences of elements from the input iterable.

Combinations are emitted in lexicographic sort order. So, if the input iterable is sorted, the combination tuples will be produced in sorted order.

Elements are treated as unique based on their position, not on their value. So if the input elements are unique, there will be no repeat values in each combination.

Equivalent to:

def combinations(iterable, r):
    # combinations('ABCD', 2) --> AB AC AD BC BD
    # combinations(range(4), 3) --> 012 013 023 123
    pool = tuple(iterable)
The code for `combinations()` can be also expressed as a subsequence of `permutations()` after filtering entries where the elements are not in sorted order (according to their position in the input pool):

```python
def combinations(iterable, r):
    pool = tuple(iterable)
    n = len(pool)
    for indices in permutations(range(n), r):
        if sorted(indices) == list(indices):
            yield tuple(pool[i] for i in indices)
```

The number of items returned is \( \frac{n!}{r! \cdot (n-r)!} \) when \( 0 \leq r \leq n \) or zero when \( r > n \).

`itertools.combinations_with_replacement(iterable, r)`

Return \( r \) length subsequences of elements from the input `iterable` allowing individual elements to be repeated more than once.
Combinations are emitted in lexicographic sort order. So, if the input iterable is sorted, the combination tuples will be produced in sorted order.

Elements are treated as unique based on their position, not on their value. So if the input elements are unique, the generated combinations will also be unique.

Equivalent to:

```python
def combinations_with_replacement(iterable, r):
    pool = tuple(iterable)
n = len(pool)
    if not n and r:
        return
    indices = [0] * r
    yield tuple(pool[i] for i in indices)
    while True:
        for i in reversed(range(r)):
            if indices[i] != n - 1:
                break
        else:
            return
        indices[i:] = [indices[i] + 1] * (r - i)
        yield tuple(pool[i] for i in indices)
```

The code for combinations_with_replacement() can be also expressed as a subsequence of product() after filtering entries where the elements are not in sorted order (according to their position in the input pool):

```python
def combinations_with_replacement(iterable, r):
    pool = tuple(iterable)
```
n = len(pool)
for indices in product(range(n), repeat=r):
    if sorted(indices) == list(indices):
        yield tuple(pool[i] for i in indices)

The number of items returned is \( \frac{(n+r-1)!}{r!} / (n-1)! \) when \( n > 0 \).

*New in version 3.1.*

**itertools.\texttt{compress}(\textit{data}, \textit{selectors})**

Make an iterator that filters elements from \textit{data} returning only those that have a corresponding element in \textit{selectors} that evaluates to True. Stops when either the \textit{data} or \textit{selectors} iterables has been exhausted. Equivalent to:

```python
def compress(data, selectors):
    # compress('ABCDEF', [1,0,1,0,1,1]) --> A C E
    return (d for d, s in zip(data, selectors) if s)
```

*New in version 3.1.*

**itertools.\texttt{count}(\textit{start}=0, \textit{step}=1)**

Make an iterator that returns evenly spaced values starting with number \textit{start}. Often used as an argument to \texttt{map()} to generate consecutive data points. Also, used with \texttt{zip()} to add sequence numbers. Equivalent to:

```python
def count(start=0, step=1):
    # count(10) --> 10 11 12 13 14 ...
    # count(2.5, 0.5) --> 2.5 3.0 3.5 ...
    n = start
    while True:
        yield n
        n += step
```
When counting with floating point numbers, better accuracy can sometimes be achieved by substituting multiplicative code such as:

```
(start + step * i for i in count())
```

*Changed in version 3.1:* Added `step` argument and allowed non-integer arguments.

**`itertools.cyle(iterable)`**

Make an iterator returning elements from the iterable and saving a copy of each. When the iterable is exhausted, return elements from the saved copy. Repeats indefinitely. Equivalent to:

```python
def cycle(iterable):
    # cycle('ABCD') --> A B C D A B C D A B C D ...
    saved = []
    for element in iterable:
        yield element
        saved.append(element)
    while saved:
        for element in saved:
            yield element
```

Note, this member of the toolkit may require significant auxiliary storage (depending on the length of the iterable).

**`itertools.dropwhile(predicate, iterable)`**

Make an iterator that drops elements from the iterable as long as the predicate is true; afterwards, returns every element. Note, the iterator does not produce any output until the predicate first becomes false, so it may have a lengthy start-up time. Equivalent
to:

```python
def dropwhile(predicate, iterable):
    iterable = iter(iterable)
    for x in iterable:
        if not predicate(x):
            yield x
        break
    for x in iterable:
        yield x
```

`itertools.filterfalse(predicate, iterable)`

Make an iterator that filters elements from iterable returning only those for which the predicate is False. If `predicate` is None, return the items that are false. Equivalent to:

```python
def filterfalse(predicate, iterable):
    if predicate is None:
        predicate = bool
    for x in iterable:
        if not predicate(x):
            yield x
```

`itertools.groupby(iterable, key=None)`

Make an iterator that returns consecutive keys and groups from the `iterable`. The `key` is a function computing a key value for each element. If not specified or is None, `key` defaults to an identity function and returns the element unchanged. Generally, the iterable needs to already be sorted on the same key function.

The operation of `groupby()` is similar to the `uniq` filter in Unix. It
generates a break or new group every time the value of the key function changes (which is why it is usually necessary to have sorted the data using the same key function). That behavior differs from SQL's GROUP BY which aggregates common elements regardless of their input order.

The returned group is itself an iterator that shares the underlying iterable with `groupby()`. Because the source is shared, when the `groupby()` object is advanced, the previous group is no longer visible. So, if that data is needed later, it should be stored as a list:

```python
groups = []
uniquekeys = []
data = sorted(data, key=keyfunc)
for k, g in groupby(data, keyfunc):
    groups.append(list(g))  # Store group iterator as a list
    uniquekeys.append(k)
```

`groupby()` is equivalent to:

```python
class groupby:
    # [k for k, g in groupby('AAAABBBCCDAABBB')]  # [k for k, g in groupby('AAAABBBCCD')]  # [list(g) for k, g in groupby('AAAABBBCCD')]  # [list(g) for k, g in groupby('AAAABBBCCCD')]  # [list(g) for k, g in groupby('AAABABCCD')]
    def __init__(self, iterable, key=None):
        if key is None:
            key = lambda x: x
        self.keyfunc = key
        self.it = iter(iterable)
        self.tgtkey = self.currkey = self.currval = next(self.it)
    def __iter__(self):
        return self
    def __next__(self):
        while self.currkey == self.tgtkey:
            self.currvalue = next(self.it)  # Exit on StopIteration
```
self.currkey = self.keyfunc(self.currvalue)
self.tgtkey = self.currkey
return (self.currkey, self._grouper(self.it))

def _grouper(self, tgtkey):
    while self.currkey == tgtkey:
        yield self.currvalue
    self.currvalue = next(self.it)  # Exit on StopIteration
    self.currkey = self.keyfunc(self.currvalue)

**itertools.islice(iterable, start, stop)**

Make an iterator that returns selected elements from the iterable. If `start` is non-zero, then elements from the iterable are skipped until start is reached. Afterward, elements are returned consecutively unless `step` is set higher than one which results in items being skipped. If `stop` is None, then iteration continues until the iterator is exhausted, if at all; otherwise, it stops at the specified position. Unlike regular slicing, **islice()** does not support negative values for `start`, `stop`, or `step`. Can be used to extract related fields from data where the internal structure has been flattened (for example, a multi-line report may list a name field on every third line).

Equivalent to:

```python
def islice(iterable, *args):
    # islice('ABCDEFG', 2) --> A B
    # islice('ABCDEFG', 2, 4) --> C D
    # islice('ABCDEFG', 2, None) --> C D E F G
    # islice('ABCDEFG', 0, None, 2) --> A C E G
    s = slice(*args)
    it = iter(range(s.start or 0, s.stop or sys.maxsize))
    nexti = next(it)
    for i, element in enumerate(iterable):
        if i == nexti:
            yield element
```
yield element
nexti = next(it)

If start is None, then iteration starts at zero. If step is None, then the step defaults to one.

`itertools.permutations(iterable, r=None)`

Return successive r length permutations of elements in the iterable.

If r is not specified or is None, then r defaults to the length of the iterable and all possible full-length permutations are generated.

Permutations are emitted in lexicographic sort order. So, if the input iterable is sorted, the permutation tuples will be produced in sorted order.

Elements are treated as unique based on their position, not on their value. So if the input elements are unique, there will be no repeat values in each permutation.

Equivalent to:

```python
def permutations(iterable, r=None):
    # permutations('ABCD', 2) --> AB AC AD BA BC CA CD DA DB DC
    # permutations(range(3)) --> 012 021 102 120 201 210
    pool = tuple(iterable)
    n = len(pool)
    r = n if r is None else r
    if r > n:
        return
    indices = list(range(n))
    cycles = list(range(n, n-r, -1))
    yield tuple(pool[i] for i in indices[:r])```
while n:
    for i in reversed(range(r)):
        cycles[i] -= 1
        if cycles[i] == 0:
            indices[i:] = indices[i+1:] + indices
            cycles[i] = n - i
        else:
            j = cycles[i]
            indices[i], indices[-j] = indices
            yield tuple(pool[i] for i in indices)
    else:
        break

return

The code for permutations() can be also expressed as a subsequence of product(), filtered to exclude entries with repeated elements (those from the same position in the input pool):

def permutations(iterable, r=None):
    pool = tuple(iterable)
    n = len(pool)
    r = n if r is None else r
    for indices in product(range(n), repeat=r):
        if len(set(indices)) == r:
            yield tuple(pool[i] for i in indices)

The number of items returned is \( n! / (n-r)! \) when \( 0 \leq r \leq n \) or zero when \( r > n \).

`itertools.product(*iterables, repeat=1)`

Cartesian product of input iterables.

Equivalent to nested for-loops in a generator expression. For example, `product(A, B)` returns the same as `((x, y) for x`
in A for y in B).

The nested loops cycle like an odometer with the rightmost element advancing on every iteration. This pattern creates a lexicographic ordering so that if the input's iterables are sorted, the product tuples are emitted in sorted order.

To compute the product of an iterable with itself, specify the number of repetitions with the optional `repeat` keyword argument. For example, `product(A, repeat=4)` means the same as `product(A, A, A, A).

This function is equivalent to the following code, except that the actual implementation does not build up intermediate results in memory:

```python
def product(*args, repeat=1):
    # product('ABCD', 'xy') --> Ax Ay Bx By Cx Cy
    # product(range(2), repeat=3) --> 000 001 010
    pools = [tuple(pool) for pool in args] * repeat
    result = [[]]
    for pool in pools:
        result = [x+[y] for x in result for y in pool]
    for prod in result:
        yield tuple(prod)
```

`itertools.repeat(object[, times])`

Make an iterator that returns `object` over and over again. Runs indefinitely unless the `times` argument is specified. Used as argument to `map()` for invariant parameters to the called function. Also used with `zip()` to create an invariant part of a tuple record. Equivalent to:
```python
def repeat(object, times=None):
    # repeat(10, 3) --> 10 10 10
    if times is None:
        while True:
            yield object
    else:
        for i in range(times):
            yield object
```

A common use for `repeat` is to supply a stream of constant values to `map` or `zip`:

```python
>>> list(map(pow, range(10), repeat(2)))
[0, 1, 4, 9, 16, 25, 36, 49, 64, 81]
```

**itertools.** `starmap(function, iterable)`

Make an iterator that computes the function using arguments obtained from the iterable. Used instead of `map()` when argument parameters are already grouped in tuples from a single iterable (the data has been “pre-zipped”). The difference between `map()` and `starmap()` parallels the distinction between `function(a,b)` and `function(*c)`. Equivalent to:

```python
def starmap(function, iterable):
    # starmap(pow, [(2,5), (3,2), (10,3)]) --> 32
    for args in iterable:
        yield function(*args)
```

**itertools.** `takewhile(predicate, iterable)`

Make an iterator that returns elements from the iterable as long as the predicate is true. Equivalent to:

```python
def takewhile(predicate, iterable):
```
# takewhile(lambda x: x<5, [1,4,6,4,1]) --> 1
for x in iterable:
    if predicate(x):
        yield x
    else:
        break

itertools.tee(iterable, n=2)
Return n independent iterators from a single iterable. Equivalent to:

def tee(iterable, n=2):
    it = iter(iterable)
    deques = [collections.deque() for i in range(n)]
    def gen(mydeque):
        while True:
            if not mydeque:
                # when the local deque is empty
                newval = next(it)
                # fetch a new value
                for d in deques:
                    # load it to all the deques
                    d.append(newval)
                yield mydeque.popleft()
        return tuple(gen(d) for d in deques)

Once tee() has made a split, the original iterable should not be used anywhere else; otherwise, the iterable could get advanced without the tee objects being informed.

This itertool may require significant auxiliary storage (depending on how much temporary data needs to be stored). In general, if one iterator uses most or all of the data before another iterator starts, it is faster to use list() instead of tee().

itertools.zip_longest(*iterables, fillvalue=None)
Make an iterator that aggregates elements from each of the
iterables. If the iterables are of uneven length, missing values are filled-in with `fillvalue`. Iteration continues until the longest iterable is exhausted. Equivalent to:

```python
class ZipExhausted(Exception):
    pass

def zip_longest(*args, **kwds):
    # zip_longest('ABCD', 'xy', fillvalue='-') -> Ax By C- D-
    fillvalue = kwds.get('fillvalue')
    counter = len(args) - 1

def sentinel():
    nonlocal counter
    if not counter:
        raise ZipExhausted
    counter -= 1
    yield fillvalue

fillers = repeat(fillvalue)
iterators = [chain(it, sentinel(), fillers) for try:]
    while iterators:
        yield tuple(map(next, iterators))
except ZipExhausted:
    pass
```

If one of the iterables is potentially infinite, then the `zip_longest()` function should be wrapped with something that limits the number of calls (for example `islice()` or `takewhile()`). If not specified, `fillvalue` defaults to None.
10.1.2. Itertools Recipes

This section shows recipes for creating an extended toolset using the existing itertools as building blocks.

The extended tools offer the same high performance as the underlying toolset. The superior memory performance is kept by processing elements one at a time rather than bringing the whole iterable into memory all at once. Code volume is kept small by linking the tools together in a functional style which helps eliminate temporary variables. High speed is retained by preferring “vectorized” building blocks over the use of for-loops and *generators* which incur interpreter overhead.

```python
def take(n, iterable):
    "Return first n items of the iterable as a list"
    return list(islice(iterable, n))

def tabulate(function, start=0):
    "Return function(0), function(1), ..."
    return map(function, count(start))

def consume(iterator, n):
    "Advance the iterator n-steps ahead. If n is None, consume entirely."
    # Use functions that consume iterators at C speed.
    if n is None:
        # feed the entire iterator into a zero-length deque
        collections.deque(iterator, maxlen=0)
    else:
        # advance to the empty slice starting at pos
        next(islice(iterator, n, n), None)

def nth(iterable, n, default=None):
    "Returns the nth item or a default value"
```

```python
return next(islice(iterable, n, None), default)

def quantify(iterable, pred=bool):
    """Count how many times the predicate is true""
    return sum(map(pred, iterable))

def padnone(iterable):
    """"""Returns the sequence elements and then returns None indefinitely.
    Useful for emulating the behavior of the built-in map() function.
    """"
    return chain(iterable, repeat(None))

def ncycles(iterable, n):
    """Returns the sequence elements n times""
    return chain.from_iterable(repeat(tuple(iterable), n))

def dotproduct(vec1, vec2):
    return sum(map(operator.mul, vec1, vec2))

def flatten(listOfLists):
    """Flatten one level of nesting""
    return chain.from_iterable(listOfLists)

def repeatfunc(func, times=None, *args):
    """"""Repeat calls to func with specified arguments
    Example: repeatfunc(random.random)
    """"
    if times is None:
        return starmap(func, repeat(args))
    return starmap(func, repeat(args, times))

def pairwise(iterable):
    """s -> (s0,s1), (s1,s2), (s2, s3), ...""
    a, b = tee(iterable)
    next(b, None)```
return zip(a, b)

def grouper(iterable, n, fillvalue=None):
    "Collect data into fixed-length chunks or blocks"
    # grouper('ABCDEFG', 3, 'x') --> ABC DEF Gxx"
    args = [iter(iterable)] * n
    return zip_longest(*args, fillvalue=fillvalue)

def roundrobin(*iterables):
    "roundrobin('ABC', 'D', 'EF') --> A D E B F C"
    # Recipe credited to George Sakkis
    pending = len(iterables)
    nexts = cycle(iter(it).__next__ for it in iterables)
    while pending:
        try:
            for next in nexts:
                yield next()
        except StopIteration:
            pending -= 1
            nexts = cycle(islice(nexts, pending))

def partition(pred, iterable):
    'Use a predicate to partition entries into false
    # partition(is_odd, range(10)) --> 0 2 4 6 8  a
    t1, t2 = tee(iterable)
    return filterfalse(pred, t1), filter(pred, t2)

def powerset(iterable):
    "powerset([1,2,3]) --> () (1) (2) (3) (1,2) (1,3) (2,3) (1,2,3)"
    s = list(iterable)
    return chain.from_iterable(combinations(s, r) for r in range(len(s)+1))

def unique_everseen(iterable, key=None):
    "List unique elements, preserving order. Remember
    # unique_everseen('AAAABBBCCDAABB') --> A B C D
    # unique_everseen('ABBCcAD', str.lower) --> A B C A
    seen = set()
seen_add = seen.add
if key is None:
    for element in filterfalse(seen.__contains__, seen_add):  # assuming seen_add is the function
        yield element
else:
    for element in iterable:
        k = key(element)
        if k not in seen:
            seen_add(k)
            yield element

def unique_justseen(iterable, key=None):
    "List unique elements, preserving order. Remember only the element just seen."
    # unique_justseen('AAAAABBBCCDAABB') --> A B C D
    # unique_justseen('ABBCcAD', str.lower) --> A B A
    return map(next, map(itemgetter(1), groupby(iterable, key=key)))

def iter_except(func, exception, first=None):
    """Call a function repeatedly until an exception is raised."

    Converts a call-until-exception interface to an iterator interface.
    Like builtins.iter(func, sentinel) but uses an exception instead of a sentinel to end the loop.

    Examples:
    iter_except(functools.partial(heappop, h), IndexError)
    iter_except(d.popitem, KeyError)
    iter_except(d.popleft, IndexError)
    iter_except(q.get_nowait, Queue.Empty)
    iter_except(s.pop, KeyError)
    """

    try:
        if first is not None:
            yield first()  # For database
    while 1:
```python
def random_product(*args, repeat=1):
    "Random selection from itertools.product(*args, repeat=repeat)"
    pools = [tuple(pool) for pool in args] * repeat
    return tuple(random.choice(pool) for pool in pools)

def random_permutation(iterable, r=None):
    "Random selection from itertools.permutations(iterable, r)"
    pool = tuple(iterable)
    r = len(pool) if r is None else r
    return tuple(random.sample(pool, r))

def random_combination(iterable, r):
    "Random selection from itertools.combinations(iterable, r)"
    pool = tuple(iterable)
    n = len(pool)
    indices = sorted(random.sample(range(n), r))
    return tuple(pool[i] for i in indices)

def random_combination_with Replacement(iterable, r):
    "Random selection from itertools.combinations_with_ replacement(iterable, r)"
    pool = tuple(iterable)
    n = len(pool)
    indices = sorted(random.randrange(n) for i in range(r))
    return tuple(pool[i] for i in indices)
```

Note, many of the above recipes can be optimized by replacing global lookups with local variables defined as default values. For example, the *dotproduct* recipe can be written as:

```python
def dotproduct(vec1, vec2, sum=sum, map=map, mul=operator.mul):
    return sum(map(mul, vec1, vec2))
```
10.2. **functools** — Higher-order functions and operations on callable objects

**Source code:** Lib/functools.py

The **functools** module is for higher-order functions: functions that act on or return other functions. In general, any callable object can be treated as a function for the purposes of this module.

The **functools** module defines the following functions:

**functools.\texttt{cmp\_to\_key}(func)**

Transform an old-style comparison function to a key function. Used with tools that accept key functions (such as \texttt{sorted()}, \texttt{min()}, \texttt{max()}, \texttt{heapq.nlargest()}, \texttt{heapq.nsmallest()}, \texttt{itertools.groupby()}). This function is primarily used as a transition tool for programs being converted from Python 2 which supported the use of comparison functions.

A comparison function is any callable that accept two arguments, compares them, and returns a negative number for less-than, zero for equality, or a positive number for greater-than. A key function is a callable that accepts one argument and returns another value indicating the position in the desired collation sequence.

Example:

```
sorted(iterable, key=cmp_to_key(locale.strcoll))
```
New in version 3.2.

@functools.lru_cache(maxsize=128, typed=False)

Decorator to wrap a function with a memoizing callable that saves up to the maxsize most recent calls. It can save time when an expensive or I/O bound function is periodically called with the same arguments.

Since a dictionary is used to cache results, the positional and keyword arguments to the function must be hashable.

If maxsize is set to None, the LRU feature is disabled and the cache can grow without bound. The LRU feature performs best when maxsize is a power-of-two.

If typed is set to True, function arguments of different types will be cached separately. For example, f(3) and f(3.0) will be treated as distinct calls with distinct results.

To help measure the effectiveness of the cache and tune the maxsize parameter, the wrapped function is instrumented with a cache_info() function that returns a named tuple showing hits, misses, maxsize and currsize. In a multi-threaded environment, the hits and misses are approximate.

The decorator also provides a cache_clear() function for clearing or invalidating the cache.

The original underlying function is accessible through the __wrapped__ attribute. This is useful for introspection, for bypassing the cache, or for rewrapping the function with a different cache.
An **LRU (least recently used) cache** works best when the most recent calls are the best predictors of upcoming calls (for example, the most popular articles on a news server tend to change each day). The cache’s size limit assures that the cache does not grow without bound on long-running processes such as web servers.

Example of an LRU cache for static web content:

```python
@lru_cache(maxsize=32)
def get_pep(num):
    'Retrieve text of a Python Enhancement Proposal'
    resource = 'http://www.python.org/dev/peps/pep-%04d/'
    try:
        with urllib.request.urlopen(resource) as s:
            return s.read()
    except urllib.error.HTTPError:
        return 'Not Found'

>>> for n in 8, 290, 308, 320, 8, 218, 320, 279, ...
...    pep = get_pep(n)
...    print(n, len(pep))

>>> get_pep.cache_info()
CacheInfo(hits=3, misses=8, maxsize=32, currsize=8)
```

Example of efficiently computing **Fibonacci numbers** using a cache to implement a **dynamic programming** technique:

```python
@lru_cache(maxsize=None)
def fib(n):
    if n < 2:
        return n
    return fib(n-1) + fib(n-2)

>>> [fib(n) for n in range(16)]
```
```python
>>> fib.cache_info()
CacheInfo(hits=28, misses=16, maxsize=None, currsize=0)
```

New in version 3.2.

Changed in version 3.3: Added the typed option.

@functools.total_ordering

Given a class defining one or more rich comparison ordering methods, this class decorator supplies the rest. This simplifies the effort involved in specifying all of the possible rich comparison operations:

The class must define one of __lt__(), __le__(), __gt__(), or __ge__(). In addition, the class should supply an __eq__() method.

For example:

```python
@total_ordering
class Student:
    def __eq__(self, other):
        return ((self.lastname.lower(), self.firstname)
                 (other.lastname.lower(), other.firstname)
    def __lt__(self, other):
        return ((self.lastname.lower(), self.firstname)
                 (other.lastname.lower(), other.firstname)
```

New in version 3.2.

functools.partial(func, *args, **keywords)
Return a new `partial` object which when called will behave like `func` called with the positional arguments `args` and keyword arguments `keywords`. If more arguments are supplied to the call, they are appended to `args`. If additional keyword arguments are supplied, they extend and override `keywords`. Roughly equivalent to:

```python
def partial(func, *args, **keywords):
    def newfunc(*fargs, **fkeywords):
        newkeywords = keywords.copy()
        newkeywords.update(fkeywords)
        return func(*(args + fargs), **newkeywords)
    newfunc.func = func
    newfunc.args = args
    newfunc.keywords = keywords
    return newfunc
```

The `partial()` is used for partial function application which “freezes” some portion of a function's arguments and/or keywords resulting in a new object with a simplified signature. For example, `partial()` can be used to create a callable that behaves like the `int()` function where the `base` argument defaults to two:

```python
>>> from functools import partial
>>> basetwo = partial(int, base=2)
>>> basetwo.__doc__ = 'Convert base 2 string to a
>>> basetwo('10010')
18
```

`functools.reduce(function, iterable[, initializer])`

Apply `function` of two arguments cumulatively to the items of `sequence`, from left to right, so as to reduce the sequence to a
single value. For example, `reduce(lambda x, y: x+y, [1, 2, 3, 4, 5])` calculates (((1+2)+3)+4)+5). The left argument, `x`, is the accumulated value and the right argument, `y`, is the update value from the sequence. If the optional `initializer` is present, it is placed before the items of the sequence in the calculation, and serves as a default when the sequence is empty. If `initializer` is not given and `sequence` contains only one item, the first item is returned.

Equivalent to:

```python
def reduce(function, iterable, initializer=None):
    it = iter(iterable)
    if initializer is None:
        value = next(it)
    else:
        value = initializer
    for element in it:
        value = function(value, element)
    return value
```

`functools.update_wrapper(wrapper, wrapped, assigned=WRAPPER_ASSIGNMENTS, updated=WRAPPER_UPDATES)`

Update a `wrapper` function to look like the `wrapped` function. The optional arguments are tuples to specify which attributes of the original function are assigned directly to the matching attributes on the wrapper function and which attributes of the wrapper function are updated with the corresponding attributes from the original function. The default values for these arguments are the module level constants `WRAPPER_ASSIGNMENTS` (which assigns to the wrapper function's `__name__`, `__module__`, `__annotations__` and `__doc__`, the documentation string) and `WRAPPER_UPDATES`
(which updates the wrapper function’s __dict__, i.e. the instance dictionary).

To allow access to the original function for introspection and other purposes (e.g. bypassing a caching decorator such as lru_cache()), this function automatically adds a __wrapped__ attribute to the wrapper that refers to the original function.

The main intended use for this function is in decorator functions which wrap the decorated function and return the wrapper. If the wrapper function is not updated, the metadata of the returned function will reflect the wrapper definition rather than the original function definition, which is typically less than helpful.

update_wrapper() may be used with callables other than functions. Any attributes named in assigned or updated that are missing from the object being wrapped are ignored (i.e. this function will not attempt to set them on the wrapper function). AttributeError is still raised if the wrapper function itself is missing any attributes named in updated.

New in version 3.2: Automatic addition of the __wrapped__ attribute.

New in version 3.2: Copying of the __annotations__ attribute by default.

Changed in version 3.2: Missing attributes no longer trigger an AttributeError.

@functools.wraps(wrapped, assigned=WRAPPER_ASSIGNMENTS, updated=WRAPPER_UPDATES)
This is a convenience function for invoking `partial(update_wrapper, wrapped=wrapped, assigned=assigned, updated=updated)` as a function decorator when defining a wrapper function. For example:

```python
>>> from functools import wraps
>>> def my_decorator(f):
...     @wraps(f)
...     def wrapper(*args, **kwds):
...         print('Calling decorated function')
...         return f(*args, **kwds)
...     return wrapper
...

>>> @my_decorator
... def example():
...     """Docstring""
...     print('Called example function')
...

>>> example()
Calling decorated function
Called example function
```

Without the use of this decorator factory, the name of the example function would have been `wrapper`, and the docstring of the original `example()` would have been lost.
10.2.1. **partial** Objects

**partial** objects are callable objects created by `partial()`. They have three read-only attributes:

**partial**. **func**
- A callable object or function. Calls to the **partial** object will be forwarded to **func** with new arguments and keywords.

**partial**. **args**
- The leftmost positional arguments that will be prepended to the positional arguments provided to a **partial** object call.

**partial**. **keywords**
- The keyword arguments that will be supplied when the **partial** object is called.

**partial** objects are like function objects in that they are callable, weak referencable, and can have attributes. There are some important differences. For instance, the **__name__** and **__doc__** attributes are not created automatically. Also, **partial** objects defined in classes behave like static methods and do not transform into bound methods during instance attribute look-up.
10.3. operator — Standard operators as functions

The operator module exports a set of efficient functions corresponding to the intrinsic operators of Python. For example, \texttt{operator.add(x, y)} is equivalent to the expression \texttt{x+y}. The function names are those used for special class methods; variants without leading and trailing \_\_ are also provided for convenience.

The functions fall into categories that perform object comparisons, logical operations, mathematical operations and sequence operations.

The object comparison functions are useful for all objects, and are named after the rich comparison operators they support:

\begin{verbatim}
operator.lt(a, b)
operator.le(a, b)
operator.eq(a, b)
operator.ne(a, b)
operator.ge(a, b)
operator.gt(a, b)
operator.__lt__(a, b)
operator.__le__(a, b)
operator.__eq__(a, b)
operator.__ne__(a, b)
operator.__ge__(a, b)
operator.__gt__(a, b)
\end{verbatim}

Perform “rich comparisons” between \texttt{a} and \texttt{b}. Specifically, \texttt{lt(a, b)} is equivalent to \texttt{a < b}, \texttt{le(a, b)} is equivalent to \texttt{a <= b},
eq(a, b) is equivalent to a == b, ne(a, b) is equivalent to a != b, gt(a, b) is equivalent to a > b and ge(a, b) is equivalent to a >= b. Note that these functions can return any value, which may or may not be interpretable as a Boolean value. See *Comparisons* for more information about rich comparisons.

The logical operations are also generally applicable to all objects, and support truth tests, identity tests, and boolean operations:

```python
operator.not_(obj)
operator.__not__(obj)
```

Return the outcome of `not obj`. (Note that there is no `__not__() method for object instances; only the interpreter core defines this operation. The result is affected by the `__bool__()` and `__len__()` methods.)

```python
operator.truth(obj)
```

Return `True` if `obj` is true, and `False` otherwise. This is equivalent to using the `bool` constructor.

```python
operator.is_(a, b)
```

Return `a is b`. Tests object identity.

```python
operator.is_not(a, b)
```

Return `a is not b`. Tests object identity.

The mathematical and bitwise operations are the most numerous:

```python
operator.abs(obj)
operator.__abs__(obj)
```

Return the absolute value of `obj`. 

operator. **add**(a, b)
operator. **__add__**(a, b)
    Return `a + b`, for `a` and `b` numbers.

operator. **and**(a, b)
operator. **__and__**(a, b)
    Return the bitwise and of `a` and `b`.

operator. **floordiv**(a, b)
operator. **__floordiv__**(a, b)
    Return `a // b`.

operator. **index**(a)
operator. **__index__**(a)
    Return `a` converted to an integer. Equivalent to `a.__index__()`. 

operator. **inv**(obj)
operator. **invert**(obj)
operator. **__inv__**(obj)
operator. **__invert__**(obj)
    Return the bitwise inverse of the number `obj`. This is equivalent to `~obj`.

operator. **lshift**(a, b)
operator. **__lshift__**(a, b)
    Return `a` shifted left by `b`.

operator. **mod**(a, b)
operator. **__mod__**(a, b)
    Return `a % b`.

operator. **mul**(a, b)
operator.__mul__(a, b)
    Return a \* b, for a and b numbers.

operator.neg(obj)
operator.__neg__(obj)
    Return obj negated (-obj).

operator.or_(a, b)
operator.__or__(a, b)
    Return the bitwise or of a and b.

operator.pos(obj)
operator.__pos__(obj)
    Return obj positive (+obj).

operator.pow(a, b)
operator.__pow__(a, b)
    Return a ** b, for a and b numbers.

operator.rshift(a, b)
operator.__rshift__(a, b)
    Return a shifted right by b.

operator.sub(a, b)
operator.__sub__(a, b)
    Return a - b.

operator.truediv(a, b)
operator.__truediv__(a, b)
    Return a / b where 2/3 is .66 rather than 0. This is also known as “true” division.
operator. \texttt{xor}(a, b)  
operator. \texttt{\_\_\_xor\_\_}(a, b)  

Return the bitwise exclusive or of \textit{a} and \textit{b}.

Operations which work with sequences (some of them with mappings too) include:

operator. \texttt{concat}(a, b)  
operator. \texttt{\_\_\_concat\_\_}(a, b)  

Return \texttt{a + b} for \textit{a} and \textit{b} sequences.

operator. \texttt{contains}(a, b)  
operator. \texttt{\_\_contains\_\_}(a, b)  

Return the outcome of the test \texttt{b in a}. Note the reversed operands.

operator. \texttt{countOf}(a, b)  

Return the number of occurrences of \textit{b} in \textit{a}.

operator. \texttt{delitem}(a, b)  
operator. \texttt{\_\_delitem\_\_}(a, b)  

Remove the value of \textit{a} at index \textit{b}.

operator. \texttt{getitem}(a, b)  
operator. \texttt{\_\_getitem\_\_}(a, b)  

Return the value of \textit{a} at index \textit{b}.

operator. \texttt{indexOf}(a, b)  

Return the index of the first of occurrence of \textit{b} in \textit{a}.

operator. \texttt{setitem}(a, b, c)  
operator. \texttt{\_\_setitem\_\_}(a, b, c)
Set the value of \( a \) at index \( b \) to \( c \).

Example: Build a dictionary that maps the ordinals from 0 to 255 to their character equivalents.

```python
>>> d = {}
>>> keys = range(256)
>>> vals = map(chr, keys)
```  
```python
map(operator.setitem, [d]*len(keys), keys, vals)
```  
The `operator` module also defines tools for generalized attribute and item lookups. These are useful for making fast field extractors as arguments for `map()`, `sorted()`, `itertools.groupby()`, or other functions that expect a function argument.

`operator.attrgetter(attr)`  
`operator.attrgetter(*attrs)`  

Return a callable object that fetches \( attr \) from its operand. If more than one attribute is requested, returns a tuple of attributes. The attribute names can also contain dots. For example:

- After \( f = \text{attrgetter('name')} \), the call \( f(b) \) returns \( b.name \).
- After \( f = \text{attrgetter('name', 'date')} \), the call \( f(b) \) returns \( (b.name, b.date) \).
- After \( f = \text{attrgetter('name.first', 'name.last')} \), the call \( f(b) \) returns \( (r.name.first, r.name.last) \).

Equivalent to:

```python
def attrgetter(*items):
    if any(not isinstance(item, str) for item in items):
        raise TypeError('attribute name must be a string')
    if len(items) == 1:
```
attr = items[0]
def g(obj):
    return resolve_attr(obj, attr)
else:
    def g(obj):
        return tuple(resolve_attr(obj, attr))
return g

def resolve_attr(obj, attr):
    for name in attr.split("."):  
        obj = getattr(obj, name)
    return obj

operator.itemgetter(item)
operator.itemgetter(*items)

Return a callable object that fetches item from its operand using the operand’s __getitem__() method. If multiple items are specified, returns a tuple of lookup values. For example:

- After f = itemgetter(2), the call f(r) returns r[2].
- After g = itemgetter(2, 5, 3), the call g(r) returns (r[2], r[5], r[3]).

Equivalent to:

def itemgetter(*items):
    if len(items) == 1:
        item = items[0]
        def g(obj):
            return obj[item]
    else:
        def g(obj):
            return tuple(obj[item] for item in it
return g
The items can be any type accepted by the operand’s \texttt{\_\_getitem\_()} method. Dictionaries accept any hashable value. Lists, tuples, and strings accept an index or a slice:

\begin{verbatim}
>>> itemgetter(1)('ABCDEFG')
'B'
>>> itemgetter(1,3,5)('ABCDEFG')
('B', 'D', 'F')
>>> itemgetter(slice(2,\texttt{None}))('ABCDEFG')
'CDEFG'
\end{verbatim}

Example of using \texttt{itemgetter()} to retrieve specific fields from a tuple record:

\begin{verbatim}
>>> inventory = [('apple', 3), ('banana', 2), ('pear', 1)]
>>> getcount = itemgetter(1)
>>> list(map(getcount, inventory))
[3, 2, 5, 1]
>>> sorted(inventory, key=getcount)
[('orange', 1), ('banana', 2), ('apple', 3), ('pear', 5)]
\end{verbatim}

\texttt{operator.methodcaller(name[, args...])}

Return a callable object that calls the method \texttt{name} on its operand. If additional arguments and/or keyword arguments are given, they will be given to the method as well. For example:

- After \texttt{f = methodcaller('name')}, the call \texttt{f(b)} returns \texttt{b.name()}
- After \texttt{f = methodcaller('name', 'foo', bar=1)}, the call \texttt{f(b)} returns \texttt{b.name('foo', bar=1)}

Equivalent to:

\begin{verbatim}
def methodcaller(name, *args, **kwargs):
\end{verbatim}
def caller(obj):
    return getattr(obj, name)(*args, **kwargs)
return caller
10.3.1. Mapping Operators to Functions

This table shows how abstract operations correspond to operator symbols in the Python syntax and the functions in the `operator` module.

<table>
<thead>
<tr>
<th>Operation</th>

</tr>
</tbody>
</table>
10.3.2. Inplace Operators

Many operations have an “in-place” version. Listed below are functions providing a more primitive access to in-place operators than the usual syntax does; for example, the statement $x += y$ is equivalent to $x = \text{operator.iadd}(x, y)$. Another way to put it is to say that $z = \text{operator.iadd}(x, y)$ is equivalent to the compound statement $z = x; z += y$.

In those examples, note that when an in-place method is called, the computation and assignment are performed in two separate steps. The in-place functions listed below only do the first step, calling the in-place method. The second step, assignment, is not handled.

For immutable targets such as strings, numbers, and tuples, the updated value is computed, but not assigned back to the input variable:

```python
>>> a = 'hello'
>>> iadd(a, ' world')
'hello world'
>>> a
'hello'
```

For mutable targets such as lists and dictionaries, the inplace method will perform the update, so no subsequent assignment is necessary:

```python
>>> s = ['h', 'e', 'l', 'l', 'o']
>>> iadd(s, [' ', 'w', 'o', 'r', 'l', 'd'])
['h', 'e', 'l', 'l', 'o', ' ', 'w', 'o', 'r', 'l', 'd']
>>> s
['h', 'e', 'l', 'l', 'o', ' ', 'w', 'o', 'r', 'l', 'd']
```
operator. **iadd**(a, b)
operator. **__iadd__**(a, b)
    a = iadd(a, b) is equivalent to a += b.

operator. **iand**(a, b)
operator. **__iand__**(a, b)
    a = iand(a, b) is equivalent to a &= b.

operator. **iconcat**(a, b)
operator. **__concat__**(a, b)
    a = icat(a, b) is equivalent to a += b for a and b sequences.

operator. **ifloordiv**(a, b)
operator. **__ifloordiv__**(a, b)
    a = ifloordiv(a, b) is equivalent to a //= b.

operator. **ilshift**(a, b)
operator. **__ilshift__**(a, b)
    a = ilshift(a, b) is equivalent to a <<= b.

operator. **imod**(a, b)
operator. **__imod__**(a, b)
    a = imod(a, b) is equivalent to a %= b.

operator. **imul**(a, b)
operator. **__imul__**(a, b)
    a = imul(a, b) is equivalent to a *= b.

operator. **ior**(a, b)
operator. **__ior__**(a, b)
    a = ior(a, b) is equivalent to a |= b.
operator. `ipow(a, b)`
operator. `__ipow__(a, b)`
    `a = ipow(a, b)` is equivalent to `a **= b`.

operator. `irshift(a, b)`
operator. `__irshift__(a, b)`
    `a = irshift(a, b)` is equivalent to `a >>= b`.

operator. `isub(a, b)`
operator. `__isub__(a, b)`
    `a = isub(a, b)` is equivalent to `a -= b`.

operator. `itruediv(a, b)`
operator. `__itruediv__(a, b)`
    `a = itruediv(a, b)` is equivalent to `a /= b`.

operator. `ixor(a, b)`
operator. `__ixor__(a, b)`
    `a = ixor(a, b)` is equivalent to `a ^= b`. 
11. File and Directory Access

The modules described in this chapter deal with disk files and directories. For example, there are modules for reading the properties of files, manipulating paths in a portable way, and creating temporary files. The full list of modules in this chapter is:

- **11.1. os.path** — Common pathname manipulations
- **11.2. fileinput** — Iterate over lines from multiple input streams
- **11.3. stat** — Interpreting stat() results
- **11.4. filecmp** — File and Directory Comparisons
  - **11.4.1. The dircmp class**
- **11.5. tempfile** — Generate temporary files and directories
  - **11.5.1. Examples**
- **11.6. glob** — Unix style pathname pattern expansion
- **11.7. fnmatch** — Unix filename pattern matching
- **11.8. linecache** — Random access to text lines
- **11.9. shutil** — High-level file operations
  - **11.9.1. Directory and files operations**
    - **11.9.1.1. copytree example**
  - **11.9.2. Archiving operations**
    - **11.9.2.1. Archiving example**
  - **11.9.3. Querying the size of the output terminal**
- **11.10. macpath** — Mac OS 9 path manipulation functions

### See also:

**Module os**

Operating system interfaces, including functions to work with files at a lower level than Python *file objects*.

**Module io**
Python's built-in I/O library, including both abstract classes and some concrete classes such as file I/O.

**Built-in function** `open()`

The standard way to open files for reading and writing with Python.
11.1. os.path — Common pathname manipulations

This module implements some useful functions on pathnames. To read or write files see open(), and for accessing the filesystem see the os module. The path parameters can be passed as either strings, or bytes. Applications are encouraged to represent file names as (Unicode) character strings. Unfortunately, some file names may not be representable as strings on Unix, so applications that need to support arbitrary file names on Unix should use bytes objects to represent path names. Vice versa, using bytes objects cannot represent all file names on Windows (in the standard mbcs encoding), hence Windows applications should use string objects to access all files.

Unlike a unix shell, Python does not do any automatic path expansions. Functions such as expanduser() and expandvars() can be invoked explicitly when an application desires shell-like path expansion. (See also the glob module.)

Note: All of these functions accept either only bytes or only string objects as their parameters. The result is an object of the same type, if a path or file name is returned.

Note: Since different operating systems have different path name conventions, there are several versions of this module in the standard library. The os.path module is always the path module suitable for the operating system Python is running on, and therefore usable for local paths. However, you can also import and use the individual modules if you want to manipulate a path that is always in
one of the different formats. They all have the same interface:

- posixpath for UNIX-style paths
- ntpath for Windows paths
- macpath for old-style MacOS paths
- os2emxpath for OS/2 EMX paths

**os.path.abspath(path)**

Return a normalized absolutized version of the pathname `path`. On most platforms, this is equivalent to calling the function `normpath()` as follows: `normpath(join(os.getcwd(), path))`.

**os.path.basename(path)**

Return the base name of pathname `path`. This is the second element of the pair returned by passing `path` to the function `split()`. Note that the result of this function is different from the Unix `basename` program; where `basename` for `/foo/bar/` returns `bar`, the `basename()` function returns an empty string (`''`).

**os.path.commonprefix(list)**

Return the longest path prefix (taken character-by-character) that is a prefix of all paths in `list`. If `list` is empty, return the empty string (`'}`). Note that this may return invalid paths because it works a character at a time.

**os.path.dirname(path)**

Return the directory name of pathname `path`. This is the first element of the pair returned by passing `path` to the function `split()`.
os.path.exists(path)

Return True if path refers to an existing path or an open file descriptor. Returns False for broken symbolic links. On some platforms, this function may return False if permission is not granted to execute os.stat() on the requested file, even if the path physically exists.

Changed in version 3.3: path can now be an integer: True is returned if it is an open file descriptor, False otherwise.

os.path.lexists(path)

Return True if path refers to an existing path. Returns True for broken symbolic links. Equivalent to exists() on platforms lacking os.lstat().

os.path.expanduser(path)

On Unix and Windows, return the argument with an initial component of ~ or ~user replaced by that user's home directory.

On Unix, an initial ~ is replaced by the environment variable HOME if it is set; otherwise the current user's home directory is looked up in the password directory through the built-in module pwd. An initial ~user is looked up directly in the password directory.

On Windows, HOME and USERPROFILE will be used if set, otherwise a combination of HOMEPATH and HOMEDRIVE will be used. An initial ~user is handled by stripping the last directory component from the created user path derived above.

If the expansion fails or if the path does not begin with a tilde, the path is returned unchanged.
os.path.expandvars(path)

Return the argument with environment variables expanded. Substrings of the form $name or ${name} are replaced by the value of environment variable name. Malformed variable names and references to non-existing variables are left unchanged.

On Windows, %name% expansions are supported in addition to $name and ${name}.

os.path.getatime(path)

Return the time of last access of path. The return value is a number giving the number of seconds since the epoch (see the time module). Raise OSError if the file does not exist or is inaccessible.

If os.stat_float_times() returns True, the result is a floating point number.

os.path.getmtime(path)

Return the time of last modification of path. The return value is a number giving the number of seconds since the epoch (see the time module). Raise OSError if the file does not exist or is inaccessible.

If os.stat_float_times() returns True, the result is a floating point number.

os.path.getctime(path)

Return the system’s ctime which, on some systems (like Unix) is the time of the last metadata change, and, on others (like Windows), is the creation time for path. The return value is a number giving the number of seconds since the epoch (see the
time module). Raise OSError if the file does not exist or is inaccessible.

os.path.getsize(path)
Return the size, in bytes, of path. Raise OSError if the file does not exist or is inaccessible.

os.path.isabs(path)
Return True if path is an absolute pathname. On Unix, that means it begins with a slash, on Windows that it begins with a (back)slash after chopping off a potential drive letter.

os.path.isfile(path)
Return True if path is an existing regular file. This follows symbolic links, so both islink() and isfile() can be true for the same path.

os.path.isdir(path)
Return True if path is an existing directory. This follows symbolic links, so both islink() and isdir() can be true for the same path.

os.path.islink(path)
Return True if path refers to a directory entry that is a symbolic link. Always False if symbolic links are not supported.

os.path.ismount(path)
Return True if pathname path is a mount point: a point in a file system where a different file system has been mounted. The function checks whether path's parent, path/.., is on a different device than path, or whether path/.. and path point to the same i-node on the same device — this should detect mount points for all
Unix and POSIX variants.

**os.path.join(path1[, path2[, ...]])**

Join one or more path components intelligently. If any component is an absolute path, all previous components (on Windows, including the previous drive letter, if there was one) are thrown away, and joining continues. The return value is the concatenation of *path1*, and optionally *path2*, etc., with exactly one directory separator (os.sep) following each non-empty part except the last. (This means that an empty last part will result in a path that ends with a separator.) Note that on Windows, since there is a current directory for each drive, `os.path.join("c:\", "foo")` represents a path relative to the current directory on drive C: (`c:\foo`), not `c:\\foo`.

**os.path.normcase(path)**

Normalize the case of a pathname. On Unix and Mac OS X, this returns the path unchanged; on case-insensitive filesystems, it converts the path to lowercase. On Windows, it also converts forward slashes to backward slashes. Raise a TypeError if the type of *path* is not `str` or `bytes`.

**os.path.normpath(path)**

Normalize a pathname by collapsing redundant separators and up-level references so that A/\B, A/\..\B and A/foo/..\B all become A/\B. This string manipulation may change the meaning of a path that contains symbolic links. On Windows, it converts forward slashes to backward slashes. To normalize case, use `normcase()`.

**os.path.realpath(path)**

Return the canonical path of the specified filename, eliminating any symbolic links encountered in the path (if they are supported by the
os.path.relpth(path, start=None)
Return a relative filepath to path either from the current directory or from an optional start directory. This is a path computation: the filesystem is not accessed to confirm the existence or nature of path or start.

start defaults to os.getcwd.

Availability: Unix, Windows.

os.path.samefile(path1, path2)
Return True if both pathname arguments refer to the same file or directory. On Unix, this is determined by the device number and inode number and raises an exception if a os.stat() call on either pathname fails.

On Windows, two files are the same if they resolve to the same final path name using the Windows API call GetFinalPathNameByHandle. This function raises an exception if handles cannot be obtained to either file.

Availability: Unix, Windows.

*Changed in version 3.2:* Added Windows support.

os.path.sameopenfile(fp1, fp2)
Return True if the file descriptors fp1 and fp2 refer to the same file.

Availability: Unix, Windows.

*Changed in version 3.2:* Added Windows support.
os.path.**samestat**(stat1, stat2)

Return True if the stat tuples stat1 and stat2 refer to the same file. These structures may have been returned by os.fstat(), os.lstat(), or os.stat(). This function implements the underlying comparison used by samefile() and sameopenfile().

Availability: Unix.

os.path.**split**(path)

Split the pathname path into a pair, (head, tail) where tail is the last pathname component and head is everything leading up to that. The tail part will never contain a slash; if path ends in a slash, tail will be empty. If there is no slash in path, head will be empty. If path is empty, both head and tail are empty. Trailing slashes are stripped from head unless it is the root (one or more slashes only). In all cases, join(head, tail) returns a path to the same location as path (but the strings may differ). Also see the functions dirname() and basename().

os.path.**splitdrive**(path)

Split the pathname path into a pair (drive, tail) where drive is either a mount point or the empty string. On systems which do not use drive specifications, drive will always be the empty string. In all cases, drive + tail will be the same as path.

On Windows, splits a pathname into drive/UNC sharepoint and relative path.

If the path contains a drive letter, drive will contain everything up to and including the colon. e.g. splitdrive("c:/dir") returns ("c:", "/dir")
If the path contains a UNC path, drive will contain the host name and share, up to but not including the fourth separator. e.g. `splitdrive("//host/computer/dir")` returns `("//host/computer", "/dir")`

```python
os.path.splitext(path)
```

Split the pathname `path` into a pair `(root, ext)` such that `root + ext == path`, and `ext` is empty or begins with a period and contains at most one period. Leading periods on the basename are ignored; `splitext('.cshrc')` returns `('.cshrc', '')`.

```python
os.path.splitext(path)
```

**Deprecated since version 3.1:** Use `splitdrive` instead.

Split the pathname `path` into a pair `(unc, rest)` so that `unc` is the UNC mount point (such as `r'\host\mount'`), if present, and `rest` the rest of the path (such as `r'\path\file.ext'`). For paths containing drive letters, `unc` will always be the empty string.

Availability: Windows.

```python
os.path.splitext(path)
```

** supports_unicode_filenames**

True if arbitrary Unicode strings can be used as file names (within limitations imposed by the file system).
11.2. **fileinput** — Iterate over lines from multiple input streams

**Source code**: Lib/fileinput.py

This module implements a helper class and functions to quickly write a loop over standard input or a list of files. If you just want to read or write one file see `open()`.

The typical use is:

```python
import fileinput
for line in fileinput.input():
    process(line)
```

This iterates over the lines of all files listed in `sys.argv[1:]`, defaulting to `sys.stdin` if the list is empty. If a filename is `'- '`, it is also replaced by `sys.stdin`. To specify an alternative list of filenames, pass it as the first argument to `input()`. A single file name is also allowed.

All files are opened in text mode by default, but you can override this by specifying the `mode` parameter in the call to `input()` or `FileInput`. If an I/O error occurs during opening or reading a file, `OSError` is raised.

*Changed in version 3.3*: `IOError` used to be raised; it is now an alias of `OSError`.

If `sys.stdin` is used more than once, the second and further use will
return no lines, except perhaps for interactive use, or if it has been explicitly reset (e.g. using \texttt{sys.stdin.seek(0)}).

Empty files are opened and immediately closed; the only time their presence in the list of filenames is noticeable at all is when the last file opened is empty.

Lines are returned with any newlines intact, which means that the last line in a file may not have one.

You can control how files are opened by providing an opening hook via the \texttt{openhook} parameter to \texttt{fileinput.input()} or \texttt{FileInput()}. The hook must be a function that takes two arguments, \texttt{filename} and \texttt{mode}, and returns an accordingly opened file-like object. Two useful hooks are already provided by this module.

The following function is the primary interface of this module:

\texttt{fileinput.input(files=None, inplace=False, backup='', bufsize=0, mode='r', openhook=None)}

Create an instance of the \texttt{FileInput} class. The instance will be used as global state for the functions of this module, and is also returned to use during iteration. The parameters to this function will be passed along to the constructor of the \texttt{FileInput} class.

The \texttt{FileInput} instance can be used as a context manager in the \texttt{with} statement. In this example, \texttt{input} is closed after the \texttt{with} statement is exited, even if an exception occurs:

\begin{verbatim}
with fileinput.input(files=('spam.txt', 'eggs.txt')) as f:
    for line in f:
        process(line)
\end{verbatim}
Changed in version 3.2: Can be used as a context manager.

The following functions use the global state created by `fileinput.input()`; if there is no active state, `RuntimeError` is raised.

`fileinput.filename()`  
Return the name of the file currently being read. Before the first line has been read, returns None.

`fileinput.fileno()`  
Return the integer “file descriptor” for the current file. When no file is opened (before the first line and between files), returns -1.

`fileinput.lineno()`  
Return the cumulative line number of the line that has just been read. Before the first line has been read, returns 0. After the last line of the last file has been read, returns the line number of that line.

`fileinput.filelineno()`  
Return the line number in the current file. Before the first line has been read, returns 0. After the last line of the last file has been read, returns the line number of that line within the file.

`fileinput.isfirstline()`  
Returns true if the line just read is the first line of its file, otherwise returns false.

`fileinput.isstdin()`  
Returns true if the last line was read from `sys.stdin`, otherwise returns false.
fileinput.nextfile()

Close the current file so that the next iteration will read the first line from the next file (if any); lines not read from the file will not count towards the cumulative line count. The filename is not changed until after the first line of the next file has been read. Before the first line has been read, this function has no effect; it cannot be used to skip the first file. After the last line of the last file has been read, this function has no effect.

fileinput.close()

Close the sequence.

The class which implements the sequence behavior provided by the module is available for subclassing as well:

class fileinput.FileInput(files=None, inplace=False, backup='', bufsize=0, mode='r', openhook=None)

Class FileInput is the implementation; its methods filename(), fileno(), lineno(), filelineno(), isfirstline(), isstdin(), nextfile() and close() correspond to the functions of the same name in the module. In addition it has a readline() method which returns the next input line, and a __getitem__() method which implements the sequence behavior. The sequence must be accessed in strictly sequential order; random access and readline() cannot be mixed.

With mode you can specify which file mode will be passed to open(). It must be one of 'r', 'rU', 'U' and 'rb'.

The openhook, when given, must be a function that takes two arguments, filename and mode, and returns an accordingly opened
file-like object. You cannot use `inplace` and `openhook` together.

A `FileInput` instance can be used as a context manager in the `with` statement. In this example, `input` is closed after the `with` statement is exited, even if an exception occurs:

```python
with FileInput(files=('spam.txt', 'eggs.txt')) as process(input)
```

*Changed in version 3.2:* Can be used as a context manager.

**Optional in-place filtering:** if the keyword argument `inplace=True` is passed to `fileinput.input()` or to the `FileInput` constructor, the file is moved to a backup file and standard output is directed to the input file (if a file of the same name as the backup file already exists, it will be replaced silently). This makes it possible to write a filter that rewrites its input file in place. If the `backup` parameter is given (typically as `backup='.<some extension>'`), it specifies the extension for the backup file, and the backup file remains around; by default, the extension is `'.bak'` and it is deleted when the output file is closed. In-place filtering is disabled when standard input is read.

The two following opening hooks are provided by this module:

`fileinput.hook_compressed(filename, mode)`

Transparently opens files compressed with gzip and bzip2 (recognized by the extensions `.gz` and `.bz2`) using the `gzip` and `bz2` modules. If the filename extension is not `.gz` or `.bz2`, the file is opened normally (ie, using `open()` without any decompression).

```python
Usage example: fi =
```
fileinput.FileInput(openhook=fileinput.hook_compressed)

fileinput.**hook_encoded**(encoding)

Returns a hook which opens each file with **codecs.open()**, using the given *encoding* to read the file.

Usage example:

```python
fi = fileinput.FileInput(openhook=fileinput.hook_encoded(encoding='iso-8859-1'))
```
11.3. `stat` — Interpreting `stat()` results

Source code: Lib/stat.py

The `stat` module defines constants and functions for interpreting the results of `os.stat()`, `os.fstat()` and `os.lstat()` (if they exist). For complete details about the `stat()`, `fstat()` and `lstat()` calls, consult the documentation for your system.

The `stat` module defines the following functions to test for specific file types:

- `stat.S_ISDIR(mode)`
  - Return non-zero if the mode is from a directory.

- `stat.S_ISCHR(mode)`
  - Return non-zero if the mode is from a character special device file.

- `stat.S_ISBLK(mode)`
  - Return non-zero if the mode is from a block special device file.

- `stat.S_ISREG(mode)`
  - Return non-zero if the mode is from a regular file.

- `stat.S_ISFIFO(mode)`
  - Return non-zero if the mode is from a FIFO (named pipe).

- `stat.S_ISLNK(mode)`
  - Return non-zero if the mode is from a symbolic link.
stat.**S_ISSOCK**(mode)

Return non-zero if the mode is from a socket.

Two additional functions are defined for more general manipulation of the file's mode:

stat.**S_IMODE**(mode)

Return the portion of the file's mode that can be set by `os.chmod()`—that is, the file's permission bits, plus the sticky bit, set-group-id, and set-user-id bits (on systems that support them).

stat.**S_IFMT**(mode)

Return the portion of the file's mode that describes the file type (used by the S_IS*() functions above).

Normally, you would use the `os.path.is*()` functions for testing the type of a file; the functions here are useful when you are doing multiple tests of the same file and wish to avoid the overhead of the `stat()` system call for each test. These are also useful when checking for information about a file that isn't handled by `os.path`, like the tests for block and character devices.

Example:

```python
import os, sys
from stat import *

def walktree(top, callback):
    '''recursively descend the directory tree rooted
calling the callback function for each regular

    for f in os.listdir(top):
        pathname = os.path.join(top, f)
        mode = os.stat(pathname).st_mode
```
if S_ISDIR(mode):
    # It's a directory, recurse into it
    walktree(pathname, callback)
elif S_ISREG(mode):
    # It's a file, call the callback function
    callback(pathname)
else:
    # Unknown file type, print a message
    print('Skipping %s' % pathname)

def visitfile(file):
    print('visiting', file)

if __name__ == '__main__':
    walktree(sys.argv[1], visitfile)

An additional utility function is provided to convert a file's mode in a human readable string:

```python
stat.filemode(mode)
```

Convert a file's mode to a string of the form ‘-rwxrwxrwx’.

*New in version 3.3.*

All the variables below are simply symbolic indexes into the 10-tuple returned by `os.stat()`, `os.fstat()` or `os.lstat()`.

```python
stat.ST_MODE
```

Inode protection mode.

```python
stat.ST_INO
```

Inode number.

```python
stat.ST_DEV
```

Device inode resides on.
**stat.ST_NLINK**
Number of links to the inode.

**stat.ST_UID**
User id of the owner.

**stat.ST_GID**
Group id of the owner.

**stat.ST_SIZE**
Size in bytes of a plain file; amount of data waiting on some special files.

**stat.ST_ATIME**
Time of last access.

**stat.ST_MTIME**
Time of last modification.

**stat.ST_CTIME**
The “ctime” as reported by the operating system. On some systems (like Unix) is the time of the last metadata change, and, on others (like Windows), is the creation time (see platform documentation for details).

The interpretation of “file size” changes according to the file type. For plain files this is the size of the file in bytes. For FIFOs and sockets under most flavors of Unix (including Linux in particular), the “size” is the number of bytes waiting to be read at the time of the call to `os.stat()`, `os.fstat()`, or `os.lstat()`; this can sometimes be useful, especially for polling one of these special files after a non-blocking open. The meaning of the size field for other character and block devices varies more, depending on the implementation of the
underlying system call.

The variables below define the flags used in the `ST_MODE` field.

Use of the functions above is more portable than use of the first set of flags:

```c
stat.S_IFSOCK
    Socket.

stat.S_IFLNK
    Symbolic link.

stat.S_IFREG
    Regular file.

stat.S_IFBLK
    Block device.

stat.S_IFDIR
    Directory.

stat.S_IFCHR
    Character device.

stat.S_IFIFO
    FIFO.
```

The following flags can also be used in the `mode` argument of `os.chmod()`:

```c
stat.S_ISUID
    Set UID bit.
```
stat. **S_ISGID**
Set-group-ID bit. This bit has several special uses. For a directory it indicates that BSD semantics is to be used for that directory: files created there inherit their group ID from the directory, not from the effective group ID of the creating process, and directories created there will also get the **S_ISGID** bit set. For a file that does not have the group execution bit (**S_IXGRP**) set, the set-group-ID bit indicates mandatory file/record locking (see also **S_ENFMT**).

stat. **S_ISVTX**
Sticky bit. When this bit is set on a directory it means that a file in that directory can be renamed or deleted only by the owner of the file, by the owner of the directory, or by a privileged process.

stat. **S_IRWXU**
Mask for file owner permissions.

stat. **S_IRUSR**
Owner has read permission.

stat. **S_IWUSR**
Owner has write permission.

stat. **S_IXUSR**
Owner has execute permission.

stat. **S_IRWXG**
Mask for group permissions.

stat. **S_IRGRP**
Group has read permission.

stat. **S_IWGRP**
Group has write permission.

\texttt{stat.S\_IXGRP}

Group has execute permission.

\texttt{stat.S\_IRWXO}

Mask for permissions for others (not in group).

\texttt{stat.S\_IROTH}

Others have read permission.

\texttt{stat.S\_IWOTH}

Others have write permission.

\texttt{stat.S\_IXOTH}

Others have execute permission.

\texttt{stat.S\_ENFMT}

System V file locking enforcement. This flag is shared with \texttt{S\_ISGID}: file/record locking is enforced on files that do not have the group execution bit (\texttt{S\_IXGRP}) set.

\texttt{stat.S\_IREAD}

Unix V7 synonym for \texttt{S\_IRUSR}.

\texttt{stat.S\_IWRITE}

Unix V7 synonym for \texttt{S\_IWUSR}.

\texttt{stat.S\_IEXEC}

Unix V7 synonym for \texttt{S\_IXUSR}.

The following flags can be used in the flags argument of \texttt{os.chflags()}:
stat. **UF_NODUMP**
   Do not dump the file.

stat. **UF_IMMUTABLE**
   The file may not be changed.

stat. **UF_APPEND**
   The file may only be appended to.

stat. **UF_OPAQUE**
   The directory is opaque when viewed through a union stack.

stat. **UF_NOUNLINK**
   The file may not be renamed or deleted.

stat. **UF_COMPRESSED**
   The file is stored compressed (Mac OS X 10.6+).

stat. **UF_HIDDEN**
   The file should not be displayed in a GUI (Mac OS X 10.5+).

stat. **SF_ARCHIVED**
   The file may be archived.

stat. **SF_IMMUTABLE**
   The file may not be changed.

stat. **SF_APPEND**
   The file may only be appended to.

stat. **SF_NOUNLINK**
   The file may not be renamed or deleted.

stat. **SF_SNAPSHOT**
The file is a snapshot file.

See the *BSD or Mac OS systems man page `chflags(2)` for more information.
11.4. `filecmp` — File and Directory Comparisons

Source code: `Lib/filecmp.py`

The `filecmp` module defines functions to compare files and directories, with various optional time/correctness trade-offs. For comparing files, see also the `difflib` module.

The `filecmp` module defines the following functions:

`filecmp.cmp(f1, f2, shallow=True)`

Compare the files named `f1` and `f2`, returning `True` if they seem equal, `False` otherwise.

If `shallow` is true, files with identical `os.stat()` signatures are taken to be equal. Otherwise, the contents of the files are compared.

Note that no external programs are called from this function, giving it portability and efficiency.

`filecmp.cmpfiles(dir1, dir2, common, shallow=True)`

Compare the files in the two directories `dir1` and `dir2` whose names are given by `common`.

Returns three lists of file names: `match`, `mismatch`, `errors`. `match` contains the list of files that match, `mismatch` contains the names of those that don't, and `errors` lists the names of files which could not be compared. Files are listed in `errors` if they don't exist in one
of the directories, the user lacks permission to read them or if the comparison could not be done for some other reason.

The shallow parameter has the same meaning and default value as for `filecmp.cmp()`.

For example, `cmpfiles('a', 'b', ['c', 'd/e'])` will compare `a/c` with `b/c` and `a/d/e` with `b/d/e`. 'c' and 'd/e' will each be in one of the three returned lists.
11.4.1. The **dir cmp** class

class filecmp.**dir cmp**(a, b, ignore=None, hide=None)

Construct a new directory comparison object, to compare the
directories *a* and *b*. *ignore* is a list of names to ignore, and defaults
to ['RCS', 'CVS', 'tags']. *hide* is a list of names to hide, and defaults to [os.curdir, os.pardir].

The **dir cmp** class compares files by doing *shallow* comparisons
as described for filecmp.cmp().

The **dir cmp** class provides the following methods:

**report()**

Print (to **sys.stdout**) a comparison between *a* and *b*.

**report_partial_closure()**

Print a comparison between *a* and *b* and common immediate
subdirectories.

**report_full_closure()**

Print a comparison between *a* and *b* and common
subdirectories (recursively).

The **dir cmp** class offers a number of interesting attributes that
may be used to get various bits of information about the directory
trees being compared.

Note that via **__getattr__()** hooks, all attributes are computed
lazily, so there is no speed penalty if only those attributes which are
lightweight to compute are used.
left
The directory $a$.
	right
The directory $b$.

left_list
Files and subdirectories in $a$, filtered by $hide$ and $ignore$.

right_list
Files and subdirectories in $b$, filtered by $hide$ and $ignore$.

common
Files and subdirectories in both $a$ and $b$.

left_only
Files and subdirectories only in $a$.

right_only
Files and subdirectories only in $b$.

common_dirs
Subdirectories in both $a$ and $b$.

common_files
Files in both $a$ and $b$.

common_funny
Names in both $a$ and $b$, such that the type differs between the directories, or names for which $os.stat()$ reports an error.

same_files
Files which are identical in both $a$ and $b$, using the class’s file comparison operator.
**diff_files**

Files which are in both \( a \) and \( b \), whose contents differ according to the class's file comparison operator.

**funny_files**

Files which are in both \( a \) and \( b \), but could not be compared.

**subdirs**

A dictionary mapping names in `common_dirs` to `dircmp` objects.

Here is a simplified example of using the `subdirs` attribute to search recursively through two directories to show common different files:

```python
>>> from filecmp import dircmp
>>> def print_diff_files(dcmp):
...     for name in dcmp.diff_files:
...         print("diff_file %s found in %s and %s" % (name, dcmp.left, dcmp.right))
...     for sub_dcmp in dcmp.subdirs.values():
...         print_diff_files(sub_dcmp)
... >>> dcmp = dircmp('dir1', 'dir2')
>>> print_diff_files(dcmp)
```
11.5. **tempfile** — Generate temporary files and directories

**Source code:** Lib/tempfile.py

This module generates temporary files and directories. It works on all supported platforms. It provides three new functions, `NamedTemporaryFile()`, `mkstemp()`, and `mkdtemp()`, which should eliminate all remaining need to use the insecure `mktemp()` function. Temporary file names created by this module no longer contain the process ID; instead a string of six random characters is used.

Also, all the user-callable functions now take additional arguments which allow direct control over the location and name of temporary files. It is no longer necessary to use the global `tempdir` variable. To maintain backward compatibility, the argument order is somewhat odd; it is recommended to use keyword arguments for clarity.

The module defines the following user-callable items:

```python
tempfile.TemporaryFile(mode='w+b', buffering=None, encoding=None, newline=None, suffix='', prefix='tmp', dir=None)
```

Return a *file-like object* that can be used as a temporary storage area. The file is created using `mkstemp()`. It will be destroyed as soon as it is closed (including an implicit close when the object is garbage collected). Under Unix, the directory entry for the file is removed immediately after the file is created. Other platforms do not support this; your code should not rely on a temporary file created using this function having or not having a visible name in
the file system.

The *mode* parameter defaults to 'w+b' so that the file created can be read and written without being closed. Binary mode is used so that it behaves consistently on all platforms without regard for the data that is stored. *buffering*, *encoding* and *newline* are interpreted as for *open()*.

The *dir*, *prefix* and *suffix* parameters are passed to *mkstemp()*.

The returned object is a true file object on POSIX platforms. On other platforms, it is a file-like object whose *file* attribute is the underlying true file object. This file-like object can be used in a *with* statement, just like a normal file.

tempfile. **NamedTemporaryFile**(*mode='w+b', buffering=None, encoding=None, newline=None, suffix='', prefix='tmp', dir=None, delete=True*)

This function operates exactly as **TemporaryFile()** does, except that the file is guaranteed to have a visible name in the file system (on Unix, the directory entry is not unlinked). That name can be retrieved from the name attribute of the file object. Whether the name can be used to open the file a second time, while the named temporary file is still open, varies across platforms (it can be so used on Unix; it cannot on Windows NT or later). If *delete* is true (the default), the file is deleted as soon as it is closed. The returned object is always a file-like object whose *file* attribute is the underlying true file object. This file-like object can be used in a *with* statement, just like a normal file.

tempfile. **SpooledTemporaryFile**(*max_size=0, mode='w+b', buffering=None, encoding=None, newline=None, suffix='', prefix='tmp', dir=None*)
This function operates exactly as `TemporaryFile()` does, except that data is spooled in memory until the file size exceeds `max_size`, or until the file's `fileno()` method is called, at which point the contents are written to disk and operation proceeds as with `TemporaryFile()`.

The resulting file has one additional method, `rollover()`, which causes the file to roll over to an on-disk file regardless of its size.

The returned object is a file-like object whose `_file` attribute is either a `io.BytesIO` or `io.StringIO` object (depending on whether binary or text `mode` was specified) or a true file object, depending on whether `rollover()` has been called. This file-like object can be used in a `with` statement, just like a normal file.

*Changed in version 3.3:* the `truncate` method now accepts a `size` argument.

tempfile. `TemporaryDirectory(suffix='', prefix='tmp', dir=None)`

This function creates a temporary directory using `mkdtemp()` (the supplied arguments are passed directly to the underlying function). The resulting object can be used as a context manager (see *With Statement Context Managers*). On completion of the context (or destruction of the temporary directory object), the newly created temporary directory and all its contents are removed from the filesystem.

The directory name can be retrieved from the `name` attribute of the returned object.

The directory can be explicitly cleaned up by calling the
cleanup() method.

*New in version 3.2.*

tempfile.mkstemp(suffix='', prefix='tmp', dir=None, text=False)

Creates a temporary file in the most secure manner possible. There are no race conditions in the file’s creation, assuming that the platform properly implements the `os.O_EXCL` flag for `os.open()`. The file is readable and writable only by the creating user ID. If the platform uses permission bits to indicate whether a file is executable, the file is executable by no one. The file descriptor is not inherited by child processes.

Unlike `TemporaryFile()`, the user of `mkstemp()` is responsible for deleting the temporary file when done with it.

If `suffix` is specified, the file name will end with that suffix, otherwise there will be no suffix. `mkstemp()` does not put a dot between the file name and the suffix; if you need one, put it at the beginning of `suffix`.

If `prefix` is specified, the file name will begin with that prefix; otherwise, a default prefix is used.

If `dir` is specified, the file will be created in that directory; otherwise, a default directory is used. The default directory is chosen from a platform-dependent list, but the user of the application can control the directory location by setting the `TMPDIR`, `TEMP` or `TMP` environment variables. There is thus no guarantee that the generated filename will have any nice properties, such as not requiring quoting when passed to external commands via `os.popen()`.
If `text` is specified, it indicates whether to open the file in binary mode (the default) or text mode. On some platforms, this makes no difference.

`mkstemp()` returns a tuple containing an OS-level handle to an open file (as would be returned by `os.open()`) and the absolute pathname of that file, in that order.

```
import tempfile
```

```
tempfile.mkdtemp(suffix='', prefix='tmp', dir=None)
```

Creates a temporary directory in the most secure manner possible. There are no race conditions in the directory’s creation. The directory is readable, writable, and searchable only by the creating user ID.

The user of `mkdtemp()` is responsible for deleting the temporary directory and its contents when done with it.

The `prefix`, `suffix`, and `dir` arguments are the same as for `mkstemp()`.

`mkdtemp()` returns the absolute pathname of the new directory.

```
import tempfile
```

```
tempfile.mktemp(suffix='', prefix='tmp', dir=None)
```

`Deprecation warning since version 2.3: Use mkstemp() instead.`

Return an absolute pathname of a file that did not exist at the time the call is made. The `prefix`, `suffix`, and `dir` arguments are the same as for `mkstemp()`.

**Warning:** Use of this function may introduce a security hole in your program. By the time you get around to doing anything with the file name it returns, someone else may have beaten you to it.
the punch. `mktemp()` usage can be replaced easily with `NamedTemporaryFile()`, passing it the `delete=False` parameter:

```python
>>> f = NamedTemporaryFile(delete=False)
>>> f.name
'/tmp/tmptjuijt'
>>> f.write(b'Hello World!
')
13
>>> f.close()
>>> os.unlink(f.name)
>>> os.path.exists(f.name)
False
```

The module uses two global variables that tell it how to construct a temporary name. They are initialized at the first call to any of the functions above. The caller may change them, but this is discouraged; use the appropriate function arguments, instead.

tempfile. `tempdir`

When set to a value other than None, this variable defines the default value for the `dir` argument to all the functions defined in this module.

If `tempdir` is unset or None at any call to any of the above functions, Python searches a standard list of directories and sets `tempdir` to the first one which the calling user can create files in. The list is:

1. The directory named by the TMPDIR environment variable.
2. The directory named by the TEMP environment variable.
3. The directory named by the TMP environment variable.
4. A platform-specific location:
- On Windows, the directories `C:\TEMP`, `C:\TMP`, `\TEMP`, and `\TMP`, in that order.
- On all other platforms, the directories `/tmp`, `/var/tmp`, and `/usr/tmp`, in that order.

5. As a last resort, the current working directory.

`tempfile.gettempdir()`

Return the directory currently selected to create temporary files in. If `tempdir` is not None, this simply returns its contents; otherwise, the search described above is performed, and the result returned.

`tempfile.gettempprefix()`

Return the filename prefix used to create temporary files. This does not contain the directory component.
11.5.1. Examples

Here are some examples of typical usage of the `tempfile` module:

```python
>>> import tempfile

# create a temporary file and write some data to it
>>> fp = tempfile.TemporaryFile()
>>> fp.write(b'Hello world!')
# read data from file
>>> fp.seek(0)
>>> fp.read()
b'Hello world!'
# close the file, it will be removed
>>> fp.close()

# create a temporary file using a context manager
>>> with tempfile.TemporaryFile() as fp:
    ...    fp.write(b'Hello world!')
    ...    fp.seek(0)
    ...    fp.read()
    b'Hello world!'
>>> # file is now closed and removed

# create a temporary directory using the context manager
>>> with tempfile.TemporaryDirectory() as tmpdirname:
    ...    print('created temporary directory', tmpdirname)
>>> # directory and contents have been removed
```
11.6. glob — Unix style pathname pattern expansion

Source code: Lib/glob.py

The `glob` module finds all the pathnames matching a specified pattern according to the rules used by the Unix shell. No tilde expansion is done, but *, ?, and character ranges expressed with [] will be correctly matched. This is done by using the `os.listdir()` and `fnmatch.fnmatch()` functions in concert, and not by actually invoking a subshell. Note that unlike `fnmatch.fnmatch()`, `glob` treats filenames beginning with a dot (.) as special cases. (For tilde and shell variable expansion, use `os.path.expanduser()` and `os.path.expandvars()`.)

For a literal match, wrap the meta-characters in brackets. For example, `'[?]` matches the character `?`.

`glob.glob(pathname)`

Return a possibly-empty list of path names that match `pathname`, which must be a string containing a path specification. `pathname` can be either absolute (like `/usr/src/Python-1.5/Makefile`) or relative (like `../../Tools/*//*.gif`), and can contain shell-style wildcards. Broken symlinks are included in the results (as in the shell).

`glob.iglob(pathname)`

Return an *iterator* which yields the same values as `glob()` without actually storing them all simultaneously.
For example, consider a directory containing only the following files: 1.gif, 2.txt, and card.gif. `glob()` will produce the following results. Notice how any leading components of the path are preserved.

```python
>>> import glob
>>> glob.glob('./[0-9].*')
['./1.gif', './2.txt']
>>> glob.glob('*.gif')
['1.gif', 'card.gif']
>>> glob.glob('?.gif')
['1.gif']
```

If the directory contains files starting with `.` they won't be matched by default. For example, consider a directory containing card.gif and .card.gif:

```python
>>> import glob
>>> glob.glob('*.gif')
['card.gif']
>>> glob.glob('.c*')
['.card.gif']
```

See also:

**Module fnmatch**

Shell-style filename (not path) expansion
11.7. fnmatch — Unix filename pattern matching

Source code: Lib/fnmatch.py

This module provides support for Unix shell-style wildcards, which are *not* the same as regular expressions (which are documented in the re module). The special characters used in shell-style wildcards are:

<table>
<thead>
<tr>
<th>Pattern</th>
<th>Meaning</th>
</tr>
</thead>
<tbody>
<tr>
<td>*</td>
<td>matches everything</td>
</tr>
<tr>
<td>?</td>
<td>matches any single character</td>
</tr>
<tr>
<td>[seq]</td>
<td>matches any character in seq</td>
</tr>
<tr>
<td>[!seq]</td>
<td>matches any character not in seq</td>
</tr>
</tbody>
</table>

For a literal match, wrap the meta-characters in brackets. For example, '[]' matches the character '[]'.

Note that the filename separator ('/' on Unix) is *not* special to this module. See module glob for pathname expansion (glob uses fnmatch() to match pathname segments). Similarly, filenames starting with a period are not special for this module, and are matched by the * and ? patterns.

fnmatch.fnmatch(filename, pattern)

Test whether the filename string matches the pattern string, returning True or False. If the operating system is case-
insensitive, then both parameters will be normalized to all lower- or upper-case before the comparison is performed. `fnmatchcase()` can be used to perform a case-sensitive comparison, regardless of whether that's standard for the operating system.

This example will print all file names in the current directory with the extension `.txt`:

```python
import fnmatch
import os

for file in os.listdir('.'):  
    if fnmatch.fnmatch(file, '*\.txt'):  
        print(file)
```

`fnmatch.fnmatchcase(filename, pattern)`
Test whether `filename` matches `pattern`, returning `True` or `False`; the comparison is case-sensitive.

`fnmatch.filter(names, pattern)`
Return the subset of the list of `names` that match `pattern`. It is the same as `[n for n in names if fnmatch(n, pattern)]`, but implemented more efficiently.

`fnmatch.translate(pattern)`
Return the shell-style `pattern` converted to a regular expression.

Example:

```python
>>> import fnmatch, re
>>> regex = fnmatch.translate('*.txt')
>>> regex
'.*\.txt$'
```
```python
>>> reobj = re.compile(regex)
>>> reobj.match('foobar.txt')
<_sre.SRE_Match object at 0x...>
```

**See also:**

**Module `glob`**

Unix shell-style path expansion.
The \texttt{linecache} module allows one to get any line from any file, while attempting to optimize internally, using a cache, the common case where many lines are read from a single file. This is used by the \texttt{traceback} module to retrieve source lines for inclusion in the formatted traceback.

The \texttt{linecache} module defines the following functions:

\begin{verbatim}
linecache.getline(filename, lineno, module_globals=None)
\end{verbatim}

Get line \texttt{lineno} from file named \texttt{filename}. This function will never raise an exception — it will return \\'\' on errors (the terminating newline character will be included for lines that are found).

If a file named \texttt{filename} is not found, the function will look for it in the module search path, \texttt{sys.path}, after first checking for a \texttt{PEP 302 \_\_loader\_\_} in \texttt{module\_globals}, in case the module was imported from a zipfile or other non-filesystem import source.

\begin{verbatim}
linecache.clearcache()
\end{verbatim}

Clear the cache. Use this function if you no longer need lines from files previously read using \texttt{getline()}. 

\begin{verbatim}
linecache.checkcache(filename=None)
\end{verbatim}

Check the cache for validity. Use this function if files in the cache may have changed on disk, and you require the updated version. If
filename is omitted, it will check all the entries in the cache.

Example:

```python
>>> import linecache
>>> linecache.getline('/etc/passwd', 4)
'sys:x:3:3:sys:/dev:/bin/sh
'```

11.9. `shutil` — High-level file operations

Source code: Lib/shutil.py

The `shutil` module offers a number of high-level operations on files and collections of files. In particular, functions are provided which support file copying and removal. For operations on individual files, see also the `os` module.

**Warning:** Even the higher-level file copying functions (`shutil.copy()`, `shutil.copy2()`) cannot copy all file metadata.

On POSIX platforms, this means that file owner and group are lost as well as ACLs. On Mac OS, the resource fork and other metadata are not used. This means that resources will be lost and file type and creator codes will not be correct. On Windows, file owners, ACLs and alternate data streams are not copied.
11.9.1. Directory and files operations

**shutil.copyfileobj**(fsrc, fdst[, length])

Copy the contents of the file-like object *fsrc* to the file-like object *fdst*. The integer *length*, if given, is the buffer size. In particular, a negative *length* value means to copy the data without looping over the source data in chunks; by default the data is read in chunks to avoid uncontrolled memory consumption. Note that if the current file position of the *fsrc* object is not 0, only the contents from the current file position to the end of the file will be copied.

**shutil.copyfile**(src, dst, *, follow_symlinks=True)

Copy the contents (no metadata) of the file named *src* to a file named *dst* and return *dst*. *src* and *dst* are path names given as strings. *dst* must be the complete target file name; look at shutil.copy() for a copy that accepts a target directory path. If *src* and *dst* specify the same file, Error is raised.

The destination location must be writable; otherwise, an OSError exception will be raised. If *dst* already exists, it will be replaced. Special files such as character or block devices and pipes cannot be copied with this function.

If *follow_symlinks* is false and *src* is a symbolic link, a new symbolic link will be created instead of copying the file *src* points to.

*Changed in version 3.3:* IOError used to be raised instead of OSError. Added *follow_symlinks* argument. Now returns *dst*.

**shutil.copymode**(src, dst, *, follow_symlinks=True)
Copy the permission bits from src to dst. The file contents, owner, and group are unaffected. src and dst are path names given as strings. If follow_symlinks is false, and both src and dst are symbolic links, copypmode() will attempt to modify the mode of dst itself (rather than the file it points to). This functionality is not available on every platform; please see copystat() for more information. If copypmode() cannot modify symbolic links on the local platform, and it is asked to do so, it will do nothing and return.

Changed in version 3.3: Added follow_symlinks argument.

```python
shutil.copystat(src, dst, *, follow_symlinks=True)
```

Copy the permission bits, last access time, last modification time, and flags from src to dst. On Linux, copystat() also copies the “extended attributes” where possible. The file contents, owner, and group are unaffected. src and dst are path names given as strings.

If follow_symlinks is false, and src and dst both refer to symbolic links, copystat() will operate on the symbolic links themselves rather than the files the symbolic links refer to–reading the information from the src symbolic link, and writing the information to the dst symbolic link.

**Note:** Not all platforms provide the ability to examine and modify symbolic links. Python itself can tell you what functionality is locally available.

- If os.chmod in os.supports_follow_symlinks is True, copystat() can modify the permission bits of a symbolic link.
- If os.utime in os.supports_follow_symlinks is True, copystat() can modify the last access and modification times of a symbolic link.
If \texttt{os.chflags \ in \ os.supports_follow_symlinks} is \texttt{True}, \texttt{copystat()} can modify the flags of a symbolic link. (\texttt{os.chflags} is not available on all platforms.)

On platforms where some or all of this functionality is unavailable, when asked to modify a symbolic link, \texttt{copystat()} will copy everything it can. \texttt{copystat()} never returns failure.

Please see \texttt{os.supports_follow_symlinks} for more information.

\textit{Changed in version 3.3:} Added \texttt{follow_symlinks} argument and support for Linux extended attributes.

\texttt{shutil.copy(src, dst, *[, follow_symlinks=True])}

Copies the file \texttt{src} to the file or directory \texttt{dst}. \texttt{src} and \texttt{dst} should be strings. If \texttt{dst} specifies a directory, the file will be copied into \texttt{dst} using the base filename from \texttt{src}. Returns the path to the newly created file.

If \texttt{follow_symlinks} is false, and \texttt{src} is a symbolic link, \texttt{dst} will be created as a symbolic link. If \texttt{follow_symlinks} is true and \texttt{src} is a symbolic link, \texttt{dst} will be a copy of the file \texttt{src} refers to.

\texttt{copy()} copies the file data and the file's permission mode (see \texttt{os.chmod()}). Other metadata, like the file's creation and modification times, is not preserved. To preserve all file metadata from the original, use \texttt{copy2()} instead.

\textit{Changed in version 3.3:} Added \texttt{follow_symlinks} argument. Now returns path to the newly created file.

\texttt{shutil.copy2(src, dst, *[, follow_symlinks=True])}

Identical to \texttt{copy()} except that \texttt{copy2()} also attempts to
preserve all file metadata.

When `follow_symlinks` is false, and `src` is a symbolic link, `copy2()` attempts to copy all metadata from the `src` symbolic link to the newly-created `dst` symbolic link. However, this functionality is not available on all platforms. On platforms where some or all of this functionality is unavailable, `copy2()` will preserve all the metadata it can; `copy2()` never returns failure.

`copy2()` uses `copystat()` to copy the file metadata. Please see `copystat()` for more information about platform support for modifying symbolic link metadata.

*Changed in version 3.3:* Added `follow_symlinks` argument, try to copy extended file system attributes too (currently Linux only). Now returns path to the newly created file.

**shutil.** `ignore_patterns(*patterns)`

This factory function creates a function that can be used as a callable for `copytree()`'s `ignore` argument, ignoring files and directories that match one of the glob-style `patterns` provided. See the example below.

**shutil.** `copytree(src, dst, symlinks=False, ignore=None, copy_function=copy2, ignore_dangling_symlinks=False)`

Recursively copy an entire directory tree rooted at `src`, returning the destination directory. The destination directory, named by `dst`, must not already exist; it will be created as well as missing parent directories. Permissions and times of directories are copied with `copystat()`, individual files are copied using `shutil.copy2()`.

If `symlinks` is true, symbolic links in the source tree are represented as symbolic links in the new tree and the metadata of the original
links will be copied as far as the platform allows; if false or omitted, the contents and metadata of the linked files are copied to the new tree.

When `symlinks` is false, if the file pointed by the symlink doesn’t exist, a exception will be added in the list of errors raised in a `Error` exception at the end of the copy process. You can set the optional `ignore_dangling_symlinks` flag to true if you want to silence this exception. Notice that this option has no effect on platforms that don’t support `os.symlink()`.

If `ignore` is given, it must be a callable that will receive as its arguments the directory being visited by `copytree()`, and a list of its contents, as returned by `os.listdir()`. Since `copytree()` is called recursively, the `ignore` callable will be called once for each directory that is copied. The callable must return a sequence of directory and file names relative to the current directory (i.e. a subset of the items in its second argument); these names will then be ignored in the copy process. `ignore_patterns()` can be used to create such a callable that ignores names based on glob-style patterns.

If exception(s) occur, an `Error` is raised with a list of reasons.

If `copy_function` is given, it must be a callable that will be used to copy each file. It will be called with the source path and the destination path as arguments. By default, `shutil.copy2()` is used, but any function that supports the same signature (like `shutil.copy()`) can be used.

*Changed in version 3.3:* Copy metadata when `symlinks` is false. Now returns `dst.`
Changed in version 3.2: Added the *copy_function* argument to be able to provide a custom copy function. Added the *ignore_dangling_symlinks* argument to silent dangling symlinks errors when *symlinks* is false.

```
shutil.rmtree(path, ignore_errors=False, onerror=None)
```

Delete an entire directory tree; *path* must point to a directory (but not a symbolic link to a directory). If *ignore_errors* is true, errors resulting from failed removals will be ignored; if false or omitted, such errors are handled by calling a handler specified by *onerror* or, if that is omitted, they raise an exception.

**Note:** On platforms that support the necessary fd-based functions a symlink attack resistant version of *rmtree()* is used by default. On other platforms, the *rmtree()* implementation is susceptible to a symlink attack: given proper timing and circumstances, attackers can manipulate symlinks on the filesystem to delete files they wouldn’t be able to access otherwise. Applications can use the *rmtree.avoids_symlink_attacks* function attribute to determine which case applies.

If *onerror* is provided, it must be a callable that accepts three parameters: *function*, *path*, and *excinfo*.

The first parameter, *function*, is the function which raised the exception; it depends on the platform and implementation. The second parameter, *path*, will be the path name passed to *function*. The third parameter, *excinfo*, will be the exception information returned by *sys.exc_info()* . Exceptions raised by *onerror* will not be caught.
Changed in version 3.3: Added a symlink attack resistant version that is used automatically if platform supports fd-based functions.

`rmtree.avoids_symlink_attacks`

Indicates whether the current platform and implementation provides a symlink attack resistant version of `rmtree()`. Currently this is only true for platforms supporting fd-based directory access functions.

New in version 3.3.

`shutil.move(src, dst)`

Recursively move a file or directory (src) to another location (dst) and return the destination.

If the destination is a directory or a symlink to a directory, then src is moved inside that directory.

The destination directory must not already exist. If the destination already exists but is not a directory, it may be overwritten depending on `os.rename()` semantics.

If the destination is on the current filesystem, then `os.rename()` is used. Otherwise, src is copied (using `shutil.copy2()`) to dst and then removed. In case of symlinks, a new symlink pointing to the target of src will be created in or as dst and src will be removed.

Changed in version 3.3: Added explicit symlink handling for foreign filesystems, thus adapting it to the behavior of GNU's `mv`. Now returns dst.

`shutil.disk_usage(path)`
Return disk usage statistics about the given path as a named tuple with the attributes total, used and free, which are the amount of total, used and free space, in bytes.

*New in version 3.3.*

Availability: Unix, Windows.

**shutil.chown(path, user=None, group=None)**

Change owner user and/or group of the given path.

*user* can be a system user name or a uid; the same applies to *group*. At least one argument is required.

See also os.chown(), the underlying function.

*Availability: Unix.*

*New in version 3.3.*

**shutil.which(cmd, mode=os.F_OK | os.X_OK, path=None)**

Return the path to an executable which would be run if the given *cmd* was called. If no *cmd* would be called, return None.

*mode* is a permission mask passed a to os.access(), by default determining if the file exists and executable.

When no *path* is specified, the results of os.environ() are used, returning either the “PATH” value or a fallback of os.defpath.

On Windows, the current directory is always prepended to the *path* whether or not you use the default or provide your own, which is the behavior the command shell uses when finding executables. Additionaly, when finding the *cmd* in the *path*, the PATHEXT
environment variable is checked. For example, if you call `shutil.which("python")`, `which()` will search `PATHEXT` to know that it should look for `python.exe` within the `path` directories. For example, on Windows:

```python
>>> shutil.which("python")
'C:\Python33\python.EXE'
```

*New in version 3.3.*

**exception** `shutil.Error`

This exception collects exceptions that are raised during a multi-file operation. For `copytree()`, the exception argument is a list of 3-tuples (`srcname`, `dstname`, `exception`).

### 11.9.1.1. copytree example

This example is the implementation of the `copytree()` function, described above, with the docstring omitted. It demonstrates many of the other functions provided by this module.

```python
def copytree(src, dst, symlinks=False):
    names = os.listdir(src)
    os.makedirs(dst)
    errors = []
    for name in names:
        srcname = os.path.join(src, name)
        dstname = os.path.join(dst, name)
        try:
            if symlinks and os.path.islink(srcname):
                linkto = os.readlink(srcname)
                os.symlink(linkto, dstname)
            elif os.path.isdir(srcname):
                copytree(srcname, dstname, symlinks)
```

else:
    copy2(srcname, dstname)
    # XXX What about devices, sockets etc.?
except OSError as why:
    errors.append((srcname, dstname, str(why))
    # catch the Error from the recursive copytree
    # continue with other files
except Error as err:
    errors.extend(err.args[0])

try:
    copystat(src, dst)
except WindowsError:
    # can't copy file access times on Windows
    pass
except OSError as why:
    errors.extend((src, dst, str(why)))
if errors:
    raise Error(errors)

Another example that uses the ignore_patterns() helper:

```python
from shutil import copytree, ignore_patterns

copytree(source, destination, ignore=ignore_patterns)
```

This will copy everything except .pyc files and files or directories whose name starts with tmp.

Another example that uses the ignore argument to add a logging call:

```python
from shutil import copytree
import logging

def _logpath(path, names):
    logging.info('Working in %s' % path)
```
return []  # nothing will be ignored

copytree(source, destination, ignore=_logpath)
11.9.2. Archiving operations

New in version 3.2.

High-level utilities to create and read compressed and archived files are also provided. They rely on the zipfile and tarfile modules.

```
shutil.make_archive(base_name, format[, root_dir[, base_dir[, verbose[, dry_run[, owner[, group[, logger]]]]]]])
```

Create an archive file (such as zip or tar) and return its name.

- `base_name` is the name of the file to create, including the path, minus any format-specific extension. `format` is the archive format: one of “zip”, “tar”, “bztar” (if the bz2 module is available) or “gztar”.

- `root_dir` is a directory that will be the root directory of the archive; for example, we typically chdir into `root_dir` before creating the archive.

- `base_dir` is the directory where we start archiving from; i.e. `base_dir` will be the common prefix of all files and directories in the archive.

- `root_dir` and `base_dir` both default to the current directory.

- `owner` and `group` are used when creating a tar archive. By default, uses the current owner and group.

- `logger` must be an object compatible with PEP 282, usually an instance of `logging.Logger`.

```
shutil.get_archive_formats()
```

Return a list of supported formats for archiving. Each element of
the returned sequence is a tuple \((\text{name}, \text{description})\)

By default \texttt{shutil} provides these formats:

- \texttt{gztar}: gzip’ed tar-file
- \texttt{bztar}: bzip2’ed tar-file (if the \texttt{bz2} module is available.)
- \texttt{tar}: uncompressed tar file
- \texttt{zip}: ZIP file

You can register new formats or provide your own archiver for any existing formats, by using \texttt{register_archive_format()}.\footnote{shutil.\texttt{register_archive_format}(\texttt{name}, \texttt{function}[,\
\texttt{extra_args}[[, \texttt{description}]]])}

Register an archiver for the format \texttt{name}. \texttt{function} is a callable that will be used to invoke the archiver.

If given, \texttt{extra_args} is a sequence of \((\text{name}, \text{value})\) pairs that will be used as extra keywords arguments when the archiver callable is used.

\texttt{description} is used by \texttt{get_archive_formats()} which returns the list of archivers. Defaults to an empty list.

\texttt{shutil.\texttt{unregister_archive_format}(\texttt{name})}

Remove the archive format \texttt{name} from the list of supported formats.

\texttt{shutil.\texttt{unpack_archive}(\texttt{filename}[[, \texttt{extract_dir}[[, \texttt{format}]]])}}

Unpack an archive. \texttt{filename} is the full path of the archive.

\texttt{extract_dir} is the name of the target directory where the archive is unpacked. If not provided, the current working directory is used.
format is the archive format: one of “zip”, “tar”, or “gztar”. Or any other format registered with register_unpack_format(). If not provided, unpack_archive() will use the archive file name extension and see if an unpacker was registered for that extension. In case none is found, a ValueError is raised.

shutil.register_unpack_format(name, extensions, function[, extra_args[, description]])

Registers an unpack format. name is the name of the format and extensions is a list of extensions corresponding to the format, like .zip for Zip files.

function is the callable that will be used to unpack archives. The callable will receive the path of the archive, followed by the directory the archive must be extracted to.

When provided, extra_args is a sequence of (name, value) tuples that will be passed as keywords arguments to the callable.

description can be provided to describe the format, and will be returned by the get_unpack_formats() function.

shutil.unregister_unpack_format(name)
Unregister an unpack format. name is the name of the format.

shutil.get_unpack_formats()
Return a list of all registered formats for unpacking. Each element of the returned sequence is a tuple (name, extensions, description).

By default shutil provides these formats:

- gztar: gzip’ed tar-file
- **bztar**: bzip2'ed tar-file (if the **bz2** module is available.)
- **tar**: uncompressed tar file
- **zip**: ZIP file

You can register new formats or provide your own unpacker for any existing formats, by using `register_unpack_format()`.

### 11.9.2.1. Archiving example

In this example, we create a gzip'ed tar-file archive containing all files found in the `.ssh` directory of the user:

```python
>>> from shutil import make_archive
>>> import os

>>> archive_name = os.path.expanduser(os.path.join('~', 'myarchive.tar.gz'))
>>> root_dir = os.path.expanduser(os.path.join('~', '.ssh'))

>>> make_archive(archive_name, 'gztar', root_dir)
'''
```

The resulting archive contains:

```
$ tar -tzvf /Users/tarek/myarchive.tar.gz
```

```

```
11.9.3. Querying the size of the output terminal

*New in version 3.3.*

```python
shutil.get_terminal_size(fallback=(columns, lines))
```

Get the size of the terminal window.

For each of the two dimensions, the environment variable, `COLUMNS` and `LINES` respectively, is checked. If the variable is defined and the value is a positive integer, it is used.

When `COLUMNS` or `LINES` is not defined, which is the common case, the terminal connected to `sys.__stdout__` is queried by invoking `os.get_terminal_size()`.

If the terminal size cannot be successfully queried, either because the system doesn't support querying, or because we are not connected to a terminal, the value given in `fallback` parameter is used. `fallback` defaults to `(80, 24)` which is the default size used by many terminal emulators.

The value returned is a named tuple of type `os.terminal_size`.

See also: The Single UNIX Specification, Version 2, Other Environment Variables.
11.10. **macpath** — Mac OS 9 path manipulation functions

This module is the Mac OS 9 (and earlier) implementation of the `os.path` module. It can be used to manipulate old-style Macintosh pathnames on Mac OS X (or any other platform).

The following functions are available in this module: `normcase()`, `normpath()`, `isabs()`, `join()`, `split()`, `isdir()`, `isfile()`, `walk()`, `exists()`. For other functions available in `os.path` dummy counterparts are available.
12. Data Persistence

The modules described in this chapter support storing Python data in a persistent form on disk. The pickle and marshal modules can turn many Python data types into a stream of bytes and then recreate the objects from the bytes. The various DBM-related modules support a family of hash-based file formats that store a mapping of strings to other strings.

The list of modules described in this chapter is:

- **12.1. pickle — Python object serialization**
  - 12.1.1. Relationship to other Python modules
  - 12.1.2. Data stream format
  - 12.1.3. Module Interface
  - 12.1.4. What can be pickled and unpickled?
  - 12.1.5. Pickling Class Instances
    - 12.1.5.1. Persistence of External Objects
    - 12.1.5.2. Dispatch Tables
    - 12.1.5.3. Handling Stateful Objects
  - 12.1.6. Restricting Globals
  - 12.1.7. Examples
- **12.2. copyreg — Register pickle support functions**
  - 12.2.1. Example
- **12.3. shelve — Python object persistence**
  - 12.3.1. Restrictions
  - 12.3.2. Example
- **12.4. marshal — Internal Python object serialization**
- **12.5. dbm — Interfaces to Unix “databases”**
  - 12.5.1. dbm.gnu — GNU's reinterpretation of dbm
  - 12.5.2. dbm.ndbm — Interface based on ndbm
  - 12.5.3. dbm.dumb — Portable DBM implementation
12.6. sqlite3 — DB-API 2.0 interface for SQLite databases
   12.6.1. Module functions and constants
   12.6.2. Connection Objects
   12.6.3. Cursor Objects
   12.6.4. Row Objects
   12.6.5. SQLite and Python types
      12.6.5.1. Introduction
      12.6.5.2. Using adapters to store additional Python types in SQLite databases
         12.6.5.2.1. Letting your object adapt itself
         12.6.5.2.2. Registering an adapter callable
      12.6.5.3. Converting SQLite values to custom Python types
      12.6.5.4. Default adapters and converters
   12.6.6. Controlling Transactions
   12.6.7. Using sqlite3 efficiently
      12.6.7.1. Using shortcut methods
      12.6.7.2. Accessing columns by name instead of by index
      12.6.7.3. Using the connection as a context manager
   12.6.8. Common issues
      12.6.8.1. Multithreading
12.1. **pickle** — Python object serialization

The **pickle** module implements a fundamental, but powerful algorithm for serializing and de-serializing a Python object structure. “Pickling” is the process whereby a Python object hierarchy is converted into a byte stream, and “unpickling” is the inverse operation, whereby a byte stream is converted back into an object hierarchy. Pickling (and unpickling) is alternatively known as “serialization”, “marshalling,” [1] or “flattening”, however, to avoid confusion, the terms used here are “pickling” and “unpickling”.

**Warning:** The **pickle** module is not intended to be secure against erroneous or maliciously constructed data. Never unpickle data received from an untrusted or unauthenticated source.
12.1.1. Relationship to other Python modules

The pickle module has an transparent optimizer (_pickle) written in C. It is used whenever available. Otherwise the pure Python implementation is used.

Python has a more primitive serialization module called marshal, but in general pickle should always be the preferred way to serialize Python objects. marshal exists primarily to support Python’s .pyc files.

The pickle module differs from marshal in several significant ways:

- The pickle module keeps track of the objects it has already serialized, so that later references to the same object won’t be serialized again. marshal doesn’t do this.

This has implications both for recursive objects and object sharing. Recursive objects are objects that contain references to themselves. These are not handled by marshal, and in fact, attempting to marshal recursive objects will crash your Python interpreter. Object sharing happens when there are multiple references to the same object in different places in the object hierarchy being serialized. pickle stores such objects only once, and ensures that all other references point to the master copy. Shared objects remain shared, which can be very important for mutable objects.

- marshal cannot be used to serialize user-defined classes and their instances. pickle can save and restore class instances
transparently, however the class definition must be importable and live in the same module as when the object was stored.

- The `marshal` serialization format is not guaranteed to be portable across Python versions. Because its primary job in life is to support `.pyc` files, the Python implementers reserve the right to change the serialization format in non-backwards compatible ways should the need arise. The `pickle` serialization format is guaranteed to be backwards compatible across Python releases.

Note that serialization is a more primitive notion than persistence; although `pickle` reads and writes file objects, it does not handle the issue of naming persistent objects, nor the (even more complicated) issue of concurrent access to persistent objects. The `pickle` module can transform a complex object into a byte stream and it can transform the byte stream into an object with the same internal structure. Perhaps the most obvious thing to do with these byte streams is to write them onto a file, but it is also conceivable to send them across a network or store them in a database. The module `shelve` provides a simple interface to pickle and unpickle objects on DBM-style database files.
12.1.2. Data stream format

The data format used by pickle is Python-specific. This has the advantage that there are no restrictions imposed by external standards such as JSON or XDR (which can’t represent pointer sharing); however it means that non-Python programs may not be able to reconstruct pickled Python objects.

By default, the pickle data format uses a relatively compact binary representation. If you need optimal size characteristics, you can efficiently compress pickled data.

The module pickletools contains tools for analyzing data streams generated by pickle. pickletools source code has extensive comments about opcodes used by pickle protocols.

There are currently 4 different protocols which can be used for pickling.

- Protocol version 0 is the original “human-readable” protocol and is backwards compatible with earlier versions of Python.
- Protocol version 1 is an old binary format which is also compatible with earlier versions of Python.
- Protocol version 2 was introduced in Python 2.3. It provides much more efficient pickling of new-style classes. Refer to PEP 307 for information about improvements brought by protocol 2.
- Protocol version 3 was added in Python 3. It has explicit support for bytes objects and cannot be unpickled by Python 2.x. This is the default as well as the current recommended protocol; use it whenever possible.
12.1.3. Module Interface

To serialize an object hierarchy, you simply call the `dumps()` function. Similarly, to de-serialize a data stream, you call the `loads()` function. However, if you want more control over serialization and de-serialization, you can create a `Pickler` or an `Unpickler` object, respectively.

The `pickle` module provides the following constants:

**pickle.HIGHEST_PROTOCOL**

The highest protocol version available. This value can be passed as a `protocol` value.

**pickle.DEFAULT_PROTOCOL**

The default protocol used for pickling. May be less than HIGHEST_PROTOCOL. Currently the default protocol is 3, a new protocol designed for Python 3.0.

The `pickle` module provides the following functions to make the pickling process more convenient:

**pickle.dump(obj, file, protocol=None, *, fix_imports=True)**

Write a pickled representation of `obj` to the open `file object file`. This is equivalent to `Pickler(file, protocol).dump(obj).

The optional `protocol` argument tells the pickler to use the given protocol; supported protocols are 0, 1, 2, 3. The default protocol is 3; a backward-incompatible protocol designed for Python 3.0.

Specifying a negative protocol version selects the highest protocol version supported. The higher the protocol used, the more recent
the version of Python needed to read the pickle produced.

The file argument must have a write() method that accepts a single bytes argument. It can thus be an on-disk file opened for binary writing, a io.BytesIO instance, or any other custom object that meets this interface.

If fix_imports is True and protocol is less than 3, pickle will try to map the new Python 3.x names to the old module names used in Python 2.x, so that the pickle data stream is readable with Python 2.x.

pickle.dumps(obj, protocol=None, *, fix_imports=True)
Return the pickled representation of the object as a bytes object, instead of writing it to a file.

The optional protocol argument tells the pickler to use the given protocol; supported protocols are 0, 1, 2, 3. The default protocol is 3; a backward-incompatible protocol designed for Python 3.0.

Specifying a negative protocol version selects the highest protocol version supported. The higher the protocol used, the more recent the version of Python needed to read the pickle produced.

If fix_imports is True and protocol is less than 3, pickle will try to map the new Python 3.x names to the old module names used in Python 2.x, so that the pickle data stream is readable with Python 2.x.

pickle.load(file, *, fix_imports=True, encoding="ASCII", errors="strict")
Read a pickled object representation from the open file object file and return the reconstituted object hierarchy specified therein. This
is equivalent to `Unpickler(file).load()`.

The protocol version of the pickle is detected automatically, so no protocol argument is needed. Bytes past the pickled object's representation are ignored.

The argument `file` must have two methods, a `read()` method that takes an integer argument, and a `readline()` method that requires no arguments. Both methods should return bytes. Thus `file` can be an on-disk file opened for binary reading, a `io.BytesIO` object, or any other custom object that meets this interface.

Optional keyword arguments are `fix_imports`, `encoding` and `errors`, which are used to control compatibility support for pickle stream generated by Python 2.x. If `fix_imports` is True, pickle will try to map the old Python 2.x names to the new names used in Python 3.x. The `encoding` and `errors` tell pickle how to decode 8-bit string instances pickled by Python 2.x; these default to ‘ASCII’ and ‘strict’, respectively.

```
pickle.loads(bytes_object, *, fix_imports=True, encoding="ASCII", errors="strict")
```

Read a pickled object hierarchy from a `bytes` object and return the reconstituted object hierarchy specified therein.

The protocol version of the pickle is detected automatically, so no protocol argument is needed. Bytes past the pickled object's representation are ignored.

Optional keyword arguments are `fix_imports`, `encoding` and `errors`, which are used to control compatibility support for pickle stream generated by Python 2.x. If `fix_imports` is True, pickle will try to map the old Python 2.x names to the new names used in Python
3.x. The *encoding* and *errors* tell pickle how to decode 8-bit string instances pickled by Python 2.x; these default to ‘ASCII’ and ‘strict’, respectively.

The **pickle** module defines three exceptions:

*exception* pickle. **PickleError**

Common base class for the other pickling exceptions. It inherits *Exception*.

*exception* pickle. **PicklingError**

Error raised when an unpicklable object is encountered by *Pickler*. It inherits **PickleError**.

Refer to *What can be pickled and unpickled?* to learn what kinds of objects can be pickled.

*exception* pickle. **UnpicklingError**

Error raised when there is a problem unpickling an object, such as a data corruption or a security violation. It inherits **PickleError**.

Note that other exceptions may also be raised during unpickling, including (but not necessarily limited to) *AttributeError*, *EOFError*, *ImportError*, and *IndexError*.

The **pickle** module exports two classes, **Pickler** and **Unpickler**:

*class* pickle. **Pickler**(*file*, *protocol=None*, *, *fix_imports=True*)

This takes a binary file for writing a pickle data stream.

The optional *protocol* argument tells the pickler to use the given protocol; supported protocols are 0, 1, 2, 3. The default protocol is 3; a backward-incompatible protocol designed for Python 3.0.
Specifying a negative protocol version selects the highest protocol version supported. The higher the protocol used, the more recent the version of Python needed to read the pickle produced.

The file argument must have a write() method that accepts a single bytes argument. It can thus be an on-disk file opened for binary writing, a io.BytesIO instance, or any other custom object that meets this interface.

If fix_imports is True and protocol is less than 3, pickle will try to map the new Python 3.x names to the old module names used in Python 2.x, so that the pickle data stream is readable with Python 2.x.

**dump**(obj)
Write a pickled representation of obj to the open file object given in the constructor.

**persistent_id**(obj)
Do nothing by default. This exists so a subclass can override it.

If persistent_id() returns None, obj is pickled as usual. Any other value causes Pickler to emit the returned value as a persistent ID for obj. The meaning of this persistent ID should be defined by Unpickler.persistent_load(). Note that the value returned by persistent_id() cannot itself have a persistent ID.

See Persistence of External Objects for details and examples of uses.

**dispatch_table**
A pickler object's dispatch table is a registry of reduction
functions of the kind which can be declared using `copyreg.pickle()`. It is a mapping whose keys are classes and whose values are reduction functions. A reduction function takes a single argument of the associated class and should conform to the same interface as a `__reduce__()` method.

By default, a pickler object will not have a `dispatch_table` attribute, and it will instead use the global dispatch table managed by the `copyreg` module. However, to customize the pickling for a specific pickler object one can set the `dispatch_table` attribute to a dict-like object. Alternatively, if a subclass of `Pickler` has a `dispatch_table` attribute then this will be used as the default dispatch table for instances of that class.

See *Dispatch Tables* for usage examples.

*New in version 3.3.*

**fast**

Deprecated. Enable fast mode if set to a true value. The fast mode disables the usage of memo, therefore speeding the pickling process by not generating superfluous PUT opcodes. It should not be used with self-referential objects, doing otherwise will cause `Pickler` to recurse infinitely.

Use `pickletools.optimize()` if you need more compact pickles.

```python
class pickle.Unpickler(file, *, fix_imports=True,
                        encoding="ASCII", errors="strict")
```

This takes a binary file for reading a pickle data stream.
The protocol version of the pickle is detected automatically, so no protocol argument is needed.

The argument *file* must have two methods, a *read()* method that takes an integer argument, and a *readline()* method that requires no arguments. Both methods should return bytes. Thus *file* can be an on-disk file object opened for binary reading, a *io.BytesIO* object, or any other custom object that meets this interface.

Optional keyword arguments are *fix_imports*, *encoding* and *errors*, which are used to control compatibility support for pickle stream generated by Python 2.x. If *fix_imports* is True, pickle will try to map the old Python 2.x names to the new names used in Python 3.x. The *encoding* and *errors* tell pickle how to decode 8-bit string instances pickled by Python 2.x; these default to ‘ASCII’ and ‘strict’, respectively.

**load()**

Read a pickled object representation from the open file object given in the constructor, and return the reconstituted object hierarchy specified therein. Bytes past the pickled object’s representation are ignored.

**persistent_load(pid)**

Raise an *UnpicklingError* by default.

If defined, *persistent_load()* should return the object specified by the persistent ID *pid*. If an invalid persistent ID is encountered, an *UnpicklingError* should be raised.

See *Persistence of External Objects* for details and examples of uses.
**find_class**(*module, name*)

Import *module* if necessary and return the object called *name* from it, where the *module* and *name* arguments are *str* objects. Note, unlike its name suggests, **find_class()** is also used for finding functions.

Subclasses may override this to gain control over what type of objects and how they can be loaded, potentially reducing security risks. Refer to *Restricting Globals* for details.
12.1.4. What can be pickled and unpickled?

The following types can be pickled:

- None, True, and False
- integers, floating point numbers, complex numbers
- strings, bytes, bytearrays
- tuples, lists, sets, and dictionaries containing only picklable objects
- functions defined at the top level of a module
- built-in functions defined at the top level of a module
- classes that are defined at the top level of a module
- instances of such classes whose __dict__ or the result of calling __getstate__() is picklable (see section Pickling Class Instances for details).

Attempts to pickle unpicklable objects will raise the PicklingError exception; when this happens, an unspecified number of bytes may have already been written to the underlying file. Trying to pickle a highly recursive data structure may exceed the maximum recursion depth, a RuntimeError will be raised in this case. You can carefully raise this limit with `sys.setrecursionlimit()`.

Note that functions (built-in and user-defined) are pickled by “fully qualified” name reference, not by value. This means that only the function name is pickled, along with the name of the module the function is defined in. Neither the function’s code, nor any of its function attributes are pickled. Thus the defining module must be importable in the unpickling environment, and the module must contain the named object, otherwise an exception will be raised. [2]
Similarly, classes are pickled by named reference, so the same restrictions in the unpickling environment apply. Note that none of the class’s code or data is pickled, so in the following example the class attribute \texttt{attr} is not restored in the unpickling environment:

```python
class Foo:
    attr = 'A class attribute'

picklestring = pickle.dumps(Foo)
```

These restrictions are why picklable functions and classes must be defined in the top level of a module.

Similarly, when class instances are pickled, their class’s code and data are not pickled along with them. Only the instance data are pickled. This is done on purpose, so you can fix bugs in a class or add methods to the class and still load objects that were created with an earlier version of the class. If you plan to have long-lived objects that will see many versions of a class, it may be worthwhile to put a version number in the objects so that suitable conversions can be made by the class’s \texttt{\_\_setstate\_\_()} method.
12.1.5. Pickling Class Instances

In this section, we describe the general mechanisms available to you to define, customize, and control how class instances are pickled and unpickled.

In most cases, no additional code is needed to make instances picklable. By default, pickle will retrieve the class and the attributes of an instance via introspection. When a class instance is unpickled, its \_init\_() method is usually *not* invoked. The default behaviour first creates an uninitialized instance and then restores the saved attributes. The following code shows an implementation of this behaviour:

```python
def save(obj):
    return (obj.__class__, obj.__dict__)
def load(cls, attributes):
    obj = cls.__new__(cls)
    obj.__dict__.update(attributes)
    return obj
```

Classes can alter the default behaviour by providing one or several special methods:

**object.\_getnewargs\_()**

In protocol 2 and newer, classes that implements the \_getnewargs\_() method can dictate the values passed to the \_new\_() method upon unpickling. This is often needed for classes whose \_new\_() method requires arguments.

**object.\_getstate\_()**
Classes can further influence how their instances are pickled; if the class defines the method `__getstate__()`, it is called and the returned object is pickled as the contents for the instance, instead of the contents of the instance’s dictionary. If the `__getstate__()` method is absent, the instance’s `__dict__` is pickled as usual.

`object.__setstate__(state)`

Upon unpickling, if the class defines `__setstate__()`, it is called with the unpickled state. In that case, there is no requirement for the state object to be a dictionary. Otherwise, the pickled state must be a dictionary and its items are assigned to the new instance’s dictionary.

**Note:** If `__getstate__()` returns a false value, the `__setstate__()` method will not be called upon unpickling.

Refer to the section *Handling Stateful Objects* for more information about how to use the methods `__getstate__()` and `__setstate__()`.

**Note:** At unpickling time, some methods like `__getattr__()`, `__getattribute__()`, or `__setattr__()` may be called upon the instance. In case those methods rely on some internal invariant being true, the type should implement `__getnewargs__()` to establish such an invariant; otherwise, neither `__new__() nor `__init__() will be called.

As we shall see, pickle does not use directly the methods described above. In fact, these methods are part of the copy protocol which implements the `__reduce__()` special method. The copy protocol
provides a unified interface for retrieving the data necessary for pickling and copying objects. [3]

Although powerful, implementing \texttt{__reduce__()} directly in your classes is error prone. For this reason, class designers should use the high-level interface (i.e., \texttt{__getnewargs__()}, \texttt{__getstate__()} and \texttt{__setstate__()} ) whenever possible. We will show, however, cases where using \texttt{__reduce__()} is the only option or leads to more efficient pickling or both.

\texttt{object.__reduce__()} 

The interface is currently defined as follows. The \texttt{__reduce__()} method takes no argument and shall return either a string or preferably a tuple (the returned object is often referred to as the “reduce value”).

If a string is returned, the string should be interpreted as the name of a global variable. It should be the object’s local name relative to its module; the pickle module searches the module namespace to determine the object's module. This behaviour is typically useful for singletons.

When a tuple is returned, it must be between two and five items long. Optional items can either be omitted, or \texttt{None} can be provided as their value. The semantics of each item are in order:

- A callable object that will be called to create the initial version of the object.
- A tuple of arguments for the callable object. An empty tuple must be given if the callable does not accept any argument.
- Optionally, the object’s state, which will be passed to the object’s \texttt{__setstate__()} method as previously described. If the object has no such method then, the value must be a
dictionary and it will be added to the object's `__dict__` attribute.

- Optionally, an iterator (and not a sequence) yielding successive items. These items will be appended to the object either using `obj.append(item)` or, in batch, using `obj.extend(list_of_items)`. This is primarily used for list subclasses, but may be used by other classes as long as they have `append()` and `extend()` methods with the appropriate signature. (Whether `append()` or `extend()` is used depends on which pickle protocol version is used as well as the number of items to append, so both must be supported.)

- Optionally, an iterator (not a sequence) yielding successive key-value pairs. These items will be stored to the object using `obj[key] = value`. This is primarily used for dictionary subclasses, but may be used by other classes as long as they implement `__setitem__()`.

```
object.__reduce_ex__(protocol)
```

Alternatively, a `__reduce_ex__()` method may be defined. The only difference is this method should take a single integer argument, the protocol version. When defined, pickle will prefer it over the `__reduce__()` method. In addition, `__reduce__()` automatically becomes a synonym for the extended version. The main use for this method is to provide backwards-compatible reduce values for older Python releases.

### 12.1.5.1. Persistence of External Objects

For the benefit of object persistence, the `pickle` module supports the notion of a reference to an object outside the pickled data stream. Such objects are referenced by a persistent ID, which should be either
a string of alphanumeric characters (for protocol 0) [4] or just an arbitrary object (for any newer protocol).

The resolution of such persistent IDs is not defined by the pickle module; it will delegate this resolution to the user defined methods on the pickler and unpickler, persistent_id() and persistent_load() respectively.

To pickle objects that have an external persistent id, the pickler must have a custom persistent_id() method that takes an object as an argument and returns either None or the persistent id for that object. When None is returned, the pickler simply pickles the object as normal. When a persistent ID string is returned, the pickler will pickle that object, along with a marker so that the unpickler will recognize it as a persistent ID.

To unpickle external objects, the unpickler must have a custom persistent_load() method that takes a persistent ID object and returns the referenced object.

Here is a comprehensive example presenting how persistent ID can be used to pickle external objects by reference.

```python
# Simple example presenting how persistent ID can be used for external objects by reference.
import pickle
import sqlite3
from collections import namedtuple

# Simple class representing a record in our database.
MemoRecord = namedtuple("MemoRecord", "key, task")

class DBPickler(pickle.Pickler):
```

def persistent_id(self, obj):
    # Instead of pickling MemoRecord as a regular
    # persistent ID.
    if isinstance(obj, MemoRecord):
        # Here, our persistent ID is simply a tuple
        # key, which refers to a specific record
        return ("MemoRecord", obj.key)
    else:
        # If obj does not have a persistent ID,
        # needs to be pickled as usual.
        return None

class DBUnpickler(pickle.Unpickler):

    def __init__(self, file, connection):
        super().__init__(file)
        self.connection = connection

    def persistent_load(self, pid):
        # This method is invoked whenever a persistent
        # Here, pid is the tuple returned by DBPickler.
        cursor = self.connection.cursor()
        type_tag, key_id = pid
        if type_tag == "MemoRecord":
            # Fetch the referenced record from the database
            cursor.execute("SELECT * FROM memos WHERE key=?", (key_id,))
            key, task = cursor.fetchone()
            return MemoRecord(key, task)
        else:
            # Always raises an error if you cannot return
            # Otherwise, the unpickler will think None
            # by the persistent ID.
            raise pickle.UnpicklingError("unsupported persistent object")
def main():
    import io
    import pprint

    # Initialize and populate our database.
    conn = sqlite3.connect(':memory:)
    cursor = conn.cursor()
    cursor.execute("CREATE TABLE memos(key INTEGER PRIMARY KEY,
task TEXT)"
    tasks = ('give food to fish',
    'prepare group meeting',
    'fight with a zebra',
)
    for task in tasks:
        cursor.execute("INSERT INTO memos VALUES(NULL, ?)"

    # Fetch the records to be pickled.
    cursor.execute("SELECT * FROM memos"
    memos = [MemoRecord(key, task) for key, task in
    # Save the records using our custom DBPickler.
    file = io.BytesIO()
    DBPickler(file).dump(memos)

    print("Pickled records:"
    pprint.pprint(memos)

    # Update a record, just for good measure.
    cursor.execute("UPDATE memos SET task='learn italian' WHERE key=1"
    # Load the records from the pickle data stream.
    file.seek(0)
    memos = DBUnpickler(file, conn).load()

    print("Unpickled records:"
    pprint.pprint(memos)
12.1.5.2. Dispatch Tables

If one wants to customize pickling of some classes without disturbing any other code which depends on pickling, then one can create a pickler with a private dispatch table.

The global dispatch table managed by the `copyreg` module is available as `copyreg.dispatch_table`. Therefore, one may choose to use a modified copy of `copyreg.dispatch_table` as a private dispatch table.

For example

```python
f = io.BytesIO()
p = pickle.Pickler(f)
p.dispatch_table = copyreg.dispatch_table.copy()
p.dispatch_table[SomeClass] = reduce_SomeClass
```

creates an instance of `pickle.Pickler` with a private dispatch table which handles the `SomeClass` class specially. Alternatively, the code

```python
class MyPickler(pickle.Pickler):
    dispatch_table = copyreg.dispatch_table.copy()
    dispatch_table[SomeClass] = reduce_SomeClass
f = io.BytesIO()
p = MyPickler(f)
```

does the same, but all instances of `MyPickler` will by default share the same dispatch table. The equivalent code using the `copyreg` module is
12.1.5.3. Handling Stateful Objects

Here's an example that shows how to modify pickling behavior for a class. The TextReader class opens a text file, and returns the line number and line contents each time its readline() method is called. If a TextReader instance is pickled, all attributes except the file object member are saved. When the instance is unpickled, the file is reopened, and reading resumes from the last location. The __setstate__() and __getstate__() methods are used to implement this behavior.

class TextReader:
    """Print and number lines in a text file."""

    def __init__(self, filename):
        self.filename = filename
        self.file = open(filename)
        self.lineno = 0

    def readline(self):
        self.lineno += 1
        line = self.file.readline()
        if not line:
            return None
        if line.endswith('
'):
            line = line[:-1]
        return "%i: %s" % (self.lineno, line)

    def __getstate__(self):
        # Copy the object's state from self.__dict__

    def __setstate__(self, state):
        self.__dict__.update(state)

    def __reduce__(self):
        return type(self), ()

    def __str__(self):
        return 'TextReader<%s>' % self.filename

    def __repr__(self):
        return '<TextReader %s>' % self.filename

    def __enter__(self):
        return self

    def __exit__(self, *args):
        self.file.close()
# all our instance attributes. Always use this method to avoid modifying the original state.
state = self.__dict__.copy()
# Remove the unpicklable entries.
del state['file']
return state

def __setstate__(self, state):
    # Restore instance attributes (i.e., filename and lineno).
    self.__dict__.update(state)
    # Restore the previously opened file's state.
    # reopen it and read from it until the line count is restored.
    file = open(self.filename)
    for _ in range(self.lineno):
        file.readline()
    # Finally, save the file.
    self.file = file

A sample usage might be something like this:

```python
>>> reader = TextReader("hello.txt")
>>> reader.readline()
'1: Hello world!'
>>> reader.readline()
'2: I am line number two.'
>>> new_reader = pickle.loads(pickle.dumps(reader))
>>> new_reader.readline()
'3: Goodbye!'
```
12.1.6. Restricting Globals

By default, unpickling will import any class or function that it finds in the pickle data. For many applications, this behaviour is unacceptable as it permits the unpickler to import and invoke arbitrary code. Just consider what this hand-crafted pickle data stream does when loaded:

```
>>> import pickle
>>> pickle.loads(b"cos\n\nsystem\n\n(S'echo hello world'
hello world
0
```

In this example, the unpickler imports the `os.system()` function and then apply the string argument “echo hello world”. Although this example is inoffensive, it is not difficult to imagine one that could damage your system.

For this reason, you may want to control what gets unpickled by customizing `Unpickler.find_class()`. Unlike its name suggests, `Unpickler.find_class()` is called whenever a global (i.e., a class or a function) is requested. Thus it is possible to either completely forbid globals or restrict them to a safe subset.

Here is an example of an unpickler allowing only few safe classes from the `builtins` module to be loaded:

```python
import builtins
import io
import pickle

safe_builtins = {
    'range',
    ```
'complex',
'set',
'frozenset',
'slice',
}

class RestrictedUnpickler(pickle.Unpickler):
    def find_class(self, module, name):
        # Only allow safe classes from builtins.
        if module == "builtins" and name in safe_builtins:
            return getattr(builtins, name)
        # Forbid everything else.
        raise pickle.UnpicklingError("global '%s.%s' is forbidden" (module, name))

def restricted_loads(s):
    """Helper function analogous to pickle.loads().""
    return RestrictedUnpickler(io.BytesIO(s)).load()

A sample usage of our unpickler working has intended:

>>> restricted_loads(pickle.dumps([[1, 2, range(15)]]))
[1, 2, range(0, 15)]
>>> restricted_loads(b"cos\nsystem\n(S'echo hello world')")
Traceback (most recent call last):
  File "", line 1, in restricted_loads
    raise pickle.UnpicklingError: global 'os.system' is forbidden
>>> restricted_loads(b"cbuiltins\neval"
... b'(S'getattr(__import__("os"),
... b'("echo hello world")'\"ntR."
Traceback (most recent call last):
  File "", line 1, in restricted_loads
    raise pickle.UnpicklingError: global 'builtins.eval' is forbidden
As our examples shows, you have to be careful with what you allow to be unpickled. Therefore if security is a concern, you may want to consider alternatives such as the marshalling API in `xmlrpc.client` or third-party solutions.
12.1.7. Examples

For the simplest code, use the `dump()` and `load()` functions.

```python
import pickle

# An arbitrary collection of objects supported by pickle.
data = {
    'a': [1, 2.0, 3, 4+6j],
    'b': ('character string', b'byte string'),
    'c': set([None, True, False])
}

with open('data.pickle', 'wb') as f:
    # Pickle the 'data' dictionary using the highest
    # protocol version available.
pickle.dump(data, f, pickle.HIGHEST_PROTOCOL)

The following example reads the resulting pickled data.

```python
import pickle

with open('data.pickle', 'rb') as f:
    # The protocol version used is detected automatically,
    # so we don't have to specify it.
data = pickle.load(f)
```

**Module copyreg**

Pickle interface constructor registration for extension types.

**Module pickletools**

Tools for working with and analyzing pickled data.
**Module** **shelve**
Indexed databases of objects; uses **pickle**.

**Module** **copy**
Shallow and deep object copying.

**Module** **marshal**
High-performance serialization of built-in types.

---

**Footnotes**

[1] Don't confuse this with the **marshal** module

[2] The exception raised will likely be an **ImportError** or an **AttributeError** but it could be something else.

[3] The **copy** module uses this protocol for shallow and deep copying operations.

[4] The limitation on alphanumeric characters is due to the fact the persistent IDs, in protocol 0, are delimited by the newline character. Therefore if any kind of newline characters occurs in persistent IDs, the resulting pickle will become unreadable.
The `copyreg` module offers a way to define functions used while pickling specific objects. The `pickle` and `copy` modules use those functions when pickling/copying those objects. The module provides configuration information about object constructors which are not classes. Such constructors may be factory functions or class instances.

`copyreg.constructor(object)`

Declares `object` to be a valid constructor. If `object` is not callable (and hence not valid as a constructor), raises `TypeError`.

`copyreg.pickle(type, function, constructor=None)`

Declares that `function` should be used as a “reduction” function for objects of type `type`. `function` should return either a string or a tuple containing two or three elements.

The optional `constructor` parameter, if provided, is a callable object which can be used to reconstruct the object when called with the tuple of arguments returned by `function` at pickling time. `TypeError` will be raised if `object` is a class or `constructor` is not callable.

See the `pickle` module for more details on the interface expected of `function` and `constructor`. Note that the `dispatch_table` attribute of a pickler object or subclass of `pickle.Pickler` can also be used for declaring reduction functions.
12.2.1. Example

The example below would like to show how to register a pickle function and how it will be used:

```python
>>> import copyreg, copy, pickle
>>> class C(object):
...     def __init__(self, a):
...         self.a = a
... >>> def pickle_c(c):
...     print("pickling a C instance...")
...     return C, (c.a,)
... >>> copyreg.pickle(C, pickle_c)
>>> c = C(1)
>>> d = copy.copy(c)
pickling a C instance...
>>> p = pickle.dumps(c)
pickling a C instance...
```
12.3. `shelve` — Python object persistence

Source code: Lib/shelve.py

A “shelf” is a persistent, dictionary-like object. The difference with “dbm” databases is that the values (not the keys!) in a shelf can be essentially arbitrary Python objects — anything that the `pickle` module can handle. This includes most class instances, recursive data types, and objects containing lots of shared sub-objects. The keys are ordinary strings.

```
shelve.open(filename, flag='c', protocol=None, writeback=False)
```

Open a persistent dictionary. The filename specified is the base filename for the underlying database. As a side-effect, an extension may be added to the filename and more than one file may be created. By default, the underlying database file is opened for reading and writing. The optional `flag` parameter has the same interpretation as the `flag` parameter of `dbm.open()`.

By default, version 3 pickles are used to serialize values. The version of the pickle protocol can be specified with the `protocol` parameter.

Because of Python semantics, a shelf cannot know when a mutable persistent-dictionary entry is modified. By default modified objects are written only when assigned to the shelf (see `Example`). If the optional `writeback` parameter is set to `True`, all entries accessed are also cached in memory, and written back on `sync()`
and close(); this can make it handier to mutate mutable entries in the persistent dictionary, but, if many entries are accessed, it can consume vast amounts of memory for the cache, and it can make the close operation very slow since all accessed entries are written back (there is no way to determine which accessed entries are mutable, nor which ones were actually mutated).

**Note:** Do not rely on the shelf being closed automatically; always call close() explicitly when you don’t need it any more, or use a with statement with `contextlib.closing()`.

**Warning:** Because the `shelve` module is backed by `pickle`, it is insecure to load a shelf from an untrusted source. Like with pickle, loading a shelf can execute arbitrary code.

Shelf objects support all methods supported by dictionaries. This eases the transition from dictionary based scripts to those requiring persistent storage.

Two additional methods are supported:

**Shelf.** `sync()`

Write back all entries in the cache if the shelf was opened with `writeback` set to True. Also empty the cache and synchronize the persistent dictionary on disk, if feasible. This is called automatically when the shelf is closed with `close()`.

**Shelf.** `close()`

Synchronize and close the persistent `dict` object. Operations on a closed shelf will fail with a `ValueError`.

**See also:** Persistent dictionary recipe with widely supported
storage formats and having the speed of native dictionaries.
12.3.1. Restrictions

- The choice of which database package will be used (such as `dbm.ndbm` or `dbm.gnu`) depends on which interface is available. Therefore it is not safe to open the database directly using `dbm`. The database is also (unfortunately) subject to the limitations of `dbm`, if it is used — this means that (the pickled representation of) the objects stored in the database should be fairly small, and in rare cases key collisions may cause the database to refuse updates.

- The `shelve` module does not support concurrent read/write access to shelved objects. (Multiple simultaneous read accesses are safe.) When a program has a shelf open for writing, no other program should have it open for reading or writing. Unix file locking can be used to solve this, but this differs across Unix versions and requires knowledge about the database implementation used.

```python
class shelve.Shelf(dict, protocol=None, writeback=False, keyencoding='utf-8')
```

A subclass of `collections.abc.MutableMapping` which stores pickled values in the `dict` object.

By default, version 0 pickles are used to serialize values. The version of the pickle protocol can be specified with the `protocol` parameter. See the `pickle` documentation for a discussion of the pickle protocols.

If the `writeback` parameter is True, the object will hold a cache of all entries accessed and write them back to the `dict` at sync and close times. This allows natural operations on mutable entries, but can consume much more memory and make sync and close take a
long time.

The `keyencoding` parameter is the encoding used to encode keys before they are used with the underlying dict.

*New in version 3.2:* The `keyencoding` parameter; previously, keys were always encoded in UTF-8.

class shelve.BsdDbShelf(dict, protocol=None, writeback=False, keyencoding='utf-8')

A subclass of `Shelf` which exposes `first()`, `next()`, `previous()`, `last()` and `set_location()` which are available in the third-party bsddb module from `pybsddb` but not in other database modules. The `dict` object passed to the constructor must support those methods. This is generally accomplished by calling one of `bsddb.hashopen()`, `bsddb.btopen()` or `bsddb.rnopen()`. The optional `protocol`, `writeback`, and `keyencoding` parameters have the same interpretation as for the `Shelf` class.

class shelve.DbfilenameShelf(filename, flag='c', protocol=None, writeback=False)

A subclass of `Shelf` which accepts a `filename` instead of a dict-like object. The underlying file will be opened using `dbm.open()`. By default, the file will be created and opened for both read and write. The optional `flag` parameter has the same interpretation as for the `open()` function. The optional `protocol` and `writeback` parameters have the same interpretation as for the `Shelf` class.
12.3.2. Example

To summarize the interface (key is a string, data is an arbitrary object):

```python
import shelve

d = shelve.open(filename) # open -- file may get suffix added by low-level library

d[key] = data # store data at key (overwrites old # using an existing key)
data = d[key] # retrieve a COPY of data at key (raise
 # such key)

del d[key] # delete data stored at key (raises # if no such key)

flag = key in d # true if the key exists
klist = list(d.keys()) # a list of all existing keys

# as d was opened WITHOUT writeback=True, beware:
d['xx'] = [0, 1, 2] # this works as expected, but
d['xx'].append(3) # *this doesn't!* -- d['xx']

# having opened d without writeback=True, you need to
temp = d['xx'] # extracts the copy
temp.append(5) # mutates the copy
d['xx'] = temp # stores the copy right back, to

# or, d=shelve.open(filename,writeback=True) would let
# d['xx'].append(5) and have it work as expected, but
# consume more memory and make the d.close() operation

d.close() # close it
```
See also:

**Module dbm**
Generic interface to dbm-style databases.

**Module pickle**
Object serialization used by shelve.
12.4. **marshal** — Internal Python object serialization

This module contains functions that can read and write Python values in a binary format. The format is specific to Python, but independent of machine architecture issues (e.g., you can write a Python value to a file on a PC, transport the file to a Sun, and read it back there). Details of the format are undocumented on purpose; it may change between Python versions (although it rarely does). [1]

This is not a general “persistence” module. For general persistence and transfer of Python objects through RPC calls, see the modules **pickle** and **shelve**. The **marshal** module exists mainly to support reading and writing the “pseudo-compiled” code for Python modules of .pyc files. Therefore, the Python maintainers reserve the right to modify the marshal format in backward incompatible ways should the need arise. If you’re serializing and de-serializing Python objects, use the **pickle** module instead – the performance is comparable, version independence is guaranteed, and pickle supports a substantially wider range of objects than marshal.

**Warning:** The **marshal** module is not intended to be secure against erroneous or maliciously constructed data. Never unmarshal data received from an untrusted or unauthenticated source.

Not all Python object types are supported; in general, only objects whose value is independent from a particular invocation of Python can be written and read by this module. The following types are supported: booleans, integers, floating point numbers, complex numbers, strings, bytes, bytearrays, tuples, lists, sets, frozensets, dictionaries, and code
objects, where it should be understood that tuples, lists, sets, frozensets and dictionaries are only supported as long as the values contained therein are themselves supported; and recursive lists, sets and dictionaries should not be written (they will cause infinite loops). The singletons `None`, `Ellipsis` and `StopIteration` can also be marshalled and unmarshalled.

There are functions that read/write files as well as functions operating on strings.

The module defines these functions:

`marshal.dump(value, file[, version])`
 Write the value on the open file. The value must be a supported type. The file must be an open file object such as `sys.stdout` or returned by `open()` or `os.popen()`. It must be opened in binary mode (`'wb'` or `'w+b'`).

If the value has (or contains an object that has) an unsupported type, a `ValueError` exception is raised — but garbage data will also be written to the file. The object will not be properly read back by `load()`.

The `version` argument indicates the data format that `dump` should use (see below).

`marshal.load(file)`
 Read one value from the open file and return it. If no valid value is read (e.g. because the data has a different Python version's incompatible marshal format), raise `EOFError`, `ValueError` or `TypeError`. The file must be an open file object opened in binary mode (`'rb'` or `'r+b'`).
Note: If an object containing an unsupported type was marshalled with dump(), load() will substitute None for the unmarshallable type.

marshal.dumps(value[, version])

Return the string that would be written to a file by dump(value, file). The value must be a supported type. Raise a ValueError exception if value has (or contains an object that has) an unsupported type.

The version argument indicates the data format that dumps should use (see below).

marshal.loads(string)

Convert the string to a value. If no valid value is found, raise EOFError, ValueError or TypeError. Extra characters in the string are ignored.

In addition, the following constants are defined:

marshal.version

Indicates the format that the module uses. Version 0 is the historical format, version 1 shares interned strings and version 2 uses a binary format for floating point numbers. The current version is 2.

Footnotes

The name of this module stems from a bit of terminology used by the designers of Modula-3 (amongst others), who use the term “marshalling” for shipping of data around in a self-contained form. Strictly speaking, “to marshal” means to

[1]
convert some data from internal to external form (in an RPC buffer for instance) and “unmarshalling” for the reverse process.
12.5. dbm — Interfaces to Unix “databases”

dbm is a generic interface to variants of the DBM database — dbm.gnu or dbm.ndbm. If none of these modules is installed, the slow-but-simple implementation in module dbm.dumb will be used. There is a third party interface to the Oracle Berkeley DB.

exception dbm.error

A tuple containing the exceptions that can be raised by each of the supported modules, with a unique exception also named dbm.error as the first item — the latter is used when dbm.error is raised.

dbm.whichdb(filename)

This function attempts to guess which of the several simple database modules available — dbm.gnu, dbm.ndbm or dbm.dumb — should be used to open a given file.

Returns one of the following values: None if the file can't be opened because it's unreadable or doesn't exist; the empty string ("") if the file's format can't be guessed; or a string containing the required module name, such as 'dbm.ndbm' or 'dbm.gnu'.

dbm.open(file, flag='r', mode=0o666)

Open the database file file and return a corresponding object.

If the database file already exists, the whichdb() function is used to determine its type and the appropriate module is used; if it does not exist, the first module listed above that can be imported is
used.

The optional *flag* argument can be:

<table>
<thead>
<tr>
<th>Value</th>
<th>Meaning</th>
</tr>
</thead>
<tbody>
<tr>
<td>'r'</td>
<td>Open existing database for reading only (default)</td>
</tr>
<tr>
<td>'w'</td>
<td>Open existing database for reading and writing</td>
</tr>
<tr>
<td>'c'</td>
<td>Open database for reading and writing, creating it if it doesn’t exist</td>
</tr>
<tr>
<td>'n'</td>
<td>Always create a new, empty database, open for reading and writing</td>
</tr>
</tbody>
</table>

The optional *mode* argument is the Unix mode of the file, used only when the database has to be created. It defaults to octal 0o666 (and will be modified by the prevailing umask).

The object returned by *open()* supports the same basic functionality as dictionaries; keys and their corresponding values can be stored, retrieved, and deleted, and the *in* operator and the keys() method are available, as well as *get()* and setdefault().

*Changed in version 3.2:* *get()* and setdefault() are now available in all database modules.

Key and values are always stored as bytes. This means that when strings are used they are implicitly converted to the default encoding before being stored.

The following example records some hostnames and a corresponding title, and then prints out the contents of the database:

```python
import dbm
```
# Open database, creating it if necessary.
db = dbm.open('cache', 'c')

# Record some values
db[b'hello'] = b'there'
db['www.python.org'] = 'Python Website'
db['www.cnn.com'] = 'Cable News Network'

# Note that the keys are considered bytes now.
assert db[b'www.python.org'] == b'Python Website'
# Notice how the value is now in bytes.
assert db['www.cnn.com'] == b'Cable News Network'

# Often-used methods of the dict interface work too.
print(db.get('python.org', b'not present'))

# Storing a non-string key or value will raise an exception (most likely a TypeError).
db['www.yahoo.com'] = 4

# Close when done.
db.close()

See also:

**Module shelf**

Persistence module which stores non-string data.

The individual submodules are described in the following sections.
12.5.1. dbm.gnu — GNU’s reinterpretation of dbm

Platforms: Unix

This module is quite similar to the dbm module, but uses the GNU library gdbm instead to provide some additional functionality. Please note that the file formats created by dbm.gnu and dbm.ndbm are incompatible.

The dbm.gnu module provides an interface to the GNU DBM library. dbm.gnu.gdbm objects behave like mappings (dictionaries), except that keys and values are always converted to bytes before storing. Printing a gdbm object doesn't print the keys and values, and the items() and values() methods are not supported.

exception dbm.gnu.error

Raised on dbm.gnu-specific errors, such as I/O errors. KeyError is raised for general mapping errors like specifying an incorrect key.

dbm.gnu.open(filename[, flag[, mode]])

Open a gdbm database and return a gdbm object. The filename argument is the name of the database file.

The optional flag argument can be:

<table>
<thead>
<tr>
<th>Value</th>
<th>Meaning</th>
</tr>
</thead>
<tbody>
<tr>
<td>'r'</td>
<td>Open existing database for reading only (default)</td>
</tr>
<tr>
<td>'w'</td>
<td>Open existing database for reading and writing</td>
</tr>
<tr>
<td></td>
<td>Open database for reading and writing, creating it if it</td>
</tr>
<tr>
<td>Value</td>
<td>Meaning</td>
</tr>
<tr>
<td>-------</td>
<td>---------</td>
</tr>
<tr>
<td>'c'</td>
<td>doesn't exist</td>
</tr>
<tr>
<td>'n'</td>
<td>Always create a new, empty database, open for reading and writing</td>
</tr>
</tbody>
</table>

The following additional characters may be appended to the flag to control how the database is opened:

<table>
<thead>
<tr>
<th>Value</th>
<th>Meaning</th>
</tr>
</thead>
<tbody>
<tr>
<td>'f'</td>
<td>Open the database in fast mode. Writes to the database will not be synchronized.</td>
</tr>
<tr>
<td>'s'</td>
<td>Synchronized mode. This will cause changes to the database to be immediately written to the file.</td>
</tr>
<tr>
<td>'u'</td>
<td>Do not lock database.</td>
</tr>
</tbody>
</table>

Not all flags are valid for all versions of `gdbm`. The module constant `open_flags` is a string of supported flag characters. The exception `error` is raised if an invalid flag is specified.

The optional `mode` argument is the Unix mode of the file, used only when the database has to be created. It defaults to octal `0o666`.

In addition to the dictionary-like methods, `gdbm` objects have the following methods:

**`gdbm.firstkey()`**

It’s possible to loop over every key in the database using this method and the `nextkey()` method. The traversal is ordered by `gdbm`’s internal hash values, and won’t be sorted by the key values. This method returns the starting key.

**`gdbm.nextkey(key)`**

Returns the key that follows `key` in the traversal. The following
code prints every key in the database `db`, without having to create a list in memory that contains them all:

```python
k = db.firstkey()
while k != None:
    print(k)
    k = db.nextkey(k)
```

`gdbm.reorganize()`

If you have carried out a lot of deletions and would like to shrink the space used by the `gdbm` file, this routine will reorganize the database. `gdbm` objects will not shorten the length of a database file except by using this reorganization; otherwise, deleted file space will be kept and reused as new (key, value) pairs are added.

`gdbm.sync()`

When the database has been opened in fast mode, this method forces any unwritten data to be written to the disk.
12.5.2. **dbm.ndbm** — Interface based on ndbm

*Platforms:* Unix

The `dbm.ndbm` module provides an interface to the Unix “(n)dbm” library. Dbm objects behave like mappings (dictionaries), except that keys and values are always stored as bytes. Printing a `dbm` object doesn't print the keys and values, and the `items()` and `values()` methods are not supported.

This module can be used with the “classic” ndbm interface or the GNU GDBM compatibility interface. On Unix, the `configure` script will attempt to locate the appropriate header file to simplify building this module.

**exception** `dbm.ndbm.error`

Raised on `dbm.ndbm`-specific errors, such as I/O errors. `KeyError` is raised for general mapping errors like specifying an incorrect key.

**dbm.ndbm.library**

Name of the `ndbm` implementation library used.

**dbm.ndbm.open(filename[, flag[, mode]])**

Open a `dbm` database and return a `dbm` object. The `filename` argument is the name of the database file (without the `.dir` or `.pag` extensions).

The optional `flag` argument must be one of these values:
<table>
<thead>
<tr>
<th>Value</th>
<th>Meaning</th>
</tr>
</thead>
<tbody>
<tr>
<td>'r'</td>
<td>Open existing database for reading only (default)</td>
</tr>
<tr>
<td>'w'</td>
<td>Open existing database for reading and writing</td>
</tr>
<tr>
<td>'c'</td>
<td>Open database for reading and writing, creating it if it doesn’t exist</td>
</tr>
<tr>
<td>'n'</td>
<td>Always create a new, empty database, open for reading and writing</td>
</tr>
</tbody>
</table>

The optional *mode* argument is the Unix mode of the file, used only when the database has to be created. It defaults to octal 0o666 (and will be modified by the prevailing umask).
12.5.3. **dbm.dumb** — Portable DBM implementation

**Note:** The `dbm.dumb` module is intended as a last resort fallback for the `dbm` module when a more robust module is not available. The `dbm.dumb` module is not written for speed and is not nearly as heavily used as the other database modules.

The `dbm.dumb` module provides a persistent dictionary-like interface which is written entirely in Python. Unlike other modules such as `dbm.gnu` no external library is required. As with other persistent mappings, the keys and values are always stored as bytes.

The module defines the following:

*exception* `dbm.dumb.error`

Raised on `dbm.dumb`-specific errors, such as I/O errors. `KeyError` is raised for general mapping errors like specifying an incorrect key.

`dbm.dumb.open(filename[, flag[, mode]])`

Open a dumbdbm database and return a dumbdbm object. The `filename` argument is the basename of the database file (without any specific extensions). When a dumbdbm database is created, files with `.dat` and `.dir` extensions are created.

The optional `flag` argument is currently ignored; the database is always opened for update, and will be created if it does not exist.

The optional `mode` argument is the Unix mode of the file, used only when the database has to be created. It defaults to octal 0o666.
(and will be modified by the prevailing umask).

In addition to the methods provided by the `collections.abc.MutableMapping` class, `dumbdbm` objects provide the following method:

```
dumbdbm. sync()
```

Synchronize the on-disk directory and data files. This method is called by the `Shelve.sync()` method.
12.6. **sqlite3** — DB-API 2.0 interface for SQLite databases

SQLite is a C library that provides a lightweight disk-based database that doesn’t require a separate server process and allows accessing the database using a nonstandard variant of the SQL query language. Some applications can use SQLite for internal data storage. It’s also possible to prototype an application using SQLite and then port the code to a larger database such as PostgreSQL or Oracle.

sqlite3 was written by Gerhard Häring and provides a SQL interface compliant with the DB-API 2.0 specification described by PEP 249.

To use the module, you must first create a `Connection` object that represents the database. Here the data will be stored in the `example.db` file:

```python
import sqlite3
conn = sqlite3.connect('example.db')
```

You can also supply the special name `:memory:` to create a database in RAM.

Once you have a `Connection`, you can create a `Cursor` object and call its `execute()` method to perform SQL commands:

```python
c = conn.cursor()

# Create table
c.execute('''create table stocks
(date text, trans text, symbol text,
```
```
qty (real, price real)''')

# Insert a row of data
_c.execute("""insert into stocks
values ('2006-01-05', 'BUY', 'RHAT', 100, 35.14)"")

# Save (commit) the changes
conn.commit()

# We can also close the cursor if we are done with it
_c.close()
```

Usually your SQL operations will need to use values from Python variables. You shouldn’t assemble your query using Python’s string operations because doing so is insecure; it makes your program vulnerable to an SQL injection attack.

Instead, use the DB-API’s parameter substitution. Put ? as a placeholder wherever you want to use a value, and then provide a tuple of values as the second argument to the cursor’s `execute()` method. (Other database modules may use a different placeholder, such as %s or :1.) For example:

```
# Never do this -- insecure!
symbol = 'IBM'
_c.execute("select * from stocks where symbol = '%s'"")

# Do this instead
t = ('IBM',)
_c.execute('select * from stocks where symbol=?', t)

# Larger example
for t in [('2006-03-28', 'BUY', 'IBM', 1000, 45.00),
          ('2006-04-05', 'BUY', 'MSFT', 1000, 72.00),
          ('2006-04-06', 'SELL', 'IBM', 500, 53.00),
          ('2006-04-15', 'BUY', 'IBM', 1000, 51.00),
          ('2006-04-16', 'BUY', 'MSFT', 2000, 65.00),
          ('2006-04-17', 'SELL', 'IBM', 700, 53.00),
          ('2006-04-18', 'BUY', 'IBM', 1000, 54.00),
          ('2006-04-19', 'BUY', 'MSFT', 1000, 62.00),
          ('2006-04-20', 'SELL', 'IBM', 500, 55.00),
          ('2006-04-21', 'BUY', 'IBM', 1000, 50.00),
          ('2006-04-22', 'BUY', 'MSFT', 2000, 60.00),
          ('2006-04-23', 'SELL', 'IBM', 700, 52.00),
          ('2006-04-24', 'BUY', 'IBM', 1000, 51.00),
          ('2006-04-25', 'BUY', 'MSFT', 1000, 72.00),
          ('2006-04-26', 'SELL', 'IBM', 500, 53.00),
          ('2006-04-27', 'BUY', 'IBM', 1000, 54.00),
          ('2006-04-28', 'BUY', 'MSFT', 2000, 65.00),
          ('2006-04-29', 'SELL', 'IBM', 700, 53.00),
          ('2006-04-30', 'BUY', 'IBM', 1000, 50.00),
          ('2006-05-01', 'BUY', 'MSFT', 1000, 72.00),
          ('2006-05-02', 'SELL', 'IBM', 500, 53.00),
          ('2006-05-03', 'BUY', 'IBM', 1000, 51.00),
          ('2006-05-04', 'BUY', 'MSFT', 2000, 62.00),
          ('2006-05-05', 'SELL', 'IBM', 700, 55.00),
          ('2006-05-06', 'BUY', 'IBM', 1000, 54.00),
          ('2006-05-07', 'BUY', 'MSFT', 2000, 65.00),
          ('2006-05-08', 'SELL', 'IBM', 700, 53.00),
          ('2006-05-09', 'BUY', 'IBM', 1000, 51.00),
          ('2006-05-10', 'BUY', 'MSFT', 1000, 72.00),
          ('2006-05-11', 'SELL', 'IBM', 500, 53.00),
          ('2006-05-12', 'BUY', 'IBM', 1000, 54.00),
        )
```
To retrieve data after executing a SELECT statement, you can either treat the cursor as an iterator, call the cursor's fetchone() method to retrieve a single matching row, or call fetchall() to get a list of the matching rows.

This example uses the iterator form:

```python
>>> c = conn.cursor()
>>> c.execute('select * from stocks order by price')
>>> for row in c:
    ...   print(row)
... ('2006-01-05', 'BUY', 'RHAT', 100, 35.14)
('2006-03-28', 'BUY', 'IBM', 1000, 45.0)
('2006-04-06', 'SELL', 'IBM', 500, 53.0)
('2006-04-05', 'BUY', 'MSOFT', 1000, 72.0)
```

   PEP written by Marc-André Lemburg.
12.6.1. Module functions and constants

sqlite3.version
   The version number of this module, as a string. This is not the version of the SQLite library.

sqlite3.version_info
   The version number of this module, as a tuple of integers. This is not the version of the SQLite library.

sqlite3.sqlite_version
   The version number of the run-time SQLite library, as a string.

sqlite3.sqlite_version_info
   The version number of the run-time SQLite library, as a tuple of integers.

sqlite3.PARSE_DECLTYPES
   This constant is meant to be used with the detect_types parameter of the connect() function.

   Setting it makes the sqlite3 module parse the declared type for each column it returns. It will parse out the first word of the declared type, i.e. for “integer primary key”, it will parse out “integer”, or for “number(10)” it will parse out “number”. Then for that column, it will look into the converters dictionary and use the converter function registered for that type there.

sqlite3.PARSE_COLNAMES
   This constant is meant to be used with the detect_types parameter of the connect() function.
Setting this makes the SQLite interface parse the column name for each column it returns. It will look for a string formed [mytype] in there, and then decide that ‘mytype’ is the type of the column. It will try to find an entry of ‘mytype’ in the converters dictionary and then use the converter function found there to return the value. The column name found in `Cursor.description` is only the first word of the column name, i.e. if you use something like ‘as "x [datetime]"’ in your SQL, then we will parse out everything until the first blank for the column name: the column name would simply be “x”.

```python
sqlite3.connect(database[, timeout, detect_types,
  isolation_level, check_same_thread, factory, cached_statements])
```

Opens a connection to the SQLite database file `database`. You can use `":memory:"` to open a database connection to a database that resides in RAM instead of on disk.

When a database is accessed by multiple connections, and one of the processes modifies the database, the SQLite database is locked until that transaction is committed. The `timeout` parameter specifies how long the connection should wait for the lock to go away until raising an exception. The default for the timeout parameter is 5.0 (five seconds).

For the `isolation_level` parameter, please see the `Connection.isolation_level` property of `Connection` objects.

SQLite natively supports only the types TEXT, INTEGER, REAL, BLOB and NULL. If you want to use other types you must add support for them yourself. The `detect_types` parameter and the using custom `converters` registered with the module-level
register_converter() function allow you to easily do that.

detect_types defaults to 0 (i.e., off, no type detection), you can set it to any combination of PARSE_DECLTYPES and PARSE_COLNAMES to turn type detection on.

By default, the sqlite3 module uses its Connection class for the connect call. You can, however, subclass the Connection class and make connect() use your class instead by providing your class for the factory parameter.

Consult the section SQLite and Python types of this manual for details.

The sqlite3 module internally uses a statement cache to avoid SQL parsing overhead. If you want to explicitly set the number of statements that are cached for the connection, you can set the cached_statements parameter. The currently implemented default is to cache 100 statements.

sqlite3.register_converter(typename, callable)

Registers a callable to convert a bytestring from the database into a custom Python type. The callable will be invoked for all database values that are of the type typename. Confer the parameter detect_types of the connect() function for how the type detection works. Note that the case of typename and the name of the type in your query must match!

sqlite3.register_adapter(type, callable)

Registers a callable to convert the custom Python type type into one of SQLite’s supported types. The callable callable accepts as single parameter the Python value, and must return a value of the following types: int, float, str or bytes.
sqlite3.**complete_statement**(sql)

Returns **True** if the string `sql` contains one or more complete SQL statements terminated by semicolons. It does not verify that the SQL is syntactically correct, only that there are no unclosed string literals and the statement is terminated by a semicolon.

This can be used to build a shell for SQLite, as in the following example:

```python
# A minimal SQLite shell for experiments
import sqlite3

con = sqlite3.connect(':memory:)
con.isolation_level = None
cur = con.cursor()

buffer = ''

print("Enter your SQL commands to execute in sqlite3.
print("Enter a blank line to exit.")

while True:
    line = input()
    if line == "":
        break
    buffer += line
    if sqlite3.complete_statement(buffer):
        try:
            buffer = buffer.strip()
            cur.execute(buffer)

            if buffer.lstrip().upper().startswith
                print(cur.fetchall())
        except sqlite3.Error as e:
```
print("An error occurred:", e.args[0])
buffer = ""
con.close()

sqlite3.enable_callback_tracebacks(flag)

By default you will not get any tracebacks in user-defined functions, aggregates, converters, authorizer callbacks etc. If you want to debug them, you can call this function with flag as True. Afterwards, you will get tracebacks from callbacks on sys.stderr. Use False to disable the feature again.
12.6.2. Connection Objects

```python
class sqlite3.Connection
```

A SQLite database connection has the following attributes and methods:

**isolation_level**
Get or set the current isolation level. None for autocommit mode or one of “DEFERRED”, “IMMEDIATE” or “EXCLUSIVE”. See section **Controlling Transactions** for a more detailed explanation.

**in_transaction**
True if a transaction is active (there are uncommitted changes), False otherwise. Read-only attribute.

New in version 3.2.

**cursor([cursorClass])**
The cursor method accepts a single optional parameter cursorClass. If supplied, this must be a custom cursor class that extends sqlite3.Cursor.

**commit()**
This method commits the current transaction. If you don’t call this method, anything you did since the last call to commit() is not visible from other database connections. If you wonder why you don’t see the data you’ve written to the database, please check you didn’t forget to call this method.

**rollback()**
This method rolls back any changes to the database since the last call to `commit()`.

**close()**
This closes the database connection. Note that this does not automatically call `commit()`. If you just close your database connection without calling `commit()` first, your changes will be lost!

**execute(sql[, parameters])**
This is a nonstandard shortcut that creates an intermediate cursor object by calling the cursor method, then calls the cursor’s `execute` method with the parameters given.

**executemany(sql[, parameters])**
This is a nonstandard shortcut that creates an intermediate cursor object by calling the cursor method, then calls the cursor’s `executemany` method with the parameters given.

**executescript(sql_script)**
This is a nonstandard shortcut that creates an intermediate cursor object by calling the cursor method, then calls the cursor’s `executescript` method with the parameters given.

**create_function(name, num_params, func)**
Creates a user-defined function that you can later use from within SQL statements under the function name `name`. `num_params` is the number of parameters the function accepts, and `func` is a Python callable that is called as the SQL function.

The function can return any of the types supported by SQLite: bytes, str, int, float and None.
Example:

```python
import sqlite3
import hashlib

def md5sum(t):
    return hashlib.md5(t).hexdigest()

con = sqlite3.connect(':memory:)
con.create_function("md5", 1, md5sum)
cur = con.cursor()
cur.execute("select md5(?)", (b"foo"))
print(cur.fetchone()[0])
```

**create_aggregate**(name, num_params, aggregate_class)

Creates a user-defined aggregate function.

The aggregate class must implement a **step** method, which accepts the number of parameters num_params, and a **finalize** method which will return the final result of the aggregate.

The **finalize** method can return any of the types supported by SQLite: bytes, str, int, float and None.

Example:

```python
import sqlite3

class MySum:
    def __init__(self):
        self.count = 0

    def step(self, value):
        self.count += value
```
def finalize(self):
    return self.count

con = sqlite3.connect(':memory:)
con.create_aggregate("mysum", 1, MySum)
cur = con.cursor()
cur.execute("create table test(i)"
cur.execute("insert into test(i) values (1)"
cur.execute("insert into test(i) values (2)"
cur.execute("select mysum(i) from test"
print(cur.fetchone()[0])

create_collation(name, callable)

Creates a collation with the specified name and callable. The callable will be passed two string arguments. It should return -1 if the first is ordered lower than the second, 0 if they are ordered equal and 1 if the first is ordered higher than the second. Note that this controls sorting (ORDER BY in SQL) so your comparisons don’t affect other SQL operations.

Note that the callable will get its parameters as Python bytestrings, which will normally be encoded in UTF-8.

The following example shows a custom collation that sorts “the wrong way”:

import sqlite3

def collate_reverse(string1, string2):
    if string1 == string2:
        return 0
    elif string1 < string2:
        return 1
    else:

To remove a collation, call `create_collation` with None as callable:

```python
con.create_collation("reverse", None)
```

**interrupt()**

You can call this method from a different thread to abort any queries that might be executing on the connection. The query will then abort and the caller will get an exception.

**set_authorizer**(authorizer_callback)

This routine registers a callback. The callback is invoked for each attempt to access a column of a table in the database. The callback should return SQLITE_OK if access is allowed, SQLITE_DENY if the entire SQL statement should be aborted with an error and SQLITE_IGNORE if the column should be treated as a NULL value. These constants are available in the `sqlite3` module.

The first argument to the callback signifies what kind of
operation is to be authorized. The second and third argument will be arguments or None depending on the first argument. The 4th argument is the name of the database ("main", "temp", etc.) if applicable. The 5th argument is the name of the innermost trigger or view that is responsible for the access attempt or None if this access attempt is directly from input SQL code.

Please consult the SQLite documentation about the possible values for the first argument and the meaning of the second and third argument depending on the first one. All necessary constants are available in the sqlite3 module.

**set_progress_handler** *(handler, n)*

This routine registers a callback. The callback is invoked for every n instructions of the SQLite virtual machine. This is useful if you want to get called from SQLite during long-running operations, for example to update a GUI.

If you want to clear any previously installed progress handler, call the method with None for handler.

**set_trace_callback** *(trace_callback)*

Registers trace_callback to be called for each SQL statement that is actually executed by the SQLite backend.

The only argument passed to the callback is the statement (as string) that is being executed. The return value of the callback is ignored. Note that the backend does not only run statements passed to the Cursor.execute() methods. Other sources include the transaction management of the Python module and the execution of triggers defined in the current database.

Passing None as trace_callback will disable the trace callback.
*New in version 3.3.*

**enable_load_extension**(enabled)

This routine allows/disallows the SQLite engine to load SQLite extensions from shared libraries. SQLite extensions can define new functions, aggregates or whole new virtual table implementations. One well-known extension is the fulltext-search extension distributed with SQLite.

Loadable extensions are disabled by default. See [1].

*New in version 3.2.*

```python
import sqlite3

con = sqlite3.connect(':memory:)

# enable extension loading
con.enable_load_extension(True)

# Load the fulltext search extension
con.execute("select load_extension('./fts3.so')")

# alternatively you can load the extension using
# con.load_extension('./fts3.so')

# disable extension loading again
con.enable_load_extension(False)

# example from SQLite wiki
con.execute("create virtual table recipe using fts3(name, ingredients)
con.executescript('''
    insert into recipe (name, ingredients) values ('broccoli stew', 'broccoli peppers cheese tomatoes');
    insert into recipe (name, ingredients) values ('pumpkin stew', 'pumpkin onions garlic celery');
    insert into recipe (name, ingredients) values ('broccoli pie', 'broccoli cheese onions flour');
    insert into recipe (name, ingredients) values ('pumpkin pie', 'pumpkin sugar flour butter');
'''")
```
for row in con.execute("select rowid, name, ingredients from recipe where name match 'pie'\n\nprint(row)")

load_extension(path)

This routine loads a SQLite extension from a shared library. You have to enable extension loading with enable_load_extension() before you can use this routine.

Loadable extensions are disabled by default. See [1].

New in version 3.2.

row_factory

You can change this attribute to a callable that accepts the cursor and the original row as a tuple and will return the real result row. This way, you can implement more advanced ways of returning results, such as returning an object that can also access columns by name.

Example:

```python
import sqlite3
def dict_factory(cursor, row):
    d = {}
    for idx, col in enumerate(cursor.description):
        d[col[0]] = row[idx]
    return d

con = sqlite3.connect(":memory:")
con.row_factory = dict_factory
cur = con.cursor()
cur.execute("select 1 as a")
```
If returning a tuple doesn’t suffice and you want name-based access to columns, you should consider setting `row_factory` to the highly-optimized `sqlite3.Row` type. `Row` provides both index-based and case-insensitive name-based access to columns with almost no memory overhead. It will probably be better than your own custom dictionary-based approach or even a `db_row` based solution.

**text_factory**

Using this attribute you can control what objects are returned for the `TEXT` data type. By default, this attribute is set to `str` and the `sqlite3` module will return Unicode objects for `TEXT`. If you want to return bytestrings instead, you can set it to `bytes`.

For efficiency reasons, there’s also a way to return `str` objects only for non-ASCII data, and `bytes` otherwise. To activate it, set this attribute to `sqlite3.OptimizedUnicode`.

You can also set it to any other callable that accepts a single bytestring parameter and returns the resulting object.

See the following example code for illustration:

```python
import sqlite3
con = sqlite3.connect(":memory:")
cur = con.cursor()

AUSTRIA = "\xd6sterreich"
```
# by default, rows are returned as Unicode
cur.execute("select ?", (AUSTRIA,))
row = cur.fetchone()
assert row[0] == AUSTRIA

# but we can make sqlite3 always return bytestrings
con.text_factory = bytes
cur.execute("select ?", (AUSTRIA,))
row = cur.fetchone()
assert type(row[0]) is bytes
# the bytestrings will be encoded in UTF-8, unless...
# database ...
assert row[0] == AUSTRIA.encode("utf-8")

# we can also implement a custom text_factory ...
# here we implement one that appends "foo" to all
con.text_factory = lambda x: x.decode("utf-8")
cur.execute("select ?", ("bar",))
row = cur.fetchone()
assert row[0] == "barfoo"

total_changes

Returns the total number of database rows that have been modified, inserted, or deleted since the database connection was opened.

iterdump

Returns an iterator to dump the database in an SQL text format. Useful when saving an in-memory database for later restoration. This function provides the same capabilities as the .dump command in the sqlite3 shell.

Example:

# Convert file existing_db.db to SQL dump file
import sqlite3, os

con = sqlite3.connect('existing_db.db')
with open('dump.sql', 'w') as f:
    for line in con.iterdump():
        f.write('%s
' % line)
12.6.3. Cursor Objects

class sqlite3.Cursor

A Cursor instance has the following attributes and methods.

```
execute(sql[, parameters])
```

Executes an SQL statement. The SQL statement may be parametrized (i.e. placeholders instead of SQL literals). The sqlite3 module supports two kinds of placeholders: question marks (qmark style) and named placeholders (named style).

Here’s an example of both styles:

```python
import sqlite3

con = sqlite3.connect(":memory:")
cur = con.cursor()
cur.execute("create table people (name_last, age)

who = "Yeltsin"
age = 72

# This is the qmark style:
cur.execute("insert into people values (?, ?)",

# And this is the named style:
cur.execute("select * from people where name_last=

print(cur.fetchone())
```

execute() will only execute a single SQL statement. If you try to execute more than one statement with it, it will raise a Warning. Use executescript() if you want to execute
multiple SQL statements with one call.

**executemany**(sql, seq_of_parameters)

Executes an SQL command against all parameter sequences or mappings found in the sequence sql. The `sqlite3` module also allows using an iterator yielding parameters instead of a sequence.

```python
import sqlite3

class IterChars:
    def __init__(self):
        self.count = ord('a')

    def __iter__(self):
        return self

    def __next__(self):
        if self.count > ord('z'):
            raise StopIteration
        self.count += 1
        return (chr(self.count - 1),) # this is a 1-tuple

con = sqlite3.connect(':memory:)
cur = con.cursor()
cur.execute("create table characters(c)"

theIter = IterChars()
cur.executemany("insert into characters(c) values (?)")
cur.execute("select c from characters"
print(cur.fetchall())
```

Here's a shorter example using a *generator*:
import sqlite3
import string

def char_generator():
    for c in string.ascii_lowercase:
        yield (c,)

con = sqlite3.connect(":memory:"
cur = con.cursor()
cur.execute("create table characters(c)"
cur.executemany("insert into characters(c) values (?)" cur.execute("select c from characters"
print(cur.fetchall())

executescript(sql_script)

This is a nonstandard convenience method for executing multiple SQL statements at once. It issues a COMMIT statement first, then executes the SQL script it gets as a parameter.

sql_script can be an instance of str or bytes.

Example:

import sqlite3

con = sqlite3.connect(":memory:"
cur = con.cursor()
cur.executescript(""
    create table person(
    firstname,
    lastname,
    age
    );
\)
create table book(
    title,
    author,
    published
);

insert into book(title, author, published)
values ('Dirk Gently''s Holistic Detective Agency',
        'Douglas Adams',
        1987);

fetchone()
Fetches the next row of a query result set, returning a single sequence, or None when no more data is available.

fetchmany(size=cursor.arraysize)
Fetches the next set of rows of a query result, returning a list. An empty list is returned when no more rows are available.

The number of rows to fetch per call is specified by the size parameter. If it is not given, the cursor’s arraysize determines the number of rows to be fetched. The method should try to fetch as many rows as indicated by the size parameter. If this is not possible due to the specified number of rows not being available, fewer rows may be returned.

Note there are performance considerations involved with the size parameter. For optimal performance, it is usually best to use the arraysize attribute. If the size parameter is used, then it is best for it to retain the same value from one fetchmany()
call to the next.

**fetchall()**
Fetches all (remaining) rows of a query result, returning a list. Note that the cursor’s arraysize attribute can affect the performance of this operation. An empty list is returned when no rows are available.

**rowcount**
Although the Cursor class of the sqlite3 module implements this attribute, the database engine’s own support for the determination of “rows affected”/”rows selected” is quirky.

For executemany() statements, the number of modifications are summed up into rowcount.

As required by the Python DB API Spec, the rowcount attribute “is -1 in case no executeXX() has been performed on the cursor or the rowcount of the last operation is not determinable by the interface”. This includes SELECT statements because we cannot determine the number of rows a query produced until all rows were fetched.

With SQLite versions before 3.6.5, rowcount is set to 0 if you make a DELETE FROM table without any condition.

**lastrowid**
This read-only attribute provides the rowid of the last modified row. It is only set if you issued a INSERT statement using the execute() method. For operations other than INSERT or when executemany() is called, lastrowid is set to None.

**description**
This read-only attribute provides the column names of the last query. To remain compatible with the Python DB API, it returns a 7-tuple for each column where the last six items of each tuple are None.

It is set for SELECT statements without any matching rows as well.
12.6.4. Row Objects

class sqlite3.Row

A Row instance serves as a highly optimized row_factory for Connection objects. It tries to mimic a tuple in most of its features.

It supports mapping access by column name and index, iteration, representation, equality testing and \texttt{len()}.

If two Row objects have exactly the same columns and their members are equal, they compare equal.

\texttt{keys()}

This method returns a tuple of column names. Immediately after a query, it is the first member of each tuple in Cursor.description.

Let's assume we initialize a table as in the example given above:

```python
c = conn.cursor()
c.execute('''create table stocks
    (date text, trans text, symbol text,
     qty real, price real)''')
c.execute('''insert into stocks
    values ('2006-01-05','BUY','RHAT',100,35.14)''')
```

Now we plug Row in:
>>> conn.row_factory = sqlite3.Row
>>> c = conn.cursor()
>>> c.execute('select * from stocks')
<sqlite3.Cursor object at 0x7f4e7dd8fa80>
>>> r = c.fetchone()
>>> type(r)
<class 'sqlite3.Row'>
>>> tuple(r)
('2006-01-05', 'BUY', 'RHAT', 100.0, 35.14)
>>> len(r)
5
>>> r[2]
'RHAT'
>>> r.keys()
['date', 'trans', 'symbol', 'qty', 'price']
>>> r['qty']
100.0
>>> for member in r:
...     print(member)
...
2006-01-05
BUY
RHAT
100.0
35.14
12.6.5. SQLite and Python types

12.6.5.1. Introduction

SQLite natively supports the following types: NULL, INTEGER, REAL, TEXT, BLOB.

The following Python types can thus be sent to SQLite without any problem:

<table>
<thead>
<tr>
<th>Python type</th>
<th>SQLite type</th>
</tr>
</thead>
<tbody>
<tr>
<td>None</td>
<td>NULL</td>
</tr>
<tr>
<td>int</td>
<td>INTEGER</td>
</tr>
<tr>
<td>float</td>
<td>REAL</td>
</tr>
<tr>
<td>str</td>
<td>TEXT</td>
</tr>
<tr>
<td>bytes</td>
<td>BLOB</td>
</tr>
</tbody>
</table>

This is how SQLite types are converted to Python types by default:

<table>
<thead>
<tr>
<th>SQLite type</th>
<th>Python type</th>
</tr>
</thead>
<tbody>
<tr>
<td>NULL</td>
<td>None</td>
</tr>
<tr>
<td>INTEGER</td>
<td>int</td>
</tr>
<tr>
<td>REAL</td>
<td>float</td>
</tr>
<tr>
<td>TEXT</td>
<td>depends on text_factory, str by default</td>
</tr>
<tr>
<td>BLOB</td>
<td>bytes</td>
</tr>
</tbody>
</table>

The type system of the sqlite3 module is extensible in two ways: you can store additional Python types in a SQLite database via object
adaptation, and you can let the `sqlite3` module convert SQLite types to different Python types via converters.

### 12.6.5.2. Using adapters to store additional Python types in SQLite databases

As described before, SQLite supports only a limited set of types natively. To use other Python types with SQLite, you must adapt them to one of the sqlite3 module's supported types for SQLite: one of NoneType, int, float, str, bytes.

The `sqlite3` module uses Python object adaptation, as described in PEP 246 for this. The protocol to use is PrepareProtocol.

There are two ways to enable the `sqlite3` module to adapt a custom Python type to one of the supported ones.

#### 12.6.5.2.1. Letting your object adapt itself

This is a good approach if you write the class yourself. Let's suppose you have a class like this:

```python
class Point:
    def __init__(self, x, y):
        self.x, self.y = x, y
```

Now you want to store the point in a single SQLite column. First you'll have to choose one of the supported types first to be used for representing the point. Let's just use str and separate the coordinates using a semicolon. Then you need to give your class a method `__conform__(self, protocol)` which must return the converted value. The parameter `protocol` will be PrepareProtocol.
import sqlite3

class Point:
    def __init__(self, x, y):
        self.x, self.y = x, y

    def __conform__(self, protocol):
        if protocol is sqlite3.PrepareProtocol:
            return "%f;%f" % (self.x, self.y)

con = sqlite3.connect(":memory:")
cur = con.cursor()

p = Point(4.0, -3.2)
cur.execute("select ?", (p,))
print(cur.fetchone()[0])

12.6.5.2.2. Registering an adapter callable

The other possibility is to create a function that converts the type to the string representation and register the function with register_adapter().

import sqlite3
class Point:
    def __init__(self, x, y):
        self.x, self.y = x, y

def adapt_point(point):
    return "%f;%f" % (point.x, point.y)

sqlite3.register_adapter(Point, adapt_point)
con = sqlite3.connect(":memory:"
cur = con.cursor()

p = Point(4.0, -3.2)
cur.execute("select ?", (p,))
print(cur.fetchone()[0])

The `sqlite3` module has two default adapters for Python's built-in `datetime.date` and `datetime.datetime` types. Now let's suppose we want to store `datetime.datetime` objects not in ISO representation, but as a Unix timestamp.

```python
import sqlite3
import datetime
import time

def adapt_datetime(ts):
    return time.mktime(ts.timetuple())

sqlite3.register_adapter(datetime.datetime, adapt_datetime)

con = sqlite3.connect(":memory:"
cur = con.cursor()

now = datetime.datetime.now()
cur.execute("select ?", (now,))
print(cur.fetchone()[0])
```

12.6.5.3. Converting SQLite values to custom Python types

Writing an adapter lets you send custom Python types to SQLite. But to make it really useful we need to make the Python to SQLite to Python roundtrip work.
Enter converters.

Let's go back to the Point class. We stored the x and y coordinates separated via semicolons as strings in SQLite.

First, we'll define a converter function that accepts the string as a parameter and constructs a Point object from it.

**Note:** Converter functions always get called with a string, no matter under which data type you sent the value to SQLite.

```python
def convert_point(s):
    x, y = map(float, s.split(b";"))
    return Point(x, y)
```

Now you need to make the sqlite3 module know that what you select from the database is actually a point. There are two ways of doing this:

- Implicitly via the declared type
- Explicitly via the column name

Both ways are described in section *Module functions and constants*, in the entries for the constants `PARSE_DECLTYPES` and `PARSE_COLNAMES`.

The following example illustrates both approaches.

```python
import sqlite3

class Point:
    def __init__(self, x, y):
        self.x, self.y = x, y
```
def __repr__(self):
    return "(%f;%f)" % (self.x, self.y)

def adapt_point(point):
    return ("%f;%f" % (point.x, point.y)).encode(\'ascii\')

def convert_point(s):
    x, y = list(map(float, s.split(b";")))
    return Point(x, y)

# Register the adapter
sqlite3.register_adapter(Point, adapt_point)

# Register the converter
sqlite3.register_converter("point", convert_point)

p = Point(4.0, -3.2)

# 1) Using declared types
con = sqlite3.connect(":memory:", detect_types=sqlite3.PARSE_DECLTYPES)
cur = con.cursor()
cur.execute("create table test(p point)")
cur.execute("insert into test(p) values (?)", (p,))
cur.execute("select p from test")
print("with declared types:", cur.fetchone()[0])
cur.close()
con.close()

# 1) Using column names
con = sqlite3.connect(":memory:", detect_types=sqlite3.PARSE_DECLTYPES)
cur = con.cursor()
cur.execute("create table test(p)")
cur.execute("insert into test(p) values (?)", (p,))
12.6.5.4. Default adapters and converters

There are default adapters for the date and datetime types in the datetime module. They will be sent as ISO dates/ISO timestamps to SQLite.

The default converters are registered under the name “date” for \texttt{datetime.date} and under the name “timestamp” for \texttt{datetime.datetime}.

This way, you can use date/timestamps from Python without any additional fiddling in most cases. The format of the adapters is also compatible with the experimental SQLite date/time functions.

The following example demonstrates this.

```python
import sqlite3
import datetime

con = sqlite3.connect(":memory:", detect_types=sqlite3.PARSE_DECLTYPES)
cur = con.cursor()
cur.execute("create table test(d date, ts timestamp)"

today = datetime.date.today()
now = datetime.datetime.now()

cur.execute("insert into test(d, ts) values (?, ?)",
            cur.execute("select d, ts from test")
row = cur.fetchone()
```
print(today, "=>", row[0], type(row[0]))
print(now, "=>", row[1], type(row[1]))

cur.execute('select current_date as "d [date]", current_timestamp as "ts [timestamp]"
row = cur.fetchone()
print("current_date", row[0], type(row[0]))
print("current_timestamp", row[1], type(row[1]))

If a timestamp stored in SQLite has a fractional part longer than 6 numbers, its value will be truncated to microsecond precision by the timestamp converter.
12.6.6. Controlling Transactions

By default, the sqlite3 module opens transactions implicitly before a Data Modification Language (DML) statement (i.e. INSERT/UPDATE/DELETE/REPLACE), and commits transactions implicitly before a non-DML, non-query statement (i.e. anything other than SELECT or the aforementioned).

So if you are within a transaction and issue a command like CREATE TABLE ..., VACUUM, PRAGMA, the sqlite3 module will commit implicitly before executing that command. There are two reasons for doing that. The first is that some of these commands don’t work within transactions. The other reason is that sqlite3 needs to keep track of the transaction state (if a transaction is active or not). The current transaction state is exposed through the Connection.in_transaction attribute of the connection object.

You can control which kind of BEGIN statements sqlite3 implicitly executes (or none at all) via the isolation_level parameter to the connect() call, or via the isolation_level property of connections.

If you want autocommit mode, then set isolation_level to None.

Otherwise leave it at its default, which will result in a plain “BEGIN” statement, or set it to one of SQLite’s supported isolation levels: “DEFERRED”, “IMMEDIATE” or “EXCLUSIVE”.

12.6.7. Using sqlite3 efficiently

12.6.7.1. Using shortcut methods

Using the nonstandard execute(), executemany() and executestorect() methods of the Connection object, your code can be written more concisely because you don’t have to create the (often superfluous) Cursor objects explicitly. Instead, the Cursor objects are created implicitly and these shortcut methods return the cursor objects. This way, you can execute a SELECT statement and iterate over it directly using only a single call on the Connection object.

```python
import sqlite3

persons = [  
    ("Hugo", "Boss"),  
    ("Calvin", "Klein")  
]

con = sqlite3.connect(":memory:")

# Create the table
con.execute("create table person(firstname, lastname)"

# Fill the table
con.executemany("insert into person(firstname, lastname) values (?, ?)"

# Print the table contents
for row in con.execute("select firstname, lastname from person")
    print(row)

print("I just deleted", con.execute("delete from person").rowcount)
```
12.6.7.2. Accessing columns by name instead of by index

One useful feature of the sqlite3 module is the built-in sqlite3.Row class designed to be used as a row factory.

Rows wrapped with this class can be accessed both by index (like tuples) and case-insensitively by name:

```python
import sqlite3
con = sqlite3.connect(":memory:")
con.row_factory = sqlite3.Row

cur = con.cursor()
cur.execute("select 'John' as name, 42 as age")
for row in cur:
    assert row[0] == row["name"]
    assert row["name"] == row["nAmE"]
    assert row[1] == row["age"]
    assert row[1] == row["AgE"]
```

12.6.7.3. Using the connection as a context manager

Connection objects can be used as context managers that automatically commit or rollback transactions. In the event of an exception, the transaction is rolled back; otherwise, the transaction is committed:

```python
import sqlite3
con = sqlite3.connect(":memory:")
```
```python
con.execute("create table person (id integer primary key, firstname varchar unique)"

# Successful, con.commit() is called automatically after
with con:
    con.execute("insert into person(firstname) values (?)")

# con.rollback() is called after the with block finishes
# exception is still raised and must be caught
try:
    with con:
        con.execute("insert into person(firstname) values (?)")
except sqlite3.IntegrityError:
    print("couldn't add Joe twice")
```
12.6.8. Common issues

12.6.8.1. Multithreading

Older SQLite versions had issues with sharing connections between threads. That's why the Python module disallows sharing connections and cursors between threads. If you still try to do so, you will get an exception at runtime.

The only exception is calling the `interrupt()` method, which only makes sense to call from a different thread.

**Footnotes**

[1] The sqlite3 module is not built with loadable extension support by default, because some platforms (notably Mac OS X) have SQLite libraries which are compiled without this feature. To get loadable extension support, you must pass `--enable-loadable-sqlite-extensions` to configure.
13. Data Compression and Archiving

The modules described in this chapter support data compression with the zlib, gzip, bzip2 and lzma algorithms, and the creation of ZIP- and tar-format archives. See also Archiving operations provided by the shutil module.

13.1. **zlib** — Compression compatible with **gzip**

For applications that require data compression, the functions in this module allow compression and decompression, using the zlib library. The zlib library has its own home page at http://www.zlib.net. There are known incompatibilities between the Python module and versions of the zlib library earlier than 1.1.3; 1.1.3 has a security vulnerability, so we recommend using 1.1.4 or later.

zlib’s functions have many options and often need to be used in a particular order. This documentation doesn’t attempt to cover all of the permutations; consult the zlib manual at http://www.zlib.net/manual.html for authoritative information.

For reading and writing `.gz` files see the **gzip** module.

The available exception and functions in this module are:

**exception** zlib.**error**

Exception raised on compression and decompression errors.

zlib.**adler32**(data[, value])

Computes a Adler-32 checksum of `data`. (An Adler-32 checksum is almost as reliable as a CRC32 but can be computed much more quickly.) If `value` is present, it is used as the starting value of the checksum; otherwise, a fixed default value is used. This allows computing a running checksum over the concatenation of several inputs. The algorithm is not cryptographically strong, and should not be used for authentication or digital signatures. Since the
algorithm is designed for use as a checksum algorithm, it is not suitable for use as a general hash algorithm.

Always returns an unsigned 32-bit integer.

Note: To generate the same numeric value across all Python versions and platforms use adler32(data) & 0xffffffff. If you are only using the checksum in packed binary format this is not necessary as the return value is the correct 32bit binary representation regardless of sign.

zlib.compress(data[, level])
Compresses the bytes in data, returning a bytes object containing compressed data. level is an integer from 0 to 9 controlling the level of compression; 1 is fastest and produces the least compression, 9 is slowest and produces the most. 0 is no compression. The default value is 6. Raises the error exception if any error occurs.

zlib.compressobj(level=-1, method=DEFLATED, wbits=15, memlevel=8, strategy=Z_DEFAULT_STRATEGY[, zdict])
Returns a compression object, to be used for compressing data streams that won’t fit into memory at once.

level is the compression level – an integer from 0 to 9. A value of 1 is fastest and produces the least compression, while a value of 9 is slowest and produces the most. 0 is no compression. The default value is 6.

method is the compression algorithm. Currently, the only supported value is DEFLATED.
**wb**its is the base two logarithm of the size of the window buffer. This should be an integer from 8 to 15. Higher values give better compression, but use more memory.

**mem**level controls the amount of memory used for internal compression state. Valid values range from 1 to 9. Higher values using more memory, but are faster and produce smaller output.

**strategy** is used to tune the compression algorithm. Possible values are `Z_DEFAULT_STRATEGY`, `Z_FILTERED`, and `Z_HUFFMAN_ONLY`.

**zdict** is a predefined compression dictionary. This is a sequence of bytes (such as a bytes object) containing subsequences that are expected to occur frequently in the data that is to be compressed. Those subsequences that are expected to be most common should come at the end of the dictionary.

*Changed in version 3.3:* Added the zdict parameter and keyword argument support.

**zlib**. **crc32**(data[, value])

Computes a CRC (Cyclic Redundancy Check) checksum of data. If value is present, it is used as the starting value of the checksum; otherwise, a fixed default value is used. This allows computing a running checksum over the concatenation of several inputs. The algorithm is not cryptographically strong, and should not be used for authentication or digital signatures. Since the algorithm is designed for use as a checksum algorithm, it is not suitable for use as a general hash algorithm.

Always returns an unsigned 32-bit integer.
Note: To generate the same numeric value across all Python versions and platforms, use `crc32(data) & 0xffffffff`. If you are only using the checksum in packed binary format this is not necessary as the return value is the correct 32-bit binary representation regardless of sign.

```python
zlib.decompress(data[, wbits[, bufsize]])
```

Decompresses the bytes in `data`, returning a bytes object containing the uncompressed data. The `wbits` parameter controls the size of the window buffer, and is discussed further below. If `bufsize` is given, it is used as the initial size of the output buffer. Raises the `error` exception if any error occurs.

The absolute value of `wbits` is the base two logarithm of the size of the history buffer (the “window size”) used when compressing data. Its absolute value should be between 8 and 15 for the most recent versions of the zlib library, larger values resulting in better compression at the expense of greater memory usage. When decompressing a stream, `wbits` must not be smaller than the size originally used to compress the stream; using a too-small value will result in an exception. The default value is therefore the highest value, 15. When `wbits` is negative, the standard `gzip` header is suppressed.

`bufsize` is the initial size of the buffer used to hold decompressed data. If more space is required, the buffer size will be increased as needed, so you don’t have to get this value exactly right; tuning it will only save a few calls to `malloc()`. The default size is 16384.

```python
zlib.decompressobj(wbits=15[, zdict])
```

Returns a decompression object, to be used for decompressing
data streams that won’t fit into memory at once.

The `wbits` parameter controls the size of the window buffer.

The `zdict` parameter specifies a predefined compression dictionary. If provided, this must be the same dictionary as was used by the compressor that produced the data that is to be decompressed.

**Note:** If `zdict` is a mutable object (such as a `bytearray`), you must not modify its contents between the call to `decompressobj()` and the first call to the decompressor’s `decompress()` method.

*Changed in version 3.3: Added the `zdict` parameter.*

Compression objects support the following methods:

**Compress.** `compress(data)`

Compress `data`, returning a bytes object containing compressed data for at least part of the data in `data`. This data should be concatenated to the output produced by any preceding calls to the `compress()` method. Some input may be kept in internal buffers for later processing.

**Compress.** `flush([mode])`

All pending input is processed, and a bytes object containing the remaining compressed output is returned. `mode` can be selected from the constants `Z_SYNC_FLUSH`, `Z_FULL_FLUSH`, or `Z_FINISH`, defaulting to `Z_FINISH`. `Z_SYNC_FLUSH` and `Z_FULL_FLUSH` allow compressing further bytestrings of data, while `Z_FINISH` finishes the compressed stream and prevents compressing any more data. After calling `flush()` with `mode` set
to Z_FINISH, the `compress()` method cannot be called again; the only realistic action is to delete the object.

**Compress. copy()**

Returns a copy of the compression object. This can be used to efficiently compress a set of data that share a common initial prefix.

Decompression objects support the following methods and attributes:

**Decompress. unused_data**

A bytes object which contains any bytes past the end of the compressed data. That is, this remains `""` until the last byte that contains compression data is available. If the whole bytestring turned out to contain compressed data, this is `b""`, an empty bytes object.

**Decompress. unconsumed_tail**

A bytes object that contains any data that was not consumed by the last `decompress()` call because it exceeded the limit for the uncompressed data buffer. This data has not yet been seen by the zlib machinery, so you must feed it (possibly with further data concatenated to it) back to a subsequent `decompress()` method call in order to get correct output.

**Decompress. eof**

A boolean indicating whether the end of the compressed data stream has been reached.

This makes it possible to distinguish between a properly-formed compressed stream, and an incomplete or truncated one.

*New in version 3.3.*
Decompress. **decompress**(*data[, max_length]*)
Decompress *data*, returning a bytes object containing the uncompressed data corresponding to at least part of the data in *string*. This data should be concatenated to the output produced by any preceding calls to the `decompress()` method. Some of the input data may be preserved in internal buffers for later processing.

If the optional parameter *max_length* is supplied then the return value will be no longer than *max_length*. This may mean that not all of the compressed input can be processed; and unconsumed data will be stored in the attribute `unconsumed_tail`. This bytestring must be passed to a subsequent call to `decompress()` if decompression is to continue. If *max_length* is not supplied then the whole input is decompressed, and `unconsumed_tail` is empty.

Decompress. **flush**(*length*)
All pending input is processed, and a bytes object containing the remaining uncompressed output is returned. After calling `flush()`, the `decompress()` method cannot be called again; the only realistic action is to delete the object.

The optional parameter *length* sets the initial size of the output buffer.

Decompress. **copy**()
Returns a copy of the decompression object. This can be used to save the state of the decompressor midway through the data stream in order to speed up random seeks into the stream at a future point.

Information about the version of the zlib library in use is available
through the following constants:

```
zlib.ZLIB_VERSION
```

The version string of the zlib library that was used for building the module. This may be different from the zlib library actually used at runtime, which is available as `ZLIB_RUNTIME_VERSION`.

```
zlib.ZLIB_RUNTIME_VERSION
```

The version string of the zlib library actually loaded by the interpreter.

*New in version 3.3.*

13.2. *gzip* — Support for *gzip* files

**Source code:** Lib/gzip.py

This module provides a simple interface to compress and decompress files just like the GNU programs *gzip* and *gunzip* would.

The data compression is provided by the *zlib* module.

The *gzip* module provides the *GzipFile* class, as well as the *open()*(*), *compress()*(*) and *decompress()*() convenience functions. The *GzipFile* class reads and writes *gzip*-format files, automatically compressing or decompressing the data so that it looks like an ordinary *file object*.

Note that additional file formats which can be decompressed by the *gzip* and *gunzip* programs, such as those produced by *compress* and *pack*, are not supported by this module.

The module defines the following items:

```python
gzip.open(filename, mode='rb', compresslevel=9, encoding=None, errors=None, newline=None)
```

Open a gzip-compressed file in binary or text mode, returning a *file object*.

The *filename* argument can be an actual filename (a *str* or *bytes* object), or an existing file object to read from or write to.
The `mode` argument can be any of `'r', 'rb', 'a', 'ab', 'w', ` or `'wb' for binary mode, or `'rt', 'at', or 'wt' for text mode. The default is `'rb'`.

The `compresslevel` argument is an integer from 0 to 9, as for the `GzipFile` constructor.

For binary mode, this function is equivalent to the `GzipFile` constructor: `GzipFile(filename, mode, compresslevel)`. In this case, the `encoding`, `errors` and `newline` arguments must not be provided.

For text mode, a `GzipFile` object is created, and wrapped in an `io.TextIOWrapper` instance with the specified encoding, error handling behavior, and line ending(s).

```
Changed in version 3.3: Added support for filename being a file object, support for text mode, and the encoding, errors and newline arguments.
```

```
class gzip.GzipFile(filename=None, mode=None, compresslevel=9, fileobj=None, mtime=None)

Constructor for the `GzipFile` class, which simulates most of the methods of a file object, with the exception of the truncate() method. At least one of `fileobj` and `filename` must be given a non-trivial value.

The new class instance is based on `fileobj`, which can be a regular file, a `io.BytesIO` object, or any other object which simulates a file. It defaults to None, in which case `filename` is opened to provide a file object.

When `fileobj` is not None, the `filename` argument is only used to be
included in the gzip file header, which may include the original filename of the uncompressed file. It defaults to the filename of fileobj, if discernible; otherwise, it defaults to the empty string, and in this case the original filename is not included in the header.

The mode argument can be any of 'r', 'rb', 'a', 'ab', 'w', or 'wb', depending on whether the file will be read or written. The default is the mode of fileobj if discernible; otherwise, the default is 'rb'.

Note that the file is always opened in binary mode. To open a compressed file in text mode, use open() (or wrap your GzipFile with an io.TextIOWrapper).

The compresslevel argument is an integer from 0 to 9 controlling the level of compression; 1 is fastest and produces the least compression, and 9 is slowest and produces the most compression. 0 is no compression. The default is 9.

The mtime argument is an optional numeric timestamp to be written to the stream when compressing. All gzip compressed streams are required to contain a timestamp. If omitted or None, the current time is used. This module ignores the timestamp when decompressing; however, some programs, such as gunzip, make use of it. The format of the timestamp is the same as that of the return value of time.time() and of the st_mtime attribute of the object returned by os.stat().

Calling a GzipFile object’s close() method does not close fileobj, since you might wish to append more material after the compressed data. This also allows you to pass a io.BytesIO object opened for writing as fileobj, and retrieve the resulting
memory buffer using the \texttt{io.BytesIO} object's \texttt{getvalue()} method.

\texttt{GzipFile} supports the \texttt{io.BufferedIOBase} interface, including iteration and the \texttt{with} statement. Only the \texttt{truncate()} method isn't implemented.

\texttt{GzipFile} also provides the following method:

\texttt{peek([n])}

Read \textit{n} uncompressed bytes without advancing the file position. At most one single read on the compressed stream is done to satisfy the call. The number of bytes returned may be more or less than requested.

\textit{New in version 3.2.}

\textit{Changed in version 3.1:} Support for the \texttt{with} statement was added, along with the \texttt{mtime} argument.

\textit{Changed in version 3.2:} Support for zero-padded and unseekable files was added.

\textit{Changed in version 3.3:} The \texttt{io.BufferedIOBase.read1()} method is now implemented.

\texttt{gzip.compress(data, compresslevel=9)}

Compress the \textit{data}, returning a \texttt{bytes} object containing the compressed data. \texttt{compresslevel} has the same meaning as in the \texttt{GzipFile} constructor above.

\textit{New in version 3.2.}
gzip. **decompress**(data)

Decompress the *data*, returning a `bytes` object containing the uncompressed data.

*New in version 3.2.*
13.2.1. Examples of usage

Example of how to read a compressed file:

```python
import gzip
with gzip.open('/home/joe/file.txt.gz', 'rb') as f:
    file_content = f.read()
```

Example of how to create a compressed GZIP file:

```python
import gzip
content = b"Lots of content here"
with gzip.open('/home/joe/file.txt.gz', 'wb') as f:
    f.write(content)
```

Example of how to GZIP compress an existing file:

```python
import gzip
with open('/home/joe/file.txt', 'rb') as f_in:
    with gzip.open('/home/joe/file.txt.gz', 'wb') as f_out:
        f_out.writelines(f_in)
```

Example of how to GZIP compress a binary string:

```python
import gzip
s_in = b"Lots of content here"
s_out = gzip.compress(s_in)
```

See also:

**Module zlib**

The basic data compression module needed to support the `gzip` file format.
13.3. bz2 — Support for bzip2 compression

This module provides a comprehensive interface for compressing and decompressing data using the bzip2 compression algorithm.

The bz2 module contains:

- The open() function and BZ2File class for reading and writing compressed files.
- The BZ2Compressor and BZ2Decompressor classes for incremental (de)compression.
- The compress() and decompress() functions for one-shot (de)compression.

All of the classes in this module may safely be accessed from multiple threads.
13.3.1. (De)compression of files

bz2. open(filename, mode='r', compresslevel=9, encoding=None, errors=None, newline=None)

Open a bzip2-compressed file in binary or text mode, returning a file object.

As with the constructor for BZ2File, the filename argument can be an actual filename (a str or bytes object), or an existing file object to read from or write to.

The mode argument can be any of 'r', 'rb', 'w', 'wb', 'a', or 'ab' for binary mode, or 'rt', 'wt', or 'at' for text mode. The default is 'rb'.

The compresslevel argument is an integer from 1 to 9, as for the BZ2File constructor.

For binary mode, this function is equivalent to the BZ2File constructor: BZ2File(filename, mode, compresslevel=compresslevel). In this case, the encoding, errors and newline arguments must not be provided.

For text mode, a BZ2File object is created, and wrapped in an io.TextIOWrapper instance with the specified encoding, error handling behavior, and line ending(s).

New in version 3.3.

class bz2.BZ2File(filename, mode='r', buffering=None, compresslevel=9)

Open a bzip2-compressed file in binary mode.
If `filename` is a `str` or `bytes` object, open the named file directly. Otherwise, `filename` should be a `file object`, which will be used to read or write the compressed data.

The `mode` argument can be either `'r'` for reading (default), `'w'` for overwriting, or `'a'` for appending. These can equivalently be given as `'rb'`, `'wb'`, and `'ab'` respectively.

If `filename` is a file object (rather than an actual file name), a mode of `'w'` does not truncate the file, and is instead equivalent to `'a'`.

The `buffering` argument is ignored. Its use is deprecated.

If `mode` is `'w'` or `'a'`, `compresslevel` can be a number between 1 and 9 specifying the level of compression: 1 produces the least compression, and 9 (default) produces the most compression.

If `mode` is `'r'`, the input file may be the concatenation of multiple compressed streams.

`BZ2File` provides all of the members specified by the `io.BufferedIOBase`, except for `detach()` and `truncate()`.

Iteration and the `with` statement are supported.

`BZ2File` also provides the following method:

```python
peek([n])
```

Return buffered data without advancing the file position. At least one byte of data will be returned (unless at EOF). The exact number of bytes returned is unspecified.

*New in version 3.3.*
Changed in version 3.1: Support for the `with` statement was added.

Changed in version 3.3: The `fileno()`, `readable()`, `seekable()`, `writable()`, `read1()` and `readinto()` methods were added.

Changed in version 3.3: Support was added for `filename` being a `file object` instead of an actual filename.

Changed in version 3.3: The `'a'` (append) mode was added, along with support for reading multi-stream files.
13.3.2. Incremental (de)compression

`class bz2.BZ2Compressor(compresslevel=9)`

Create a new compressor object. This object may be used to compress data incrementally. For one-shot compression, use the `compress()` function instead.

`compresslevel`, if given, must be a number between 1 and 9. The default is 9.

`compress(data)`

Provide data to the compressor object. Returns a chunk of compressed data if possible, or an empty byte string otherwise.

When you have finished providing data to the compressor, call the `flush()` method to finish the compression process.

`flush()`

Finish the compression process. Returns the compressed data left in internal buffers.

The compressor object may not be used after this method has been called.

`class bz2.BZ2Decompressor`  

Create a new decompressor object. This object may be used to decompress data incrementally. For one-shot compression, use the `decompress()` function instead.

**Note:** This class does not transparently handle inputs containing multiple compressed streams, unlike `decompress()` and `BZ2File`. If you need to decompress a multi-stream input with...
**BZ2Decompressor**, you must use a new decompressor for each stream.

**decompress**(data)

Provide data to the decompressor object. Returns a chunk of decompressed data if possible, or an empty byte string otherwise.

Attempting to decompress data after the end of the current stream is reached raises an **EOFError**. If any data is found after the end of the stream, it is ignored and saved in the **unused_data** attribute.

**eof**

True if the end-of-stream marker has been reached.

*New in version 3.3.*

**unused_data**

Data found after the end of the compressed stream.

If this attribute is accessed before the end of the stream has been reached, its value will be `b''`. 
13.3.3. One-shot (de)compression

bz2. `compress(data, compresslevel=9)`

Compress `data`.

`compresslevel`, if given, must be a number between 1 and 9. The default is 9.

For incremental compression, use a `BZ2Compressor` instead.

bz2. `decompress(data)`

Decompress `data`.

If `data` is the concatenation of multiple compressed streams, decompress all of the streams.

For incremental decompression, use a `BZ2Decompressor` instead.

*Changed in version 3.3:* Support for multi-stream inputs was added.
13.4. **lzma** — Compression using the LZMA algorithm

*New in version 3.3.*

This module provides classes and convenience functions for compressing and decompressing data using the LZMA compression algorithm. Also included is a file interface supporting the `.xz` and legacy `.lzma` file formats used by the `xz` utility, as well as raw compressed streams.

The interface provided by this module is very similar to that of the `bz2` module. However, note that `LZMAFile` is *not* thread-safe, unlike `bz2.BZ2File`, so if you need to use a single `LZMAFile` instance from multiple threads, it is necessary to protect it with a lock.

**exception** `lzma.LZMAError`

This exception is raised when an error occurs during compression or decompression, or while initializing the compressor/decompressor state.
13.4.1. Reading and writing compressed files

`lzma.open(filename, mode="rb", *, format=None, check=-1, preset=None, filters=None, encoding=None, errors=None, newline=None)`

Open an LZMA-compressed file in binary or text mode, returning a `file object`.

The `filename` argument can be either an actual file name (given as a `str` or `bytes` object), in which case the named file is opened, or it can be an existing file object to read from or write to.

The `mode` argument can be any of "r", "rb", "w", "wb", "a" or "ab" for binary mode, or "rt", "wt", or "at" for text mode. The default is "rb".

When opening a file for reading, the `format` and `filters` arguments have the same meanings as for `LZMADecompressor`. In this case, the `check` and `preset` arguments should not be used.

When opening a file for writing, the `format`, `check`, `preset` and `filters` arguments have the same meanings as for `LZMACompressor`.

For binary mode, this function is equivalent to the `LZMAFile` constructor: `LZMAFile(filename, mode, ...)`. In this case, the `encoding`, `errors` and `newline` arguments must not be provided.

For text mode, a `LZMAFile` object is created, and wrapped in an `io.TextIOWrapper` instance with the specified encoding, error handling behavior, and line ending(s).
class lzma.LZMAFile(filename=None, mode="r", *, format=None, check=-1, preset=None, filters=None)

Open an LZMA-compressed file in binary mode.

An LZMAFile can wrap an already-open file object, or operate directly on a named file. The filename argument specifies either the file object to wrap, or the name of the file to open (as a str or bytes object). When wrapping an existing file object, the wrapped file will not be closed when the LZMAFile is closed.

The mode argument can be either "r" for reading (default), "w" for overwriting, or "a" for appending. These can equivalently be given as "rb", "wb", and "ab" respectively.

If filename is a file object (rather than an actual file name), a mode of "w" does not truncate the file, and is instead equivalent to "a".

When opening a file for reading, the input file may be the concatenation of multiple separate compressed streams. These are transparently decoded as a single logical stream.

When opening a file for reading, the format and filters arguments have the same meanings as for LZMADecompressor. In this case, the check and preset arguments should not be used.

When opening a file for writing, the format, check, preset and filters arguments have the same meanings as for LZMACompressor.

LZMAFile supports all the members specified by io.BufferedIOBase, except for detach() and truncate(). Iteration and the with statement are supported.

The following method is also provided:
peek(size=-1)

Return buffered data without advancing the file position. At least one byte of data will be returned, unless EOF has been reached. The exact number of bytes returned is unspecified (the size argument is ignored).
13.4.2. Compressing and decompressing data in memory

```python
class lzma.LZMACompressor(format=FORMAT_XZ, check=-1, preset=None, filters=None)
```

Create a compressor object, which can be used to compress data incrementally.

For a more convenient way of compressing a single chunk of data, see `compress()`.

The `format` argument specifies what container format should be used. Possible values are:

- FORMAT_XZ: The `.xz` container format.
  This is the default format.
- FORMAT_ALONE: The legacy `.lzma` container format.
  This format is more limited than `.xz` – it does not support integrity checks or multiple filters.
- FORMAT_RAW: A raw data stream, not using any container format.
  This format specifier does not support integrity checks, and requires that you always specify a custom filter chain (for both compression and decompression). Additionally, data compressed in this manner cannot be decompressed using FORMAT_AUTO (see LZMADecompressor).

The `check` argument specifies the type of integrity check to include in the compressed data. This check is used when decompressing, to ensure that the data has not been corrupted. Possible values
are:

- **CHECK_NONE**: No integrity check. This is the default (and the only acceptable value) for FORMAT_ALONE and FORMAT_RAW.
- **CHECK_CRC32**: 32-bit Cyclic Redundancy Check.
- **CHECK_CRC64**: 64-bit Cyclic Redundancy Check. This is the default for FORMAT_XZ.
- **CHECK_SHA256**: 256-bit Secure Hash Algorithm.

If the specified check is not supported, an **LZMAError** is raised.

The compression settings can be specified either as a preset compression level (with the *preset* argument), or in detail as a custom filter chain (with the *filters* argument).

The *preset* argument (if provided) should be an integer between 0 and 9 (inclusive), optionally OR-ed with the constant PRESET_EXTREME. If neither *preset* nor *filters* are given, the default behavior is to use PRESET_DEFAULT (preset level 6). Higher presets produce smaller output, but make the compression process slower.

**Note:** In addition to being more CPU-intensive, compression with higher presets also requires much more memory (and produces output that needs more memory to decompress). With preset 9 for example, the overhead for an **LZMACompressor** object can be as high as 800 MiB. For this reason, it is generally best to stick with the default preset.

The *filters* argument (if provided) should be a filter chain specifier. See *Specifying custom filter chains* for details.

**compress**(data)
Compress *data* (a *bytes* object), returning a *bytes* object containing compressed data for at least part of the input. Some of *data* may be buffered internally, for use in later calls to *compress()* and *flush()*.

The returned data should be concatenated with the output of any previous calls to *compress()*.

**flush()**

Finish the compression process, returning a *bytes* object containing any data stored in the compressor’s internal buffers.

The compressor cannot be used after this method has been called.

```python
class lzma.LZMADEcompressor(format=FORMAT_AUTO, memlimit=None, filters=None)

Create a decompressor object, which can be used to decompress data incrementally.

For a more convenient way of decompressing an entire compressed stream at once, see *decompress()*.

The *format* argument specifies the container format that should be used. The default is FORMAT_AUTO, which can decompress both *.xz* and *.lzma* files. Other possible values are FORMAT_XZ, FORMAT_ALONE, and FORMAT_RAW.

The *memlimit* argument specifies a limit (in bytes) on the amount of memory that the decompressor can use. When this argument is used, decompression will fail with an *LZMAError* if it is not possible to decompress the input within the given memory limit.

The *filters* argument specifies the filter chain that was used to
create the stream being decompressed. This argument is required if `format` is `FORMAT_RAW`, but should not be used for other formats. See *Specifying custom filter chains* for more information about filter chains.

**Note:** This class does not transparently handle inputs containing multiple compressed streams, unlike `decompress()` and `LZMAFile`. To decompress a multi-stream input with `LZMADecompressor`, you must create a new decompressor for each stream.

```python
decompress(data)
```
Decompress `data` (a `bytes` object), returning a `bytes` object containing the decompressed data for at least part of the input. Some of `data` may be buffered internally, for use in later calls to `decompress()`. The returned data should be concatenated with the output of any previous calls to `decompress()`.

```python
check
```
The ID of the integrity check used by the input stream. This may be `CHECK_UNKNOWN` until enough of the input has been decoded to determine what integrity check it uses.

```python
eof
```
True if the end-of-stream marker has been reached.

```python
unused_data
```
Data found after the end of the compressed stream.

Before the end of the stream is reached, this will be `b""`.

```python
lzma.compress(data, format=FORMAT_XZ, check=-1)
```
Compress data (a `bytes` object), returning the compressed data as a `bytes` object.

See **LZMACompressor** above for a description of the `format`, `check`, `preset` and `filters` arguments.

```python
lzma.decompress(data, format=FORMAT_AUTO, memlimit=None, filters=None)
```

Decompress data (a `bytes` object), returning the uncompressed data as a `bytes` object.

If `data` is the concatenation of multiple distinct compressed streams, decompress all of these streams, and return the concatenation of the results.

See **LZMADecompressor** above for a description of the `format`, `memlimit` and `filters` arguments.
13.4.3. Miscellaneous

`lzma.is_check_supported(check)`

Returns true if the given integrity check is supported on this system.

CHECK_NONE and CHECK_CRC32 are always supported. CHECK_CRC64 and CHECK_SHA256 may be unavailable if you are using a version of liblzma that was compiled with a limited feature set.
13.4.4. Specifying custom filter chains

A filter chain specifier is a sequence of dictionaries, where each dictionary contains the ID and options for a single filter. Each dictionary must contain the key "id", and may contain additional keys to specify filter-dependent options. Valid filter IDs are as follows:

- Compression filters:
  - FILTER_LZMA1 (for use with FORMAT_ALONE)
  - FILTER_LZMA2 (for use with FORMAT_XZ and FORMAT_RAW)

- Delta filter:
  - FILTER_DELTA

- Branch-Call-Jump (BCJ) filters:
  - FILTER_X86
  - FILTER_IA64
  - FILTER_ARM
  - FILTER_ARMTHUMB
  - FILTER_POWERPC
  - FILTER_SPARC

A filter chain can consist of up to 4 filters, and cannot be empty. The last filter in the chain must be a compression filter, and any other filters must be delta or BCJ filters.

Compression filters support the following options (specified as additional entries in the dictionary representing the filter):

- preset: A compression preset to use as a source of default values for options that are not specified explicitly.
- dict_size: Dictionary size in bytes. This should be
between 4 KiB and 1.5 GiB (inclusive).

- **lc**: Number of literal context bits.
- **lp**: Number of literal position bits. The sum \( \text{lc} + \text{lp} \) must be at most 4.
- **pb**: Number of position bits; must be at most 4.
- **mode**: MODE_FAST or MODE_NORMAL.
- **nice_len**: What should be considered a “nice length” for a match. This should be 273 or less.
- **mf**: What match finder to use – MF_HC3, MF_HC4, MF_BT2, MF_BT3, or MF_BT4.
- **depth**: Maximum search depth used by match finder. 0 (default) means to select automatically based on other filter options.

The delta filter stores the differences between bytes, producing more repetitive input for the compressor in certain circumstances. It only supports a single match finder. The delta filter supports only one option, `dist`. This indicates the distance between bytes to be subtracted. The default is 1, i.e. take the differences between adjacent bytes.

The BCJ filters are intended to be applied to machine code. They convert relative branches, calls and jumps in the code to use absolute addressing, with the aim of increasing the redundancy that can be exploited by the compressor. These filters support one option, `start_offset`. This specifies the address that should be mapped to the beginning of the input data. The default is 0.
13.4.5. Examples

Reading in a compressed file:

```python
import lzma
with lzma.open("file.xz") as f:
    file_content = f.read()
```

Creating a compressed file:

```python
import lzma
data = b"Insert Data Here"
with lzma.open("file.xz", "w") as f:
    f.write(data)
```

Compressing data in memory:

```python
import lzma
data_in = b"Insert Data Here"
data_out = lzma.compress(data_in)
```

Incremental compression:

```python
import lzma
lzc = lzma.LZMACompressor()
out1 = lzc.compress(b"Some data\n")
out2 = lzc.compress(b"Another piece of data\n")
out3 = lzc.compress(b"Even more data\n")
out4 = lzc.flush()
# Concatenate all the partial results:
result = b"".join([out1, out2, out3, out4])
```

Writing compressed data to an already-open file:
import lzma

with open("file.xz", "wb") as f:
    f.write(b"This data will not be compressed\n")

with lzma.open(f, "w") as lzf:
    lzf.write(b"This *will* be compressed\n")
    f.write(b"Not compressed\n")

Creating a compressed file using a custom filter chain:

import lzma

my_filters = [
    {
        "id": lzma.FILTER_DELTA,  "dist": 5,
    },
    {
        "id": lzma.FILTER_LZMA2,  "preset": 7 | lzma.PRESET_EXTREME
    }
]

with lzma.open("file.xz", "w", filters=my_filters) as f:
    f.write(b"blah blah blah")
13.5. zipfile — Work with ZIP archives

Source code: Lib/zipfile.py

The ZIP file format is a common archive and compression standard. This module provides tools to create, read, write, append, and list a ZIP file. Any advanced use of this module will require an understanding of the format, as defined in PKZIP Application Note.

This module does not currently handle multi-disk ZIP files. It can handle ZIP files that use the ZIP64 extensions (that is ZIP files that are more than 4 GiB in size). It supports decryption of encrypted files in ZIP archives, but it currently cannot create an encrypted file. Decryption is extremely slow as it is implemented in native Python rather than C.

The module defines the following items:

*exception* zipfile.*BadZipFile*

    The error raised for bad ZIP files.

    *New in version 3.2.*

*exception* zipfile.*BadZipfile*

    Alias of *BadZipFile*, for compatibility with older Python versions.

    *Deprecated since version 3.2.*

*exception* zipfile.*LargeZipFile*
The error raised when a ZIP file would require ZIP64 functionality but that has not been enabled.

class zipfile.ZipFile

The class for reading and writing ZIP files. See section ZipFile Objects for constructor details.

class zipfile.PyZipFile

Class for creating ZIP archives containing Python libraries.

class zipfile.ZipInfo(filename='NoName', date_time=(1980, 1, 1, 0, 0, 0))

Class used to represent information about a member of an archive. Instances of this class are returned by the getinfo() and infolist() methods of ZipFile objects. Most users of the zipfile module will not need to create these, but only use those created by this module. filename should be the full name of the archive member, and date_time should be a tuple containing six fields which describe the time of the last modification to the file; the fields are described in section ZipInfo Objects.

zipfile.is_zipfile(filename)

Returns True if filename is a valid ZIP file based on its magic number, otherwise returns False. filename may be a file or file-like object too.

Changed in version 3.1: Support for file and file-like objects.

zipfile.ZIP_STORED

The numeric constant for an uncompressed archive member.

zipfile.ZIP_DEFLATED

The numeric constant for the usual ZIP compression method. This
requires the `zlib` module.

zipfile.\texttt{ZIP\_BZIP2}

The numeric constant for the BZIP2 compression method. This requires the `bz2` module.

\textit{New in version 3.3.}

zipfile.\texttt{ZIP\_LZMA}

The numeric constant for the LZMA compression method. This requires the `lzma` module.

\textit{New in version 3.3.}

\textbf{Note:} The ZIP file format specification has included support for bzip2 compression since 2001, and for LZMA compression since 2006. However, some tools (including older Python releases) do not support these compression methods, and may either refuse to process the ZIP file altogether, or fail to extract individual files.

\textbf{See also:}

\textbf{PKZIP Application Note}

Documentation on the ZIP file format by Phil Katz, the creator of the format and algorithms used.

\textbf{Info-ZIP Home Page}

Information about the Info-ZIP project’s ZIP archive programs and development libraries.
13.5.1. ZipFile Objects

```
class zipfile.ZipFile(file, mode='r',
                     compression=ZIP_STORED, allowZip64=False)
```

Open a ZIP file, where `file` can be either a path to a file (a string) or a file-like object. The `mode` parameter should be `'r'` to read an existing file, `'w'` to truncate and write a new file, or `'a'` to append to an existing file. If `mode` is `'a'` and `file` refers to an existing ZIP file, then additional files are added to it. If `file` does not refer to a ZIP file, then a new ZIP archive is appended to the file. This is meant for adding a ZIP archive to another file (such as `python.exe`). If `mode` is `a` and the file does not exist at all, it is created. `compression` is the ZIP compression method to use when writing the archive, and should be `ZIP_STORED`, `ZIP_DEFLATED`, `ZIP_BZIP2` or `ZIP_LZMA`; unrecognized values will cause `RuntimeError` to be raised. If `ZIP_DEFLATED`, `ZIP_BZIP2` or `ZIP_LZMA` is specified but the corresponded module (`zlib`, `bz2` or `lzma`) is not available, `RuntimeError` is also raised. The default is `ZIP_STORED`. If `allowZip64` is `True` zipfile will create ZIP files that use the ZIP64 extensions when the zipfile is larger than 2 GiB. If it is false (the default) zipfile will raise an exception when the ZIP file would require ZIP64 extensions. ZIP64 extensions are disabled by default because the default `zip` and `unzip` commands on Unix (the InfoZIP utilities) don’t support these extensions.

If the file is created with mode `'a'` or `'w'` and then `closed` without adding any files to the archive, the appropriate ZIP structures for an empty archive will be written to the file.
ZipFile is also a context manager and therefore supports the `with` statement. In the example, `myzip` is closed after the `with` statement’s suite is finished—even if an exception occurs:

```python
with ZipFile('spam.zip', 'w') as myzip:
    myzip.write('eggs.txt')
```

*New in version 3.2:* Added the ability to use `ZipFile` as a context manager.

*Changed in version 3.3:* Added support for `bzip2` and `lzma` compression.

**ZipFile.close()**

Close the archive file. You must call `close()` before exiting your program or essential records will not be written.

**ZipFile.getinfo(name)**

Return a `ZipInfo` object with information about the archive member `name`. Calling `getinfo()` for a name not currently contained in the archive will raise a `KeyError`.

**ZipFile.infolist()**

Return a list containing a `ZipInfo` object for each member of the archive. The objects are in the same order as their entries in the actual ZIP file on disk if an existing archive was opened.

**ZipFile.namelist()**

Return a list of archive members by name.

**ZipFile.open(name, mode='r', pwd=None)**

Extract a member from the archive as a file-like object (`ZipExtFile`).
name is the name of the file in the archive, or a ZipInfo object. The mode parameter, if included, must be one of the following: 'r' (the default), 'U', or 'rU'. Choosing 'U' or 'rU' will enable universal newlines support in the read-only object. pwd is the password used for encrypted files. Calling open() on a closed ZipFile will raise a RuntimeError.

**Note:** The file-like object is read-only and provides the following methods: `read()`, `readline()`, `readlines()`, `__iter__()`, `__next__()`. 

**Note:** If the ZipFile was created by passing in a file-like object as the first argument to the constructor, then the object returned by open() shares the ZipFile’s file pointer. Under these circumstances, the object returned by open() should not be used after any additional operations are performed on the ZipFile object. If the ZipFile was created by passing in a string (the filename) as the first argument to the constructor, then open() will create a new file object that will be held by the ZipExtFile, allowing it to operate independently of the ZipFile. 

**Note:** The open(), read() and extract() methods can take a filename or a ZipInfo object. You will appreciate this when trying to read a ZIP file that contains members with duplicate names. 

**ZipFile.**extract**(member, path=None, pwd=None)**

Extract a member from the archive to the current working directory; member must be its full name or a ZipInfo object. Its file information is extracted as accurately as possible. path specifies a different directory to extract to. member can be a filename or a
ZipInfo object. *pwd* is the password used for encrypted files.

**Note:** If a member filename is an absolute path, a drive/UNC sharepoint and leading (back)slashes will be stripped, e.g.://foo/bar becomes foo/bar on Unix, and C:\foo\bar becomes foo\bar on Windows. And all ".." components in a member filename will be removed, e.g.: ../../foo/../../ba..r becomes foo../ba..r. On Windows illegal characters (:, <, >, |, ", ?, and *) replaced by underscore (_).

**ZipFile**. `extractall(path=None, members=None, pwd=None)`

Extract all members from the archive to the current working directory. *path* specifies a different directory to extract to. *members* is optional and must be a subset of the list returned by *namelist()*.*pwd* is the password used for encrypted files.

**Warning:** Never extract archives from untrusted sources without prior inspection. It is possible that files are created outside of *path*, e.g. members that have absolute filenames starting with "/" or filenames with two dots "..".

*Changed in version 3.3.1:* The zipfile module attempts to prevent that. See *extract()* note.

**ZipFile**. `printdir()`

Print a table of contents for the archive to `sys.stdout`.

**ZipFile**. `setpassword(pwd)`

Set *pwd* as default password to extract encrypted files.

**ZipFile**. `read(name, pwd=None)`
Return the bytes of the file `name` in the archive. `name` is the name of the file in the archive, or a `ZipInfo` object. The archive must be open for read or append. `pwd` is the password used for encrypted files and, if specified, it will override the default password set with `setpassword()`. Calling `read()` on a closed ZipFile will raise a `RuntimeError`.

**ZipFile.**`testzip()`

Read all the files in the archive and check their CRC’s and file headers. Return the name of the first bad file, or else return None. Calling `testzip()` on a closed ZipFile will raise a `RuntimeError`.

**ZipFile.**`write(filename, arcname=None, compress_type=None)`

Write the file named `filename` to the archive, giving it the archive name `arcname` (by default, this will be the same as `filename`, but without a drive letter and with leading path separators removed). If given, `compress_type` overrides the value given for the `compression` parameter to the constructor for the new entry. The archive must be open with mode `'w'` or `'a'` – calling `write()` on a ZipFile created with mode `'r'` will raise a `RuntimeError`. Calling `write()` on a closed ZipFile will raise a `RuntimeError`.

**Note:** There is no official file name encoding for ZIP files. If you have unicode file names, you must convert them to byte strings in your desired encoding before passing them to `write()`. WinZip interprets all file names as encoded in CP437, also known as DOS Latin.

**Note:** Archive names should be relative to the archive root, that is, they should not start with a path separator.
**Note:** If `arcname` (or `filename`, if `arcname` is not given) contains a null byte, the name of the file in the archive will be truncated at the null byte.

```python
ZipFile.writestr(zinfo_or_arcname, bytes[, compress_type])
```

Write the string `bytes` to the archive; `zinfo_or_arcname` is either the file name it will be given in the archive, or a `ZipInfo` instance. If it's an instance, at least the filename, date, and time must be given. If it's a name, the date and time is set to the current date and time. The archive must be opened with mode `'w'` or `'a'` – calling `writestr()` on a ZipFile created with mode `'r'` will raise a `RuntimeError`. Calling `writestr()` on a closed ZipFile will raise a `RuntimeError`.

If given, `compress_type` overrides the value given for the `compression` parameter to the constructor for the new entry, or in the `zinfo_or_arcname` (if that is a `ZipInfo` instance).

**Note:** When passing a `ZipInfo` instance as the `zinfo_or_arcname` parameter, the compression method used will be that specified in the `compress_type` member of the given `ZipInfo` instance. By default, the `ZipInfo` constructor sets this member to `ZIP_STORED`.

*Changed in version 3.2: The `compress_type` argument.*

The following data attributes are also available:

```python
ZipFile.debug
```

The level of debug output to use. This may be set from 0 (the default, no output) to 3 (the most output). Debugging information is
written to sys.stdout.

**ZipFile.comment**

The comment text associated with the ZIP file. If assigning a comment to a `ZipFile` instance created with mode ‘a’ or ‘w’, this should be a string no longer than 65535 bytes. Comments longer than this will be truncated in the written archive when `close()` is called.
13.5.2. PyZipFile Objects

The PyZipFile constructor takes the same parameters as the ZipFile constructor, and one additional parameter, optimize.

```
class zipfile. PyZipFile (file, mode='r',
   compression=ZIP_STORED, allowZip64=False, optimize=-1)
```

*New in version 3.2:* The optimize parameter.

Instances have one method in addition to those of ZipFile objects:

```
writepy(pathname, basename='')
```

Search for files *.py* and add the corresponding file to the archive.

If the optimize parameter to PyZipFile was not given or -1, the corresponding file is a *.pyo* file if available, else a *.pyc* file, compiling if necessary.

If the optimize parameter to PyZipFile was 0, 1 or 2, only files with that optimization level (see compile()) are added to the archive, compiling if necessary.

If the path name is a file, the filename must end with *.py*, and just the (corresponding *.py[co]*) file is added at the top level (no path information). If the path name is a file that does not end with *.py*, a RuntimeError will be raised. If it is a directory, and the directory is not a package directory, then all the files *.py[co]* are added at the top level. If the directory is a package directory, then all *.py[co]* are added under the
package name as a file path, and if any subdirectories are package directories, all of these are added recursively. basename is intended for internal use only. The writepy() method makes archives with file names like this:

```
string.pyc          # Top level name
test/__init__.pyc   # Package directory
test/testall.pyc    # Module test.test
test/bogus/__init__.pyc  # Subpackage directory
test/bogus/myfile.pyc # Submodule test.bogus
```
13.5.3. ZipInfo Objects

Instances of the ZipInfo class are returned by the getinfo() and infolist() methods of ZipFile objects. Each object stores information about a single member of the ZIP archive.

Instances have the following attributes:

**ZipInfo.** \texttt{filename}

Name of the file in the archive.

**ZipInfo.** \texttt{date_time}

The time and date of the last modification to the archive member. This is a tuple of six values:

<table>
<thead>
<tr>
<th>Index</th>
<th>Value</th>
</tr>
</thead>
<tbody>
<tr>
<td>0</td>
<td>Year (&gt;= 1980)</td>
</tr>
<tr>
<td>1</td>
<td>Month (one-based)</td>
</tr>
<tr>
<td>2</td>
<td>Day of month (one-based)</td>
</tr>
<tr>
<td>3</td>
<td>Hours (zero-based)</td>
</tr>
<tr>
<td>4</td>
<td>Minutes (zero-based)</td>
</tr>
<tr>
<td>5</td>
<td>Seconds (zero-based)</td>
</tr>
</tbody>
</table>

\textbf{Note:} The ZIP file format does not support timestamps before 1980.

**ZipInfo.** \texttt{compress_type}

Type of compression for the archive member.

**ZipInfo.** \texttt{comment}
Comment for the individual archive member.

**ZipInfo**. *extra*
Expansion field data. The **PKZIP Application Note** contains some comments on the internal structure of the data contained in this string.

**ZipInfo**. *create_system*
System which created ZIP archive.

**ZipInfo**. *create_version*
PKZIP version which created ZIP archive.

**ZipInfo**. *extract_version*
PKZIP version needed to extract archive.

**ZipInfo**. *reserved*
Must be zero.

**ZipInfo**. *flag_bits*
ZIP flag bits.

**ZipInfo**. *volume*
Volume number of file header.

**ZipInfo**. *internal_attr*
Internal attributes.

**ZipInfo**. *external_attr*
External file attributes.

**ZipInfo**. *header_offset*
Byte offset to the file header.
ZipInfo. **CRC**
CRC-32 of the uncompressed file.

ZipInfo. **compress_size**
Size of the compressed data.

ZipInfo. **file_size**
Size of the uncompressed file.
13.6. **tarfile** — Read and write tar archive files

**Source code:** Lib/tarfile.py

The `tarfile` module makes it possible to read and write tar archives, including those using gzip, bz2 and lzma compression. Use the `zipfile` module to read or write `.zip` files, or the higher-level functions in `shutil`.

Some facts and figures:

- reads and writes `gzip`, `bz2` and `lzma` compressed archives.
- read/write support for the POSIX.1-1988 (ustar) format.
- read/write support for the GNU tar format including `longname` and `longlink` extensions, read-only support for all variants of the `sparse` extension including restoration of sparse files.
- read/write support for the POSIX.1-2001 (pax) format.
- handles directories, regular files, hardlinks, symbolic links, fifos, character devices and block devices and is able to acquire and restore file information like timestamp, access permissions and owner.

*Changed in version 3.3:* Added support for `lzma` compression.

`tarfile.open(name=None, mode='r', fileobj=None, buFSIZE=10240, **kwARGS)`

Return a `TarFile` object for the pathname `name`. For detailed information on `TarFile` objects and the keyword arguments that are allowed, see `TarFile Objects`. 
*mode* has to be a string of the form `'filemode[:compression]'`, it defaults to `'r'`. Here is a full list of mode combinations:

<table>
<thead>
<tr>
<th>mode</th>
<th>action</th>
</tr>
</thead>
<tbody>
<tr>
<td><code>'r'</code> or <code>'r:*'</code></td>
<td>Open for reading with transparent compression (recommended).</td>
</tr>
<tr>
<td><code>'r:'</code></td>
<td>Open for reading exclusively without compression.</td>
</tr>
<tr>
<td><code>'r:gz'</code></td>
<td>Open for reading with gzip compression.</td>
</tr>
<tr>
<td><code>'r:bz2'</code></td>
<td>Open for reading with bzip2 compression.</td>
</tr>
<tr>
<td><code>'r:xz'</code></td>
<td>Open for reading with lzma compression.</td>
</tr>
</tbody>
</table>
| `'a'` or `'a:'` | Open for appending with no compression.  
The file is created if it does not exist. |
| `'w'` or `'w:'` | Open for uncompressed writing.                                   |
| `'w:gz'`  | Open for gzip compressed writing.                                      |
| `'w:bz2'` | Open for bzip2 compressed writing.                                     |
| `'w:xz'`  | Open for lzma compressed writing.                                      |

Note that `'a:gz'`, `'a:bz2'` or `'a:xz'` is not possible. If *mode* is not suitable to open a certain (compressed) file for reading, *ReadError* is raised. Use *mode* `'r'` to avoid this. If a compression method is not supported, *CompressionError* is raised.

If *fileobj* is specified, it is used as an alternative to a *file object* opened in binary mode for *name*. It is supposed to be at position 0.

For special purposes, there is a second format for *mode*: `'filemode|[compression]'`. *tarfile.open()* will return a
**TarFile** object that processes its data as a stream of blocks. No random seeking will be done on the file. If given, `fileobj` may be any object that has a `read()` or `write()` method (depending on the `mode`). `buFSIZE` specifies the blocksize and defaults to $20 \times 512$ bytes. Use this variant in combination with e.g. `sys.stdin`, a socket `file object` or a tape device. However, such a `TarFile` object is limited in that it does not allow to be accessed randomly, see *Examples*. The currently possible modes:

<table>
<thead>
<tr>
<th>Mode</th>
<th>Action</th>
</tr>
</thead>
<tbody>
<tr>
<td>'r</td>
<td>*'</td>
</tr>
<tr>
<td>'r'</td>
<td></td>
</tr>
<tr>
<td>'r</td>
<td>gz'</td>
</tr>
<tr>
<td>'r</td>
<td>bz2'</td>
</tr>
<tr>
<td>'r</td>
<td>xz'</td>
</tr>
<tr>
<td>'w'</td>
<td></td>
</tr>
<tr>
<td>'w</td>
<td>gz'</td>
</tr>
<tr>
<td>'w</td>
<td>bz2'</td>
</tr>
<tr>
<td>'w</td>
<td>xz'</td>
</tr>
</tbody>
</table>

**class** `tarfile.TarFile`

Class for reading and writing tar archives. Do not use this class directly, better use `tarfile.open()` instead. See *TarFile Objects*.

**tarfile.is_tarfile(name)**

Return `True` if `name` is a tar archive file, that the `tarfile` module
The `tarfile` module defines the following exceptions:

**exception** `tarfile.TarError`
Base class for all `tarfile` exceptions.

**exception** `tarfile.ReadError`
Is raised when a tar archive is opened, that either cannot be handled by the `tarfile` module or is somehow invalid.

**exception** `tarfile.CompressionError`
Is raised when a compression method is not supported or when the data cannot be decoded properly.

**exception** `tarfile.StreamError`
Is raised for the limitations that are typical for stream-like `TarFile` objects.

**exception** `tarfile.ExtractError`
Is raised for non-fatal errors when using `TarFile.extract()`, but only if `TarFile.errorlevel==2`.

**exception** `tarfile.HeaderError`
Is raised by `TarInfo.frombuf()` if the buffer it gets is invalid.

Each of the following constants defines a tar archive format that the `tarfile` module is able to create. See section *Supported tar formats* for details.

`tarfile.USTAR_FORMAT`
POSIX.1-1988 (ustar) format.
The default format for creating archives. This is currently

**GNU_FORMAT**

GNU tar format.

**PAX_FORMAT**

POSIX.1-2001 (pax) format.

**DEFAULT_FORMAT**

The default character encoding: 'utf-8' on Windows, `sys.getfilesystemencoding()` otherwise.
13.6.1. TarFile Objects

The **TarFile** object provides an interface to a tar archive. A tar archive is a sequence of blocks. An archive member (a stored file) is made up of a header block followed by data blocks. It is possible to store a file in a tar archive several times. Each archive member is represented by a **TarInfo** object, see **TarInfo Objects** for details.

A **TarFile** object can be used as a context manager in a **with** statement. It will automatically be closed when the block is completed. Please note that in the event of an exception an archive opened for writing will not be finalized; only the internally used file object will be closed. See the **Examples** section for a use case.

*New in version 3.2:* Added support for the context manager protocol.

```python
class tarfile.**TarFile**(name=None, mode='r', fileobj=None, format=DEFAULT_FORMAT, tarinfo=TarInfo, dereference=False, ignore_zeros=False, encoding=ENCODING, errors='surrogateescape', pax_headers=None, debug=0, errorlevel=0)
```

All following arguments are optional and can be accessed as instance attributes as well.

- **name** is the pathname of the archive. It can be omitted if **fileobj** is given. In this case, the file object's name attribute is used if it exists.

- **mode** is either `'r'` to read from an existing archive, `'a'` to append data to an existing file or `'w'` to create a new file overwriting an existing one.

If **fileobj** is given, it is used for reading or writing data. If it can be
determined, \texttt{mode} is overridden by \texttt{fileobj}'s mode. \texttt{fileobj} will be used from position 0.

\textbf{Note:} \texttt{fileobj} is not closed, when \texttt{TarFile} is closed.

\texttt{format} controls the archive format. It must be one of the constants \texttt{USTAR_FORMAT}, \texttt{GNU_FORMAT} or \texttt{PAX_FORMAT} that are defined at module level.

The \texttt{tarinfo} argument can be used to replace the default \texttt{TarInfo} class with a different one.

If \texttt{dereference} is \texttt{False}, add symbolic and hard links to the archive. If it is \texttt{True}, add the content of the target files to the archive. This has no effect on systems that do not support symbolic links.

If \texttt{ignore_zeros} is \texttt{False}, treat an empty block as the end of the archive. If it is \texttt{True}, skip empty (and invalid) blocks and try to get as many members as possible. This is only useful for reading concatenated or damaged archives.

\texttt{debug} can be set from 0 (no debug messages) up to 3 (all debug messages). The messages are written to \texttt{sys.stderr}.

If \texttt{errorlevel} is 0, all errors are ignored when using \texttt{TarFile.extract()}. Nevertheless, they appear as error messages in the debug output, when debugging is enabled. If 1, all \texttt{fatal} errors are raised as \texttt{OSError} exceptions. If 2, all \texttt{non-fatal} errors are raised as \texttt{TarError} exceptions as well.

The \texttt{encoding} and \texttt{errors} arguments define the character encoding to be used for reading or writing the archive and how conversion
errors are going to be handled. The default settings will work for most users. See section *Unicode issues* for in-depth information.

*Changed in version 3.2:* Use 'surrogateescape' as the default for the *errors* argument.

The *pax_headers* argument is an optional dictionary of strings which will be added as a pax global header if *format* is *PAX_FORMAT*.

**TarFile.open(...)**

Alternative constructor. The *tarfile.open()* function is actually a shortcut to this classmethod.

**TarFile.getmember*name*)**

Return a *TarInfo* object for member *name*. If *name* can not be found in the archive, *KeyError* is raised.

*Note:* If a member occurs more than once in the archive, its last occurrence is assumed to be the most up-to-date version.

**TarFile.getmembers**

Return the members of the archive as a list of *TarInfo* objects. The list has the same order as the members in the archive.

**TarFile.getnames**

Return the members as a list of their names. It has the same order as the list returned by *getmembers()*.

**TarFile.list*(verbose=True)**

Print a table of contents to *sys.stdout*. If *verbose* is *False*, only the names of the members are printed. If it is *True*, output similar
to that of `ls -l` is produced.

**TarFile.next()**

Return the next member of the archive as a `TarInfo` object, when `TarFile` is opened for reading. Return `None` if there is no more available.

**TarFile.extractall(path=".", members=None)**

Extract all members from the archive to the current working directory or directory path. If optional `members` is given, it must be a subset of the list returned by `getmembers()`. Directory information like owner, modification time and permissions are set after all members have been extracted. This is done to work around two problems: A directory’s modification time is reset each time a file is created in it. And, if a directory’s permissions do not allow writing, extracting files to it will fail.

**Warning:** Never extract archives from untrusted sources without prior inspection. It is possible that files are created outside of path, e.g. members that have absolute filenames starting with "/" or filenames with two dots "..".

**TarFile.extract(member, path="", set_attrs=True)**

Extract a member from the archive to the current working directory, using its full name. Its file information is extracted as accurately as possible. `member` may be a filename or a `TarInfo` object. You can specify a different directory using `path`. File attributes (owner, mtime, mode) are set unless `set_attrs` is False.

**Note:** The `extract()` method does not take care of several extraction issues. In most cases you should consider using the
extractall() method.

**Warning:** See the warning for `extractall()`.

*Changed in version 3.2:* Added the `set_attrs` parameter.

**TarFile**. `extractfile(member)`

Extract a member from the archive as a file object. `member` may be a filename or a `TarInfo` object. If `member` is a regular file or a link, an `io.BufferedReader` object is returned. Otherwise, `None` is returned.

*Changed in version 3.3:* Return an `io.BufferedReader` object.

**TarFile**. `add(name, arcname=None, recursive=True, exclude=None, *, filter=None)`

Add the file `name` to the archive. `name` may be any type of file (directory, fifo, symbolic link, etc.). If given, `arcname` specifies an alternative name for the file in the archive. Directories are added recursively by default. This can be avoided by setting `recursive` to `False`. If `exclude` is given, it must be a function that takes one filename argument and returns a boolean value. Depending on this value the respective file is either excluded (`True`) or added (`False`). If `filter` is specified it must be a keyword argument. It should be a function that takes a `TarInfo` object argument and returns the changed `TarInfo` object. If it instead returns `None` the `TarInfo` object will be excluded from the archive. See *Examples* for an example.

*Changed in version 3.2:* Added the `filter` parameter.

*Deprecated since version 3.2:* The `exclude` parameter is
deprecated, please use the filter parameter instead.

**TarFile.** `addfile(tarinfo, fileobj=None)`

Add the `TarInfo` object `tarinfo` to the archive. If `fileobj` is given, `tarinfo.size` bytes are read from it and added to the archive. You can create `TarInfo` objects using `gettarinfo()`.

**Note:** On Windows platforms, `fileobj` should always be opened with mode 'rb' to avoid irritation about the file size.

**TarFile.** `gettarinfo(name=None, arcname=None, fileobj=None)`

Create a `TarInfo` object for either the file name or the file object `fileobj` (using `os.fstat()` on its file descriptor). You can modify some of the `TarInfo`'s attributes before you add it using `addfile()`. If given, `arcname` specifies an alternative name for the file in the archive.

**TarFile.** `close()`

Close the `TarFile`. In write mode, two finishing zero blocks are appended to the archive.

**TarFile.** `pax_headers`

A dictionary containing key-value pairs of pax global headers.
13.6.2. TarInfo Objects

A **TarInfo** object represents one member in a **TarFile**. Aside from storing all required attributes of a file (like file type, size, time, permissions, owner etc.), it provides some useful methods to determine its type. It does *not* contain the file's data itself.

**TarInfo** objects are returned by **TarFile's** methods **getmember()**, **getmembers()** and **gettarinfo()**.

```python
class tarfile.TarInfo(name="")
    Create a TarInfo object.
```

```python
TarInfo.frombuf(buf)
    Create and return a TarInfo object from string buffer buf.

    Raises HeaderError if the buffer is invalid..
```

```python
TarInfo.fromtarfile(tarfile)
    Read the next member from the TarFile object tarfile and return it as a TarInfo object.
```

```python
TarInfo.tobuf(format=DEFAULT_FORMAT, encoding=ENCODING, errors='surrogateescape')
    Create a string buffer from a TarInfo object. For information on the arguments see the constructor of the TarFile class.

    Changed in version 3.2: Use 'surrogatescape' as the default for the errors argument.
```

A **TarInfo** object has the following public data attributes:
TarInfo.name
   Name of the archive member.

TarInfo.size
   Size in bytes.

TarInfo.mtime
   Time of last modification.

TarInfo.mode
   Permission bits.

TarInfo.type
   File type. type is usually one of these constants: REGTYPE, AREGTYPE, LNKTYPE, SYMTYPE, DIRTYPE, FIFOTYPE, CONTTYPE, CHRTYPE, BLKTYPE, GNUTYPE_SPARSE. To determine the type of a TarInfo object more conveniently, use the is_*() methods below.

TarInfo.linkname
   Name of the target file name, which is only present in TarInfo objects of type LNKTYPE and SYMTYPE.

TarInfo.uid
   User ID of the user who originally stored this member.

TarInfo.gid
   Group ID of the user who originally stored this member.

TarInfo.uname
   User name.

TarInfo.gname
Group name.

TarInfo. **pax_headers**

A dictionary containing key-value pairs of an associated pax extended header.

A **TarInfo** object also provides some convenient query methods:

TarInfo. **isfile()**

Return **True** if the Tarinfo object is a regular file.

TarInfo. **isreg()**

Same as **isfile()**.

TarInfo. **isdir()**

Return **True** if it is a directory.

TarInfo. **issym()**

Return **True** if it is a symbolic link.

TarInfo. **islnk()**

Return **True** if it is a hard link.

TarInfo. **ischr()**

Return **True** if it is a character device.

TarInfo. **isblk()**

Return **True** if it is a block device.

TarInfo. **isfifo()**

Return **True** if it is a FIFO.

TarInfo. **isdev()**
Return `True` if it is one of character device, block device or FIFO.
13.6.3. Examples

How to extract an entire tar archive to the current working directory:

```python
import tarfile
tar = tarfile.open("sample.tar.gz")
tar.extractall()
tar.close()
```

How to extract a subset of a tar archive with `TarFile.extractall()` using a generator function instead of a list:

```python
import os
import tarfile
def py_files(members):
    for tarinfo in members:
        if os.path.splitext(tarinfo.name)[1] == ".py"
            yield tarinfo

tar = tarfile.open("sample.tar.gz")
tar.extractall(members=py_files(tar))
tar.close()
```

How to create an uncompressed tar archive from a list of filenames:

```python
import tarfile
tar = tarfile.open("sample.tar", "w")
for name in ["foo", "bar", "quux"]:
    tar.add(name)
tar.close()
```

The same example using the `with` statement:
import tarfile

with tarfile.open("sample.tar", "w") as tar:
    for name in ["foo", "bar", "quux"]:
        tar.add(name)

How to read a gzip compressed tar archive and display some member information:

import tarfile
tar = tarfile.open("sample.tar.gz", "r:gz")
for tarinfo in tar:
    print(tarinfo.name, "is", tarinfo.size, "bytes in size and is")
    if tarinfo.isreg():
        print("a regular file.")
    elif tarinfo.isdir():
        print("a directory.")
    else:
        print("something else.")
tar.close()

How to create an archive and reset the user information using the filter parameter in TarFile.add():

import tarfile
def reset(tarinfo):
    tarinfo.uid = tarinfo.gid = 0
    tarinfo.uname = tarinfo.gname = "root"
    return tarinfo
tar = tarfile.open("sample.tar.gz", "w:gz")
tar.add("foo", filter=reset)
tar.close()
13.6.4. Supported tar formats

There are three tar formats that can be created with the `tarfile` module:

- The POSIX.1-1988 ustar format (USTAR_FORMAT). It supports filenames up to a length of at best 256 characters and linknames up to 100 characters. The maximum file size is 8 GiB. This is an old and limited but widely supported format.

- The GNU tar format (GNU_FORMAT). It supports long filenames and linknames, files bigger than 8 GiB and sparse files. It is the de facto standard on GNU/Linux systems. `tarfile` fully supports the GNU tar extensions for long names, sparse file support is read-only.

- The POSIX.1-2001 pax format (PAX_FORMAT). It is the most flexible format with virtually no limits. It supports long filenames and linknames, large files and stores pathnames in a portable way. However, not all tar implementations today are able to handle pax archives properly.

  The pax format is an extension to the existing ustar format. It uses extra headers for information that cannot be stored otherwise. There are two flavours of pax headers: Extended headers only affect the subsequent file header, global headers are valid for the complete archive and affect all following files. All the data in a pax header is encoded in UTF-8 for portability reasons.

There are some more variants of the tar format which can be read, but not created:
• The ancient V7 format. This is the first tar format from Unix Seventh Edition, storing only regular files and directories. Names must not be longer than 100 characters, there is no user/group name information. Some archives have miscalculated header checksums in case of fields with non-ASCII characters.

• The SunOS tar extended format. This format is a variant of the POSIX.1-2001 pax format, but is not compatible.
13.6.5. Unicode issues

The tar format was originally conceived to make backups on tape drives with the main focus on preserving file system information. Nowadays tar archives are commonly used for file distribution and exchanging archives over networks. One problem of the original format (which is the basis of all other formats) is that there is no concept of supporting different character encodings. For example, an ordinary tar archive created on a UTF-8 system cannot be read correctly on a Latin-1 system if it contains non-ASCII characters. Textual metadata (like filenames, linknames, user/group names) will appear damaged. Unfortunately, there is no way to autodetect the encoding of an archive. The pax format was designed to solve this problem. It stores non-ASCII metadata using the universal character encoding UTF-8.

The details of character conversion in `tarfile` are controlled by the `encoding` and `errors` keyword arguments of the `TarFile` class.

`encoding` defines the character encoding to use for the metadata in the archive. The default value is `sys.getfilesystemencoding()` or 'ascii' as a fallback. Depending on whether the archive is read or written, the metadata must be either decoded or encoded. If `encoding` is not set appropriately, this conversion may fail.

The `errors` argument defines how characters are treated that cannot be converted. Possible values are listed in section `Codec Base Classes`. The default scheme is 'surrogateescape' which Python also uses for its file system calls, see `File Names, Command Line Arguments, and Environment Variables`.

In case of PAX_FORMAT archives, `encoding` is generally not needed
because all the metadata is stored using UTF-8. `encoding` is only used in the rare cases when binary pax headers are decoded or when strings with surrogate characters are stored.
14. File Formats

The modules described in this chapter parse various miscellaneous file formats that aren't markup languages and are not related to e-mail.

14.1. **csv — CSV File Reading and Writing**

The so-called CSV (Comma Separated Values) format is the most common import and export format for spreadsheets and databases. CSV format was used for many years prior to attempts to describe the format in a standardized way in [RFC 4180](https://www.rfc-editor.org/rfc/rfc4180). The lack of a well-defined standard means that subtle differences often exist in the data produced and consumed by different applications. These differences can make it annoying to process CSV files from multiple sources. Still, while the delimiters and quoting characters vary, the overall format is similar enough that it is possible to write a single module which can efficiently manipulate such data, hiding the details of reading and writing the data from the programmer.

The **csv** module implements classes to read and write tabular data in CSV format. It allows programmers to say, “write this data in the format preferred by Excel,” or “read data from this file which was generated by Excel,” without knowing the precise details of the CSV format used by Excel. Programmers can also describe the CSV formats understood by other applications or define their own special-purpose CSV formats.

The **csv** module’s **reader** and **writer** objects read and write sequences. Programmers can also read and write data in dictionary form using the **DictReader** and **DictWriter** classes.

**See also:**

[PEP 305 - CSV File API](https://www.python.org/dev/peps/pep-0305/)
The Python Enhancement Proposal which proposed this addition to Python.
14.1.1. Module Contents

The csv module defines the following functions:

`csv.reader(csvfile, dialect='excel', **fmtparams)`

Return a reader object which will iterate over lines in the given `csvfile`. `csvfile` can be any object which supports the `iterator` protocol and returns a string each time its `__next__()` method is called — `file objects` and list objects are both suitable. If `csvfile` is a file object, it should be opened with `newline=''`. [1] An optional `dialect` parameter can be given which is used to define a set of parameters specific to a particular CSV dialect. It may be an instance of a subclass of the `Dialect` class or one of the strings returned by the `list_dialects()` function. The other optional `fmtparams` keyword arguments can be given to override individual formatting parameters in the current dialect. For full details about the dialect and formatting parameters, see section `Dialects and Formatting Parameters`.

Each row read from the csv file is returned as a list of strings. No automatic data type conversion is performed unless the `QUOTE_NONNUMERIC` format option is specified (in which case unquoted fields are transformed into floats).

A short usage example:

```python
>>> import csv
>>> with open('eggs.csv', newline='') as csvfile:
...     spamreader = csv.reader(csvfile, delimiter=' ', quotechar='|')
...     for row in spamreader:
...         print(', '.join(row))
Spam, Spam, Spam, Spam, Spam, Baked Beans
```
csv.writer(csvfile, dialect='excel', **fmtparams)

Return a writer object responsible for converting the user’s data into delimited strings on the given file-like object. csvfile can be any object with a write() method. If csvfile is a file object, it should be opened with newline='' [1]. An optional dialect parameter can be given which is used to define a set of parameters specific to a particular CSV dialect. It may be an instance of a subclass of the Dialect class or one of the strings returned by the list_dialects() function. The other optional fmtparams keyword arguments can be given to override individual formatting parameters in the current dialect. For full details about the dialect and formatting parameters, see section Dialects and Formatting Parameters. To make it as easy as possible to interface with modules which implement the DB API, the value None is written as the empty string. While this isn’t a reversible transformation, it makes it easier to dump SQL NULL data values to CSV files without preprocessing the data returned from a cursor.fetch* call. All other non-string data are stringified with str() before being written.

A short usage example:

```python
import csv
with open('eggs.csv', 'w', newline='') as csvfile:
    spamwriter = csv.writer(csvfile, delimiter='|
                                 quotechar='|', quoting=csv.QUOTE_ALL)
    spamwriter.writerow(['Spam'] * 5 + ['Baked Beans'])
    spamwriter.writerow(['Spam', 'Lovely Spam', 'Wonderful Spam'])
```
csv.register_dialect(name[, dialect], **fmtparams)

Associate dialect with name. name must be a string. The dialect can be specified either by passing a sub-class of Dialect, or by fmtparams keyword arguments, or both, with keyword arguments overriding parameters of the dialect. For full details about the dialect and formatting parameters, see section Dialects and Formatting Parameters.

csv.unregister_dialect(name)

Delete the dialect associated with name from the dialect registry. An Error is raised if name is not a registered dialect name.

csv.get_dialect(name)

Return the dialect associated with name. An Error is raised if name is not a registered dialect name. This function returns an immutable Dialect.

csv.list_dialects()

Return the names of all registered dialects.

csv.field_size_limit([new_limit])

Returns the current maximum field size allowed by the parser. If new_limit is given, this becomes the new limit.

The csv module defines the following classes:

class csv.DictReader(csvfile, fieldnames=None, restkey=None, restval=None, dialect='excel', *args, **kwds)

Create an object which operates like a regular reader but maps the information read into a dict whose keys are given by the optional fieldnames parameter. If the fieldnames parameter is omitted, the values in the first row of the csvfile will be used as the fieldnames.
If the row read has more fields than the fieldnames sequence, the remaining data is added as a sequence keyed by the value of `restkey`. If the row read has fewer fields than the fieldnames sequence, the remaining keys take the value of the optional `restval` parameter. Any other optional or keyword arguments are passed to the underlying `reader` instance.

```python
class csv.DictWriter(csvfile, fieldnames, restval='', extrasaction='raise', dialect='excel', *args, **kwds)
```

Create an object which operates like a regular writer but maps dictionaries onto output rows. The `fieldnames` parameter identifies the order in which values in the dictionary passed to the `writerow()` method are written to the `csvfile`. The optional `restval` parameter specifies the value to be written if the dictionary is missing a key in `fieldnames`. If the dictionary passed to the `writerow()` method contains a key not found in `fieldnames`, the optional `extrasaction` parameter indicates what action to take. If it is set to `raise` a `ValueError` is raised. If it is set to `ignore`, extra values in the dictionary are ignored. Any other optional or keyword arguments are passed to the underlying `writer` instance.

Note that unlike the `DictReader` class, the `fieldnames` parameter of the `DictWriter` is not optional. Since Python’s `dict` objects are not ordered, there is not enough information available to deduce the order in which the row should be written to the `csvfile`.

```python
class csv.Dialect
```

The `Dialect` class is a container class relied on primarily for its attributes, which are used to define the parameters for a specific `reader` or `writer` instance.
The `excel` class defines the usual properties of an Excel-generated CSV file. It is registered with the dialect name 'excel'.

The `excel_tab` class defines the usual properties of an Excel-generated TAB-delimited file. It is registered with the dialect name 'excel-tab'.

The `unix_dialect` class defines the usual properties of a CSV file generated on UNIX systems, i.e. using '\n' as line terminator and quoting all fields. It is registered with the dialect name 'unix'.

New in version 3.2.

The `Sniffer` class is used to deduce the format of a CSV file.

The `Sniffer` class provides two methods:

- `sniff(sample, delimiters=None)`
  Analyze the given `sample` and return a `Dialect` subclass reflecting the parameters found. If the optional `delimiters` parameter is given, it is interpreted as a string containing possible valid delimiter characters.

- `has_header(sample)`
  Analyze the sample text (presumed to be in CSV format) and return `True` if the first row appears to be a series of column headers.
An example for Sniffer use:

```python
with open('example.csv') as csvfile:
    dialect = csv.Sniffer().sniff(csvfile.read(1024))
    csvfile.seek(0)
    reader = csv.reader(csvfile, dialect)
    # ... process CSV file contents here ...
```

The csv module defines the following constants:

**csv.QUOTE_ALL**
Instructs writer objects to quote all fields.

**csv.QUOTE_MINIMAL**
Instructs writer objects to only quote those fields which contain special characters such as delimiter, quotechar or any of the characters in lineterminator.

**csv.QUOTE_NONNUMERIC**
Instructs writer objects to quote all non-numeric fields.

Instructs the reader to convert all non-quoted fields to type float.

**csv.QUOTENONE**
Instructs writer objects to never quote fields. When the current delimiter occurs in output data it is preceded by the current escapechar character. If escapechar is not set, the writer will raise Error if any characters that require escaping are encountered.

Instructs reader to perform no special processing of quote characters.

The csv module defines the following exception:
exception csv. **Error**

Raised by any of the functions when an error is detected.
14.1.2. Dialects and Formatting Parameters

To make it easier to specify the format of input and output records, specific formatting parameters are grouped together into dialects. A dialect is a subclass of the Dialect class having a set of specific methods and a single validate() method. When creating reader or writer objects, the programmer can specify a string or a subclass of the Dialect class as the dialect parameter. In addition to, or instead of, the dialect parameter, the programmer can also specify individual formatting parameters, which have the same names as the attributes defined below for the Dialect class.

Dialects support the following attributes:

**Dialect.delimiter**

A one-character string used to separate fields. It defaults to ",".

**Dialect.doublequote**

Controls how instances of quotechar appearing inside a field should be themselves be quoted. When True, the character is doubled. When False, the escapechar is used as a prefix to the quotechar. It defaults to True.

On output, if doublequote is False and no escapechar is set, Error is raised if a quotechar is found in a field.

**Dialect.escapechar**

A one-character string used by the writer to escape the delimiter if quoting is set to QUOTE_NONE and the quotechar if doublequote is False. On reading, the escapechar removes any special meaning
from the following character. It defaults to `None`, which disables escaping.

**Dialect.** `lineterminator`

The string used to terminate lines produced by the `writer`. It defaults to `'
'`.

**Note:** The `reader` is hard-coded to recognise either `''` or `'
'` as end-of-line, and ignores `lineterminator`. This behavior may change in the future.

**Dialect.** `quotechar`

A one-character string used to quote fields containing special characters, such as the `delimiter` or `quotechar`, or which contain new-line characters. It defaults to `'"'`.

**Dialect.** `quoting`

Controls when quotes should be generated by the writer and recognised by the reader. It can take on any of the `QUOTE_*` constants (see section `Module Contents`) and defaults to `QUOTE_MINIMAL`.

**Dialect.** `skipinitialspace`

When `True`, whitespace immediately following the `delimiter` is ignored. The default is `False`.

**Dialect.** `strict`

When `True`, raise exception `Error` on bad CSV input. The default is `False`. 
14.1.3. Reader Objects

Reader objects (DictReader instances and objects returned by the reader() function) have the following public methods:

csvreader.__next__()

    Return the next row of the reader’s iterable object as a list, parsed according to the current dialect. Usually you should call this as next(reader).

Reader objects have the following public attributes:

csvreader.dialect

    A read-only description of the dialect in use by the parser.

csvreader.line_num

    The number of lines read from the source iterator. This is not the same as the number of records returned, as records can span multiple lines.

DictReader objects have the following public attribute:

csvreader.fieldnames

    If not passed as a parameter when creating the object, this attribute is initialized upon first access or when the first record is read from the file.
14.1.4. Writer Objects

Writer objects (DictWriter instances and objects returned by the writer() function) have the following public methods. A row must be a sequence of strings or numbers for Writer objects and a dictionary mapping fieldnames to strings or numbers (by passing them through str() first) for DictWriter objects. Note that complex numbers are written out surrounded by parens. This may cause some problems for other programs which read CSV files (assuming they support complex numbers at all).

csvwriter.writerow(row)

Write the row parameter to the writer’s file object, formatted according to the current dialect.

csvwriter.writerows(rows)

Write all the rows parameters (a list of row objects as described above) to the writer’s file object, formatted according to the current dialect.

Writer objects have the following public attribute:

csvwriter.dialect

A read-only description of the dialect in use by the writer.

DictWriter objects have the following public method:

DictWriter.writerowheader()

Write a row with the field names (as specified in the constructor).

New in version 3.2.
14.1.5. Examples

The simplest example of reading a CSV file:

```python
import csv
with open('some.csv', newline='') as f:
    reader = csv.reader(f)
    for row in reader:
        print(row)
```

Reading a file with an alternate format:

```python
import csv
with open('passwd', newline='') as f:
    reader = csv.reader(f, delimiter=':', quoting=csv.QUOTE_NONE)
    for row in reader:
        print(row)
```

The corresponding simplest possible writing example is:

```python
import csv
with open('some.csv', 'w', newline='') as f:
    writer = csv.writer(f)
    writer.writerows(someiterable)
```

Since `open()` is used to open a CSV file for reading, the file will by default be decoded into unicode using the system default encoding (see `locale.getpreferredencoding()`). To decode a file using a different encoding, use the `encoding` argument of `open`:

```python
import csv
with open('some.csv', newline='', encoding='utf-8') as f:
    reader = csv.reader(f)
```
The same applies to writing in something other than the system default encoding: specify the encoding argument when opening the output file.

Registering a new dialect:

```python
import csv
csv.register_dialect('unixpwd', delimiter=':', quoting=csv.QUOTE_ALL)
with open('passwd', newline='') as f:
    reader = csv.reader(f, 'unixpwd')
```

A slightly more advanced use of the reader — catching and reporting errors:

```python
import csv, sys
filename = 'some.csv'
with open(filename, newline='') as f:
    reader = csv.reader(f)
    try:
        for row in reader:
            print(row)
    except csv.Error as e:
        sys.exit('file {}, line {}: {}'.format(filename, e.lineno, e.message))
```

And while the module doesn’t directly support parsing strings, it can easily be done:

```python
import csv
for row in csv.reader([['one', 'two', 'three']]):
    print(row)
```
Footnotes

(1, 2) If `newline=''` is not specified, newlines embedded inside quoted fields will not be interpreted correctly, and on platforms that use `\r\n` linendings on write an extra `\r` will be added. It should always be safe to specify `newline=''`, since the csv module does its own *(universal)* newline handling.
14.2. configparser — Configuration file parser

This module provides the `ConfigParser` class which implements a basic configuration language which provides a structure similar to what's found in Microsoft Windows INI files. You can use this to write Python programs which can be customized by end users easily.

**Note:** This library does not interpret or write the value-type prefixes used in the Windows Registry extended version of INI syntax.

**See also:**

**Module** `shlex`

Support for creating Unix shell-like mini-languages which can be used as an alternate format for application configuration files.

**Module** `json`

The json module implements a subset of JavaScript syntax which can also be used for this purpose.
Let's take a very basic configuration file that looks like this:

```
[DEFAULT]
ServerAliveInterval = 45
Compression = yes
CompressionLevel = 9
ForwardX11 = yes

[bitbucket.org]
User = hg

[topsecret.server.com]
Port = 50022
ForwardX11 = no
```

The structure of INI files is described in the following section. Essentially, the file consists of sections, each of which contains keys with values. `configparser` classes can read and write such files. Let's start by creating the above configuration file programatically.

```python
>>> import configparser
>>> config = configparser.ConfigParser()
>>> config['DEFAULT'] = {'ServerAliveInterval': '45',
                        'Compression': 'yes',
                        'CompressionLevel': '9'}
>>> config['bitbucket.org'] = {}  
>>> config['bitbucket.org']['User'] = 'hg'
>>> config['topsecret.server.com'] = {} 
>>> topsecret = config['topsecret.server.com']
>>> topsecret['Port'] = '50022'  # mutates the parser
>>> topsecret['ForwardX11'] = 'no'  # same here
>>> config['DEFAULT']['ForwardX11'] = 'yes'
>>> with open('example.ini', 'w') as configfile:
    config.write(configfile)
```
As you can see, we can treat a config parser much like a dictionary. There are differences, outlined later, but the behavior is very close to what you would expect from a dictionary.

Now that we have created and saved a configuration file, let's read it back and explore the data it holds.

```python
>>> import configparser
>>> config = configparser.ConfigParser()
>>> config.sections()
[]
>>> config.read('example.ini')
['example.ini']
>>> config.sections()
['bitbucket.org', 'topsecret.server.com']
>>> 'bitbucket.org' in config
True
>>> 'bytebong.com' in config
False
>>> config['bitbucket.org']['User']
'hg'
>>> config['DEFAULT']['Compression']
'yes'
>>> topsecret = config['topsecret.server.com']
>>> topsecret['ForwardX11']
'no'
>>> topsecret['Port']
'50022'
>>> for key in config['bitbucket.org']: print(key)
... user
compressionlevel
serveraliveinterval
As we can see above, the API is pretty straightforward. The only bit of magic involves the DEFAULT section which provides default values for all other sections [1]. Note also that keys in sections are case-insensitive and stored in lowercase [1].
14.2.2. Supported Datatypes

Config parsers do not guess datatypes of values in configuration files, always storing them internally as strings. This means that if you need other datatypes, you should convert on your own:

```python
>>> int(topsecret['Port'])
50022
>>> float(topsecret['CompressionLevel'])
9.0
```

Extracting Boolean values is not that simple, though. Passing the value to `bool()` would do no good since `bool('False')` is still `True`. This is why config parsers also provide `getboolean()`. This method is case-insensitive and recognizes Boolean values from 'yes'/no', 'on'/off' and '1'/0' [1]. For example:

```python
>>> topsecret.getboolean('ForwardX11')
False
>>> config['bitbucket.org'].getboolean('ForwardX11')
True
>>> config.getboolean('bitbucket.org', 'Compression')
True
```

Apart from `getboolean()`, config parsers also provide equivalent `getint()` and `getfloat()` methods, but these are far less useful since conversion using `int()` and `float()` is sufficient for these types.
14.2.3. Fallback Values

As with a dictionary, you can use a section's `get()` method to provide fallback values:

```python
>>> topsecret.get('Port')
'50022'
>>> topsecret.get('CompressionLevel')
'9'
>>> topsecret.get('Cipher')
>>> topsecret.get('Cipher', '3des-cbc')
'3des-cbc'
```

Please note that default values have precedence over fallback values. For instance, in our example the `CompressionLevel` key was specified only in the `'DEFAULT'` section. If we try to get it from the section `'topsecret.server.com'`, we will always get the default, even if we specify a fallback:

```python
>>> topsecret.get('CompressionLevel', '3')
'9'
```

One more thing to be aware of is that the parser-level `get()` method provides a custom, more complex interface, maintained for backwards compatibility. When using this method, a fallback value can be provided via the `fallback` keyword-only argument:

```python
>>> config.get('bitbucket.org', 'monster',
...             fallback='No such things as monsters')
'No such things as monsters'
```

The same `fallback` argument can be used with the `getint()`,

getfloat() and getboolean() methods, for example:

```python
>>> 'BatchMode' in topsecret
False
>>> topsecret.getboolean('BatchMode', fallback=True)
True
>>> config['DEFAULT']['BatchMode'] = 'no'
>>> topsecret.getboolean('BatchMode', fallback=True)
False
```
14.2.4. Supported INI File Structure

A configuration file consists of sections, each led by a [section] header, followed by key/value entries separated by a specific string (= or : by default [1]). By default, section names are case sensitive but keys are not [1]. Leading and trailing whitespace is removed from keys and values. Values can be omitted, in which case the key/value delimiter may also be left out. Values can also span multiple lines, as long as they are indented deeper than the first line of the value. Depending on the parser’s mode, blank lines may be treated as parts of multiline values or ignored.

Configuration files may include comments, prefixed by specific characters (# and ; by default [1]). Comments may appear on their own on an otherwise empty line, possibly indented. [1]

For example:

```
[Simple Values]
key=value
spaces in keys=allowed
spaces in values=allowed as well
spaces around the delimiter = obviously
you can also use : to delimit keys from values

[All Values Are Strings]
values like this: 1000000
or this: 3.14159265359
are they treated as numbers? : no
integers, floats and booleans are held as: strings
can use the API to get converted values directly: true
```

[Multiline Values]
chorus: I'm a lumberjack, and I'm okay
       I sleep all night and I work all day

[No Values]
key_without_value
empty_string_value_here =

[You can use comments]
# like this
; or this

# By default only in an empty line.
# Inline comments can be harmful because they prevent
# from using the delimiting characters as parts of values.
# That being said, this can be customized.

[Sections Can Be Indented]
can_values_be_as_well = True
does_that_mean_anything_special = False
purpose = formatting for readability
multiline_values = are
    handled just fine as
    long as they are indented
    deeper than the first line
    of a value
# Did I mention we can indent comments, too?
14.2.5. Interpolation of values

On top of the core functionality, ConfigParser supports interpolation. This means values can be preprocessed before returning them from get() calls.

class configparser. BasicInterpolation

The default implementation used by ConfigParser. It enables values to contain format strings which refer to other values in the same section, or values in the special default section [1]. Additional default values can be provided on initialization.

For example:

```
[Paths]
home_dir: /Users
my_dir: %(home_dir)s/lumberjack
my_pictures: %(my_dir)s/Pictures
```

In the example above, ConfigParser with interpolation set to BasicInterpolation() would resolve %(home_dir)s to the value of home_dir (/Users in this case). %(my_dir)s in effect would resolve to /Users/lumberjack. All interpolations are done on demand so keys used in the chain of references do not have to be specified in any specific order in the configuration file.

With interpolation set to None, the parser would simply return %(my_dir)s/Pictures as the value of my_pictures and %(home_dir)s/lumberjack as the value of my_dir.

class configparser. ExtendedInterpolation

An alternative handler for interpolation which implements a more
advanced syntax, used for instance in zc.buildout. Extended interpolation is using `${section:option}` to denote a value from a foreign section. Interpolation can span multiple levels. For convenience, if the section: part is omitted, interpolation defaults to the current section (and possibly the default values from the special section).

For example, the configuration specified above with basic interpolation, would look like this with extended interpolation:

```
[Paths]
home_dir: /Users
my_dir: ${home_dir}/lumberjack
my_pictures: ${my_dir}/Pictures
```

Values from other sections can be fetched as well:

```
[Common]
home_dir: /Users
library_dir: /Library
system_dir: /System
macports_dir: /opt/local

[Frameworks]
Python: 3.2
path: ${Common:system_dir}/Library/Frameworks/

[Arthur]
nickname: Two Sheds
last_name: Jackson
my_dir: ${Common:home_dir}/twosheds
my_pictures: ${my_dir}/Pictures
python_dir: ${Frameworks:path}/Python/Versions/${Frameworks:Python}
```
Mapping protocol access is a generic name for functionality that enables using custom objects as if they were dictionaries. In case of `configparser`, the mapping interface implementation is using the `parser['section']['option']` notation.

`parser['section']` in particular returns a proxy for the section's data in the parser. This means that the values are not copied but they are taken from the original parser on demand. What's even more important is that when values are changed on a section proxy, they are actually mutated in the original parser.

`configparser` objects behave as close to actual dictionaries as possible. The mapping interface is complete and adheres to the `MutableMapping` ABC. However, there are a few differences that should be taken into account:

- By default, all keys in sections are accessible in a case-insensitive manner [1]. E.g. for `option in parser['section']` yields only `optionxform`'ed option key names. This means lowercased keys by default. At the same time, for a section that holds the key 'a', both expressions return True:

  ```
  "a" in parser["section"]
  "A" in parser["section"]
  ```

- All sections include `DEFAULTSECT` values as well which means that `.clear()` on a section may not leave the section visibly empty. This is because default values cannot be deleted from the
section (because technically they are not there). If they are overridden in the section, deleting causes the default value to be visible again. Trying to delete a default value causes a KeyError.

- **DEFAULTSECT** cannot be removed from the parser:
  - trying to delete it raises `ValueError`,
  - `parser.clear()` leaves it intact,
  - `parser.popitem()` never returns it.

- `parser.get(section, option, **kwargs)` - the second argument is not a fallback value. Note however that the section-level `get()` methods are compatible both with the mapping protocol and the classic `configparser` API.

- `parser.items()` is compatible with the mapping protocol (returns a list of `section_name`, `section_proxy` pairs including the DEFAULTSECT). However, this method can also be invoked with arguments: `parser.items(section, raw, vars)`. The latter call returns a list of `option`, `value` pairs for a specified section, with all interpolations expanded (unless `raw=True` is provided).

The mapping protocol is implemented on top of the existing legacy API so that subclasses overriding the original interface still should have mappings working as expected.
14.2.7. Customizing Parser Behaviour

There are nearly as many INI format variants as there are applications using it. `configparser` goes a long way to provide support for the largest sensible set of INI styles available. The default functionality is mainly dictated by historical background and it’s very likely that you will want to customize some of the features.

The most common way to change the way a specific config parser works is to use the `__init__() options:

- `defaults`, default value: None
  
  This option accepts a dictionary of key-value pairs which will be initially put in the `DEFAULT` section. This makes for an elegant way to support concise configuration files that don’t specify values which are the same as the documented default.

  Hint: if you want to specify default values for a specific section, use `read_dict()` before you read the actual file.

- `dict_type`, default value: `collections.OrderedDict`
  
  This option has a major impact on how the mapping protocol will behave and how the written configuration files look. With the default ordered dictionary, every section is stored in the order they were added to the parser. Same goes for options within sections.

  An alternative dictionary type can be used for example to sort sections and options on write-back. You can also use a regular dictionary for performance reasons.

  Please note: there are ways to add a set of key-value pairs in a
single operation. When you use a regular dictionary in those operations, the order of the keys may be random. For example:

```python
>>> parser = configparser.ConfigParser()
>>> parser.read_dict({'section1': {'key1': 'value',
                                     'key2': 'value',
                                     'key3': 'value',
                                     'section2': {'keyA': 'value',
                                                   'keyB': 'value',
                                                   'keyC': 'value',
                                                   'section3': {'foo': 'x',
                                                                 'bar': 'y',
                                                                 'baz': 'z'}}
                                 ...
                                 })
>>> parser.sections()
['section3', 'section2', 'section1']
>>> [option for option in parser['section3']]
['baz', 'foo', 'bar']
```

In these operations you need to use an ordered dictionary as well:

```python
>>> from collections import OrderedDict
>>> parser = configparser.ConfigParser()
>>> parser.read_dict(
...
...
...
...  OrderedDict((
...   ('s1',
...    OrderedDict((
...       ('1', '2'),
...       ('3', '4'),
...       ('5', '6'),
...    ))
...  ),
...  ('s2',
...   OrderedDict((
...      ('a', 'b'),
...      ('c', 'd'),
...    ))
... )
... )
```
>>> parser.sections()
['s1', 's2']
>>> [option for option in parser['s1']]
['1', '3', '5']
>>> [option for option in parser['s2'].values()]
['b', 'd', 'f']

- `allow_no_value`, default value: False

Some configuration files are known to include settings without values, but which otherwise conform to the syntax supported by `configparser`. The `allow_no_value` parameter to the constructor can be used to indicate that such values should be accepted:

```python
>>> import configparser
>>> sample_config = ""
... [mysqld]
... user = mysql
... pid-file = /var/run/mysqld/mysqld.pid
... skip-external-locking
... old_passwords = 1
... skip-bdb
... # we don't need ACID today
... skip-innodb
... ""
```
>>> # Settings with values are treated as before
>>> config['mysqld']['user']
'mysql'

>>> # Settings without values provide None:
>>> config['mysqld']['skip-bdb']

>>> # Settings which aren't specified still raise
>>> config['mysqld']['does-not-exist']
Traceback (most recent call last):
...
  KeyError: 'does-not-exist'

- **delimiters**, default value: ('=', ':')

Delimiters are substrings that delimit keys from values within a section. The first occurrence of a delimiting substring on a line is considered a delimiter. This means values (but not keys) can contain the delimiters.

See also the **space_around_delimiters** argument to ConfigParser.write().

- **comment_prefixes**, default value: ('#', ';')

- **inline_comment_prefixes**, default value: None

Comment prefixes are strings that indicate the start of a valid comment within a config file. **comment_prefixes** are used only on otherwise empty lines (optionally indented) whereas **inline_comment_prefixes** can be used after every valid value (e.g. section names, options and empty lines as well). By default inline comments are disabled and '#' and ';' are used as prefixes for whole line comments.
Changed in version 3.2: In previous versions of `configparser` behaviour matched `comment_prefixes=('#',';')` and `inline_comment_prefixes=(';',)`.

Please note that config parsers don’t support escaping of comment prefixes so using `inline_comment_prefixes` may prevent users from specifying option values with characters used as comment prefixes. When in doubt, avoid setting `inline_comment_prefixes`. In any circumstances, the only way of storing comment prefix characters at the beginning of a line in multiline values is to interpolate the prefix, for example:

```python
>>> from configparser import ConfigParser, ExtendedInterpolation
>>> parser = ConfigParser(interpolation=ExtendedInterpolation(),
                          comment_prefixes=('#',),
                          inline_comment_prefixes=(',',))
>>> parser.read_string(""
... [DEFAULT]
... hash = #
...
... [hashes]
... shebang =
... ${hash}!/usr/bin/env python
... ${hash} -*- coding: utf-8 -*-
...
... extensions =
... enabled_extension
... another_extension
... #disabled_by_comment
... yet_another_extension
...
... interpolation not necessary = if # is not at even in multiline values = line #1
... line #2
... line #3
... """
```
>>> print(parser['hashes']['shebang'])
#!/usr/bin/env python
# -*- coding: utf-8 -*-

>>> print(parser['hashes']['extensions'])

enabled_extension
another_extension
yet_another_extension

>>> print(parser['hashes']['interpolation not necessary'])
if # is not at line start

>>> print(parser['hashes']['even in multiline values'])
line #1
line #2
line #3

- **strict**, default value: True

  When set to True, the parser will not allow for any section or option duplicates while reading from a single source (using `read_file()`, `read_string()` or `read_dict()`). It is recommended to use strict parsers in new applications.

  *Changed in version 3.2:* In previous versions of `configparser` behaviour matched `strict=False`.

- **empty_lines_in_values**, default value: True

  In config parsers, values can span multiple lines as long as they are indented more than the key that holds them. By default parsers also let empty lines to be parts of values. At the same time, keys can be arbitrarily indented themselves to improve readability. In consequence, when configuration files get big and complex, it is easy for the user to lose track of the file structure.
Take for instance:

```
[Section]
key = multiline
    value with a gotcha

this = is still a part of the multiline value of 'key'
```

This can be especially problematic for the user to see if she's using a proportional font to edit the file. That is why when your application does not need values with empty lines, you should consider disallowing them. This will make empty lines split keys every time. In the example above, it would produce two keys, `key` and `this`.

- **default_section**, default value: `configparser.DEFAULTSECT` (that is: "DEFAULT")

The convention of allowing a special section of default values for other sections or interpolation purposes is a powerful concept of this library, letting users create complex declarative configurations. This section is normally called "DEFAULT" but this can be customized to point to any other valid section name. Some typical values include: "general" or "common". The name provided is used for recognizing default sections when reading from any source and is used when writing configuration back to a file. Its current value can be retrieved using the `parser_instance.default_section` attribute and may be modified at runtime (i.e. to convert files from one format to another).

- **interpolation**, default value:
Interpolation behaviour may be customized by providing a custom handler through the `interpolation` argument. None can be used to turn off interpolation completely, `ExtendedInterpolation()` provides a more advanced variant inspired by zc.buildout. More on the subject in the dedicated documentation section. 

`RawConfigParser` has a default value of None.

More advanced customization may be achieved by overriding default values of these parser attributes. The defaults are defined on the classes, so they may be overriden by subclasses or by attribute assignment.

`configparser.BOOLEAN_STATES` By default when using `getboolean()`, config parsers consider the following values True: `'1'`, `'yes'`, `'true'`, `'on'` and the following values False: `'0'`, `'no'`, `'false'`, `'off'`. You can override this by specifying a custom dictionary of strings and their Boolean outcomes. For example:

```python
>>> custom = configparser.ConfigParser()
>>> custom['section1'] = {'funky': 'nope'}
>>> custom['section1'].getboolean('funky')
Traceback (most recent call last):
  ... ValueError: Not a boolean: nope
>>> custom.BOOLEAN_STATES = {'sure': True, 'nope'
>>> custom['section1'].getboolean('funky')
False
```

Other typical Boolean pairs include accept/reject or enabled/disabled.
configparser.**optionxform**(option)

This method transforms option names on every read, get, or set operation. The default converts the name to lowercase. This also means that when a configuration file gets written, all keys will be lowercase. Override this method if that's unsuitable. For example:

```python
>>> config = ""
... [Section1]
... Key = Value
...
... [Section2]
... AnotherKey = Value
""
>>> typical = configparser.ConfigParser()
>>> typical.read_string(config)
>>> list(typical['Section1'].keys())
['key']
>>> list(typical['Section2'].keys())
['anotherkey']
>>> custom = configparser.RawConfigParser()
>>> custom.optionxform = lambda option: option
>>> custom.read_string(config)
>>> list(custom['Section1'].keys())
['Key']
>>> list(custom['Section2'].keys())
['AnotherKey']
```

**configparser.SECTCRE**

A compiled regular expression used to parse section headers. The default matches `[section]` to the name "section". Whitespace is considered part of the section name, thus `[ larch ]` will be read as a section of name "larch". Override this attribute if that's unsuitable. For example:
```python
>>> config = ""
... [Section 1]
... option = value
...
... [ Section 2 ]
... another = val
... ""

>>> typical = ConfigParser()
>>> typical.read_string(config)
>>> typical.sections()
['Section 1', ' Section 2 ']

>>> custom = ConfigParser()
>>> custom.SECTCRE = re.compile(r"\[ *(?P<header>.*?) *\]"

>>> custom.read_string(config)
>>> custom.sections()
['Section 1', 'Section 2']
```

**Note:** While ConfigParser objects also use an OPTCRE attribute for recognizing option lines, it’s not recommended to override it because that would interfere with constructor options `allow_no_value` and `delimiters`. 
14.2.8. Legacy API Examples

Mainly because of backwards compatibility concerns, `configparser` provides also a legacy API with explicit `get/set` methods. While there are valid use cases for the methods outlined below, mapping protocol access is preferred for new projects. The legacy API is at times more advanced, low-level and downright counterintuitive.

An example of writing to a configuration file:

```python
import configparser

config = configparser.RawConfigParser()

# Please note that using RawConfigParser's set function,
# non-string values to keys internally, but will record
# attempting to write to a file or when you get it in
# values using the mapping protocol or ConfigParser's
# such assignments to take place.
config.add_section('Section1')
config.set('Section1', 'an_int', '15')
config.set('Section1', 'a_bool', 'true')
config.set('Section1', 'a_float', '3.1415')
config.set('Section1', 'baz', 'fun')
config.set('Section1', 'bar', 'Python')
config.set('Section1', 'foo', '%(bar)s is %(baz)s!')

# Writing our configuration file to 'example.cfg'
with open('example.cfg', 'w') as configfile:
    config.write(configfile)
```

An example of reading the configuration file again:

```python
import configparser
```
```python
config = configparser.RawConfigParser()
config.read('example.cfg')

# getfloat() raises an exception if the value is not
# getint() and getboolean() also do this for their
a_float = config.getfloat('Section1', 'a_float')
an_int = config.getint('Section1', 'an_int')
print(a_float + an_int)

# Notice that the next output does not interpolate '%(bar)s' or '%(baz)s'.
# This is because we are using a RawConfigParser().
if config.getboolean('Section1', 'a_bool'):
    print(config.get('Section1', 'foo'))

To get interpolation, use ConfigParser:

```
Default values are available in both types of ConfigParsers. They are used in interpolation if an option used is not defined elsewhere.

```python
import configparser

# New instance with 'bar' and 'baz' defaulting to 'Life'
config = configparser.ConfigParser({'bar': 'Life', 'baz': 'hard'})
config.read('example.cfg')

print(config.get('Section1', 'foo'))  # -> "Python is fun!"
config.remove_option('Section1', 'bar')
config.remove_option('Section1', 'baz')
print(config.get('Section1', 'foo'))  # -> "Life is hard!"
```
14.2.9. ConfigParser Objects

class configparser.ConfigParser(defaults=None,
dict_type= collections.OrderedDict, allow_no_value=False, delimiters=
(‘=’, ‘:’), comment_prefixes=('#', ';'), inline_comment_prefixes=None,
strict=True, empty_lines_in_values=True,
default_section=configparser.DEFAULTSECT,
interpolation=BasicInterpolation())

The main configuration parser. When defaults is given, it is initialized into the dictionary of intrinsic defaults. When dict_type is given, it will be used to create the dictionary objects for the list of sections, for the options within a section, and for the default values.

When delimiters is given, it is used as the set of substrings that divide keys from values. When comment_prefixes is given, it will be used as the set of substrings that prefix comments in otherwise empty lines. Comments can be indented. When inline_comment_prefixes is given, it will be used as the set of substrings that prefix comments in non-empty lines.

When strict is True (the default), the parser won’t allow for any section or option duplicates while reading from a single source (file, string or dictionary), raising DuplicateSectionError or DuplicateOptionError. When empty_lines_in_values is False (default: True), each empty line marks the end of an option. Otherwise, internal empty lines of a multiline option are kept as part of the value. When allow_no_value is True (default: False), options without values are accepted; the value held for these is None and they are serialized without the trailing delimiter.

When default_section is given, it specifies the name for the special section holding default values for other sections and interpolation
purposes (normally named "DEFAULT"). This value can be retrieved and changed on runtime using the default_section instance attribute.

Interpolation behaviour may be customized by providing a custom handler through the interpolation argument. None can be used to turn off interpolation completely, ExtendedInterpolation() provides a more advanced variant inspired by zc.buildout. More on the subject in the dedicated documentation section.

All option names used in interpolation will be passed through the optionxform() method just like any other option name reference. For example, using the default implementation of optionxform() (which converts option names to lower case), the values foo %(bar)s and foo %(BAR)s are equivalent.

Changed in version 3.1: The default dict_type is collections.OrderedDict.

Changed in version 3.2: allow_no_value, delimiters, comment_prefixes, strict, empty_lines_in_values, default_section and interpolation were added.

defaults()

Return a dictionary containing the instance-wide defaults.

sections()

Return a list of the sections available; the default section is not included in the list.

add_section(section)

Add a section named section to the instance. If a section by the given name already exists, DuplicateSectionError is
raised. If the default section name is passed, **ValueError** is raised. The name of the section must be a string; if not, **TypeError** is raised.

*Changed in version 3.2:* Non-string section names raise **TypeError**.

**has_section**(section)

Indicates whether the named section is present in the configuration. The default section is not acknowledged.

**options**(section)

Return a list of options available in the specified section.

**has_option**(section, option)

If the given section exists, and contains the given option, return **True**; otherwise return **False**. If the specified section is **None** or an empty string, DEFAULT is assumed.

**read**(filenames, encoding=None)

Attempt to read and parse a list of filenames, returning a list of filenames which were successfully parsed. If filenames is a string, it is treated as a single filename. If a file named in filenames cannot be opened, that file will be ignored. This is designed so that you can specify a list of potential configuration file locations (for example, the current directory, the user’s home directory, and some system-wide directory), and all existing configuration files in the list will be read. If none of the named files exist, the **ConfigParser** instance will contain an empty dataset. An application which requires initial values to be loaded from a file should load the required file or files using **read_file()** before calling **read()** for any optional files:
import configparser, os

config = configparser.ConfigParser()
config.read_file(open('defaults.cfg'))
config.read(['site.cfg', os.path.expanduser('~/encoding=cp1250')])

New in version 3.2: The encoding parameter. Previously, all files were read using the default encoding for open().

read_file(f, source=None)
Read and parse configuration data from f which must be an iterable yielding Unicode strings (for example files opened in text mode).

Optional argument source specifies the name of the file being read. If not given and f has a name attribute, that is used for source; the default is '<???>'.

New in version 3.2: Replaces readfp().

read_string(string, source='<string>')
Parse configuration data from a string.

Optional argument source specifies a context-specific name of the string passed. If not given, '<string>' is used. This should commonly be a filesystem path or a URL.

New in version 3.2.

read_dict(dictionary, source='<dict>')
Load configuration from any object that provides a dict-like items() method. Keys are section names, values are
dictionaries with keys and values that should be present in the section. If the used dictionary type preserves order, sections and their keys will be added in order. Values are automatically converted to strings.

Optional argument source specifies a context-specific name of the dictionary passed. If not given, `<dict>` is used.

This method can be used to copy state between parsers.

*New in version 3.2.*

```python
get(section, option, *, raw=False, vars=None[, fallback])
```

Get an option value for the named section. If vars is provided, it must be a dictionary. The option is looked up in vars (if provided), section, and in DEFAULTSECT in that order. If the key is not found and fallback is provided, it is used as a fallback value. None can be provided as a fallback value.

All the `%` interpolations are expanded in the return values, unless the raw argument is true. Values for interpolation keys are looked up in the same manner as the option.

*Changed in version 3.2:* Arguments raw, vars and fallback are keyword only to protect users from trying to use the third argument as the fallback fallback (especially when using the mapping protocol).

```python
getint(section, option, *, raw=False, vars=None[, fallback])
```

A convenience method which coerces the option in the specified section to an integer. See `get()` for explanation of raw, vars and fallback.
getfloat(section, option, *, raw=False, vars=None[, fallback])

A convenience method which coerces the option in the specified section to a floating point number. See get() for explanation of raw, vars and fallback.

getboolean(section, option, *, raw=False, vars=None[, fallback])

A convenience method which coerces the option in the specified section to a Boolean value. Note that the accepted values for the option are '1', 'yes', 'true', and 'on', which cause this method to return True, and '0', 'no', 'false', and 'off', which cause it to return False. These string values are checked in a case-insensitive manner. Any other value will cause it to raise ValueError. See get() for explanation of raw, vars and fallback.

items(raw=False, vars=None)

items(section, raw=False, vars=None)

When section is not given, return a list of section_name, section_proxy pairs, including DEFAULTSECT.

Otherwise, return a list of name, value pairs for the options in the given section. Optional arguments have the same meaning as for the get() method.

Changed in version 3.2: Items present in vars no longer appear in the result. The previous behaviour mixed actual parser options with variables provided for interpolation.

set(section, option, value)

If the given section exists, set the given option to the specified
value; otherwise raise **NoSectionError**. option and value must be strings; if not, **TypeError** is raised.

**write**(fileobject, **space_around_delimiters**=True)
Write a representation of the configuration to the specified **file object**, which must be opened in text mode (accepting strings). This representation can be parsed by a future **read()** call. If **space_around_delimiters** is true, delimiters between keys and values are surrounded by spaces.

**remove_option**(section, option)
Remove the specified option from the specified section. If the section does not exist, raise **NoSectionError**. If the option existed to be removed, return **True**; otherwise return **False**.

**remove_section**(section)
Remove the specified section from the configuration. If the section in fact existed, return **True**. Otherwise return **False**.

**optionxform**(option)
Transforms the option name option as found in an input file or as passed in by client code to the form that should be used in the internal structures. The default implementation returns a lower-case version of option; subclasses may override this or client code can set an attribute of this name on instances to affect this behavior.

You don’t need to subclass the parser to use this method, you can also set it on an instance, to a function that takes a string argument and returns a string. Setting it to **str**, for example, would make option names case sensitive:
cfgparser = ConfigParser()
cfgparser.optionxform = str

Note that when reading configuration files, whitespace around the option names is stripped before `optionxform()` is called.

**readfp**(fp, filename=None)

*Deprecated since version 3.2: Use `read_file()` instead.*

*Changed in version 3.2: `readfp()` now iterates on `f` instead of calling `f.readline()`.*

For existing code calling `readfp()` with arguments which don’t support iteration, the following generator may be used as a wrapper around the file-like object:

```python
def readline_generator(f):
    line = f.readline()
    while line:
        yield line
        line = f.readline()
```

Instead of `parser.readfp(f)` use `parser.read_file(readline_generator(f))`.

**configparser.MAX_INTERPOLATION_DEPTH**

The maximum depth for recursive interpolation for `get()` when the `raw` parameter is false. This is relevant only when the default `interpolation` is used.
14.2.10. RawConfigParser Objects

```python
class configparser.RawConfigParser(defaults=None,
   dict_type=collections.OrderedDict, allow_no_value=False, *,
   delimiters=('=', ':'), comment_prefixes=('#', ';'),
   inline_comment_prefixes=None, strict=True,
   empty_lines_in_values=True,
   default_section=configparser.DEFAULTSECT[ , interpolation])
```

Legacy variant of the `ConfigParser` with interpolation disabled by default and unsafe `add_section` and `set` methods.

**Note:** Consider using `ConfigParser` instead which checks types of the values to be stored internally. If you don't want interpolation, you can use `ConfigParser(interpolation=None)`.

**add_section**(`section`)

Add a section named `section` to the instance. If a section by the given name already exists, `DuplicateSectionError` is raised. If the `default section` name is passed, `ValueError` is raised.

Type of `section` is not checked which lets users create non-string named sections. This behaviour is unsupported and may cause internal errors.

**set**(`section`, `option`, `value`)

If the given section exists, set the given option to the specified value; otherwise raise `NoSectionError`. While it is possible to use `RawConfigParser` (or `ConfigParser` with `raw` parameters set to true) for *internal* storage of non-string values,
full functionality (including interpolation and output to files) can only be achieved using string values.

This method lets users assign non-string values to keys internally. This behaviour is unsupported and will cause errors when attempting to write to a file or get it in non-raw mode. **Use the mapping protocol API** which does not allow such assignments to take place.
14.2.11. Exceptions

`exception configparser.Error`
Base class for all other `configparser` exceptions.

`exception configparser.NoSectionError`
Exception raised when a specified section is not found.

`exception configparser.DuplicateSectionError`
Exception raised if `add_section()` is called with the name of a section that is already present or in strict parsers when a section if found more than once in a single input file, string or dictionary.

*New in version 3.2:* Optional `source` and `lineno` attributes and arguments to `__init__()` were added.

`exception configparser.DuplicateOptionError`
Exception raised by strict parsers if a single option appears twice during reading from a single file, string or dictionary. This catches misspellings and case sensitivity-related errors, e.g. a dictionary may have two keys representing the same case-insensitive configuration key.

`exception configparser.NoOptionError`
Exception raised when a specified option is not found in the specified section.

`exception configparser.InterpolationError`
Base class for exceptions raised when problems occur performing string interpolation.

`exception configparser.InterpolationDepthError`
Exception raised when string interpolation cannot be completed because the number of iterations exceeds `MAX_INTERPOLATION_DEPTH`. Subclass of `InterpolationError`.

```
exception configparser. InterpolationMissingOptionError
    Exception raised when an option referenced from a value does not exist. Subclass of `InterpolationError`.
```

```
exception configparser. InterpolationSyntaxError
    Exception raised when the source text into which substitutions are made does not conform to the required syntax. Subclass of `InterpolationError`.
```

```
exception configparser. MissingSectionHeaderError
    Exception raised when attempting to parse a file which has no section headers.
```

```
exception configparser. ParsingError
    Exception raised when errors occur attempting to parse a file.

    Changed in version 3.2: The `filename` attribute and `__init__()` argument were renamed to `source` for consistency.
```

Footnotes

[1] Config parsers allow for heavy customization. If you are interested in changing the behaviour outlined by the footnote reference, consult the Customizing Parser Behaviour section.

```
14.3. **netrc** — netrc file processing

**Source code:** [Lib/netrc.py](Lib/netrc.py)

The `netrc` class parses and encapsulates the netrc file format used by the Unix `ftp` program and other FTP clients.

```python
class netrc
```

A `netrc` instance or subclass instance encapsulates data from a netrc file. The initialization argument, if present, specifies the file to parse. If no argument is given, the file `.netrc` in the user’s home directory will be read. Parse errors will raise `NetrcParseError` with diagnostic information including the file name, line number, and terminating token. If no argument is specified on a POSIX system, the presence of passwords in the `.netrc` file will raise a `NetrcParseError` if the file ownership or permissions are insecure (owned by a user other than the user running the process, or accessible for read or write by any other user). This implements security behavior equivalent to that of `ftp` and other programs that use `.netrc`.

*Changed in version 3.3.3:* Added the POSIX permission check.

```python
exception NetrcParseError
```

Exception raised by the `netrc` class when syntactical errors are encountered in source text. Instances of this exception provide three interesting attributes: `msg` is a textual explanation of the error, `filename` is the name of the source file, and `lineno` gives
the line number on which the error was found.
14.3.1. netrc Objects

A netrc instance has the following methods:

netrc.authenticateators(host)

Return a 3-tuple (login, account, password) of authenticators for host. If the netrc file did not contain an entry for the given host, return the tuple associated with the 'default' entry. If neither matching host nor default entry is available, return None.

netrc.__repr__()

Dump the class data as a string in the format of a netrc file. (This discards comments and may reorder the entries.)

Instances of netrc have public instance variables:

netrc.hosts

Dictionary mapping host names to (login, account, password) tuples. The 'default' entry, if any, is represented as a pseudo-host by that name.

netrc.macros

Dictionary mapping macro names to string lists.

Note: Passwords are limited to a subset of the ASCII character set. All ASCII punctuation is allowed in passwords, however, note that whitespace and non-printable characters are not allowed in passwords. This is a limitation of the way the .netrc file is parsed and may be removed in the future.
14.4. `xdrlib` — Encode and decode XDR data

Source code: Lib/xdrlib.py

The `xdrlib` module supports the External Data Representation Standard as described in [RFC 1014](https://tools.ietf.org/html/rfc1014), written by Sun Microsystems, Inc. June 1987. It supports most of the data types described in the RFC.

The `xdrlib` module defines two classes, one for packing variables into XDR representation, and another for unpacking from XDR representation. There are also two exception classes.

```python
class xdrlib.Packer
    Packer is the class for packing data into XDR representation. The Packer class is instantiated with no arguments.

class xdrlib.Unpacker(data)
    Unpacker is the complementary class which unpacks XDR data values from a string buffer. The input buffer is given as data.
```

See also:

This RFC defined the encoding of data which was XDR at the time this module was originally written. It has apparently been obsoleted by [RFC 1832](https://tools.ietf.org/html/rfc1832).

Newer RFC that provides a revised definition of XDR.
14.4.1. Packer Objects

Packer instances have the following methods:

Packer.get_buffer()

Returns the current pack buffer as a string.

Packer.reset()

Resets the pack buffer to the empty string.

In general, you can pack any of the most common XDR data types by calling the appropriate pack_type() method. Each method takes a single argument, the value to pack. The following simple data type packing methods are supported: pack_uint(), pack_int(), pack_enum(), pack_bool(), pack_uhyper(), and pack_hyper().

Packer.pack_float(value)

Packs the single-precision floating point number value.

Packer.pack_double(value)

Packs the double-precision floating point number value.

The following methods support packing strings, bytes, and opaque data:

Packer.pack_fstring(n, s)

Packs a fixed length string, s. n is the length of the string but it is not packed into the data buffer. The string is padded with null bytes if necessary to guaranteed 4 byte alignment.

Packer.pack_fopaque(n, data)
Packs a fixed length opaque data stream, similarly to `pack_fstring()`.

**Packer.** `pack_string(s)`

Packs a variable length string, `s`. The length of the string is first packed as an unsigned integer, then the string data is packed with `pack_fstring()`.

**Packer.** `pack_opaque(data)`

Packs a variable length opaque data string, similarly to `pack_string()`.

**Packer.** `pack_bytes(bytes)`

Packs a variable length byte stream, similarly to `pack_string()`.

The following methods support packing arrays and lists:

**Packer.** `pack_list(list, pack_item)`

Packs a list of homogeneous items. This method is useful for lists with an indeterminate size; i.e. the size is not available until the entire list has been walked. For each item in the list, an unsigned integer 1 is packed first, followed by the data value from the list. `pack_item` is the function that is called to pack the individual item. At the end of the list, an unsigned integer 0 is packed.

For example, to pack a list of integers, the code might appear like this:

```python
import xdrlib
p = xdrlib.Packer()
p.pack_list([1, 2, 3], p.pack_int)
```

**Packer.** `pack_farray(n, array, pack_item)`
Packs a fixed length list (array) of homogeneous items. $n$ is the length of the list; it is not packed into the buffer, but a ValueError exception is raised if $\text{len(array)}$ is not equal to $n$. As above, $\text{pack_item}$ is the function used to pack each element.

Packer. \texttt{pack\_array}(list, \texttt{pack\_item})

Packs a variable length list of homogeneous items. First, the length of the list is packed as an unsigned integer, then each element is packed as in \texttt{pack\_farray()} above.
14.4.2. Unpacker Objects

The `Unpacker` class offers the following methods:

Unpacker. `reset(data)`

Resets the string buffer with the given `data`.

Unpacker. `get_position()`

Returns the current unpack position in the data buffer.

Unpacker. `set_position(position)`

Sets the data buffer unpack position to `position`. You should be careful about using `get_position()` and `set_position()`.

Unpacker. `get_buffer()`

Returns the current unpack data buffer as a string.

Unpacker. `done()`

Indicates unpack completion. Raises an `Error` exception if all of the data has not been unpacked.

In addition, every data type that can be packed with a `Packer`, can be unpacked with an `Unpacker`. Unpacking methods are of the form `unpack_type()`, and take no arguments. They return the unpacked object.

Unpacker. `unpack_float()`

Unpacks a single-precision floating point number.

Unpacker. `unpack_double()`

Unpacks a double-precision floating point number, similarly to `unpack_float()`.
In addition, the following methods unpack strings, bytes, and opaque data:

Unpacker. `unpack_fstring(n)`
Unpacks and returns a fixed length string. \( n \) is the number of characters expected. Padding with null bytes to guaranteed 4 byte alignment is assumed.

Unpacker. `unpack_fopaque(n)`
Unpacks and returns a fixed length opaque data stream, similarly to `unpack_fstring()`.

Unpacker. `unpack_string()`
Unpacks and returns a variable length string. The length of the string is first unpacked as an unsigned integer, then the string data is unpacked with `unpack_fstring()`.

Unpacker. `unpack_opaque()`
Unpacks and returns a variable length opaque data string, similarly to `unpack_string()`.

Unpacker. `unpack_bytes()`
Unpacks and returns a variable length byte stream, similarly to `unpack_string()`.

The following methods support unpacking arrays and lists:

Unpacker. `unpack_list(unpack_item)`
Unpacks and returns a list of homogeneous items. The list is unpacked one element at a time by first unpacking an unsigned integer flag. If the flag is 1, then the item is unpacked and appended to the list. A flag of 0 indicates the end of the list.
unpack_item is the function that is called to unpack the items.

Unpacker. **unpack_farray**(n, unpack_item)

Unpacks and returns (as a list) a fixed length array of homogeneous items. n is number of list elements to expect in the buffer. As above, unpack_item is the function used to unpack each element.

Unpacker. **unpack_array**(unpack_item)

Unpacks and returns a variable length list of homogeneous items. First, the length of the list is unpacked as an unsigned integer, then each element is unpacked as in unpack_farray() above.
14.4.3. Exceptions

Exceptions in this module are coded as class instances:

```
exception xdrlib.Error
    The base exception class. Error has a single public attribute msg containing the description of the error.
```

```
exception xdrlib.ConversionError
    Class derived from Error. Contains no additional instance variables.
```

Here is an example of how you would catch one of these exceptions:

```
import xdrlib
p = xdrlib.Packer()
try:
    p.pack_double(8.01)
except xdrlib.ConversionError as instance:
    print('packing the double failed:', instance.msg)
```
This module provides an interface for reading and writing the “property list” XML files used mainly by Mac OS X.

The property list (.plist) file format is a simple XML pickle supporting basic object types, like dictionaries, lists, numbers and strings. Usually the top level object is a dictionary.

To write out and to parse a plist file, use the writePlist() and readPlist() functions.

To work with plist data in bytes objects, use writePlistToBytes() and readPlistFromBytes().

Values can be strings, integers, floats, booleans, tuples, lists, dictionaries (but only with string keys), Data or datetime.datetime objects. String values (including dictionary keys) have to be unicode strings – they will be written out as UTF-8.

The <data> plist type is supported through the Data class. This is a thin wrapper around a Python bytes object. Use Data if your strings contain control characters.

See also:

PList manual page
This module defines the following functions:

**plistlib.\textbf{readPlist}(pathOrFile)**

Read a plist file. \textit{pathOrFile} may either be a file name or a (readable and binary) file object. Return the unpacked root object (which usually is a dictionary).

The XML data is parsed using the Expat parser from \texttt{xml.parsers.expat} – see its documentation for possible exceptions on ill-formed XML. Unknown elements will simply be ignored by the plist parser.

**plistlib.\textbf{writePlist}(rootObject, pathOrFile)**

Write \textit{rootObject} to a plist file. \textit{pathOrFile} may either be a file name or a (writable and binary) file object.

A \texttt{TypeError} will be raised if the object is of an unsupported type or a container that contains objects of unsupported types.

**plistlib.\textbf{readPlistFromBytes}(data)**

Read a plist data from a bytes object. Return the root object.

**plistlib.\textbf{writePlistToBytes}(rootObject)**

Return \textit{rootObject} as a plist-formatted bytes object.

The following class is available:

**class plistlib.\textbf{Data}(data)**

Return a “data” wrapper object around the bytes object \textit{data}. This is used in functions converting from/to plists to represent the <data> type available in plists.
It has one attribute, `data`, that can be used to retrieve the Python bytes object stored in it.
14.5.1. Examples

Generating a plist:

```python
pl = dict(
    aString = "Doodah",
    aList = ["A", "B", 12, 32.1, [1, 2, 3]],
    aFloat = 0.1,
    anInt = 728,
    aDict = dict(
        anotherString = "<hello & hi there!>",
        aThirdString = "M\xe4ssig, Ma\xdf",
        aTrueValue = True,
        aFalseValue = False,
    ),
    someData = Data(b"<binary gunk>"),
    someMoreData = Data(b"<lots of binary gunk>" * 1)
)
writePlist(pl, fileName)
```

Parsing a plist:

```python
pl = readPlist(pathOrFile)
print(pl["aKey"])
```
15. Cryptographic Services

The modules described in this chapter implement various algorithms of a cryptographic nature. They are available at the discretion of the installation. On Unix systems, the `crypt` module may also be available. Here's an overview:

- **15.1. hashlib** — Secure hashes and message digests
- **15.2. hmac** — Keyed-Hashing for Message Authentication

Hardcore cypherpunks will probably find the cryptographic modules written by A.M. Kuchling of further interest; the package contains modules for various encryption algorithms, most notably AES. These modules are not distributed with Python but available separately. See the URL [http://www.pycrypto.org](http://www.pycrypto.org) for more information.
15.1. hashlib — Secure hashes and message digests

Source code: Lib/hashlib.py

This module implements a common interface to many different secure hash and message digest algorithms. Included are the FIPS secure hash algorithms SHA1, SHA224, SHA256, SHA384, and SHA512 (defined in FIPS 180-2) as well as RSA’s MD5 algorithm (defined in Internet RFC 1321). The terms “secure hash” and “message digest” are interchangeable. Older algorithms were called message digests. The modern term is secure hash.

Note: If you want the adler32 or crc32 hash functions, they are available in the zlib module.

Warning: Some algorithms have known hash collision weaknesses, refer to the “See also” section at the end.

There is one constructor method named for each type of hash. All return a hash object with the same simple interface. For example: use sha1() to create a SHA1 hash object. You can now feed this object with bytes-like objects (normally bytes) using the update() method. At any point you can ask it for the digest of the concatenation of the data fed to it so far using the digest() or hexdigest() methods.

Note: For better multithreading performance, the Python GIL is released for data larger than 2047 bytes at object creation or on update.
Note: Feeding string objects into update() is not supported, as hashes work on bytes, not on characters.

Constructors for hash algorithms that are always present in this module are md5(), sha1(), sha224(), sha256(), sha384(), and sha512(). Additional algorithms may also be available depending upon the OpenSSL library that Python uses on your platform.

For example, to obtain the digest of the byte string b'Nobody inspects the spammish repetition':

```python
>>> import hashlib
>>> m = hashlib.md5()
>>> m.update(b"Nobody inspects")
>>> m.update(b" the spammish repetition")
>>> m.digest()
b'\xbbd\x9c\x83\xdd\xa5\xda9\xce\xa1\xe9'
>>> m.digest_size
16
>>> m.block_size
64
```

More condensed:

```python
>>> hashlib.sha224(b"Nobody inspects the spammish repetition")
'\xa4\x33\xda5\xe8\xad\x4c\x03\xe5\xd6\x8e\xe7\xb1\x8b\x97\xeb\x0e\x88\x0d\x79\x7a
```

hashlib.new(name[, data])

Is a generic constructor that takes the string name of the desired algorithm as its first parameter. It also exists to allow access to the above listed hashes as well as any other algorithms that your OpenSSL library may offer. The named constructors are much
faster than `new()` and should be preferred.

Using `new()` with an algorithm provided by OpenSSL:

```python
>>> h = hashlib.new('ripemd160')
>>> h.update(b"Nobody inspects the spammish repetition")
>>> h.hexdigest()
'cc4a5ce1b3df48aec5d22d1f22d1f616b894a0b894eccc'
```

Hashlib provides the following constant attributes:

**hashlib.**`algorithms_guaranteed`  
Contains the names of the hash algorithms guaranteed to be supported by this module on all platforms.

*New in version 3.2.*

**hashlib.**`algorithms_available`  
Contains the names of the hash algorithms that are available in the running Python interpreter. These names will be recognized when passed to `new()` . `algorithms_guaranteed` will always be a subset. Duplicate algorithms with different name formats may appear in this set (thanks to OpenSSL).

*New in version 3.2.*

The following values are provided as constant attributes of the hash objects returned by the constructors:

**hash.**`digest_size`  
The size of the resulting hash in bytes.

**hash.**`block_size`  
The internal block size of the hash algorithm in bytes.
A hash object has the following methods:

hash.update(arg)

Update the hash object with the object arg, which must be interpretable as a buffer of bytes. Repeated calls are equivalent to a single call with the concatenation of all the arguments: m.update(a); m.update(b) is equivalent to m.update(a+b).

Changed in version 3.1: The Python GIL is released to allow other threads to run while hash updates on data larger than 2047 bytes is taking place when using hash algorithms supplied by OpenSSL.

hash.digest()

Return the digest of the data passed to the update() method so far. This is a bytes object of size digest_size which may contain bytes in the whole range from 0 to 255.

hash.hexdigest()

Like digest() except the digest is returned as a string object of double length, containing only hexadecimal digits. This may be used to exchange the value safely in email or other non-binary environments.

hash.copy()

Return a copy (“clone”) of the hash object. This can be used to efficiently compute the digests of data sharing a common initial substring.

Module hmac

A module to generate message authentication codes using
hashes.

**Module base64**

Another way to encode binary hashes for non-binary environments.

The FIPS 180-2 publication on Secure Hash Algorithms.

Wikipedia article with information on which algorithms have known issues and what that means regarding their use.
15.2. hmac — Keyed-Hashing for Message Authentication

Source code: Lib/hmac.py

This module implements the HMAC algorithm as described by RFC 2104.

hmac.new(key, msg=None, digestmod=None)

Return a new hmac object. key is a bytes object giving the secret key. If msg is present, the method call update(msg) is made. digestmod is the digest constructor or module for the HMAC object to use. It defaults to the hashlib.md5 constructor.

An HMAC object has the following methods:

HMAC.update(msg)

Update the hmac object with the bytes object msg. Repeated calls are equivalent to a single call with the concatenation of all the arguments: m.update(a); m.update(b) is equivalent to m.update(a + b).

HMAC.digest()

Return the digest of the bytes passed to the update() method so far. This bytes object will be the same length as the digest_size of the digest given to the constructor. It may contain non-ASCII bytes, including NUL bytes.

Warning: When comparing the output of digest() to an
externally-supplied digest during a verification routine, it is recommended to use the `compare_digest()` function instead of the `==` operator to reduce the vulnerability to timing attacks.

**HMAC.hexdigest()**

Like `digest()` except the digest is returned as a string twice the length containing only hexadecimal digits. This may be used to exchange the value safely in email or other non-binary environments.

**Warning:** When comparing the output of `hexdigest()` to an externally-supplied digest during a verification routine, it is recommended to use the `compare_digest()` function instead of the `==` operator to reduce the vulnerability to timing attacks.

**HMAC.copy()**

Return a copy (“clone”) of the hmac object. This can be used to efficiently compute the digests of strings that share a common initial substring.

This module also provides the following helper function:

**hmac.compare_digest(a, b)**

Return `a == b`. This function uses an approach designed to prevent timing analysis by avoiding content-based short circuiting behaviour, making it appropriate for cryptography. `a` and `b` must both be of the same type: either `str` (ASCII only, as e.g. returned by `HMAC.hexdigest()`), or a `bytes-like object`.

**Note:** If `a` and `b` are of different lengths, or if an error occurs, a timing attack could theoretically reveal information about the
types and lengths of $a$ and $b$—but not their values.

*New in version 3.3.*

16. Generic Operating System Services

The modules described in this chapter provide interfaces to operating system features that are available on (almost) all operating systems, such as files and a clock. The interfaces are generally modeled after the Unix or C interfaces, but they are available on most other systems as well. Here’s an overview:

- **16.1. os — Miscellaneous operating system interfaces**
  - 16.1.1. File Names, Command Line Arguments, and Environment Variables
  - 16.1.2. Process Parameters
  - 16.1.3. File Object Creation
  - 16.1.4. File Descriptor Operations
    - 16.1.4.1. open() flag constants
    - 16.1.4.2. Querying the size of a terminal
  - 16.1.5. Files and Directories
    - 16.1.5.1. Linux extended attributes
  - 16.1.6. Process Management
  - 16.1.7. Interface to the scheduler
  - 16.1.8. Miscellaneous System Information
  - 16.1.9. Miscellaneous Functions
- **16.2. io — Core tools for working with streams**
  - 16.2.1. Overview
    - 16.2.1.1. Text I/O
    - 16.2.1.2. Binary I/O
    - 16.2.1.3. Raw I/O
  - 16.2.2. High-level Module Interface
    - 16.2.2.1. In-memory streams
  - 16.2.3. Class hierarchy
16.2.3.1. I/O Base Classes
16.2.3.2. Raw File I/O
16.2.3.3. Buffered Streams
16.2.3.4. Text I/O

16.2.4. Performance
16.2.4.1. Binary I/O
16.2.4.2. Text I/O
16.2.4.3. Multi-threading
16.2.4.4. Reentrancy

16.3. time — Time access and conversions

16.1. os — Miscellaneous operating system interfaces

This module provides a portable way of using operating system dependent functionality. If you just want to read or write a file see `open()`, if you want to manipulate paths, see the `os.path` module, and if you want to read all the lines in all the files on the command line see the `fileinput` module. For creating temporary files and directories see the `tempfile` module, and for high-level file and directory handling see the `shutil` module.

Notes on the availability of these functions:

- The design of all built-in operating system dependent modules of Python is such that as long as the same functionality is available, it uses the same interface; for example, the function `os.stat(path)` returns stat information about `path` in the same format (which happens to have originated with the POSIX interface).
- Extensions peculiar to a particular operating system are also available through the `os` module, but using them is of course a threat to portability.
- All functions accepting path or file names accept both bytes and string objects, and result in an object of the same type, if a path or file name is returned.
- An “Availability: Unix” note means that this function is commonly found on Unix systems. It does not make any claims about its existence on a specific operating system.
- If not separately noted, all functions that claim “Availability: Unix” are supported on Mac OS X, which builds on a Unix core.
Note: All functions in this module raise **OSError** in the case of invalid or inaccessible file names and paths, or other arguments that have the correct type, but are not accepted by the operating system.

```python
exception os.error
    An alias for the built-in OSError exception.
```

```python
os.name
    The name of the operating system dependent module imported. The following names have currently been registered: "posix", "nt", "mac", "os2", "ce", "java".
```

See also: **sys.platform** has a finer granularity. **os.uname()** gives system-dependent version information. The **platform** module provides detailed checks for the system's identity.
16.1.1. File Names, Command Line Arguments, and Environment Variables

In Python, file names, command line arguments, and environment variables are represented using the string type. On some systems, decoding these strings to and from bytes is necessary before passing them to the operating system. Python uses the file system encoding to perform this conversion (see `sys.getfilesystemencoding()`).

*Changed in version 3.1:* On some systems, conversion using the file system encoding may fail. In this case, Python uses the `surrogateescape` encoding error handler, which means that undecodable bytes are replaced by a Unicode character U+DCxx on decoding, and these are again translated to the original byte on encoding.

The file system encoding must guarantee to successfully decode all bytes below 128. If the file system encoding fails to provide this guarantee, API functions may raise UnicodeErrors.
16.1.2. Process Parameters

These functions and data items provide information and operate on the current process and user.

**os.ctermid()**

Return the filename corresponding to the controlling terminal of the process.

Availability: Unix.

**os.environ**

A *mapping* object representing the string environment. For example, `environ['HOME']` is the pathname of your home directory (on some platforms), and is equivalent to `getenv("HOME")` in C.

This mapping is captured the first time the `os` module is imported, typically during Python startup as part of processing `site.py`. Changes to the environment made after this time are not reflected in `os.environ`, except for changes made by modifying `os.environ` directly.

If the platform supports the `putenv()` function, this mapping may be used to modify the environment as well as query the environment. `putenv()` will be called automatically when the mapping is modified.

On Unix, keys and values use `sys.getfilesystemencoding()` and 'surrogateescape' error handler. Use `environb` if you would like to use a different encoding.
Note: Calling `putenv()` directly does not change `os.environ`, so it's better to modify `os.environ`.

Note: On some platforms, including FreeBSD and Mac OS X, setting `environ` may cause memory leaks. Refer to the system documentation for `putenv()`.

If `putenv()` is not provided, a modified copy of this mapping may be passed to the appropriate process-creation functions to cause child processes to use a modified environment.

If the platform supports the `unsetenv()` function, you can delete items in this mapping to unset environment variables. `unsetenv()` will be called automatically when an item is deleted from `os.environ`, and when one of the `pop()` or `clear()` methods is called.

`os.environb` Bytes version of `environ`: a `mapping` object representing the environment as byte strings. `environ` and `environb` are synchronized (modify `environb` updates `environ`, and vice versa).

`environb` is only available if `supports_bytes_environ` is True.

*New in version 3.2.*

`os.chdir(path)`
`os.fchdir(fd)`
`os.getcwdb()`

These functions are described in *Files and Directories*.
os. **fsencode**(filename)

Encode filename to the filesystem encoding with 'surrogateescape' error handler, or 'strict' on Windows; return bytes unchanged.

**fsdecode()** is the reverse function.

New in version 3.2.

os. **fsdecode**(filename)

Decode filename from the filesystem encoding with 'surrogateescape' error handler, or 'strict' on Windows; return str unchanged.

**fsencode()** is the reverse function.

New in version 3.2.

os. **getenv**(key, default=None)

Return the value of the environment variable key if it exists, or default if it doesn't. key, default and the result are str.

On Unix, keys and values are decoded with `sys.getfilesystemencoding()` and 'surrogateescape' error handler. Use **os.getenvb()** if you would like to use a different encoding.

Availability: most flavors of Unix, Windows.

os. **getenvb**(key, default=None)

Return the value of the environment variable key if it exists, or default if it doesn't. key, default and the result are bytes.
Availability: most flavors of Unix.

New in version 3.2.

**os.get_exec_path(env=None)**
Returns the list of directories that will be searched for a named executable, similar to a shell, when launching a process. `env`, when specified, should be an environment variable dictionary to lookup the PATH in. By default, when `env` is None, environ is used.

New in version 3.2.

**os.getegid()**
Return the effective group id of the current process. This corresponds to the “set id” bit on the file being executed in the current process.

Availability: Unix.

**os.geteuid()**
Return the current process’s effective user id.

Availability: Unix.

**os.getgid()**
Return the real group id of the current process.

Availability: Unix.

**os.getgrouplist(user, group)**
Return list of group ids that `user` belongs to. If `group` is not in the list, it is included; typically, `group` is specified as the group ID field from the password record for `user`.
Availability: Unix.

New in version 3.3.

**os.getgroups()**

Return list of supplemental group ids associated with the current process.

Availability: Unix.

**Warning:** On Mac OS X, `getgroups()` behavior differs somewhat from other Unix platforms. If the Python interpreter was built with a deployment target of 10.5 or earlier, `getgroups()` returns the list of effective group ids associated with the current user process; this list is limited to a system-defined number of entries, typically 16, and may be modified by calls to `setgroups()` if suitably privileged. If built with a deployment target greater than 10.5, `getgroups()` returns the current group access list for the user associated with the effective user id of the process; the group access list may change over the lifetime of the process, it is not affected by calls to `setgroups()`, and its length is not limited to 16. The deployment target value, `MACOSX_DEPLOYMENT_TARGET`, can be obtained with `sysconfig.get_config_var()`.

**os.getlogin()**

Return the name of the user logged in on the controlling terminal of the process. For most purposes, it is more useful to use the environment variables LOGNAME or USERNAME to find out who the user is, or `pwd.getpwuid(os.getuid())[0]` to get the login name of the currently effective user id.
Availability: Unix, Windows.

**os.getpgid(pid)**

Return the process group id of the process with process id \textit{pid}. If \textit{pid} is 0, the process group id of the current process is returned.

Availability: Unix.

**os.getpgrp()**

Return the id of the current process group.

Availability: Unix.

**os.getpid()**

Return the current process id.

Availability: Unix, Windows.

**os.getppid()**

Return the parent's process id. When the parent process has exited, on Unix the id returned is the one of the init process (1), on Windows it is still the same id, which may be already reused by another process.

Availability: Unix, Windows.

*Changed in version 3.2: Added support for Windows.*

**os.getpriority\((which, who)\)**

Get program scheduling priority. The value \textit{which} is one of \texttt{PRI0\_PROCESS}, \texttt{PRI0\_PGRP}, or \texttt{PRI0\_USER}, and \textit{who} is interpreted relative to \textit{which} (a process identifier for \texttt{PRI0\_PROCESS}, process group identifier for \texttt{PRI0\_PGRP}, and a user ID for \texttt{PRI0\_USER}). A zero value for \textit{who} denotes
(respectively) the calling process, the process group of the calling process, or the real user ID of the calling process.

Availability: Unix.

*New in version 3.3.*

```python
os.PRIOR_PROCESS
os.PRIOR_PGRP
os.PRIOR_USER
```

Parameters for the `getpriority()` and `setpriority()` functions.

Availability: Unix.

*New in version 3.3.*

```python
os.getresuid()
```

Return a tuple (ruid, euid, suid) denoting the current process’s real, effective, and saved user ids.

Availability: Unix.

*New in version 3.2.*

```python
os.getresgid()
```

Return a tuple (rgid, egid, sgid) denoting the current process’s real, effective, and saved group ids.

Availability: Unix.

*New in version 3.2.*

```python
os.getuid()
```

Return the current process’s user id.
Availability: Unix.

**os.initgroups(username, gid)**

Call the system initgroups() to initialize the group access list with all of the groups of which the specified username is a member, plus the specified group id.

Availability: Unix.

*New in version 3.2.*

**os.putenv(key, value)**

Set the environment variable named key to the string value. Such changes to the environment affect subprocesses started with `os.system()`, `popen()` or `fork()` and `execv()`.

Availability: most flavors of Unix, Windows.

**Note:** On some platforms, including FreeBSD and Mac OS X, setting `environ` may cause memory leaks. Refer to the system documentation for `putenv`.

When `putenv()` is supported, assignments to items in `os.environ` are automatically translated into corresponding calls to `putenv()`; however, calls to `putenv()` don’t update `os.environ`, so it is actually preferable to assign to items of `os.environ`.

**os.setegid(egid)**

Set the current process’s effective group id.

Availability: Unix.
os. **seteuid**(*euid*)
Set the current process's effective user id.

Availability: Unix.

os. **setgid**(*gid*)
Set the current process' group id.

Availability: Unix.

os. **setgroups**(*groups*)
Set the list of supplemental group ids associated with the current process to *groups*. *groups* must be a sequence, and each element must be an integer identifying a group. This operation is typically available only to the superuser.

Availability: Unix.

**Note:** On Mac OS X, the length of *groups* may not exceed the system-defined maximum number of effective group ids, typically 16. See the documentation for **getgroups()** for cases where it may not return the same group list set by calling setgroups().

os. **setpgrp**()
Call the system call setpgrp() or setpgrp(0, 0) depending on which version is implemented (if any). See the Unix manual for the semantics.

Availability: Unix.

os. **setpgid**(*pid*, *pgrp*)
Call the system call setpgid() to set the process group id of the process with id *pid* to the process group with id *pgrp*. See the Unix
manual for the semantics.

Availability: Unix.

**os.setpriority**(*which, who, priority*)

Set program scheduling priority. The value *which* is one of **PRI0_PROCESS**, **PRI0_PGRP**, or **PRI0_USER**, and *who* is interpreted relative to *which* (a process identifier for **PRI0_PROCESS**, process group identifier for **PRI0_PGRP**, and a user ID for **PRI0_USER**). A zero value for *who* denotes (respectively) the calling process, the process group of the calling process, or the real user ID of the calling process. *priority* is a value in the range -20 to 19. The default priority is 0; lower priorities cause more favorable scheduling.

Availability: Unix

*New in version 3.3.*

**os.setregid**(*rgid, egid*)

Set the current process’s real and effective group ids.

Availability: Unix.

**os.setresgid**(*rgid, egid, sgid*)

Set the current process’s real, effective, and saved group ids.

Availability: Unix.

*New in version 3.2.*

**os.setresuid**(*ruid, euid, suid*)

Set the current process’s real, effective, and saved user ids.
Availability: Unix.

New in version 3.2.

**os.setreuid(ruid, euid)**
Set the current process’s real and effective user ids.

Availability: Unix.

**os.getsid(pid)**
Call the system call getsid(). See the Unix manual for the semantics.

Availability: Unix.

**os.setsid()**
Call the system call setsid(). See the Unix manual for the semantics.

Availability: Unix.

**os.setuid(uid)**
Set the current process’s user id.

Availability: Unix.

**os.strerror(code)**
Return the error message corresponding to the error code in `code`. On platforms where `strerror()` returns `NULL` when given an unknown error number, `ValueError` is raised.

Availability: Unix, Windows.

**os.supports_bytes_environ**
True if the native OS type of the environment is bytes (eg. False on Windows).

*New in version 3.2.*

**os.umask(mask)**

Set the current numeric umask and return the previous umask.

*Availability: Unix, Windows.*

**os.uname()**

Returns information identifying the current operating system. The return value is an object with five attributes:

- sysname - operating system name
- nodename - name of machine on network (implementation-defined)
- release - operating system release
- version - operating system version
- machine - hardware identifier

For backwards compatibility, this object is also iterable, behaving like a five-tuple containing sysname, nodename, release, version, and machine in that order.

Some systems truncate nodename to 8 characters or to the leading component; a better way to get the hostname is `socket.gethostname()` or even `socket.gethostbyaddr(socket.gethostname())`.

*Availability: recent flavors of Unix.*

*Changed in version 3.3:* Return type changed from a tuple to a tuple-like object with named attributes.
os.*unsetenv(key)*

Unset (delete) the environment variable named key. Such changes to the environment affect subprocesses started with os.system(), popen() or fork() and execv().

When unsetenv() is supported, deletion of items in os.environ is automatically translated into a corresponding call to unsetenv(); however, calls to unsetenv() don't update os.environ, so it is actually preferable to delete items of os.environ.

Availability: most flavors of Unix, Windows.
16.1.3. File Object Creation

This function creates new file objects. (See also open() for opening file descriptors.)

```python
os.fdopen(fd, *args, **kwargs)
```

Return an open file object connected to the file descriptor `fd`. This is an alias of the `open()` built-in function and accepts the same arguments. The only difference is that the first argument of `fdopen()` must always be an integer.
16.1.4. File Descriptor Operations

These functions operate on I/O streams referenced using file descriptors.

File descriptors are small integers corresponding to a file that has been opened by the current process. For example, standard input is usually file descriptor 0, standard output is 1, and standard error is 2. Further files opened by a process will then be assigned 3, 4, 5, and so forth. The name “file descriptor” is slightly deceptive; on Unix platforms, sockets and pipes are also referenced by file descriptors.

The `fileno()` method can be used to obtain the file descriptor associated with a `file object` when required. Note that using the file descriptor directly will bypass the file object methods, ignoring aspects such as internal buffering of data.

**os. close(fd)**

Close file descriptor `fd`.

Availability: Unix, Windows.

**Note:** This function is intended for low-level I/O and must be applied to a file descriptor as returned by `os.open()` or `pipe()`. To close a “file object” returned by the built-in function `open()` or by `popen()` or `fdopen()`, use its `close()` method.

**os. closerange(fd_low, fd_high)**

Close all file descriptors from `fd_low` (inclusive) to `fd_high` (exclusive), ignoring errors. Equivalent to (but much faster than):
```python
for fd in range(fd_low, fd_high):
    try:
        os.close(fd)
    except OSError:
        pass
```

Availability: Unix, Windows.

**os.device_encoding(fd)**

Return a string describing the encoding of the device associated with `fd` if it is connected to a terminal; else return None.

**os.dup(fd)**

Return a duplicate of file descriptor `fd`.

Availability: Unix, Windows.

**os.dup2(fd, fd2)**

Duplicate file descriptor `fd` to `fd2`, closing the latter first if necessary.

Availability: Unix, Windows.

**os.fchmod(fd, mode)**

Change the mode of the file given by `fd` to the numeric `mode`. See the docs for `chmod()` for possible values of `mode`. As of Python 3.3, this is equivalent to `os.chmod(fd, mode)`.

Availability: Unix.

**os.fchown(fd, uid, gid)**

Change the owner and group id of the file given by `fd` to the numeric `uid` and `gid`. To leave one of the ids unchanged, set it to -1. See `chown()`. As of Python 3.3, this is equivalent to `os.chown(fd, uid, gid)`. 
Availability: Unix.

**os.fdatasync**(fd)

Force write of file with file descriptor *fd* to disk. Does not force update of metadata.

Availability: Unix.

**Note:** This function is not available on MacOS.

**os.fpathconf**(fd, name)

Return system configuration information relevant to an open file. *name* specifies the configuration value to retrieve; it may be a string which is the name of a defined system value; these names are specified in a number of standards (POSIX.1, Unix 95, Unix 98, and others). Some platforms define additional names as well. The names known to the host operating system are given in the `pathconf_names` dictionary. For configuration variables not included in that mapping, passing an integer for *name* is also accepted.

If *name* is a string and is not known, `ValueError` is raised. If a specific value for *name* is not supported by the host system, even if it is included in `pathconf_names`, an `OSError` is raised with `errno.EINVAL` for the error number.

As of Python 3.3, this is equivalent to `os.pathconf(fd, name)`.

Availability: Unix.

**os.fstat**(fd)

Return status for file descriptor *fd*, like `stat()`. As of Python 3.3,
this is equivalent to `os.stat(fd)`.

Availability: Unix, Windows.

**os. `fstatvfs(fd)`**

Return information about the filesystem containing the file associated with file descriptor `fd`, like `statvfs()`. As of Python 3.3, this is equivalent to `os.statvfs(fd)`.

Availability: Unix.

**os. `fsync(fd)`**

Force write of file with file descriptor `fd` to disk. On Unix, this calls the native `fsync()` function; on Windows, the MS `_commit()` function.

If you’re starting with a buffered Python file object `f`, first do `f.flush()`, and then do `os.fsync(f.fileno())`, to ensure that all internal buffers associated with `f` are written to disk.

Availability: Unix, Windows.

**os. `ftruncate(fd, length)`**

Truncate the file corresponding to file descriptor `fd`, so that it is at most `length` bytes in size. As of Python 3.3, this is equivalent to `os.truncate(fd, length)`.

Availability: Unix.

**os. `isatty(fd)`**

Return `True` if the file descriptor `fd` is open and connected to a tty(-like) device, else `False`.
os. `lockf(fd, cmd, len)`

Apply, test or remove a POSIX lock on an open file descriptor. `fd` is an open file descriptor. `cmd` specifies the command to use - one of `F_LOCK`, `F_TLOCK`, `F_ULOCK` or `F_TEST`. `len` specifies the section of the file to lock.

Availability: Unix.

*New in version 3.3.*

---

os. `F_LOCK`

os. `F_TLOCK`

os. `F_ULOCK`

os. `F_TEST`

Flags that specify what action `lockf()` will take.

Availability: Unix.

*New in version 3.3.*

---

os. `lseek(fd, pos, how)`

Set the current position of file descriptor `fd` to position `pos`, modified by `how`: `SEEK_SET` or 0 to set the position relative to the beginning of the file; `SEEK_CUR` or 1 to set it relative to the current position; `SEEK_END` or 2 to set it relative to the end of the file. Return the new cursor position in bytes, starting from the beginning.

Availability: Unix, Windows.

os. `SEEK_SET`

os. `SEEK_CUR`

os. `SEEK_END`

Parameters to the `lseek()` function. Their values are 0, 1, and 2,
respectively.

Availability: Unix, Windows.

*New in version 3.3:* Some operating systems could support additional values, like `os.SEEK_HOLE` or `os.SEEK_DATA`.

**`os.open(file, flags, mode=0o777, *, dir_fd=None)`**

Open the file `file` and set various flags according to `flags` and possibly its mode according to `mode`. When computing `mode`, the current umask value is first masked out. Return the file descriptor for the newly opened file.

For a description of the flag and mode values, see the C run-time documentation; flag constants (like `O_RDONLY` and `O_WRONLY`) are defined in this module too (see `open()` flag constants). In particular, on Windows adding `O_BINARY` is needed to open files in binary mode.

This function can support *paths relative to directory descriptors*.

Availability: Unix, Windows.

**Note:** This function is intended for low-level I/O. For normal usage, use the built-in function `open()`, which returns a *file object* with `read()` and `write()` methods (and many more). To wrap a file descriptor in a file object, use `fdopen()`.

*New in version 3.3:* The `dir_fd` argument.

**`os.openpty()`**

Open a new pseudo-terminal pair. Return a pair of file descriptors (`master`, `slave`) for the pty and the tty, respectively. For a
(slightly) more portable approach, use the \texttt{pty} module.

Availability: some flavors of Unix.

\texttt{os.pipe()}

Create a pipe. Return a pair of file descriptors \((r, w)\) usable for reading and writing, respectively.

Availability: Unix, Windows.

\texttt{os.pipe2(flags)}

Create a pipe with \texttt{flags} set atomically. \texttt{flags} can be constructed by ORing together one or more of these values: \texttt{O_NONBLOCK}, \texttt{O_CLOEXEC}. Return a pair of file descriptors \((r, w)\) usable for reading and writing, respectively.

Availability: some flavors of Unix.

\textit{New in version 3.3.}

\texttt{os.posix_fallocate(fd, offset, len)}

Ensures that enough disk space is allocated for the file specified by \texttt{fd} starting from \texttt{offset} and continuing for \texttt{len} bytes.

Availability: Unix.

\textit{New in version 3.3.}

\texttt{os.posix_fadvise(fd, offset, len, advice)}

Announces an intention to access data in a specific pattern thus allowing the kernel to make optimizations. The advice applies to the region of the file specified by \texttt{fd} starting at \texttt{offset} and continuing for \texttt{len} bytes. \texttt{advice} is one of \texttt{POSIX_FADV_NORMAL}, \texttt{POSIX_FADV_SEQUENTIAL}, \texttt{POSIX_FADV_RANDOM},
POSIX_FADV_NOREUSE, POSIX_FADV_WILLNEED or POSIX_FADV_DONTNEED.

Availability: Unix.

New in version 3.3.

os.POSIX_FADV_NORMAL
os.POSIX_FADV_SEQUENTIAL
os.POSIX_FADV_RANDOM
os.POSIX_FADV_NOREUSE
os.POSIX_FADV_WILLNEED
os.POSIX_FADV_DONTNEED

Flags that can be used in advice in posix_fadvise() that specify the access pattern that is likely to be used.

Availability: Unix.

New in version 3.3.

os.pread(fd, buffersize, offset)
Read from a file descriptor, fd, at a position of offset. It will read up to buffersize number of bytes. The file offset remains unchanged.

Availability: Unix.

New in version 3.3.

os.pwrite(fd, string, offset)
Write string to a file descriptor, fd, from offset, leaving the file offset unchanged.

Availability: Unix.
New in version 3.3.

**os.read(fd, n)**

Read at most \( n \) bytes from file descriptor \( fd \). Return a bytestring containing the bytes read. If the end of the file referred to by \( fd \) has been reached, an empty bytestring object is returned.

**Availability:** Unix, Windows.

**Note:** This function is intended for low-level I/O and must be applied to a file descriptor as returned by `os.open()` or `pipe()`. To read a “file object” returned by the built-in function `open()` or by `popen()` or `fdopen()`, or `sys.stdin`, use its `read()` or `readline()` methods.

**os.sendfile(out, in, offset, nbytes)**

**os.sendfile(out, in, offset, nbytes, headers=None, trailers=None, flags=0)**

Copy \( n \) bytes from file descriptor \( in \) to file descriptor \( out \) starting at \( offset \). Return the number of bytes sent. When EOF is reached return 0.

The first function notation is supported by all platforms that define `sendfile()`.

On Linux, if \( offset \) is given as None, the bytes are read from the current position of \( in \) and the position of \( in \) is updated.

The second case may be used on Mac OS X and FreeBSD where `headers` and `trailers` are arbitrary sequences of buffers that are written before and after the data from \( in \) is written. It returns the same as the first case.
On Mac OS X and FreeBSD, a value of 0 for nbytes specifies to send until the end of in is reached.

All platforms support sockets as out file descriptor, and some platforms allow other types (e.g. regular file, pipe) as well.

Availability: Unix.

*New in version 3.3.*

**os.SF_NODISKIO**

**os.SF_MNOWAIT**

**os.SF_SYNC**

Parameters to the `sendfile()` function, if the implementation supports them.

Availability: Unix.

*New in version 3.3.*

**os.readv(fd, buffers)**

Read from a file descriptor into a number of writable buffers. `buffers` is an arbitrary sequence of writable buffers. Returns the total number of bytes read.

Availability: Unix.

*New in version 3.3.*

**os.tcgetpgrp(fd)**

Return the process group associated with the terminal given by `fd` (an open file descriptor as returned by `os.open()`).

Availability: Unix.
os. `tcsetpgrp(fd, pg)`

Set the process group associated with the terminal given by `fd` (an open file descriptor as returned by `os.open()` ) to `pg`.

Availability: Unix.

os. `ttyname(fd)`

Return a string which specifies the terminal device associated with file descriptor `fd`. If `fd` is not associated with a terminal device, an exception is raised.

Availability: Unix.

os. `write(fd, str)`

Write the bytestring in `str` to file descriptor `fd`. Return the number of bytes actually written.

Availability: Unix, Windows.

**Note:** This function is intended for low-level I/O and must be applied to a file descriptor as returned by `os.open()` or `pipe()`. To write a “file object” returned by the built-in function `open()` or by `popen()` or `fdopen()`, or `sys.stdout` or `sys.stderr`, use its `write()` method.

os. `writev(fd, buffers)`

Write the contents of `buffers` to file descriptor `fd`, where `buffers` is an arbitrary sequence of buffers. Returns the total number of bytes written.

Availability: Unix.

*New in version 3.3.*
16.1.4.1. open( ) flag constants

The following constants are options for the flags parameter to the open( ) function. They can be combined using the bitwise OR operator |. Some of them are not available on all platforms. For descriptions of their availability and use, consult the open(2) manual page on Unix or the MSDN on Windows.

- os.O_RDONLY
- os.O_WRONLY
- os.O_RDWR
- os.O_APPEND
- os.O_CREAT
- os.O_EXCL
- os.O_TRUNC

These constants are available on Unix and Windows.

- os.O_DSYNC
- os.O_RSYNC
- os.O_SYNC
- os.O_NDELAY
- os.O_NONBLOCK
- os.O_NOCTTY
- os.O_SHLOCK
- os.O_EXLOCK
- os.O_CLOEXEC

These constants are only available on Unix.

*Changed in version 3.3:* Add O_CLOEXEC constant.

- os.O_BINARY
- os.O_NOINHERIT
os.O_SHORT_LIVED
os.O_TEMPORARY
os.O_RANDOM
os.O_SEQUENTIAL
os.O_TEXT

These constants are only available on Windows.

os.O_ASYNC
os.O_DIRECT
os.O_DIRECTORY
os.O_NOFOLLOW
os.O_NOATIME

These constants are GNU extensions and not present if they are not defined by the C library.

os.RTLD_LAZY
os.RTLD_NOW
os.RTLD_GLOBAL
os.RTLD_LOCAL
os.RTLD_NODELETE
os.RTLD_NOLOAD
os.RTLD_DEEPBIND

See the Unix manual page dlopen(3).

New in version 3.3.

16.1.4.2. Querying the size of a terminal

New in version 3.3.

os.get_terminal_size(fd=STDOUT_FILENO)

Return the size of the terminal window as (columns, lines), tuple of type terminal_size.
The optional argument `fd` (default `STDOUT_FILENO`, or standard output) specifies which file descriptor should be queried.

If the file descriptor is not connected to a terminal, an `OSError` is raised.

`shutil.get_terminal_size()` is the high-level function which should normally be used, `os.get_terminal_size` is the low-level implementation.

Availability: Unix, Windows.

```
class os.terminal_size
```

A subclass of tuple, holding `(columns, lines)` of the terminal window size.

**columns**

Width of the terminal window in characters.

**lines**

Height of the terminal window in characters.
16.1.5. Files and Directories

On some Unix platforms, many of these functions support one or more of these features:

- **specifying a file descriptor:** For some functions, the `path` argument can be not only a string giving a path name, but also a file descriptor. The function will then operate on the file referred to by the descriptor. (For POSIX systems, Python will call the `f...` version of the function.)

  You can check whether or not `path` can be specified as a file descriptor on your platform using `os.supports_fd`. If it is unavailable, using it will raise a `NotImplementedError`.

  If the function also supports `dir_fd` or `follow_symlinks` arguments, it is an error to specify one of those when supplying `path` as a file descriptor.

- **paths relative to directory descriptors:** If `dir_fd` is not `None`, it should be a file descriptor referring to a directory, and the path to operate on should be relative; `path` will then be relative to that directory. If the path is absolute, `dir_fd` is ignored. (For POSIX systems, Python will call the `...at` or `f...at` version of the function.)

  You can check whether or not `dir_fd` is supported on your platform using `os.supports_dir_fd`. If it is unavailable, using it will raise a `NotImplementedError`.

- **not following symlinks:** If `follow_symlinks` is `False`, and the last element of the path to operate on is a symbolic link, the function
will operate on the symbolic link itself instead of the file the link points to. (For POSIX systems, Python will call the ... version of the function.)

You can check whether or not follow_symlinks is supported on your platform using os.supports_follow_symlinks. If it is unavailable, using it will raise a NotImplementedError.

```
import os

os.access(path, mode, *, dir_fd=None, effective_ids=False, follow_symlinks=True)
```

Use the real uid/gid to test for access to `path`. Note that most operations will use the effective uid/gid, therefore this routine can be used in a suid/sgid environment to test if the invoking user has the specified access to `path`. `mode` should be `F_OK` to test the existence of `path`, or it can be the inclusive OR of one or more of `R_OK`, `W_OK`, and `X_OK` to test permissions. Return `True` if access is allowed, `False` if not. See the Unix man page `access(2)` for more information.

This function can support specifying paths relative to directory descriptors and not following symlinks.

If `effective_ids` is True, `access()` will perform its access checks using the effective uid/gid instead of the real uid/gid. `effective_ids` may not be supported on your platform; you can check whether or not it is available using `os.supports_effective_ids`. If it is unavailable, using it will raise a `NotImplementedError`.

Availability: Unix, Windows.

**Note:** Using `access()` to check if a user is authorized to e.g. open a file before actually doing so using `open()` creates a
security hole, because the user might exploit the short time interval between checking and opening the file to manipulate it. It's preferable to use *EAFP* techniques. For example:

```python
if os.access("myfile", os.R_OK):
    with open("myfile") as fp:
        return fp.read()
return "some default data"
```

is better written as:

```python
try:
    fp = open("myfile")
except PermissionError:
    return "some default data"
else:
    with fp:
        return fp.read()
```

**Note:** I/O operations may fail even when `access()` indicates that they would succeed, particularly for operations on network filesystems which may have permissions semantics beyond the usual POSIX permission-bit model.

*Changed in version 3.3:* Added the `dir_fd`, `effective_ids`, and `follow_symlinks` parameters.

```python
os.F_OK
os.R_OK
os.W_OK
os.X_OK
```

Values to pass as the `mode` parameter of `access()` to test the existence, readability, writability and executability of `path`, respectively.
os.\texttt{chdir}(path)
Change the current working directory to \textit{path}.

This function can support \textit{specifying a file descriptor}. The descriptor must refer to an opened directory, not an open file.

Availability: Unix, Windows.

\textit{New in version 3.3:} Added support for specifying \textit{path} as a file descriptor on some platforms.

os.\texttt{chflags}(path, flags, *, follow\_symlinks=True)
Set the flags of \textit{path} to the numeric \textit{flags}. \textit{flags} may take a combination (bitwise OR) of the following values (as defined in the \texttt{stat} module):

- \texttt{stat.UF_NODUMP}
- \texttt{stat.UF_IMMUTABLE}
- \texttt{stat.UF_APPEND}
- \texttt{stat.UF_OPAQUE}
- \texttt{stat.UF_NOUNLINK}
- \texttt{stat.UF_COMPRESSED}
- \texttt{stat.UF_HIDDEN}
- \texttt{stat.SF_ARCHIVED}
- \texttt{stat.SF_IMMUTABLE}
- \texttt{stat.SF_APPEND}
- \texttt{stat.SF_NOUNLINK}
- \texttt{stat.SF_SNAPSHOT}

This function can support \textit{not following symlinks}.

Availability: Unix.

\textit{New in version 3.3:} The \texttt{follow\_symlinks} argument.
os.chmod(path, mode, *, dir_fd=None, follow_symlinks=True)

Change the mode of path to the numeric mode. mode may take one of the following values (as defined in the stat module) or bitwise ORed combinations of them:

- stat.S_ISUID
- stat.S_ISGID
- stat.S_ENFMT
- stat.S_ISVTX
- stat.S_IREAD
- stat.S_IWRITE
- stat.S_IEXEC
- stat.S_IRWXU
- stat.S_IRUSR
- stat.S_IWUSR
- stat.S_IXUSR
- stat.S_IRWXG
- stat.S_IRGRP
- stat.S_IWGRP
- stat.S_IXGRP
- stat.S_IRWXO
- stat.S_IROTH
- stat.S_IWOTH
- stat.S_IXOTH

This function can support specifying a file descriptor, paths relative to directory descriptors and not following symlinks.

Availability: Unix, Windows.

**Note:** Although Windows supports chmod(), you can only set the file’s read-only flag with it (via the stat.S_IWRITE and
stat.S_IREAD constants or a corresponding integer value). All other bits are ignored.

*New in version 3.3:* Added support for specifying *path* as an open file descriptor, and the *dir_fd* and *follow_symlinks* arguments.

**os.chown**(path, *uid, gid*, *, dir_fd=None, follow_symlinks=True)

Change the owner and group id of *path* to the numeric *uid* and *gid*. To leave one of the ids unchanged, set it to -1.

This function can support *specifying a file descriptor*, *paths relative to directory descriptors* and *not following symlinks*.

See *shutil.chown()* for a higher-level function that accepts names in addition to numeric ids.

Availability: Unix.

*New in version 3.3:* Added support for specifying an open file descriptor for *path*, and the *dir_fd* and *follow_symlinks* arguments.

**os.chroot**(path)

Change the root directory of the current process to *path*.

Availability: Unix.

**os.fchdir**(fd)

Change the current working directory to the directory represented by the file descriptor *fd*. The descriptor must refer to an opened directory, not an open file. As of Python 3.3, this is equivalent to *os.chdir(fd)*.

Availability: Unix.
os.**getcwd()**
Return a string representing the current working directory.

Availability: Unix, Windows.

os.**getcwdb()**
Return a bytestring representing the current working directory.

Availability: Unix, Windows.

os.**lchflags**(path, flags)
Set the flags of path to the numeric flags, like `chflags()`, but do not follow symbolic links. As of Python 3.3, this is equivalent to `os.chflags(path, flags, follow_symlinks=False)`.

Availability: Unix.

os.**lchmod**(path, mode)
Change the mode of path to the numeric mode. If path is a symlink, this affects the symlink rather than the target. See the docs for `chmod()` for possible values of mode. As of Python 3.3, this is equivalent to `os.chmod(path, mode, follow_symlinks=False)`.

Availability: Unix.

os.**lchown**(path, uid, gid)
Change the owner and group id of path to the numeric uid and gid. This function will not follow symbolic links. As of Python 3.3, this is equivalent to `os.chown(path, uid, gid, follow_symlinks=False)`.

Availability: Unix.
os.\texttt{link}(src, dst, *, src\_dir\_fd=None, dst\_dir\_fd=None, follow\_symlinks=True)

Create a hard link pointing to src named dst.

This function can support specifying src\_dir\_fd and/or dst\_dir\_fd to supply \textit{paths relative to directory descriptors}, and \textit{not following symlinks}.

Availability: Unix, Windows.

\textit{Changed in version 3.2}: Added Windows support.

\textit{New in version 3.3}: Added the src\_dir\_fd, dst\_dir\_fd, and follow\_symlinks arguments.

\texttt{os.\texttt{listdir}(path='.' )}

Return a list containing the names of the entries in the directory given by path. The list is in arbitrary order, and does not include the special entries \texttt{'.'}, \texttt{'. '} and \texttt{'. .' } even if they are present in the directory.

\textit{path} may be either of type \texttt{str} or of type \texttt{bytes}. If \texttt{path} is of type \texttt{bytes}, the filenames returned will also be of type \texttt{bytes}; in all other circumstances, they will be of type \texttt{str}.

This function can also support \textit{specifying a file descriptor}; the file descriptor must refer to a directory.

\begin{table}[h]
\centering
\begin{tabular}{|c|c|}
\hline
\textbf{Note}: To encode \texttt{str} filenames to \texttt{bytes}, use \texttt{fsencode( ).} \\
\hline
\end{tabular}
\end{table}

Availability: Unix, Windows.

\textit{Changed in version 3.2}: The \texttt{path} parameter became optional.
New in version 3.3: Added support for specifying an open file descriptor for path.

os.lstat(path, *, dir_fd=None)
Perform the equivalent of an lstat() system call on the given path. Similar to stat(), but does not follow symbolic links. On platforms that do not support symbolic links, this is an alias for stat(). As of Python 3.3, this is equivalent to os.stat(path, dir_fd=dir_fd, follow_symlinks=False).

This function can also support \textit{paths relative to directory descriptors}.

Changed in version 3.2: Added support for Windows 6.0 (Vista) symbolic links.

Changed in version 3.3: Added the \textit{dir_fd} parameter.

os.makedir(path, mode=0o777, *, dir_fd=None)
Create a directory named \textit{path} with numeric mode \textit{mode}.

On some systems, \textit{mode} is ignored. Where it is used, the current umask value is first masked out. If the directory already exists, OSError is raised.

This function can also support \textit{paths relative to directory descriptors}.

It is also possible to create temporary directories; see the \texttt{tempfile} module's \texttt{tempfile.mkdtemp()} function.

Availability: Unix, Windows.

New in version 3.3: The \textit{dir_fd} argument.
**os.makedirs**(*path*, *mode=0o777*, *exist_ok=False*)

Recursive directory creation function. Like **mkdir()**, but makes all intermediate-level directories needed to contain the leaf directory.

The default *mode* is 0o777 (octal). On some systems, *mode* is ignored. Where it is used, the current umask value is first masked out.

If *exist_ok* is False (the default), an **OSError** is raised if the target directory already exists. If *exist_ok* is True an **OSError** is still raised if the umask-masked *mode* is different from the existing *mode*, on systems where the mode is used. **OSError** will also be raised if the directory creation fails.

**Note:** **makedirs()** will become confused if the path elements to create include **pardir** (eg. ".." on UNIX systems).

This function handles UNC paths correctly.

*New in version 3.2*: The **exist_ok** parameter.

**os.mkfifo**(*path*, *mode=0o666*, *, *dir_fd=None*)

Create a FIFO (a named pipe) named *path* with numeric mode *mode*. The current umask value is first masked out from the mode.

This function can also support **paths relative to directory descriptors**.

FIFOs are pipes that can be accessed like regular files. FIFOs exist until they are deleted (for example with **os.unlink()**). Generally, FIFOs are used as rendezvous between “client” and “server” type processes: the server opens the FIFO for reading, and the client opens it for writing. Note that **mkfifo()** doesn’t open the FIFO —
it just creates the rendezvous point.

Availability: Unix.

*New in version 3.3:* The `dir_fd` argument.

```python
os.mknod(filename, mode=0o600, device=0, *, dir_fd=None)
```

Create a filesystem node (file, device special file or named pipe) named `filename`. `mode` specifies both the permissions to use and the type of node to be created, being combined (bitwise OR) with one of `stat.S_IFREG`, `stat.S_IFCHR`, `stat.S_IFBLK`, and `stat.S_IFIFO` (those constants are available in `stat`). For `stat.S_IFCHR` and `stat.S_IFBLK`, `device` defines the newly created device special file (probably using `os.makedev()`), otherwise it is ignored.

This function can also support *paths relative to directory descriptors*.

*New in version 3.3:* The `dir_fd` argument.

```python
os.major(device)
```

Extract the device major number from a raw device number (usually the `st_dev` or `st_rdev` field from `stat`).

```python
os.minor(device)
```

Extract the device minor number from a raw device number (usually the `st_dev` or `st_rdev` field from `stat`).

```python
os.makedev(major, minor)
```

Compose a raw device number from the major and minor device numbers.
os. **pathconf**(*path, name*)

Return system configuration information relevant to a named file. *name* specifies the configuration value to retrieve; it may be a string which is the name of a defined system value; these names are specified in a number of standards (POSIX.1, Unix 95, Unix 98, and others). Some platforms define additional names as well. The names known to the host operating system are given in the **pathconf_names** dictionary. For configuration variables not included in that mapping, passing an integer for *name* is also accepted.

If *name* is a string and is not known, **ValueError** is raised. If a specific value for *name* is not supported by the host system, even if it is included in **pathconf_names**, an **OSError** is raised with **errno.EINVAL** for the error number.

This function can support **specifying a file descriptor**.

Availability: Unix.

os. **pathconf_names**

Dictionary mapping names accepted by **pathconf()** and **fpathconf()** to the integer values defined for those names by the host operating system. This can be used to determine the set of names known to the system.

Availability: Unix.

os. **readlink**(*path, *, dir_fd=None*)

Return a string representing the path to which the symbolic link points. The result may be either an absolute or relative pathname; if it is relative, it may be converted to an absolute pathname using **os.path.join(os.path.dirname(path), result)**.
If the path is a string object, the result will also be a string object, and the call may raise an UnicodeDecodeError. If the path is a bytes object, the result will be a bytes object.

This function can also support *paths relative to directory descriptors*.

Availability: Unix, Windows

*Changed in version 3.2:* Added support for Windows 6.0 (Vista) symbolic links.

*New in version 3.3:* The dir_fd argument.

**os.remove**(path, *, dir_fd=None)

Remove (delete) the file path. If path is a directory, OSError is raised. Use rmdir() to remove directories.

This function can support *paths relative to directory descriptors*.

On Windows, attempting to remove a file that is in use causes an exception to be raised; on Unix, the directory entry is removed but the storage allocated to the file is not made available until the original file is no longer in use.

This function is identical to unlink().

Availability: Unix, Windows.

*New in version 3.3:* The dir_fd argument.

**os.removedirs**(path)

Remove directories recursively. Works like rmdir() except that, if
the leaf directory is successfully removed, \texttt{removedirs()} tries to
successively remove every parent directory mentioned in \textit{path} until
an error is raised (which is ignored, because it generally means
that a parent directory is not empty). For example, \texttt{os.removedirs('foo/bar/baz')} will first remove the
directory 'foo/bar/baz', and then remove 'foo/bar' and
'foo' if they are empty. Raises \texttt{OSError} if the leaf directory
could not be successfully removed.

\texttt{os.rename(src, dst, *, src_dir_fd=None, dst_dir_fd=None)}
Rename the file or directory \texttt{src} to \texttt{dst}. If \texttt{dst} is a directory,
\texttt{OSError} will be raised. On Unix, if \texttt{dst} exists and is a file, it will be
replaced silently if the user has permission. The operation may fail
on some Unix flavors if \texttt{src} and \texttt{dst} are on different filesystems. If
successful, the renaming will be an atomic operation (this is a
POSIX requirement). On Windows, if \texttt{dst} already exists, \texttt{OSError}
will be raised even if it is a file.

This function can support specifying \texttt{src_dir_fd} and/or \texttt{dst_dir_fd} to
supply \textit{paths relative to directory descriptors}.

If you want cross-platform overwriting of the destination, use
\texttt{replace()}. 

Availability: Unix, Windows.

\textit{New in version 3.3}: The \texttt{src_dir_fd} and \texttt{dst_dir_fd} arguments.

\texttt{os.renames(old, new)}
Recursive directory or file renaming function. Works like
\texttt{rename()}, except creation of any intermediate directories needed
to make the new pathname good is attempted first. After the
rename, directories corresponding to rightmost path segments of
the old name will be pruned away using `removedirs()`.

**Note:** This function can fail with the new directory structure made if you lack permissions needed to remove the leaf directory or file.

```python
os.replace(src, dst, *, src_dir_fd=None, dst_dir_fd=None)
```

Rename the file or directory `src` to `dst`. If `dst` is a directory, `OSError` will be raised. If `dst` exists and is a file, it will be replaced silently if the user has permission. The operation may fail if `src` and `dst` are on different filesystems. If successful, the renaming will be an atomic operation (this is a POSIX requirement).

This function can support specifying `src_dir_fd` and/or `dst_dir_fd` to supply *paths relative to directory descriptors*.

Availability: Unix, Windows.

*New in version 3.3.*

```python
os.rmdir(path, *, dir_fd=None)
```

Remove (delete) the directory `path`. Only works when the directory is empty, otherwise, `OSError` is raised. In order to remove whole directory trees, `shutil.rmtree()` can be used.

This function can support *paths relative to directory descriptors*.

Availability: Unix, Windows.

*New in version 3.3:* The `dir_fd` parameter.

```python
os.stat(path, *, dir_fd=None, follow_symlinks=True)
```

Perform the equivalent of a `stat()` system call on the given path.
The return value is an object whose attributes correspond roughly to the members of the `stat` structure, namely:

- `st_mode` - protection bits,
- `st_ino` - inode number,
- `st_dev` - device,
- `st_nlink` - number of hard links,
- `st_uid` - user id of owner,
- `st_gid` - group id of owner,
- `st_size` - size of file, in bytes,
- `st_atime` - time of most recent access expressed in seconds,
- `st_mtime` - time of most recent content modification expressed in seconds,
- `st_ctime` - platform dependent; time of most recent metadata change on Unix, or the time of creation on Windows, expressed in seconds
- `st_atime_ns` - time of most recent access expressed in nanoseconds as an integer,
- `st_mtime_ns` - time of most recent content modification expressed in nanoseconds as an integer,
- `st_ctime_ns` - platform dependent; time of most recent metadata change on Unix, or the time of creation on Windows, expressed in nanoseconds as an integer

On some Unix systems (such as Linux), the following attributes may also be available:

- `st_blocks` - number of 512-byte blocks allocated for file
- `st_blksize` - filesystem blocksize for efficient file system I/O
- `st_rdev` - type of device if an inode device
- `st_flags` - user defined flags for file

On other Unix systems (such as FreeBSD), the following attributes may be available (but may be only filled out if root tries to use them):

- `st_gen` - file generation number
- `st_birthtime` - time of file creation

On Mac OS systems, the following attributes may also be available:

- `st_rsize`
- `st_creator`
- `st_type`

**Note:** The exact meaning and resolution of the `st_atime`, `st_mtime`, and `st_ctime` attributes depend on the operating system and the file system. For example, on Windows systems using the FAT or FAT32 file systems, `st_mtime` has 2-second resolution, and `st_atime` has only 1-day resolution. See your operating system documentation for details. Similarly, although `st_atime_ns`, `st_mtime_ns`, and `st_ctime_ns` are always expressed in nanoseconds, many systems do not provide nanosecond precision. On systems that do provide nanosecond precision, the floating-point object used to store `st_atime`, `st_mtime`, and `st_ctime` cannot preserve all of it, and as such will be slightly inexact. If you need the exact timestamps you should always use `st_atime_ns`, `st_mtime_ns`, and `st_ctime_ns`.

For backward compatibility, the return value of `stat()` is also
accessible as a tuple of at least 10 integers giving the most important (and portable) members of the stat structure, in the order st_mode, st_ino, st_dev, st_nlink, st_uid, st_gid, st_size, st_atime, st_mtime, st_ctime. More items may be added at the end by some implementations.

This function can support specifying a file descriptor and not following symlinks.

The standard module stat defines functions and constants that are useful for extracting information from a stat structure. (On Windows, some items are filled with dummy values.)

Example:

```python
>>> import os
>>> statinfo = os.stat('somefile.txt')
>>> statinfo
posix.stat_result(st_mode=33188, st_ino=7876932, st_nlink=1, st_uid=501, st_gid=501, st_size=264, st_mtime=1297230027, st_ctime=1297230027)
>>> statinfo.st_size
264
```

Availability: Unix, Windows.

New in version 3.3: Added the dir_fd and follow_symlinks arguments, specifying a file descriptor instead of a path, and the st_atime_ns, st_mtime_ns, and st_ctime_ns members.

**os.stat_float_times([newvalue])**

Determine whether stat_result represents time stamps as float objects. If newvalue is True, future calls to stat() return floats, if
it is False, future calls return ints. If newvalue is omitted, return the current setting.

For compatibility with older Python versions, accessing stat_result as a tuple always returns integers.

Python now returns float values by default. Applications which do not work correctly with floating point time stamps can use this function to restore the old behaviour.

The resolution of the timestamps (that is the smallest possible fraction) depends on the system. Some systems only support second resolution; on these systems, the fraction will always be zero.

It is recommended that this setting is only changed at program startup time in the __main__ module; libraries should never change this setting. If an application uses a library that works incorrectly if floating point time stamps are processed, this application should turn the feature off until the library has been corrected.

Deprecated since version 3.3.

os.statvfs(path)

Perform a statvfs() system call on the given path. The return value is an object whose attributes describe the filesystem on the given path, and correspond to the members of the statvfs structure, namely: f_bsize, f_frsise, f_blocks, f_bfree, f_bavail, f_files, f_ffree, f_favail, f_flag, f_namemax.

Two module-level constants are defined for the f_flag attribute's
bit-flags: if ST_RDONLY is set, the filesystem is mounted read-only, and if ST_NOSUID is set, the semantics of setuid/setgid bits are disabled or not supported.

This function can support specifying a file descriptor.

Changed in version 3.2: The ST_RDONLY and ST_NOSUID constants were added.

Availability: Unix.

New in version 3.3: Added support for specifying an open file descriptor for path.

os.supports_dir_fd

A Set object indicating which functions in the os module permit use of their dir_fd parameter. Different platforms provide different functionality, and an option that might work on one might be unsupported on another. For consistency's sakes, functions that support dir_fd always allow specifying the parameter, but will raise an exception if the functionality is not actually available.

To check whether a particular function permits use of its dir_fd parameter, use the in operator on supports_dir_fd. As an example, this expression determines whether the dir_fd parameter of os.stat() is locally available:

```python
os.stat in os.supports_dir_fd
```

Currently dir_fd parameters only work on Unix platforms; none of them work on Windows.

New in version 3.3.
**os.supports_effective_ids**

A Set object indicating which functions in the os module permit use of the effective_ids parameter for `os.access()`. If the local platform supports it, the collection will contain `os.access()`, otherwise it will be empty.

To check whether you can use the effective_ids parameter for `os.access()`, use the in operator on `supports_dir_fd`, like so:

```python
os.access in os.supports_effective_ids
```

Currently effective_ids only works on Unix platforms; it does not work on Windows.

*New in version 3.3.*

**os.supports_fd**

A Set object indicating which functions in the os module permit specifying their path parameter as an open file descriptor. Different platforms provide different functionality, and an option that might work on one might be unsupported on another. For consistency's sakes, functions that support fd always allow specifying the parameter, but will raise an exception if the functionality is not actually available.

To check whether a particular function permits specifying an open file descriptor for its path parameter, use the in operator on `supports_fd`. As an example, this expression determines whether os.chdir() accepts open file descriptors when called on your local platform:

```python
os.chdir in os.supports_fd
```
New in version 3.3.

**os.supports_follow_symlinks**

A Set object indicating which functions in the os module permit use of their follow_symlinks parameter. Different platforms provide different functionality, and an option that might work on one might be unsupported on another. For consistency’s sakes, functions that support follow_symlinks always allow specifying the parameter, but will raise an exception if the functionality is not actually available.

To check whether a particular function permits use of its follow_symlinks parameter, use the in operator on supports_follow_symlinks. As an example, this expression determines whether the follow_symlinks parameter of os.stat() is locally available:

```python
os.stat in os.supports_follow_symlinks
```

New in version 3.3.

**os.symlink**

( source, link_name, target_is_directory=False, *, dir_fd=None )

Create a symbolic link pointing to source named link_name.

On Windows, a symlink represents either a file or a directory, and does not morph to the target dynamically. If the target is present, the type of the symlink will be created to match. Otherwise, the symlink will be created as a directory if target_is_directory is True or a file symlink (the default) otherwise. On non-Windows platforms, target_is_directory is ignored.

Symbolic link support was introduced in Windows 6.0 (Vista).
symlink() will raise a `NotImplementedError` on Windows versions earlier than 6.0.

This function can support *paths relative to directory descriptors*.

**Note:** On Windows, the `SeCreateSymbolicLinkPrivilege` is required in order to successfully create symlinks. This privilege is not typically granted to regular users but is available to accounts which can escalate privileges to the administrator level. Either obtaining the privilege or running your application as an administrator are ways to successfully create symlinks. `OSError` is raised when the function is called by an unprivileged user.

Availability: Unix, Windows.

*Changed in version 3.2:* Added support for Windows 6.0 (Vista) symbolic links.

*New in version 3.3:* Added the `dir_fd` argument, and now allow `target_is_directory` on non-Windows platforms.

**os.sync()**

Force write of everything to disk.

Availability: Unix.

*New in version 3.3.*

**os.truncate(path, length)**

Truncate the file corresponding to `path`, so that it is at most `length` bytes in size.

This function can support *specifying a file descriptor*. 
Availability: Unix.

New in version 3.3.

**os.unlink(path, *, dir_fd=None)**
Remove (delete) the file *path*. This function is identical to `remove()`; the `unlink` name is its traditional Unix name. Please see the documentation for `remove()` for further information.

Availability: Unix, Windows.

New in version 3.3: The `dir_fd` parameter.

**os.utime(path, times=None, *, ns=None, dir_fd=None, follow_symlinks=True)**
Set the access and modified times of the file specified by *path*.

`utime()` takes two optional parameters, `times` and `ns`. These specify the times set on *path* and are used as follows:

- If `ns` is not None, it must be a 2-tuple of the form `(atime_ns, mtime_ns)` where each member is an int expressing nanoseconds.
- If `times` is not None, it must be a 2-tuple of the form `(atime, mtime)` where each member is an int or float expressing seconds.
- If `times` and `ns` are both None, this is equivalent to specifying `ns=(atime_ns, mtime_ns)` where both times are the current time.

It is an error to specify tuples for both `times` and `ns`.

Whether a directory can be given for *path* depends on whether the operating system implements directories as files (for example,
Windows does not. Note that the exact times you set here may not be returned by a subsequent `stat()` call, depending on the resolution with which your operating system records access and modification times; see `stat()`. The best way to preserve exact times is to use the `st_atime_ns` and `st_mtime_ns` fields from the `os.stat()` result object with the `ns` parameter to `utime`.

This function can support specifying a file descriptor, paths relative to directory descriptors and not following symlinks.

Availability: Unix, Windows.

*New in version 3.3:* Added support for specifying an open file descriptor for *path*, and the `dir_fd`, `follow_symlinks`, and `ns` parameters.

```
\texttt{os.walk(top, topdown=True, onerror=None, followlinks=False)}
```

Generate the file names in a directory tree by walking the tree either top-down or bottom-up. For each directory in the tree rooted at directory *top* (including *top* itself), it yields a 3-tuple *(dirpath, dirnames, filenames)*.

*dirpath* is a string, the path to the directory. *dirname* is a list of the names of the subdirectories in *dirpath* (excluding `.` and `..' ).

*filenames* is a list of the names of the non-directory files in *dirpath*. Note that the names in the lists contain no path components. To get a full path (which begins with *top*) to a file or directory in *dirpath*, do `os.path.join(dirpath, name)`.

If optional argument *topdown* is *True* or not specified, the triple for a directory is generated before the triples for any of its subdirectories (directories are generated top-down). If *topdown* is *False*, the triple for a directory is generated after the triples for all
of its subdirectories (directories are generated bottom-up).

When `topdown` is True, the caller can modify the `dirnames` list in-place (perhaps using `del` or slice assignment), and `walk()` will only recurse into the subdirectories whose names remain in `dirnames`; this can be used to prune the search, impose a specific order of visiting, or even to inform `walk()` about directories the caller creates or renames before it resumes `walk()` again. Modifying `dirnames` when `topdown` is False is ineffective, because in bottom-up mode the directories in `dirnames` are generated before `dirpath` itself is generated.

By default, errors from the `listdir()` call are ignored. If optional argument `onerror` is specified, it should be a function; it will be called with one argument, an `OSError` instance. It can report the error to continue with the walk, or raise the exception to abort the walk. Note that the filename is available as the `filename` attribute of the exception object.

By default, `walk()` will not walk down into symbolic links that resolve to directories. Set `followlinks` to True to visit directories pointed to by symlinks, on systems that support them.

**Note:** Be aware that setting `followlinks` to True can lead to infinite recursion if a link points to a parent directory of itself. `walk()` does not keep track of the directories it visited already.

**Note:** If you pass a relative pathname, don’t change the current working directory between resumptions of `walk()`. `walk()` never changes the current directory, and assumes that its caller doesn’t either.
This example displays the number of bytes taken by non-directory files in each directory under the starting directory, except that it doesn’t look under any CVS subdirectory:

```python
import os
from os.path import join, getsize
for root, dirs, files in os.walk('python/Lib/email', topdown=True, onerror=None, *, follow_symlinks=False, dir_fd=None)
    print(root, 'consumes', end=' ')  # don't visit CVS dirs
    print(sum(getsize(join(root, name)) for name in files), end=' ')  # bytes in
    if 'CVS' in dirs:
        dirs.remove('CVS')  # don't visit CVS dirs
```

In the next example, walking the tree bottom-up is essential: `rmdir()` doesn’t allow deleting a directory before the directory is empty:

```python
# Delete everything reachable from the directory named in "top",
# assuming there are no symbolic links.
# CAUTION: This is dangerous! For example, if "top" == "/", it
# could delete all your disk files.
import os
for root, dirs, files in os.walk(top='.', topdown=False, onerror=None, *, follow_symlinks=False, dir_fd=None)
    for name in files:
        os.remove(os.path.join(root, name))
    for name in dirs:
        os.rmdir(os.path.join(root, name))
```

This behaves exactly like `walk()`, except that it yields a 4-tuple `(dirpath, dirnames, filenames, dirfd)`, and it supports `dir_fd`. 
dirpath, dirnames and filenames are identical to walk() output, and dirfd is a file descriptor referring to the directory dirpath.

This function always supports paths relative to directory descriptors and not following symlinks. Note however that, unlike other functions, the fwalk() default value for follow_symlinks is False.

**Note:** Since fwalk() yields file descriptors, those are only valid until the next iteration step, so you should duplicate them (e.g. with dup()) if you want to keep them longer.

This example displays the number of bytes taken by non-directory files in each directory under the starting directory, except that it doesn't look under any CVS subdirectory:

```python
import os
for root, dirs, files, rootfd in os.fwalk('python/Lib/email
print(root, "consumes", end="")
print(sum([os.stat(name, dir_fd=rootfd).st_size
    end="")
print("bytes in", len(files), "non-directory
if 'CVS' in dirs:
    dirs.remove('CVS') # don't visit CVS dire
```

In the next example, walking the tree bottom-up is essential: rmdir() doesn't allow deleting a directory before the directory is empty:

```python
# Delete everything reachable from the directory # assuming there are no symbolic links.
# CAUTION: This is dangerous! For example, if t
# could delete all your disk files.
import os
for root, dirs, files, rootfd in os.fwalk(top, to
Availability: Unix.

*New in version 3.3.*

## 16.1.5.1. Linux extended attributes

*New in version 3.3.*

These functions are all available on Linux only.

**`os.getxattr(path, attribute, *, follow_symlinks=True)`**

Return the value of the extended filesystem attribute `attribute` for `path`. `attribute` can be bytes or str. If it is str, it is encoded with the filesystem encoding.

This function can support *specifying a file descriptor* and *not following symlinks*.

**`os.listxattr(path=None, *, follow_symlinks=True)`**

Return a list of the extended filesystem attributes on `path`. The attributes in the list are represented as strings decoded with the filesystem encoding. If `path` is None, `listxattr()` will examine the current directory.

This function can support *specifying a file descriptor* and *not following symlinks*.

**`os.removexattr(path, attribute, *, follow_symlinks=True)`**
Removes the extended filesystem attribute `attribute` from `path`. `attribute` should be bytes or str. If it is a string, it is encoded with the filesystem encoding.

This function can support *specifying a file descriptor* and *not following symlinks*.

```python
os.setxattr(path, attribute, value, flags=0, *,
            follow_symlinks=True)
```

Set the extended filesystem attribute `attribute` on `path` to `value`. `attribute` must be a bytes or str with no embedded NULs. If it is a str, it is encoded with the filesystem encoding. `flags` may be `XATTR_REPLACE` or `XATTR_CREATE`. If `XATTR_REPLACE` is given and the attribute does not exist, `EEXISTS` will be raised. If `XATTR_CREATE` is given and the attribute already exists, the attribute will not be created and `ENODATA` will be raised.

This function can support *specifying a file descriptor* and *not following symlinks*.

**Note:** A bug in Linux kernel versions less than 2.6.39 caused the flags argument to be ignored on some filesystems.

```python
os.XATTR_SIZE_MAX
```

The maximum size the value of an extended attribute can be. Currently, this is 64 KiB on Linux.

```python
os.XATTR_CREATE
```

This is a possible value for the flags argument in `setxattr()`. It indicates the operation must create an attribute.

```python
os.XATTR_REPLACE
```
This is a possible value for the flags argument in `setxattr()`. It indicates the operation must replace an existing attribute.
16.1.6. Process Management

These functions may be used to create and manage processes.

The various exec* functions take a list of arguments for the new program loaded into the process. In each case, the first of these arguments is passed to the new program as its own name rather than as an argument a user may have typed on a command line. For the C programmer, this is the argv[0] passed to a program’s main(). For example, os.execv('/bin/echo', ['foo', 'bar']) will only print bar on standard output; foo will seem to be ignored.

os.abort()

Generate a SIGABRT signal to the current process. On Unix, the default behavior is to produce a core dump; on Windows, the process immediately returns an exit code of 3. Be aware that calling this function will not call the Python signal handler registered for SIGABRT with signal.signal().

Availability: Unix, Windows.

os.execl(path, arg0, arg1, ...)
os.execle(path, arg0, arg1, ..., env)
os.execlp(file, arg0, arg1, ...)
os.execlepe(file, arg0, arg1, ..., env)
os.execv(path, args)
os.execve(path, args, env)
os.execvp(file, args)
os.execvpe(file, args, env)

These functions all execute a new program, replacing the current process; they do not return. On Unix, the new executable is loaded
into the current process, and will have the same process id as the caller. Errors will be reported as OSError exceptions.

The current process is replaced immediately. Open file objects and descriptors are not flushed, so if there may be data buffered on these open files, you should flush them using sys.stdout.flush() or os.fsync() before calling an exec* function.

The “l” and “v” variants of the exec* functions differ in how command-line arguments are passed. The “l” variants are perhaps the easiest to work with if the number of parameters is fixed when the code is written; the individual parameters simply become additional parameters to the exec1*() functions. The “v” variants are good when the number of parameters is variable, with the arguments being passed in a list or tuple as the args parameter. In either case, the arguments to the child process should start with the name of the command being run, but this is not enforced.

The variants which include a “p” near the end (exclp(), exclpe(), execvp(), and execvpe()) will use the PATH environment variable to locate the program file. When the environment is being replaced (using one of the exec*e variants, discussed in the next paragraph), the new environment is used as the source of the PATH variable. The other variants, excl(), execle(), execv(), and execve(), will not use the PATH variable to locate the executable; path must contain an appropriate absolute or relative path.

For execle(), exclpe(), execve(), and execvpe() (note that these all end in “e”), the env parameter must be a mapping which is used to define the environment variables for the new
process (these are used instead of the current process' environment); the functions `execl()`, `execlp()`, `execv()`, and `execvp()` all cause the new process to inherit the environment of the current process.

For `execve()` on some platforms, *path* may also be specified as an open file descriptor. This functionality may not be supported on your platform; you can check whether or not it is available using `os.supports_fd`. If it is unavailable, using it will raise a `NotImplementedError`.

Availability: Unix, Windows.

*New in version 3.3:* Added support for specifying an open file descriptor for *path* for `execve()`.

`os._exit(n)`

Exit the process with status *n*, without calling cleanup handlers, flushing stdio buffers, etc.

Availability: Unix, Windows.

**Note:** The standard way to exit is `sys.exit(n)`. `_exit()` should normally only be used in the child process after a `fork()`.

The following exit codes are defined and can be used with `_exit()`, although they are not required. These are typically used for system programs written in Python, such as a mail server’s external command delivery program.

**Note:** Some of these may not be available on all Unix platforms,
since there is some variation. These constants are defined where they are defined by the underlying platform.

**os.** `.EX_OK`
Exit code that means no error occurred.

Availability: Unix.

**os.** `.EX_USAGE`
Exit code that means the command was used incorrectly, such as when the wrong number of arguments are given.

Availability: Unix.

**os.** `.EX_DATAERR`
Exit code that means the input data was incorrect.

Availability: Unix.

**os.** `.EX_NOINPUT`
Exit code that means an input file did not exist or was not readable.

Availability: Unix.

**os.** `.EX_NOUSER`
Exit code that means a specified user did not exist.

Availability: Unix.

**os.** `.EX_NOHOST`
Exit code that means a specified host did not exist.

Availability: Unix.

**os.** `.EX_UNAVAILABLE`
Exit code that means that a required service is unavailable.

Availability: Unix.

**os. EXSOFTWARE**
Exit code that means an internal software error was detected.

Availability: Unix.

**os. EXOSERR**
Exit code that means an operating system error was detected, such as the inability to fork or create a pipe.

Availability: Unix.

**os. EXOSFILE**
Exit code that means some system file did not exist, could not be opened, or had some other kind of error.

Availability: Unix.

**os. EXCANTCREAT**
Exit code that means a user specified output file could not be created.

Availability: Unix.

**os. EXIOERR**
Exit code that means that an error occurred while doing I/O on some file.

Availability: Unix.

**os. EXTEMPFAIL**
Exit code that means a temporary failure occurred. This indicates
something that may not really be an error, such as a network connection that couldn’t be made during a retryable operation.

Availability: Unix.

**os.EX_PROTOCOL**

Exit code that means that a protocol exchange was illegal, invalid, or not understood.

Availability: Unix.

**os.EX_NOPERM**

Exit code that means that there were insufficient permissions to perform the operation (but not intended for file system problems).

Availability: Unix.

**os.EX_CONFIG**

Exit code that means that some kind of configuration error occurred.

Availability: Unix.

**os.EX_NOTFOUND**

Exit code that means something like “an entry was not found”.

Availability: Unix.

**os.fork()**

Fork a child process. Return 0 in the child and the child’s process id in the parent. If an error occurs OSError is raised.

Note that some platforms including FreeBSD <= 6.3, Cygwin and OS/2 EMX have known issues when using fork() from a thread.
Availability: Unix.

**os.forkpty()**
Fork a child process, using a new pseudo-terminal as the child's controlling terminal. Return a pair of (pid, fd), where pid is 0 in the child, the new child's process id in the parent, and fd is the file descriptor of the master end of the pseudo-terminal. For a more portable approach, use the pty module. If an error occurs OSError is raised.

Availability: some flavors of Unix.

**os.kill(pid, sig)**
Send signal sig to the process pid. Constants for the specific signals available on the host platform are defined in the signal module.

Windows: The signal.CTRL_C_EVENT and signal.CTRL_BREAK_EVENT signals are special signals which can only be sent to console processes which share a common console window, e.g., some subprocesses. Any other value for sig will cause the process to be unconditionally killed by the TerminateProcess API, and the exit code will be set to sig. The Windows version of kill() additionally takes process handles to be killed.

See also signal.pthread_kill().

*New in version 3.2:* Windows support.

**os.killpg(pgid, sig)**
Send the signal sig to the process group pgid.
Availability: Unix.

**os.nice**(increment)
Add increment to the process’s “niceness”. Return the new niceness.

Availability: Unix.

**os.plock**(op)
Lock program segments into memory. The value of op (defined in `<sys/lock.h>`) determines which segments are locked.

Availability: Unix.

**os.popen**(…)
Run child processes, returning opened pipes for communications. These functions are described in section *File Object Creation*.

**os.spawnl**(mode, path, …)
**os.spawnle**(mode, path, …, env)
**os.spawnlp**(mode, file, …)
**os.spawnlpe**(mode, file, …, env)
**os.spawnv**(mode, path, args)
**os.spawnve**(mode, path, args, env)
**os.spawnvp**(mode, file, args)
**os.spawnvpe**(mode, file, args, env)
Execute the program path in a new process.

(Note that the subprocess module provides more powerful facilities for spawning new processes and retrieving their results; using that module is preferable to using these functions. Check especially the Replacing Older Functions with the subprocess Module section.)
If `mode` is `P_NOWAIT`, this function returns the process id of the new process; if `mode` is `P_WAIT`, returns the process's exit code if it exits normally, or `-signal`, where `signal` is the signal that killed the process. On Windows, the process id will actually be the process handle, so can be used with the `waitpid()` function.

The “l” and “v” variants of the `spawn*` functions differ in how command-line arguments are passed. The “l” variants are perhaps the easiest to work with if the number of parameters is fixed when the code is written; the individual parameters simply become additional parameters to the `spawnl*()` functions. The “v” variants are good when the number of parameters is variable, with the arguments being passed in a list or tuple as the `args` parameter. In either case, the arguments to the child process must start with the name of the command being run.

The variants which include a second “p” near the end (`spawnlp()`, `spawnlpe()`, `spawnvp()`, and `spawnvpe()`) will use the PATH environment variable to locate the program file. When the environment is being replaced (using one of the `spawn*e` variants, discussed in the next paragraph), the new environment is used as the source of the PATH variable. The other variants, `spawnl()`, `spawnle()`, `spawnv()`, and `spawnve()`, will not use the PATH variable to locate the executable; `path` must contain an appropriate absolute or relative path.

For `spawnle()`, `spawnlpe()`, `spawnve()`, and `spawnvpe()` (note that these all end in “e”), the `env` parameter must be a mapping which is used to define the environment variables for the new process (they are used instead of the current process' environment); the functions `spawnl()`, `spawnlp()`, `spawnv()`,
and `spawnvp()` all cause the new process to inherit the environment of the current process. Note that keys and values in the `env` dictionary must be strings; invalid keys or values will cause the function to fail, with a return value of 127.

As an example, the following calls to `spawnlp()` and `spawnvpe()` are equivalent:

```python
import os
os.spawnlp(os.P_WAIT, 'cp', 'cp', 'index.html', '
L = ['cp', 'index.html', '/dev/null']
os.spawnvpe(os.P_WAIT, 'cp', L, os.environ)
```

Availability: Unix, Windows. `spawnlp()`, `spawnlpe()`, `spawnvp()` and `spawnvpe()` are not available on Windows. `spawnle()` and `spawnve()` are not thread-safe on Windows; we advise you to use the `subprocess` module instead.

**os.P_NOWAIT**

**os.P_NOWAITO**

Possible values for the `mode` parameter to the `spawn*` family of functions. If either of these values is given, the `spawn*()` functions will return as soon as the new process has been created, with the process id as the return value.

Availability: Unix, Windows.

**os.P_WAIT**

Possible value for the `mode` parameter to the `spawn*` family of functions. If this is given as `mode`, the `spawn*()` functions will not return until the new process has run to completion and will return
the exit code of the process the run is successful, or \texttt{signal} if a signal kills the process.

Availability: Unix, Windows.

\texttt{os.P\_DETACH}
\texttt{os.P\_OVERLAY}

Possible values for the \textit{mode} parameter to the \texttt{spawn*} family of functions. These are less portable than those listed above. \texttt{P\_DETACH} is similar to \texttt{P\_NOWAIT}, but the new process is detached from the console of the calling process. If \texttt{P\_OVERLAY} is used, the current process will be replaced; the \texttt{spawn*} function will not return.

Availability: Windows.

\texttt{os.startfile(path[, operation])}

Start a file with its associated application.

When \textit{operation} is not specified or \texttt{open}, this acts like double-clicking the file in Windows Explorer, or giving the file name as an argument to the \texttt{start} command from the interactive command shell: the file is opened with whatever application (if any) its extension is associated.

When another \textit{operation} is given, it must be a “command verb” that specifies what should be done with the file. Common verbs documented by Microsoft are \texttt{print} and \texttt{edit} (to be used on files) as well as \texttt{explore} and \texttt{find} (to be used on directories).

\texttt{startfile()} returns as soon as the associated application is launched. There is no option to wait for the application to close,
and no way to retrieve the application's exit status. The path parameter is relative to the current directory. If you want to use an absolute path, make sure the first character is not a slash ('/'); the underlying Win32 ShellExecute() function doesn't work if it is. Use the os.path.normpath() function to ensure that the path is properly encoded for Win32.

Availability: Windows.

```python
os.system(command)
```

Execute the command (a string) in a subshell. This is implemented by calling the Standard C function system(), and has the same limitations. Changes to sys.stdin, etc. are not reflected in the environment of the executed command. If command generates any output, it will be sent to the interpreter standard output stream.

On Unix, the return value is the exit status of the process encoded in the format specified for wait(). Note that POSIX does not specify the meaning of the return value of the C system() function, so the return value of the Python function is system-dependent.

On Windows, the return value is that returned by the system shell after running command. The shell is given by the Windows environment variable COMSPEC: it is usually cmd.exe, which returns the exit status of the command run; on systems using a non-native shell, consult your shell documentation.

The subprocess module provides more powerful facilities for spawning new processes and retrieving their results; using that module is preferable to using this function. See the Replacing Older Functions with the subprocess Module section in the
subprocess documentation for some helpful recipes.

Availability: Unix, Windows.

os.\texttt{times}()

Returns the current global process times. The return value is an object with five attributes:

- \texttt{user} - user time
- \texttt{system} - system time
- \texttt{children\_user} - user time of all child processes
- \texttt{children\_system} - system time of all child processes
- \texttt{elapsed} - elapsed real time since a fixed point in the past

For backwards compatibility, this object also behaves like a five-tuple containing \texttt{user}, \texttt{system}, \texttt{children\_user}, \texttt{children\_system}, and \texttt{elapsed} in that order.

See the Unix manual page \texttt{times(2)} or the corresponding Windows Platform API documentation. On Windows, only user and \texttt{system} are known; the other attributes are zero. On OS/2, only \texttt{elapsed} is known; the other attributes are zero.

Availability: Unix, Windows.

\textit{Changed in version 3.3:} Return type changed from a tuple to a tuple-like object with named attributes.

os.\texttt{wait}()

Wait for completion of a child process, and return a tuple containing its pid and exit status indication: a 16-bit number, whose low byte is the signal number that killed the process, and whose high byte is the exit status (if the signal number is zero); the high bit of the low byte is set if a core file was produced.
Availability: Unix.

\texttt{os.waitid(idtype, id, options)}

Wait for the completion of one or more child processes. \texttt{idtype} can be \texttt{P_PID}, \texttt{P_PGID} or \texttt{P_ALL}. \texttt{id} specifies the pid to wait on. \texttt{options} is constructed from the ORing of one or more of \texttt{WEXITED}, \texttt{WSTOPPED} or \texttt{WCONTINUED} and additionally may be ORed with \texttt{WNOHANG} or \texttt{WNOWAIT}. The return value is an object representing the data contained in the \texttt{siginfo_t} structure, namely: \texttt{si_pid}, \texttt{si_uid}, \texttt{si_signo}, \texttt{si_status}, \texttt{si_code} or None if \texttt{WNOHANG} is specified and there are no children in a waitable state.

Availability: Unix.

\textit{New in version 3.3.}

\texttt{os.P_PID}
\texttt{os.P_PGID}
\texttt{os.P_ALL}

These are the possible values for \texttt{idtype} in \texttt{waitid()}. They affect how \texttt{id} is interpreted.

Availability: Unix.

\textit{New in version 3.3.}

\texttt{os.WEXITED}
\texttt{os.WSTOPPED}
\texttt{os.WCONTINUED}
\texttt{os.WNOHANG}

Flags that can be used in \texttt{options} in \texttt{waitid()} that specify what child signal to wait for.

Availability: Unix.
New in version 3.3.

**os.CLD_EXITED**
**os.CLD_DUMPED**
**os.CLD_TRAPPED**
**os.CLD_CONTINUED**

These are the possible values for `si_code` in the result returned by `waitid()`.

Availability: Unix.

New in version 3.3.

**os.waitpid(pid, options)**

The details of this function differ on Unix and Windows.

On Unix: Wait for completion of a child process given by process id `pid`, and return a tuple containing its process id and exit status indication (encoded as for `wait()`). The semantics of the call are affected by the value of the integer `options`, which should be `0` for normal operation.

If `pid` is greater than `0`, `waitpid()` requests status information for that specific process. If `pid` is `0`, the request is for the status of any child in the process group of the current process. If `pid` is `-1`, the request pertains to any child of the current process. If `pid` is less than `-1`, status is requested for any process in the process group `-pid` (the absolute value of `pid`).

An `OSError` is raised with the value of `errno` when the syscall returns `-1`.

On Windows: Wait for completion of a process given by process
handle *pid*, and return a tuple containing *pid*, and its exit status shifted left by 8 bits (shifting makes cross-platform use of the function easier). A *pid* less than or equal to 0 has no special meaning on Windows, and raises an exception. The value of integer *options* has no effect. *pid* can refer to any process whose id is known, not necessarily a child process. The `spawn*` functions called with `P_NOWAIT` return suitable process handles.

**os.wait3(*options*)**

Similar to `waitpid()`, except no process id argument is given and a 3-element tuple containing the child's process id, exit status indication, and resource usage information is returned. Refer to `resource.getrusage()` for details on resource usage information. The option argument is the same as that provided to `waitpid()` and `wait4()`.

Availability: Unix.

**os.wait4(*pid, options*)**

Similar to `waitpid()`, except a 3-element tuple, containing the child's process id, exit status indication, and resource usage information is returned. Refer to `resource.getrusage()` for details on resource usage information. The arguments to `wait4()` are the same as those provided to `waitpid()`.

Availability: Unix.

**os.WNOHANG**

The option for `waitpid()` to return immediately if no child process status is available immediately. The function returns (0, 0) in this case.
Availability: Unix.

**os.WCONTINUED**

This option causes child processes to be reported if they have been continued from a job control stop since their status was last reported.

Availability: some Unix systems.

**os.WUNTRACED**

This option causes child processes to be reported if they have been stopped but their current state has not been reported since they were stopped.

Availability: Unix.

The following functions take a process status code as returned by `system()`, `wait()`, or `waitpid()` as a parameter. They may be used to determine the disposition of a process.

**os.WCOREDUMP(status)**

Return True if a core dump was generated for the process, otherwise return False.

Availability: Unix.

**os.WIFCONTINUED(status)**

Return True if the process has been continued from a job control stop, otherwise return False.

Availability: Unix.

**os.WIFSTOPPED(status)**

Return True if the process has been stopped, otherwise return
False.

Availability: Unix.

`os.WIFSIGNALED(status)`
Return True if the process exited due to a signal, otherwise return False.

Availability: Unix.

`os.WIFEXITED(status)`
Return True if the process exited using the `exit(2)` system call, otherwise return False.

Availability: Unix.

`os.WEXITSTATUS(status)`
If `WIFEXITED(status)` is true, return the integer parameter to the `exit(2)` system call. Otherwise, the return value is meaningless.

Availability: Unix.

`os.WSTOPSIG(status)`
Return the signal which caused the process to stop.

Availability: Unix.

`os.WTERMSIG(status)`
Return the signal which caused the process to exit.

Availability: Unix.
16.1.7. Interface to the scheduler

These functions control how a process is allocated CPU time by the operating system. They are only available on some Unix platforms. For more detailed information, consult your Unix manpages.

*New in version 3.3.*

The following scheduling policies are exposed if they are a supported by the operating system.

- **os. SCHED_OTHER**
  The default scheduling policy.

- **os. SCHED_BATCH**
  Scheduling policy for CPU-intensive processes that tries to preserve interactivity on the rest of the computer.

- **os. SCHED_IDLE**
  Scheduling policy for extremely low priority background tasks.

- **os. SCHED_SPORADIC**
  Scheduling policy for sporadic server programs.

- **os. SCHED_FIFO**
  A First In First Out scheduling policy.

- **os. SCHED_RR**
  A round-robin scheduling policy.

- **os. SCHED_RESET_ON_FORK**
  This flag can OR'ed with any other scheduling policy. When a process with this flag set forks, its child’s scheduling policy and
priority are reset to the default.

```python
class os.sched_param(sched_priority)
```
This class represents tunable scheduling parameters used in `sched_setparam()`, `sched_setscheduler()`, and `sched_getparam()`. It is immutable.

At the moment, there is only one possible parameter:

```python
sched_priority
```

The scheduling priority for a scheduling policy.

```python
os.sched_get_priority_min(policy)
```
Get the minimum priority value for `policy`. `policy` is one of the scheduling policy constants above.

```python
os.sched_get_priority_max(policy)
```
Get the maximum priority value for `policy`. `policy` is one of the scheduling policy constants above.

```python
os.sched_setscheduler(pid, policy, param)
```
Set the scheduling policy for the process with PID `pid`. A `pid` of 0 means the calling process. `policy` is one of the scheduling policy constants above. `param` is a `sched_param` instance.

```python
os.sched_getscheduler(pid)
```
Return the scheduling policy for the process with PID `pid`. A `pid` of 0 means the calling process. The result is one of the scheduling policy constants above.

```python
os.sched_setparam(pid, param)
```
Set a scheduling parameters for the process with PID `pid`. A `pid` of 0 means the calling process. `param` is a `sched_param` instance.
os. `sched_getparam(pid)`
Return the scheduling parameters as a `sched_param` instance for the process with PID `pid`. A `pid` of 0 means the calling process.

os. `sched_rr_get_interval(pid)`
Return the round-robin quantum in seconds for the process with PID `pid`. A `pid` of 0 means the calling process.

os. `sched_yield()`
Voluntarily relinquish the CPU.

os. `sched_setaffinity(pid, mask)`
Restrict the process with PID `pid` (or the current process if zero) to a set of CPUs. `mask` is an iterable of integers representing the set of CPUs to which the process should be restricted.

os. `sched_getaffinity(pid)`
Return the set of CPUs the process with PID `pid` (or the current process if zero) is restricted to.

See also: `multiprocessing.cpu_count()` returns the number of CPUs in the system.
16.1.8. Miscellaneous System Information

**os.confstr(name)**
Return string-valued system configuration values. *name* specifies the configuration value to retrieve; it may be a string which is the name of a defined system value; these names are specified in a number of standards (POSIX, Unix 95, Unix 98, and others). Some platforms define additional names as well. The names known to the host operating system are given as the keys of the `confstr_names` dictionary. For configuration variables not included in that mapping, passing an integer for *name* is also accepted.

If the configuration value specified by *name* isn't defined, None is returned.

If *name* is a string and is not known, `ValueError` is raised. If a specific value for *name* is not supported by the host system, even if it is included in `confstr_names`, an `OSError` is raised with `errno.EINVAL` for the error number.

Availability: Unix.

**os.confstr_names**
Dictionary mapping names accepted by `confstr()` to the integer values defined for those names by the host operating system. This can be used to determine the set of names known to the system.

Availability: Unix.

**os.getloadavg()**
Return the number of processes in the system run queue averaged
over the last 1, 5, and 15 minutes or raises OSError if the load average was unobtainable.

Availability: Unix.

`os.sysconf(name)`
Return integer-valued system configuration values. If the configuration value specified by `name` isn't defined, -1 is returned. The comments regarding the `name` parameter for `confstr()` apply here as well; the dictionary that provides information on the known names is given by `sysconf_names`.

Availability: Unix.

`os.sysconf_names`
Dictionary mapping names accepted by `sysconf()` to the integer values defined for those names by the host operating system. This can be used to determine the set of names known to the system.

Availability: Unix.

The following data values are used to support path manipulation operations. These are defined for all platforms.

Higher-level operations on pathnames are defined in the `os.path` module.

`os.curdir`
The constant string used by the operating system to refer to the current directory. This is '.' for Windows and POSIX. Also available via `os.path`.

`os.pardir`
The constant string used by the operating system to refer to the parent directory. This is `..` for Windows and POSIX. Also available via `os.path`.

**os.sep**

The character used by the operating system to separate pathname components. This is `/` for POSIX and `\\` for Windows. Note that knowing this is not sufficient to be able to parse or concatenate pathnames — use `os.path.split()` and `os.path.join()` — but it is occasionally useful. Also available via `os.path`.

**os.altsep**

An alternative character used by the operating system to separate pathname components, or None if only one separator character exists. This is set to `/` on Windows systems where `sep` is a backslash. Also available via `os.path`.

**os.extsep**

The character which separates the base filename from the extension; for example, the `.' in `os.py`. Also available via `os.path`.

**os.pathsep**

The character conventionally used by the operating system to separate search path components (as in PATH), such as `:' for POSIX or `;' for Windows. Also available via `os.path`.

**os.defpath**

The default search path used by `exec*p*` and `spawn*p*` if the environment doesn’t have a `PATH` key. Also available via `os.path`. 
**os. linesep**
The string used to separate (or, rather, terminate) lines on the current platform. This may be a single character, such as '
' for POSIX, or multiple characters, for example, '\r\n' for Windows. Do not use os.linesep as a line terminator when writing files opened in text mode (the default); use a single '\n' instead, on all platforms.

**os. devnull**
The file path of the null device. For example: '/dev/null' for POSIX, 'nul' for Windows. Also available via os.path.
16.1.9. Miscellaneous Functions

**os.urandom(n)**

Return a string of \( n \) random bytes suitable for cryptographic use.

This function returns random bytes from an OS-specific randomness source. The returned data should be unpredictable enough for cryptographic applications, though its exact quality depends on the OS implementation. On a Unix-like system this will query `/dev/urandom`, and on Windows it will use CryptGenRandom(). If a randomness source is not found, `NotImplementedError` will be raised.

For an easy-to-use interface to the random number generator provided by your platform, please see `random.SystemRandom`. 
16.2. **io** — Core tools for working with streams
16.2.1. Overview

The `io` module provides Python’s main facilities for dealing with various types of I/O. There are three main types of I/O: text I/O, binary I/O and raw I/O. These are generic categories, and various backing stores can be used for each of them. A concrete object belonging to any of these categories is called a file object. Other common terms are stream and file-like object.

Independently of its category, each concrete stream object will also have various capabilities: it can be read-only, write-only, or read-write. It can also allow arbitrary random access (seeking forwards or backwards to any location), or only sequential access (for example in the case of a socket or pipe).

All streams are careful about the type of data you give to them. For example giving a `str` object to the `write()` method of a binary stream will raise a `TypeError`. So will giving a `bytes` object to the `write()` method of a text stream.

*Changed in version 3.3:* Operations that used to raise `IOError` now raise `OSError`, since `IOError` is now an alias of `OSError`.

16.2.1.1. Text I/O

Text I/O expects and produces `str` objects. This means that whenever the backing store is natively made of bytes (such as in the case of a file), encoding and decoding of data is made transparently as well as optional translation of platform-specific newline characters.

The easiest way to create a text stream is with `open()`, optionally
specifying an encoding:

```python
f = open("myfile.txt", "r", encoding="utf-8")
```

In-memory text streams are also available as `StringIO` objects:

```python
f = io.StringIO("some initial text data")
```

The text stream API is described in detail in the documentation of `TextIOWrapper`.

### 16.2.1.2. Binary I/O

Binary I/O (also called *buffered I/O*) expects and produces `bytes` objects. No encoding, decoding, or newline translation is performed. This category of streams can be used for all kinds of non-text data, and also when manual control over the handling of text data is desired.

The easiest way to create a binary stream is with `open()` with `'b'` in the mode string:

```python
f = open("myfile.jpg", "rb")
```

In-memory binary streams are also available as `BytesIO` objects:

```python
f = io.BytesIO(b"some initial binary data: \x00\x01"
```

The binary stream API is described in detail in the docs of `BufferedIOBase`.

Other library modules may provide additional ways to create text or binary streams. See `socket.socket.makefile()` for example.
16.2.1.3. Raw I/O

Raw I/O (also called unbuffered I/O) is generally used as a low-level building-block for binary and text streams; it is rarely useful to directly manipulate a raw stream from user code. Nevertheless, you can create a raw stream by opening a file in binary mode with buffering disabled:

```
f = open("myfile.jpg", "rb", buffering=0)
```

The raw stream API is described in detail in the docs of `RawIOBase`. 
16.2.2. High-level Module Interface

io.\texttt{DEFAULT\\_BUFFER\\_SIZE}

An int containing the default buffer size used by the module's buffered I/O classes. \texttt{open()} uses the file's blksize (as obtained by \texttt{os.stat()}) if possible.

\texttt{io.open(file, mode='r', buffering=-1, encoding=None, errors=None, newline=None, closefd=True, opener=None)}

This is an alias for the builtin \texttt{open()} function.

\texttt{exception io.\texttt{BlockingIOError}}

This is a compatibility alias for the builtin \texttt{BlockingIOError} exception.

\texttt{exception io.\texttt{UnsupportedOperation}}

An exception inheriting \texttt{OSError} and \texttt{ValueError} that is raised when an unsupported operation is called on a stream.

16.2.2.1. In-memory streams

It is also possible to use a \texttt{str} or \texttt{bytes}-like object as a file for both reading and writing. For strings \texttt{StringIO} can be used like a file opened in text mode. \texttt{BytesIO} can be used like a file opened in binary mode. Both provide full read-write capabilities with random access.

\textbf{See also:}

\texttt{sys}

contains the standard IO streams: \texttt{sys.stdin}, \texttt{sys.stdout},
and `sys.stderr`. 
16.2.3. Class hierarchy

The implementation of I/O streams is organized as a hierarchy of classes. First abstract base classes (ABCs), which are used to specify the various categories of streams, then concrete classes providing the standard stream implementations.

**Note:** The abstract base classes also provide default implementations of some methods in order to help implementation of concrete stream classes. For example, `BufferedIOBase` provides unoptimized implementations of `readinto()` and `readline()`.

At the top of the I/O hierarchy is the abstract base class `IOBase`. It defines the basic interface to a stream. Note, however, that there is no separation between reading and writing to streams; implementations are allowed to raise `UnsupportedOperation` if they do not support a given operation.

The `RawIOBase` ABC extends `IOBase`. It deals with the reading and writing of bytes to a stream. `FileIO` subclasses `RawIOBase` to provide an interface to files in the machine’s file system.

The `BufferedIOBase` ABC deals with buffering on a raw byte stream (`RawIOBase`). Its subclasses, `BufferedWriter`, `BufferedReader`, and `BufferedRWPair` buffer streams that are readable, writable, and both readable and writable. `BufferedRandom` provides a buffered interface to random access streams. Another `BufferedIOBase` subclass, `BytesIO`, is a stream of in-memory bytes.
The **TextIOBase** ABC, another subclass of **I0Base**, deals with streams whose bytes represent text, and handles encoding and decoding to and from strings. **TextIOWrapper**, which extends it, is a buffered text interface to a buffered raw stream (**BufferedI0Base**). Finally, **StringIO** is an in-memory stream for text.

Argument names are not part of the specification, and only the arguments of **open()** are intended to be used as keyword arguments.

The following table summarizes the ABCs provided by the **io** module:

<table>
<thead>
<tr>
<th>ABC</th>
<th>Inherits</th>
<th>Stub Methods</th>
<th>Mixin Methods and Properties</th>
</tr>
</thead>
<tbody>
<tr>
<td><strong>IOBase</strong></td>
<td></td>
<td><strong>fileno</strong>, <strong>seek</strong>, and <strong>truncate</strong></td>
<td><strong>close</strong>, <strong>closed</strong>, <strong><strong>enter</strong></strong>, <strong><strong>exit</strong></strong>, <strong>flush</strong>, <strong>isatty</strong>, <strong><strong>iter</strong></strong>, <strong><strong>next</strong></strong>, <strong>readable</strong>, <strong>readline</strong>, <strong>readlines</strong>, <strong>seekable</strong>, <strong>tell</strong>, <strong>writable</strong>, and <strong>writelines</strong></td>
</tr>
<tr>

<td>Inherited <strong>IOBase</strong> methods,</td>
</tr>
</tbody>
</table>
16.2.3.1. I/O Base Classes

class io.IOBase

The abstract base class for all I/O classes, acting on streams of bytes. There is no public constructor.

This class provides empty abstract implementations for many methods that derived classes can override selectively; the default implementations represent a file that cannot be read, written or seeked.

Even though IOBase does not declare read(), readinto(), or write() because their signatures will vary, implementations and clients should consider those methods part of the interface. Also, implementations may raise a ValueError (or UnsupportedOperation) when operations they do not support are called.

The basic type used for binary data read from or written to a file is bytes. bytearrays are accepted too, and in some cases (such as readinto()) required. Text I/O classes work with str data.

Note that calling any method (even inquiries) on a closed stream is undefined. Implementations may raise ValueError in this case.

IOBase (and its subclasses) supports the iterator protocol, meaning that an IOBase object can be iterated over yielding the lines in a stream. Lines are defined slightly differently depending on whether the stream is a binary stream (yielding bytes), or a text
stream (yielding character strings). See `readline()` below.

`IOBase` is also a context manager and therefore supports the `with` statement. In this example, `file` is closed after the `with` statement's suite is finished—even if an exception occurs:

```python
with open('spam.txt', 'w') as file:
    file.write('Spam and eggs!')
```

`IOBase` provides these data attributes and methods:

**close()**

Flush and close this stream. This method has no effect if the file is already closed. Once the file is closed, any operation on the file (e.g. reading or writing) will raise a `ValueError`.

As a convenience, it is allowed to call this method more than once; only the first call, however, will have an effect.

**closed**

True if the stream is closed.

**fileno()**

Return the underlying file descriptor (an integer) of the stream if it exists. An `OSError` is raised if the IO object does not use a file descriptor.

**flush()**

Flush the write buffers of the stream if applicable. This does nothing for read-only and non-blocking streams.

**isatty()**

Return `True` if the stream is interactive (i.e., connected to a
terminal/tty device).

**readable()**
Return True if the stream can be read from. If False, read() will raise OSError.

**readline(limit=-1)**
Read and return one line from the stream. If limit is specified, at most limit bytes will be read.

The line terminator is always b'\n' for binary files; for text files, the newlines argument to open() can be used to select the line terminator(s) recognized.

**readlines(hint=-1)**
Read and return a list of lines from the stream. hint can be specified to control the number of lines read: no more lines will be read if the total size (in bytes/characters) of all lines so far exceeds hint.

Note that it's already possible to iterate on file objects using:

```
for line in file: ...
```

without calling file.readlines().

**seek(offset, whence=SEEK_SET)**
Change the stream position to the given byte offset. offset is interpreted relative to the position indicated by whence. Values for whence are:

- SEEK_SET or 0 – start of the stream (the default); offset should be zero or positive
- SEEK_CUR or 1 – current stream position; offset may be negative
SEEK_END or \( 2 \) – end of the stream; \( offset \) is usually negative

Return the new absolute position.

*New in version 3.1:* The SEEK_* constants.

*New in version 3.3:* Some operating systems could support additional values, like `os.SEEK_HOLE` or `os.SEEK_DATA`. The valid values for a file could depend on it being open in text or binary mode.

**seekable()**

Return True if the stream supports random access. If False, `seek()`, `tell()` and `truncate()` will raise `OSError`.

**tell()**

Return the current stream position.

**truncate(size=None)**

Resize the stream to the given `size` in bytes (or the current position if `size` is not specified). The current stream position isn't changed. This resizing can extend or reduce the current file size. In case of extension, the contents of the new file area depend on the platform (on most systems, additional bytes are zero-filled, on Windows they're undetermined). The new file size is returned.

**writable()**

Return True if the stream supports writing. If False, `write()` and `truncate()` will raise `OSError`.

**writelines(lines)**
Write a list of lines to the stream. Line separators are not added, so it is usual for each of the lines provided to have a line separator at the end.

*class* `io.RawIOBase`

Base class for raw binary I/O. It inherits `IOBase`. There is no public constructor.

Raw binary I/O typically provides low-level access to an underlying OS device or API, and does not try to encapsulate it in high-level primitives (this is left to Buffered I/O and Text I/O, described later in this page).

In addition to the attributes and methods from `IOBase`, `RawIOBase` provides the following methods:

`read(n=-1)`

Read up to *n* bytes from the object and return them. As a convenience, if *n* is unspecified or -1, `readall()` is called. Otherwise, only one system call is ever made. Fewer than *n* bytes may be returned if the operating system call returns fewer than *n* bytes.

If 0 bytes are returned, and *n* was not 0, this indicates end of file. If the object is in non-blocking mode and no bytes are available, None is returned.

`readall()`

Read and return all the bytes from the stream until EOF, using multiple calls to the stream if necessary.

`readinto(b)`

Read up to `len(b)` bytes into `bytearray b` and return the
number of bytes read. If the object is in non-blocking mode and no bytes are available, None is returned.

write(b)
Write the given bytes or bytearray object, b, to the underlying raw stream and return the number of bytes written. This can be less than len(b), depending on specifics of the underlying raw stream, and especially if it is in non-blocking mode. None is returned if the raw stream is set not to block and no single byte could be readily written to it.

class io.BufferedIOBase
Base class for binary streams that support some kind of buffering. It inherits IOBase. There is no public constructor.

The main difference with RawIOBase is that methods read(), readinto() and write() will try (respectively) to read as much input as requested or to consume all given output, at the expense of making perhaps more than one system call.

In addition, those methods can raise BlockingIOError if the underlying raw stream is in non-blocking mode and cannot take or give enough data; unlike their RawIOBase counterparts, they will never return None.

Besides, the read() method does not have a default implementation that defers to readinto().

A typical BufferedIOBase implementation should not inherit from a RawIOBase implementation, but wrap one, like BufferedWriter and BufferedReader do.
BufferedIOBase provides or overrides these methods and attribute in addition to those from I0Base:

**raw**
The underlying raw stream (a RawIOBase instance) that BufferedIOBase deals with. This is not part of the BufferedIOBase API and may not exist on some implementations.

**detach()**
Separate the underlying raw stream from the buffer and return it.

After the raw stream has been detached, the buffer is in an unusable state.

Some buffers, like BytesIO, do not have the concept of a single raw stream to return from this method. They raise UnsupportedOperation.

*New in version 3.1.*

**read***(n=-1)**
Read and return up to n bytes. If the argument is omitted, None, or negative, data is read and returned until EOF is reached. An empty bytes object is returned if the stream is already at EOF.

If the argument is positive, and the underlying raw stream is not interactive, multiple raw reads may be issued to satisfy the byte count (unless EOF is reached first). But for interactive raw streams, at most one raw read will be issued, and a short result does not imply that EOF is imminent.
A `BlockingIOError` is raised if the underlying raw stream is in non-blocking-mode, and has no data available at the moment.

### `read1(n=-1)`
Read and return up to `n` bytes, with at most one call to the underlying raw stream’s `read()` method. This can be useful if you are implementing your own buffering on top of a `BufferedIOBase` object.

### `readinto(b)`
Read up to `len(b)` bytes into bytearray `b` and return the number of bytes read.

Like `read()`, multiple reads may be issued to the underlying raw stream, unless the latter is interactive.

A `BlockingIOError` is raised if the underlying raw stream is in non-blocking-mode, and has no data available at the moment.

### `write(b)`
Write the given `bytes` or `bytearray` object, `b` and return the number of bytes written (never less than `len(b)`, since if the write fails an `OSError` will be raised). Depending on the actual implementation, these bytes may be readily written to the underlying stream, or held in a buffer for performance and latency reasons.

When in non-blocking mode, a `BlockingIOError` is raised if the data needed to be written to the raw stream but it couldn’t accept all the data without blocking.
16.2.3.2. Raw File I/O

```
class io.FileIO(name, mode='r', closefd=True, opener=None)
```

FileIO represents an OS-level file containing bytes data. It implements the RawIOBase interface (and therefore the IOBase interface, too).

The name can be one of two things:

- a character string or bytes object representing the path to the file which will be opened;
- an integer representing the number of an existing OS-level file descriptor to which the resulting FileIO object will give access.

The mode can be 'r', 'w', 'x' or 'a' for reading (default), writing, exclusive creation or appending. The file will be created if it doesn’t exist when opened for writing or appending; it will be truncated when opened for writing. FileExistsError will be raised if it already exists when opened for creating. Opening a file for creating implies writing, so this mode behaves in a similar way to 'w'. Add a '+' to the mode to allow simultaneous reading and writing.

The read() (when called with a positive argument), readinto() and write() methods on this class will only make one system call.

A custom opener can be used by passing a callable as opener. The underlying file descriptor for the file object is then obtained by calling opener with (name, flags). opener must return an open file descriptor (passing os.open as opener results in functionality
similar to passing None).

See the `open()` built-in function for examples on using the `opener` parameter.

*Changed in version 3.3:* The `opener` parameter was added. The `\x` mode was added.

In addition to the attributes and methods from `IOBase` and `RawIOBase`, `FileIO` provides the following data attributes:

**mode**

The mode as given in the constructor.

**name**

The file name. This is the file descriptor of the file when no name is given in the constructor.

### 16.2.3.3. Buffered Streams

Buffered I/O streams provide a higher-level interface to an I/O device than raw I/O does.

```python
class io.BytesIO([initial_bytes])
```

A stream implementation using an in-memory bytes buffer. It inherits `BufferedIOBase`.

The argument `initial_bytes` contains optional initial bytes data.

`BytesIO` provides or overrides these methods in addition to those from `BufferedIOBase` and `IOBase`:

`getbuffer()`
Return a readable and writable view over the contents of the buffer without copying them. Also, mutating the view will transparently update the contents of the buffer:

```python
g>>> b = io.BytesIO(b"abcdef")
g>>> view = b.getbuffer()
g>>> view[2:4] = b"56"
g>>> b.getvalue()
b'ab56ef'
```

**Note:** As long as the view exists, the `BytesIO` object cannot be resized.

*New in version 3.2.*

**`getvalue()`**

Return `bytes` containing the entire contents of the buffer.

**`read1()`**

In `BytesIO`, this is the same as `read()`.

*class* `io.BufferedReader`*(raw, buffer_size=DEFAULT_BUFFER_SIZE)*

A buffer providing higher-level access to a readable, sequential `RawIOBase` object. It inherits `BufferedIOBase`. When reading data from this object, a larger amount of data may be requested from the underlying raw stream, and kept in an internal buffer. The buffered data can then be returned directly on subsequent reads.

The constructor creates a `BufferedReader` for the given readable `raw` stream and `buffer_size`. If `buffer_size` is omitted, `DEFAULT_BUFFER_SIZE` is used.
BufferedReader provides or overrides these methods in addition to those from BufferedReader and IOBase:

**peek([n])**

Return bytes from the stream without advancing the position. At most one single read on the raw stream is done to satisfy the call. The number of bytes returned may be less or more than requested.

**read([n])**

Read and return n bytes, or if n is not given or negative, until EOF or if the read call would block in non-blocking mode.

**read1(n)**

Read and return up to n bytes with only one call on the raw stream. If at least one byte is buffered, only buffered bytes are returned. Otherwise, one raw stream read call is made.

```
class io.BufferedWriter(raw, buffer_size=DEFAULT_BUFFER_SIZE)
```

A buffer providing higher-level access to a writeable, sequential RawIOBase object. It inherits BufferedReader. When writing to this object, data is normally placed into an internal buffer. The buffer will be written out to the underlying RawIOBase object under various conditions, including:

- when the buffer gets too small for all pending data;
- when flush() is called;
- when a seek() is requested (for BufferedWriter objects);
- when the BufferedWriter object is closed or destroyed.

The constructor creates a BufferedWriter for the given writeable raw stream. If the buffer_size is not given, it defaults to
BufferedWriter provides or overrides these methods in addition to those from BufferedReader and BufferedWriter:

**flush()**
Force bytes held in the buffer into the raw stream. A BlockingIOError should be raised if the raw stream blocks.

**write(b)**
Write the bytes or bytearray object, b and return the number of bytes written. When in non-blocking mode, a BlockingIOError is raised if the buffer needs to be written out but the raw stream blocks.

```python
class io.BufferedRandom(raw, buffer_size=DEFAULT_BUFFER_SIZE)
```
A buffered interface to random access streams. It inherits BufferedReader and BufferedWriter, and further supports seek() and tell() functionality.

The constructor creates a reader and writer for a seekable raw stream, given in the first argument. If the buffer_size is omitted it defaults to DEFAULT_BUFFER_SIZE.

BufferedReader is capable of anything BufferedReader or BufferedWriter can do.

```python
class io.BufferedRWPair(reader, writer, buffer_size=DEFAULT_BUFFER_SIZE)
```
A buffered I/O object combining two unidirectional RawI0Base objects – one readable, the other writeable – into a single
bidirectional endpoint. It inherits BufferedIOMixin.

reader and writer are RawIOBase objects that are readable and writeable respectively. If the buffer_size is omitted it defaults to DEFAULT_BUFFER_SIZE.

BufferedReader implements all of BufferedIOMixin's methods except for detach(), which raises UnsupportedOperation.

**Warning:** BufferedReader does not attempt to synchronize accesses to its underlying raw streams. You should not pass it the same object as reader and writer; use BufferedReader instead.

16.2.3.4. Text I/O

class io.TextIOMixin

Base class for text streams. This class provides a character and line based interface to stream I/O. There is no readinto() method because Python's character strings are immutable. It inherits IOMixin. There is no public constructor.

TextIOMixin provides or overrides these data attributes and methods in addition to those from IOMixin:

- **encoding**
  The name of the encoding used to decode the stream's bytes into strings, and to encode strings into bytes.

- **errors**
  The error setting of the decoder or encoder.
newlines
A string, a tuple of strings, or None, indicating the newlines translated so far. Depending on the implementation and the initial constructor flags, this may not be available.

buffer
The underlying binary buffer (a BufferedIOBase instance) that TextIOWrapper deals with. This is not part of the TextIOWrapper API and may not exist in some implementations.

detach()
Separate the underlying binary buffer from the TextIOWrapper and return it.

After the underlying buffer has been detached, the TextIOWrapper is in an unusable state.

Some TextIOWrapper implementations, like StringIO, may not have the concept of an underlying buffer and calling this method will raise UnsupportedOperation.

New in version 3.1.

read(n)
Read and return at most n characters from the stream as a single str. If n is negative or None, reads until EOF.

readline(limit=-1)
Read until newline or EOF and return a single str. If the stream is already at EOF, an empty string is returned.

If limit is specified, at most limit characters will be read.
seek(offset, whence=SEEK_SET)

Change the stream position to the given offset. Behaviour depends on the whence parameter:

- SEEK_SET or 0: seek from the start of the stream (the default); offset must either be a number returned by TextIOWrapper.tell(), or zero. Any other offset value produces undefined behaviour.
- SEEK_CUR or 1: “seek” to the current position; offset must be zero, which is a no-operation (all other values are unsupported).
- SEEK_END or 2: seek to the end of the stream; offset must be zero (all other values are unsupported).

Return the new absolute position as an opaque number.

New in version 3.1: The SEEK_* constants.

tell()

Return the current stream position as an opaque number. The number does not usually represent a number of bytes in the underlying binary storage.

write(s)

Write the string s to the stream and return the number of characters written.

class io.TextIOWrapper(buffer, encoding=None, errors=None, newline=None, line_buffering=False, write_through=False)

A buffered text stream over a BufferedIOBase binary stream. It inherits TextIOWrapper.

encoding gives the name of the encoding that the stream will be decoded or encoded with. It defaults to
locale.getpreferredencoding(False).

errors is an optional string that specifies how encoding and decoding errors are to be handled. Pass 'strict' to raise a ValueError exception if there is an encoding error (the default of None has the same effect), or pass 'ignore' to ignore errors. (Note that ignoring encoding errors can lead to data loss.) 'replace' causes a replacement marker (such as '?' ) to be inserted where there is malformed data. When writing, 'xmlcharrefreplace' (replace with the appropriate XML character reference) or 'backslashreplace' (replace with backslashed escape sequences) can be used. Any other error handling name that has been registered with codecs.register_error() is also valid.

newline controls how line endings are handled. It can be None, '', '\n', '\r', and '\r\n'. It works as follows:

- When reading input from the stream, if newline is None, universal newlines mode is enabled. Lines in the input can end in '\n', '\r', or '\r\n', and these are translated into '\n' before being returned to the caller. If it is '', universal newlines mode is enabled, but line endings are returned to the caller untranslated. If it has any of the other legal values, input lines are only terminated by the given string, and the line ending is returned to the caller untranslated.
- When writing output to the stream, if newline is None, any '\n' characters written are translated to the system default line separator, os.linesep. If newline is '' or '\n', no translation takes place. If newline is any of the other legal values, any '\n' characters written are translated to the given string.
If `line_buffering` is `True`, `flush()` is implied when a call to `write` contains a newline character.

If `write_through` is `True`, calls to `write()` are guaranteed not to be buffered: any data written on the `TextIOWrapper` object is immediately handled to its underlying binary `buffer`.

*Changed in version 3.3:* The `write_through` argument has been added.

*Changed in version 3.3:* The default `encoding` is now `locale.getpreferredencoding(False)` instead of `locale.getpreferredencoding()`. Don’t change temporary the locale encoding using `locale.setlocale()`, use the current locale encoding instead of the user preferred encoding.

`TextIOWrapper` provides one attribute in addition to those of `TextIOWrapper` and its parents:

**line_buffering**

Whether line buffering is enabled.

```python
class io.StringIO(initial_value='', newline=None)
An in-memory stream for text I/O.
```

The initial value of the buffer (an empty string by default) can be set by providing `initial_value`. The `newline` argument works like that of `TextIOWrapper`. The default is to do no newline translation.

`StringIO` provides this method in addition to those from `TextIOWrapper` and its parents:

```python
getvalue()
```
Return a `str` containing the entire contents of the buffer at any time before the `StringIO` object's `close()` method is called.

Example usage:

```python
import io
output = io.StringIO()
output.write('First line.
')
print('Second line.', file=output)

# Retrieve file contents -- this will be
# 'First line.
Second line.'
contents = output.getvalue()

# Close object and discard memory buffer --
# .getvalue() will now raise an exception.
output.close()
```

```python
class io.IncrementalNewlineDecoder
    A helper codec that decodes newlines for universal newlines mode.
    It inherits codecs.IncrementalDecoder.
```
16.2.4. Performance

This section discusses the performance of the provided concrete I/O implementations.

16.2.4.1. Binary I/O

By reading and writing only large chunks of data even when the user asks for a single byte, buffered I/O hides any inefficiency in calling and executing the operating system's unbuffered I/O routines. The gain depends on the OS and the kind of I/O which is performed. For example, on some modern OSes such as Linux, unbuffered disk I/O can be as fast as buffered I/O. The bottom line, however, is that buffered I/O offers predictable performance regardless of the platform and the backing device. Therefore, it is almost always preferable to use buffered I/O rather than unbuffered I/O for binary data.

16.2.4.2. Text I/O

Text I/O over a binary storage (such as a file) is significantly slower than binary I/O over the same storage, because it requires conversions between unicode and binary data using a character codec. This can become noticeable handling huge amounts of text data like large log files. Also, TextIOWrapper.tell() and TextIOWrapper.seek() are both quite slow due to the reconstruction algorithm used.

StringIO, however, is a native in-memory unicode container and will exhibit similar speed to BytesIO.
16.2.4.3. Multi-threading

FileIO objects are thread-safe to the extent that the operating system calls (such as `read(2)` under Unix) they wrap are thread-safe too.

Binary buffered objects (instances of `BufferedReader`, `BufferedWriter`, `BufferedRandom` and `BufferedRWPair`) protect their internal structures using a lock; it is therefore safe to call them from multiple threads at once.

`TextIOWrapper` objects are not thread-safe.

16.2.4.4. Reentrancy

Binary buffered objects (instances of `BufferedReader`, `BufferedWriter`, `BufferedRandom` and `BufferedRWPair`) are not reentrant. While reentrant calls will not happen in normal situations, they can arise from doing I/O in a `signal` handler. If a thread tries to re-enter a buffered object which it is already accessing, a `RuntimeError` is raised. Note this doesn't prohibit a different thread from entering the buffered object.

The above implicitly extends to text files, since the `open()` function will wrap a buffered object inside a `TextIOWrapper`. This includes standard streams and therefore affects the built-in function `print()` as well.
16.3. time — Time access and conversions

This module provides various time-related functions. For related functionality, see also the datetime and calendar modules.

Although this module is always available, not all functions are available on all platforms. Most of the functions defined in this module call platform C library functions with the same name. It may sometimes be helpful to consult the platform documentation, because the semantics of these functions varies among platforms.

An explanation of some terminology and conventions is in order.

- The epoch is the point where the time starts. On January 1st of that year, at 0 hours, the “time since the epoch” is zero. For Unix, the epoch is 1970. To find out what the epoch is, look at \texttt{gmtime(0)}.

- The functions in this module may not handle dates and times before the epoch or far in the future. The cut-off point in the future is determined by the C library; for 32-bit systems, it is typically in 2038.

- Year 2000 (Y2K) issues: Python depends on the platform’s C library, which generally doesn’t have year 2000 issues, since all dates and times are represented internally as seconds since the epoch. Function \texttt{strptime()} can parse 2-digit years when given \%y format code. When 2-digit years are parsed, they are converted according to the POSIX and ISO C standards: values 69–99 are mapped to 1969–1999, and values 0–68 are mapped to 2000–2068.
• UTC is Coordinated Universal Time (formerly known as Greenwich Mean Time, or GMT). The acronym UTC is not a mistake but a compromise between English and French.

• DST is Daylight Saving Time, an adjustment of the timezone by (usually) one hour during part of the year. DST rules are magic (determined by local law) and can change from year to year. The C library has a table containing the local rules (often it is read from a system file for flexibility) and is the only source of True Wisdom in this respect.

• The precision of the various real-time functions may be less than suggested by the units in which their value or argument is expressed. E.g. on most Unix systems, the clock “ticks” only 50 or 100 times a second.

• On the other hand, the precision of time() and sleep() is better than their Unix equivalents: times are expressed as floating point numbers, time() returns the most accurate time available (using Unix gettimeofday() where available), and sleep() will accept a time with a nonzero fraction (Unix select() is used to implement this, where available).

• The time value as returned by gmtime(), localtime(), and strftime(), and accepted by asctime(), mktime() and strftime(), is a sequence of 9 integers. The return values of gmtime(), localtime(), and strftime() also offer attribute names for individual fields.

See struct_time for a description of these objects.

Changed in version 3.3: The struct_time type was extended to provide the tm_gmtoff and tm_zone attributes when platform
supports corresponding \texttt{struct tm} members.

- Use the following functions to convert between time representations:

<table>
<thead>
<tr>
<th>From</th>
<th>To</th>
<th>Use</th>
</tr>
</thead>
<tbody>
<tr>
<td><code>seconds</code> since the epoch</td>
<td><code>struct_time</code> in UTC</td>
<td>\texttt{gmtime()}</td>
</tr>
<tr>
<td><code>seconds</code> since the epoch</td>
<td><code>struct_time</code> in local time</td>
<td>\texttt{localtime()}</td>
</tr>
<tr>
<td><code>struct_time</code> in UTC</td>
<td><code>seconds</code> since the epoch</td>
<td>\texttt{calendar.timegm()}</td>
</tr>
<tr>
<td><code>struct_time</code> in local time</td>
<td><code>seconds</code> since the epoch</td>
<td>\texttt{mktime()}</td>
</tr>
</tbody>
</table>

The module defines the following functions and data items:

**\texttt{time.altzone}**

The offset of the local DST timezone, in seconds west of UTC, if one is defined. This is negative if the local DST timezone is east of UTC (as in Western Europe, including the UK). Only use this if \texttt{daylight} is nonzero.

**\texttt{time.asctime([t])}**

Convert a tuple or \texttt{struct_time} representing a time as returned by \texttt{gmtime()} or \texttt{localtime()} to a string of the following form: \texttt{'Sun Jun 20 23:21:05 1993'}. If \texttt{t} is not provided, the current time as returned by \texttt{localtime()} is used. Locale information is not used by \texttt{asctime()}. 
Note: Unlike the C function of the same name, `asctime()` does not add a trailing newline.

time.clock()
On Unix, return the current processor time as a floating point number expressed in seconds. The precision, and in fact the very definition of the meaning of “processor time”, depends on that of the C function of the same name, but in any case, this is the function to use for benchmarking Python or timing algorithms.

On Windows, this function returns wall-clock seconds elapsed since the first call to this function, as a floating point number, based on the Win32 function `QueryPerformanceCounter()`. The resolution is typically better than one microsecond.

Deprecated since version 3.3: The behaviour of this function depends on the platform: use `perf_counter()` or `process_time()` instead, depending on your requirements, to have a well defined behaviour.

time.clock_getres(clk_id)
Return the resolution (precision) of the specified clock `clk_id`.

Availability: Unix.

New in version 3.3.

time.clock_gettime(clk_id)
Return the time of the specified clock `clk_id`.

Availability: Unix.
New in version 3.3.

time.clock_settime(clk_id, time)
Set the time of the specified clock
clk_id.

Availability: Unix.

New in version 3.3.

time.CLOCK_HIGHRES
The Solaris OS has a CLOCK_HIGHRES timer that attempts to use an optimal hardware source, and may give close to nanosecond resolution. CLOCK_HIGHRES is the nonadjustable, high-resolution clock.

Availability: Solaris.

New in version 3.3.

time.CLOCK_MONOTONIC
Clock that cannot be set and represents monotonic time since some unspecified starting point.

Availability: Unix.

New in version 3.3.

time.CLOCK_MONOTONIC_RAW
Similar to CLOCK_MONOTONIC, but provides access to a raw hardware-based time that is not subject to NTP adjustments.

Availability: Linux 2.6.28 or later.

New in version 3.3.
time.\textbf{CLOCK\_PROCESS\_CPUTIME\_ID}\newline
High-resolution per-process timer from the CPU.

Availability: Unix.

\textit{New in version 3.3.}

time.\textbf{CLOCK\_REALTIME}\newline
System-wide real-time clock. Setting this clock requires appropriate privileges.

Availability: Unix.

\textit{New in version 3.3.}

time.\textbf{CLOCK\_THREAD\_CPUTIME\_ID}\newline
Thread-specific CPU-time clock.

Availability: Unix.

\textit{New in version 3.3.}

time.\textbf{ctime([secs])}\newline
Convert a time expressed in seconds since the epoch to a string representing local time. If secs is not provided or \texttt{None}, the current time as returned by \texttt{time()} is used. \texttt{ctime(secs)} is equivalent to \texttt{asctime(localtime(secs))}. Locale information is not used by \texttt{ctime()}.

time.\textbf{daylight}\newline
Nonzero if a DST timezone is defined.

time.\textbf{get\_clock\_info(name)}\newline
Get information on the specified clock as a namespace object.
Supported clock names and the corresponding functions to read their value are:

- 'clock': `time.clock()`
- 'monotonic': `time.monotonic()`
- 'perf_counter': `time.perf_counter()`
- 'process_time': `time.process_time()`
- 'time': `time.time()`

The result has the following attributes:

- **adjustable**: True if the clock can be changed automatically (e.g. by a NTP daemon) or manually by the system administrator, False otherwise
- **implementation**: The name of the underlying C function used to get the clock value
- **monotonic**: True if the clock cannot go backward, False otherwise
- **resolution**: The resolution of the clock in seconds (float)

*New in version 3.3.*

`time.gmtime([secs])`

Convert a time expressed in seconds since the epoch to a `struct_time` in UTC in which the dst flag is always zero. If `secs` is not provided or `None`, the current time as returned by `time()` is used. Fractions of a second are ignored. See above for a description of the `struct_time` object. See `calendar.timegm()` for the inverse of this function.

`time.localtime([secs])`

Like `gmtime()` but converts to local time. If `secs` is not provided or `None`, the current time as returned by `time()` is used. The dst
flag is set to 1 when DST applies to the given time.

**time.mktime(t)**

This is the inverse function of `localtime()`. Its argument is the `struct_time` or full 9-tuple (since the dst flag is needed; use -1 as the dst flag if it is unknown) which expresses the time in local time, not UTC. It returns a floating point number, for compatibility with `time()`. If the input value cannot be represented as a valid time, either `OverflowError` or `ValueError` will be raised (which depends on whether the invalid value is caught by Python or the underlying C libraries). The earliest date for which it can generate a time is platform-dependent.

**time.monotonic()**

Return the value (in fractional seconds) of a monotonic clock, i.e. a clock that cannot go backwards. The clock is not affected by system clock updates. The reference point of the returned value is undefined, so that only the difference between the results of consecutive calls is valid.

On Windows versions older than Vista, `monotonic()` detects `GetTickCount()` integer overflow (32 bits, roll-over after 49.7 days). It increases an internal epoch (reference time) by $2^{32}$ each time that an overflow is detected. The epoch is stored in the process-local state and so the value of `monotonic()` may be different in two Python processes running for more than 49 days. On more recent versions of Windows and on other operating systems, `monotonic()` is system-wide.

Availability: Windows, Mac OS X, Linux, FreeBSD, OpenBSD, Solaris.
New in version 3.3.

**time.perf_counter**

Return the value (in fractional seconds) of a performance counter, i.e. a clock with the highest available resolution to measure a short duration. It does include time elapsed during sleep and is system-wide. The reference point of the returned value is undefined, so that only the difference between the results of consecutive calls is valid.

New in version 3.3.

**time.process_time**

Return the value (in fractional seconds) of the sum of the system and user CPU time of the current process. It does not include time elapsed during sleep. It is process-wide by definition. The reference point of the returned value is undefined, so that only the difference between the results of consecutive calls is valid.

New in version 3.3.

**time.sleep(secs)**

Suspend execution for the given number of seconds. The argument may be a floating point number to indicate a more precise sleep time. The actual suspension time may be less than that requested because any caught signal will terminate the sleep() following execution of that signal's catching routine. Also, the suspension time may be longer than requested by an arbitrary amount because of the scheduling of other activity in the system.

**time.strftime(format[, t])**

Convert a tuple or struct_time representing a time as returned
by `gmtime()` or `localtime()` to a string as specified by the *format* argument. If *t* is not provided, the current time as returned by `localtime()` is used. *format* must be a string. *ValueError* is raised if any field in *t* is outside of the allowed range.

0 is a legal argument for any position in the time tuple; if it is normally illegal the value is forced to a correct one.

The following directives can be embedded in the *format* string. They are shown without the optional field width and precision specification, and are replaced by the indicated characters in the `strftime()` result:

<table>
<thead>
<tr>
<th>Directive</th>
<th>Meaning</th>
<th>Notes</th>
</tr>
</thead>
<tbody>
<tr>
<td>%a</td>
<td>Locale's abbreviated weekday name.</td>
<td></td>
</tr>
<tr>
<td>%A</td>
<td>Locale's full weekday name.</td>
<td></td>
</tr>
<tr>
<td>%b</td>
<td>Locale's abbreviated month name.</td>
<td></td>
</tr>
<tr>
<td>%B</td>
<td>Locale's full month name.</td>
<td></td>
</tr>
<tr>
<td>%C</td>
<td>Locale's appropriate date and time representation.</td>
<td></td>
</tr>
<tr>
<td>%d</td>
<td>Day of the month as a decimal number [01,31].</td>
<td></td>
</tr>
<tr>
<td>%H</td>
<td>Hour (24-hour clock) as a decimal number [00,23].</td>
<td></td>
</tr>
<tr>
<td>%I</td>
<td>Hour (12-hour clock) as a decimal number [01,12].</td>
<td></td>
</tr>
<tr>
<td>%j</td>
<td>Day of the year as a decimal number [001,366].</td>
<td></td>
</tr>
<tr>
<td>%m</td>
<td>Month as a decimal number [01,12].</td>
<td></td>
</tr>
<tr>
<td>%M</td>
<td>Minute as a decimal number [00,59].</td>
<td></td>
</tr>
<tr>
<td>Directive</td>
<td>Description</td>
<td>Notes</td>
</tr>
<tr>
<td>-----------</td>
<td>-------------</td>
<td>-------</td>
</tr>
<tr>
<td>%p</td>
<td>Locale’s equivalent of either AM or PM.</td>
<td>(1)</td>
</tr>
<tr>
<td>%S</td>
<td>Second as a decimal number [00,61].</td>
<td>(2)</td>
</tr>
<tr>
<td>%U</td>
<td>Week number of the year (Sunday as the first day of the week) as a decimal number [00,53]. All days in a new year preceding the first Sunday are considered to be in week 0.</td>
<td>(3)</td>
</tr>
<tr>
<td>%W</td>
<td>Week number of the year (Monday as the first day of the week) as a decimal number [00,53]. All days in a new year preceding the first Monday are considered to be in week 0.</td>
<td>(3)</td>
</tr>
<tr>
<td>%x</td>
<td>Locale's appropriate date representation.</td>
<td></td>
</tr>
<tr>
<td>%X</td>
<td>Locale's appropriate time representation.</td>
<td></td>
</tr>
<tr>
<td>%y</td>
<td>Year without century as a decimal number [00,99].</td>
<td></td>
</tr>
<tr>
<td>%Y</td>
<td>Year with century as a decimal number.</td>
<td></td>
</tr>
<tr>
<td>%z</td>
<td>Time zone offset indicating a positive or negative time difference from UTC/GMT of the form +HHMM or -HHMM, where H represents decimal hour digits and M represents decimal minute digits [-23:59, +23:59].</td>
<td></td>
</tr>
<tr>
<td>%Z</td>
<td>Time zone name (no characters if no time zone exists).</td>
<td></td>
</tr>
<tr>
<td>%%</td>
<td>A literal '%' character.</td>
<td></td>
</tr>
</tbody>
</table>

Notes:

1. When used with the `strptime()` function, the %p directive
only affects the output hour field if the %I directive is used to parse the hour.

2. The range really is 0 to 61; value 60 is valid in timestamps representing leap seconds and value 61 is supported for historical reasons.

3. When used with the strftime() function, %U and %W are only used in calculations when the day of the week and the year are specified.

Here is an example, a format for dates compatible with that specified in the RFC 2822 Internet email standard. [1]

```python
>>> from time import gmtime, strftime
>>> strftime("%a, %d %b %Y %H:%M:%S +0000", gmtime)'Thu, 28 Jun 2001 14:17:15 +0000'
```

Additional directives may be supported on certain platforms, but only the ones listed here have a meaning standardized by ANSI C. To see the full set of format codes supported on your platform, consult the strftime(3) documentation.

On some platforms, an optional field width and precision specification can immediately follow the initial '%', of a directive in the following order; this is also not portable. The field width is normally 2 except for %j where it is 3.

```python
>>> from time import strftime
>>> strftime("%a %b %d %H:%M:%S %Y", gmtime)
'Thu, 28 Jun 2001 14:17:15 +0000'
```

Parse a string representing a time according to a format. The return value is a struct_time as returned by gmtime() or localtime().

The format parameter uses the same directives as those used by strftime(); it defaults to "%a %b %d %H:%M:%S %Y" which
matches the formatting returned by `ctime()`. If `string` cannot be parsed according to `format`, or if it has excess data after parsing, `ValueError` is raised. The default values used to fill in any missing data when more accurate values cannot be inferred are 

\[ (1900, 1, 1, 0, 0, 0, 0, 1, -1) \]

Both `string` and `format` must be strings.

For example:

```python
>>> import time
>>> time.strptime("30 Nov 00", "%d %b %y")
(time.struct_time(tm_year=2000, tm_mon=11, tm_mday=30, tm_hour=0, tm_min=0, tm_sec=0, tm_wday=3, tm_yday=335, tm_isdst=-1),)
```

Support for the `%%Z` directive is based on the values contained in `tzname` and whether `daylight` is true. Because of this, it is platform-specific except for recognizing UTC and GMT which are always known (and are considered to be non-daylight savings timezones).

Only the directives specified in the documentation are supported. Because `strftime()` is implemented per platform it can sometimes offer more directives than those listed. But `strptime()` is independent of any platform and thus does not necessarily support all directives available that are not documented as supported.

`class time.struct_time`

The type of the time value sequence returned by `gmtime()`, `localtime()`, and `strptime()`. It is an object with a `named tuple` interface: values can be accessed by index and
by attribute name. The following values are present:

<table>
<thead>
<tr>
<th>Index</th>
<th>Attribute</th>
<th>Values</th>
</tr>
</thead>
<tbody>
<tr>
<td>0</td>
<td>tm_year</td>
<td>(for example, 1993)</td>
</tr>
<tr>
<td>1</td>
<td>tm_mon</td>
<td>range [1, 12]</td>
</tr>
<tr>
<td>2</td>
<td>tm_mday</td>
<td>range [1, 31]</td>
</tr>
<tr>
<td>3</td>
<td>tm_hour</td>
<td>range [0, 23]</td>
</tr>
<tr>
<td>4</td>
<td>tm_min</td>
<td>range [0, 59]</td>
</tr>
<tr>
<td>5</td>
<td>tm_sec</td>
<td>range [0, 61]; see (2) in strftime() description</td>
</tr>
<tr>
<td>6</td>

<td>0, 1 or -1; see below</td>
</tr>
<tr>
<td>N/A</td>
<td>tm_zone</td>
<td>abbreviation of timezone name</td>
</tr>
<tr>
<td>N/A</td>
<td>tm_gmtoff</td>
<td>offset east of UTC in seconds</td>
</tr>
</tbody>
</table>

Note that unlike the C structure, the month value is a range of [1, 12], not [0, 11]. A -1 argument as the daylight savings flag, passed to mktime() will usually result in the correct daylight savings state to be filled in.

When a tuple with an incorrect length is passed to a function expecting a struct_time, or having elements of the wrong type, a TypeError is raised.

*Changed in version 3.3:* tm_gmtoff and tm_zone attributes are available on platforms with C library supporting the corresponding fields in struct tm.

```
import time
time.time()
```
Return the time in seconds since the epoch as a floating point number. Note that even though the time is always returned as a floating point number, not all systems provide time with a better precision than 1 second. While this function normally returns non-decreasing values, it can return a lower value than a previous call if the system clock has been set back between the two calls.

**time.timezone**

The offset of the local (non-DST) timezone, in seconds west of UTC (negative in most of Western Europe, positive in the US, zero in the UK).

**time.tzname**

A tuple of two strings: the first is the name of the local non-DST timezone, the second is the name of the local DST timezone. If no DST timezone is defined, the second string should not be used.

**time.tzset()**

Resets the time conversion rules used by the library routines. The environment variable TZ specifies how this is done.

**Availability:** Unix.

**Note:** Although in many cases, changing the TZ environment variable may affect the output of functions like `localtime()` without calling `tzset()`, this behavior should not be relied on. The TZ environment variable should contain no whitespace.

The standard format of the TZ environment variable is (whitespace added for clarity):

```
std_offset [dst [offset [,start[/time], end[/time]]]]
```
Where the components are:

**std** and **dst**
Three or more alphanumerics giving the timezone abbreviations. These will be propagated into time.tzname

**offset**
The offset has the form: ± hh[:mm[:ss]]. This indicates the value added the local time to arrive at UTC. If preceded by a ‘-‘, the timezone is east of the Prime Meridian; otherwise, it is west. If no offset follows dst, summer time is assumed to be one hour ahead of standard time.

**start[/time], end[/time]**
Indicates when to change to and back from DST. The format of the start and end dates are one of the following:

\[Jn\]
The Julian day \( n \) (1 <= \( n \) <= 365). Leap days are not counted, so in all years February 28 is day 59 and March 1 is day 60.

\[n\]
The zero-based Julian day (0 <= \( n \) <= 365). Leap days are counted, and it is possible to refer to February 29.

\[Mm.n.d\]
The \( d \)’th day (0 <= \( d \) <= 6) or week \( n \) of month \( m \) of the year (1 <= \( n \) <= 5, 1 <= \( m \) <= 12, where week 5 means “the last \( d \) day in month \( m \)” which may occur in either the fourth or the fifth week). Week 1 is the first week in which the \( d \)’th day occurs. Day zero is Sunday.

**time** has the same format as **offset** except that no leading sign (‘-‘ or ‘+’) is allowed. The default, if time is not given, is 02:00:00.
On many Unix systems (including *BSD, Linux, Solaris, and Darwin), it is more convenient to use the system’s zoneinfo (tzfile(5)) database to specify the timezone rules. To do this, set the TZ environment variable to the path of the required timezone datafile, relative to the root of the systems ‘zoneinfo’ timezone database, usually located at `/usr/share/zoneinfo`. For example, 'US/Eastern', 'Australia/Melbourne', 'Egypt' or 'Europe/Amsterdam'.

```
>>> os.environ['TZ'] = 'US/Eastern'
>>> time.tzset()
>>> time.tzname(('EST', 'EDT'))
>>> os.environ['TZ'] = 'Egypt'
>>> time.tzset()
>>> time.tzname(('EET', 'EEST'))
```

16.4. **argparse** — Parser for command-line options, arguments and sub-commands

*New in version 3.2.*

**Source code:** Lib/argparse.py

The **argparse** module makes it easy to write user-friendly command-line interfaces. The program defines what arguments it requires, and **argparse** will figure out how to parse those out of `sys.argv`. The **argparse** module also automatically generates help and usage messages and issues errors when users give the program invalid arguments.

**Tutorial**

This page contains the API reference information. For a more gentle introduction to Python command-line parsing, have a look at the [argparse tutorial](http://docs.python.org/library/argparse.html).
16.4.1. Example

The following code is a Python program that takes a list of integers and produces either the sum or the max:

```python
import argparse

parser = argparse.ArgumentParser(description='Process some integers.

parser.add_argument('integers', metavar='N', type=int, help='an integer for the accumulator

parser.add_argument('--sum', dest='accumulate', action='const', const=sum, default=max, help='sum the integers (default: find the max)

args = parser.parse_args()
print(args.accumulate(args.integers))
```

Assuming the Python code above is saved into a file called `prog.py`, it can be run at the command line and provides useful help messages:

```
$ python prog.py -h
usage: prog.py [-h] [--sum] N [N ...]
Process some integers.

positional arguments:
  N       an integer for the accumulator

optional arguments:
  -h, --help  show this help message and exit
  --sum      sum the integers (default: find the max)
```

When run with the appropriate arguments, it prints either the sum or
the max of the command-line integers:

```
$ python prog.py 1 2 3 4
4
$ python prog.py 1 2 3 4 --sum
10
```

If invalid arguments are passed in, it will issue an error:

```
$ python prog.py a b c
usage: prog.py [-h] [--sum] N [N ...]
prog.py: error: argument N: invalid int value: 'a'
```

The following sections walk you through this example.

### 16.4.1.1. Creating a parser

The first step in using the `argparse` is creating an `ArgumentParser` object:

```
>>> parser = argparse.ArgumentParser(description='Process some integers.
```

The `ArgumentParser` object will hold all the information necessary to parse the command line into Python data types.

### 16.4.1.2. Adding arguments

Filling an `ArgumentParser` with information about program arguments is done by making calls to the `add_argument()` method. Generally, these calls tell the `ArgumentParser` how to take the strings on the command line and turn them into objects. This
information is stored and used when `parse_args()` is called. For example:

```python
>>> parser.add_argument('integers', metavar='N', type=int,
                     help='an integer for the accumulator')
>>> parser.add_argument('--sum', dest='accumulate',
                     const=sum, default=max,
                     help='sum the integers (default: find the max)')
```

Later, calling `parse_args()` will return an object with two attributes, `integers` and `accumulate`. The `integers` attribute will be a list of one or more ints, and the `accumulate` attribute will be either the `sum()` function, if `--sum` was specified at the command line, or the `max()` function if it was not.

### 16.4.1.3. Parsing arguments

`ArgumentParser` parses arguments through the `parse_args()` method. This will inspect the command line, convert each argument to the appropriate type and then invoke the appropriate action. In most cases, this means a simple `Namespace` object will be built up from attributes parsed out of the command line:

```python
>>> parser.parse_args(['--sum', '7', '-1', '42'])
Namespace(accumulate=<built-in function sum>, integers=[7, -1, 42])
```

In a script, `parse_args()` will typically be called with no arguments, and the `ArgumentParser` will automatically determine the command-line arguments from `sys.argv`.
16.4.2. ArgumentParser objects

class argparse.ArgumentParser(prog=None, usage=None, description=None, epilog=None, parents=[], formatter_class=argparse.HelpFormatter, prefix_chars='-', fromfile_prefix_chars=None, argument_default=None, conflict_handler='error', add_help=True)

Create a new ArgumentParser object. All parameters should be passed as keyword arguments. Each parameter has its own more detailed description below, but in short they are:

- **prog** - The name of the program (default: `sys.argv[0]`)
- **usage** - The string describing the program usage (default: generated from arguments added to parser)
- **description** - Text to display before the argument help (default: none)
- **epilog** - Text to display after the argument help (default: none)
- **parents** - A list of ArgumentParser objects whose arguments should also be included
- **formatter_class** - A class for customizing the help output
- **prefix_chars** - The set of characters that prefix optional arguments (default: ‘-‘)
- **fromfile_prefix_chars** - The set of characters that prefix files from which additional arguments should be read (default: None)
- **argument_default** - The global default value for arguments (default: None)
- **conflict_handler** - The strategy for resolving conflicting optionals (usually unnecessary)
- **add_help** - Add a -h/--help option to the parser (default: True)

The following sections describe how each of these are used.
16.4.2.1. prog

By default, `ArgumentParser` objects uses `sys.argv[0]` to determine how to display the name of the program in help messages. This default is almost always desirable because it will make the help messages match how the program was invoked on the command line. For example, consider a file named `myprogram.py` with the following code:

```python
import argparse
parser = argparse.ArgumentParser()
parser.add_argument('--foo', help='foo help')
args = parser.parse_args()
```

The help for this program will display `myprogram.py` as the program name (regardless of where the program was invoked from):

```
$ python myprogram.py --help
usage: myprogram.py [-h] [--foo FOO]

optional arguments:
  -h, --help    show this help message and exit
  --foo FOO     foo help
$ cd ..
$ python subdir\myprogram.py --help
usage: myprogram.py [-h] [--foo FOO]

optional arguments:
  -h, --help    show this help message and exit
  --foo FOO     foo help
```

To change this default behavior, another value can be supplied using the `prog=` argument to `ArgumentParser`: 
Note that the program name, whether determined from `sys.argv[0]` or from the `prog=` argument, is available to help messages using the `%(prog)s` format specifier.

16.4.2.2. usage

By default, `ArgumentParser` calculates the usage message from the arguments it contains:
optional arguments:
   -h, --help    show this help message and exit
   --foo [FOO]   foo help

The default message can be overridden with the usage= keyword argument:

```python
>>> parser = argparse.ArgumentParser(prog='PROG', usage=
>>> parser.add_argument('--foo', nargs='?', help='foo help'
>>> parser.add_argument('bar', nargs='+', help='bar help'
>>> parser.print_help()
usage: PROG [options]

positional arguments:
   bar       bar help

optional arguments:
   -h, --help    show this help message and exit
   --foo [FOO]   foo help
```

The %(prog)s format specifier is available to fill in the program name in your usage messages.

### 16.4.2.3. description

Most calls to the `ArgumentParser` constructor will use the `description=` keyword argument. This argument gives a brief description of what the program does and how it works. In help messages, the description is displayed between the command-line usage string and the help messages for the various arguments:

```python
>>> parser = argparse.ArgumentParser(description='A foo that bars'
```
A foo that bars

optional arguments:
- h, --help show this help message and exit

And that's how you'd foo a bar

As with the description argument, the epilog text is by default line-wrapped, but this behavior can be adjusted with the formatter_class argument to ArgumentParser.
16.4.2.5. parents

Sometimes, several parsers share a common set of arguments. Rather than repeating the definitions of these arguments, a single parser with all the shared arguments and passed to parents= argument to ArgumentParser can be used. The parents= argument takes a list of ArgumentParser objects, collects all the positional and optional actions from them, and adds these actions to the ArgumentParser object being constructed:

```python
>>> parent_parser = argparse.ArgumentParser(add_help=True)
>>> parent_parser.add_argument('--parent', type=int)

>>> foo_parser = argparse.ArgumentParser(parents=[parent_parser])
>>> foo_parser.add_argument('foo')
>>> foo_parser.parse_args(['--parent', '2', 'XXX'])
Namespace(foo='XXX', parent=2)

>>> bar_parser = argparse.ArgumentParser(parents=[parent_parser])
>>> bar_parser.add_argument('--bar')
>>> bar_parser.parse_args(['--bar', 'YYY'])
Namespace(bar='YYY', parent=None)
```

Note that most parent parsers will specify add_help=False. Otherwise, the ArgumentParser will see two -h/--help options (one in the parent and one in the child) and raise an error.

**Note:** You must fully initialize the parsers before passing them via parents=. If you change the parent parsers after the child parser, those changes will not be reflected in the child.

16.4.2.6. formatter_class
ArgumentParser objects allow the help formatting to be customized by specifying an alternate formatting class. Currently, there are four such classes:

class argparse.RawDescriptionHelpFormatter
class argparse.RawTextHelpFormatter
class argparse.ArgumentDefaultsHelpFormatter
class argparse.MetavarTypeHelpFormatter

RawDescriptionHelpFormatter and RawTextHelpFormatter give more control over how textual descriptions are displayed. By default, ArgumentParser objects line-wrap the description and epilog texts in command-line help messages:

```python
>>> parser = argparse.ArgumentParser(
...     prog='PROG',
...     description='''this description was indented weird
...                 but that is okay''',
...     epilog='''
...         likewise for this epilog whose whitespace will be cleaned up and whose words will be wrapped across a couple lines'''
...
>>> parser.print_help()
usage: PROG [-h]

this description was indented weird but that is okay

optional arguments:
  -h, --help  show this help message and exit

likewise for this epilog whose whitespace will be cleaned up and whose words will be wrapped across a couple lines
```
Passing `RawDescriptionHelpFormatter` as `formatter_class=indicates that `description` and `epilog` are already correctly formatted and should not be line-wrapped:

```python
>>> parser = argparse.ArgumentParser(
...     prog='PROG',
...     formatter_class=argparse.RawDescriptionHelpFormatter,
...     description=textwrap.dedent('''
... Please do not mess up this text!
... --------------------------------
... I have indented it
... exactly the way
... I want it
... '''))
>>> parser.print_help()
usage: PROG [-h]

Please do not mess up this text!
--------------------------------
    I have indented it
    exactly the way
    I want it

optional arguments:
    -h, --help    show this help message and exit
```

`RawTextHelpFormatter` maintains whitespace for all sorts of help text, including argument descriptions.

`ArgumentDefaultsHelpFormatter` automatically adds information about default values to each of the argument help messages:

```python
>>> parser = argparse.ArgumentParser(  
...     prog='PROG',  
...     formatter_class=argparse.ArgumentParser.DefaultsHelpFormatter)  
```
MetavarTypeHelpFormatter uses the name of the type argument for each argument as the display name for its values (rather than using the dest as the regular formatter does):

```python
>>> parser = argparse.ArgumentParser(
...     prog='PROG',
...     formatter_class=argparse.MetavarTypeHelpFormatter

>>> parser.add_argument('--foo', type=int)
>>> parser.add_argument('bar', type=float)
>>> parser.print_help()
usage: PROG [-h] [--foo int] [bar [bar ...]]

positional arguments:
    bar            BAR! (default: [1, 2, 3])

optional arguments:
    -h, --help     show this help message and exit
    --foo int      FOO! (default: 42)
```

16.4.2.7. prefix_chars

Most command-line options will use `-` as the prefix, e.g. `-f/--foo`. 
Parsers that need to support different or additional prefix characters, e.g. for options like `+f` or `/foo`, may specify them using the `prefix_chars=` argument to the `ArgumentParser` constructor:

```python
>>> parser = argparse.ArgumentParser(prog='PROG', prefix_chars='-')
>>> parser.add_argument('+f')
>>> parser.add_argument('++bar')
>>> parser.parse_args('+f X ++bar Y'.split())
Namespace(bar='Y', f='X')
```

The `prefix_chars=` argument defaults to `-`. Supplying a set of characters that does not include `-` will cause `-f/--foo` options to be disallowed.

### 16.4.2.8. `fromfile_prefix_chars`

Sometimes, for example when dealing with a particularly long argument lists, it may make sense to keep the list of arguments in a file rather than typing it out at the command line. If the `fromfile_prefix_chars=` argument is given to the `ArgumentParser` constructor, then arguments that start with any of the specified characters will be treated as files, and will be replaced by the arguments they contain. For example:

```python
>>> with open('args.txt', 'w') as fp:
...     fp.write('-f\nbar')
>>> parser = argparse.ArgumentParser(fromfile_prefix_chars='-')
>>> parser.add_argument('-f')
>>> parser.parse_args(['-f', 'foo', '@args.txt'])
Namespace(f='bar')
```

Arguments read from a file must by default be one per line (but see
also `convert_arg_line_to_args()`) and are treated as if they were in the same place as the original file referencing argument on the command line. So in the example above, the expression `['-f', 'foo', '@args.txt']` is considered equivalent to the expression `['-f', 'foo', '-f', 'bar']`.

The `fromfile_prefix_chars=` argument defaults to None, meaning that arguments will never be treated as file references.

### 16.4.2.9. argument_default

Generally, argument defaults are specified either by passing a default to `add_argument()` or by calling the `set_defaults()` methods with a specific set of name-value pairs. Sometimes however, it may be useful to specify a single parser-wide default for arguments. This can be accomplished by passing the `argument_default=` keyword argument to `ArgumentParser`. For example, to globally suppress attribute creation on `parse_args()` calls, we supply `argument_default=SUPPRESS`:

```python
>>> parser = argparse.ArgumentParser(argument_default=None)
>>> parser.add_argument('--foo')
>>> parser.add_argument('bar', nargs='?')
>>> parser.parse_args(['--foo', '1', 'BAR'])
Namespace(bar='BAR', foo='1')
>>> parser.parse_args([])
Namespace()
```

### 16.4.2.10. conflict_handler

`ArgumentParser` objects do not allow two actions with the same
option string. By default, `ArgumentParser` objects raises an exception if an attempt is made to create an argument with an option string that is already in use:

```python
>>> parser = argparse.ArgumentParser(prog='PROG')
>>> parser.add_argument('-f', '--foo', help='old foo help')
>>> parser.add_argument('--foo', help='new foo help')
Traceback (most recent call last):
  ... ArgumentError: argument --foo: conflicting option string
```

Sometimes (e.g. when using `parents`) it may be useful to simply override any older arguments with the same option string. To get this behavior, the value `'resolve'` can be supplied to the `conflict_handler=` argument of `ArgumentParser`:

```python
>>> parser = argparse.ArgumentParser(prog='PROG', conflict_handler='resolve')
>>> parser.add_argument('-f', '--foo', help='old foo help')
>>> parser.add_argument('--foo', help='new foo help')
>>> parser.print_help()
usage: PROG [-h] [-f FOO] [--foo FOO]

optional arguments:
  -h, --help     show this help message and exit
  -f FOO         old foo help
  --foo FOO      new foo help
```

Note that `ArgumentParser` objects only remove an action if all of its option strings are overridden. So, in the example above, the old `-f/--foo` action is retained as the `-f` action, because only the `--foo` option string was overridden.
16.4.2.11. add_help

By default, ArgumentParser objects add an option which simply displays the parser's help message. For example, consider a file named myprogram.py containing the following code:

```python
import argparse
parser = argparse.ArgumentParser()
parser.add_argument('--foo', help='foo help')
args = parser.parse_args()
```

If `-h` or `--help` is supplied at the command line, the ArgumentParser help will be printed:

```plaintext
$ python myprogram.py --help
usage: myprogram.py [-h] [--foo FOO]

optional arguments:
  -h, --help    show this help message and exit
  --foo FOO     foo help
```

Occasionally, it may be useful to disable the addition of this help option. This can be achieved by passing `False` as the `add_help=` argument to `ArgumentParser`:

```python
>>> parser = argparse.ArgumentParser(prog='PROG', add_help=False)
>>> parser.add_argument('--foo', help='foo help')
>>> parser.print_help()
usage: PROG [--foo FOO]

optional arguments:
  --foo FOO     foo help
```
The help option is typically `-h/--help`. The exception to this is if the `prefix_chars=` is specified and does not include `-`, in which case `-h` and `--help` are not valid options. In this case, the first character in `prefix_chars` is used to prefix the help options:

```python
>>> parser = argparse.ArgumentParser(prog='PROG', prefix_chars='-')
>>> parser.print_help()
usage: PROG [+h]

optional arguments:
  +h, ++help show this help message and exit
```
16.4.3. The add_argument() method

ArgumentParser.add_argument(name or flags..., [action][, nargs][, const][, default][, type][, choices][, required][, help][, metavar][, dest])

Define how a single command-line argument should be parsed. Each parameter has its own more detailed description below, but in short they are:

- **name or flags** - Either a name or a list of option strings, e.g. `foo` or `-f, --foo`.
- **action** - The basic type of action to be taken when this argument is encountered at the command line.
- **nargs** - The number of command-line arguments that should be consumed.
- **const** - A constant value required by some action and nargs selections.
- **default** - The value produced if the argument is absent from the command line.
- **type** - The type to which the command-line argument should be converted.
- **choices** - A container of the allowable values for the argument.
- **required** - Whether or not the command-line option may be omitted (optionals only).
- **help** - A brief description of what the argument does.
- **metavar** - A name for the argument in usage messages.
- **dest** - The name of the attribute to be added to the object returned by `parse_args()`.

The following sections describe how each of these are used.

16.4.3.1. name or flags
The `add_argument()` method must know whether an optional argument, like `-f` or `--foo`, or a positional argument, like a list of filenames, is expected. The first arguments passed to `add_argument()` must therefore be either a series of flags, or a simple argument name. For example, an optional argument could be created like:

```python
>>> parser.add_argument('-f', '--foo')
```

while a positional argument could be created like:

```python
>>> parser.add_argument('bar')
```

When `parse_args()` is called, optional arguments will be identified by the `-` prefix, and the remaining arguments will be assumed to be positional:

```python
>>> parser = argparse.ArgumentParser(prog='PROG')
>>> parser.add_argument('-f', '--foo')
>>> parser.add_argument('bar')
>>> parser.parse_args(['BAR'])
Namespace(bar='BAR', foo=None)
>>> parser.parse_args(['BAR', '--foo', 'FOO'])
Namespace(bar='BAR', foo='FOO')
>>> parser.parse_args(['--foo', 'FOO'])
usage: PROG [-h] [-f FOO] bar
PROG: error: too few arguments
```

16.4.3.2. action

`ArgumentParser` objects associate command-line arguments with actions. These actions can do just about anything with the command-
line arguments associated with them, though most actions simply add an attribute to the object returned by `parse_args()`. The `action` keyword argument specifies how the command-line arguments should be handled. The supported actions are:

- **'store'** - This just stores the argument's value. This is the default action. For example:

  ```python
  >>> parser = argparse.ArgumentParser()
  >>> parser.add_argument('--foo')
  >>> parser.parse_args('--foo 1'.split())
  Namespace(foo='1')
  ```

- **'store_const'** - This stores the value specified by the `const` keyword argument. (Note that the `const` keyword argument defaults to the rather unhelpful `None`.) The `'store_const'` action is most commonly used with optional arguments that specify some sort of flag. For example:

  ```python
  >>> parser = argparse.ArgumentParser()
  >>> parser.add_argument('--foo', action='store_const')
  >>> parser.parse_args('--foo'.split())
  Namespace(foo=42)
  ```

- **'store_true'** and **'store_false'** - These store the values `True` and `False` respectively. These are special cases of `'store_const'`. For example:

  ```python
  >>> parser = argparse.ArgumentParser()
  >>> parser.add_argument('--foo', action='store_true')
  >>> parser.add_argument('--bar', action='store_false')
  >>> parser.parse_args('--foo --bar'.split())
  Namespace(bar=False, foo=True)
  ```
- `'append'` - This stores a list, and appends each argument value to the list. This is useful to allow an option to be specified multiple times. Example usage:

```python
>>> parser = argparse.ArgumentParser()
>>> parser.add_argument('--foo', action='append')
>>> parser.parse_args(['--foo 1', '--foo 2'].split())
Namespace(foo=['1', '2'])
```

- `'append_const'` - This stores a list, and appends the value specified by the `const` keyword argument to the list. (Note that the `const` keyword argument defaults to `None`.) The `'append_const'` action is typically useful when multiple arguments need to store constants to the same list. For example:

```python
>>> parser = argparse.ArgumentParser()
>>> parser.add_argument('--str', dest='types', action='append_const')
>>> parser.add_argument('--int', dest='types', action='append_const')
>>> parser.parse_args(['--str', '--int'].split())
Namespace(types=[<class 'str'>, <class 'int'>])
```

- `'count'` - This counts the number of times a keyword argument occurs. For example, this is useful for increasing verbosity levels:

```python
>>> parser = argparse.ArgumentParser()
>>> parser.add_argument('--verbose', '-v', action='count')
>>> parser.parse_args(['-vvv'].split())
Namespace(verbose=3)
```

- `'help'` - This prints a complete help message for all the options in the current parser and then exits. By default a help action is
automatically added to the parser. See `ArgumentParser` for details of how the output is created.

- `'version'` - This expects a `version=` keyword argument in the `add_argument()` call, and prints version information and exits when invoked:

```python
>>> import argparse
>>> parser = argparse.ArgumentParser(prog='PROG')
>>> parser.add_argument('--version', action='version')
>>> parser.parse_args(['--version'])
PROG 2.0
```

You can also specify an arbitrary action by passing an object that implements the Action API. The easiest way to do this is to extend `argparse.Action`, supplying an appropriate `__call__` method. The `__call__` method should accept four parameters:

- `parser` - The `ArgumentParser` object which contains this action.
- `namespace` - The `Namespace` object that will be returned by `parse_args()`. Most actions add an attribute to this object.
- `values` - The associated command-line arguments, with any type conversions applied. (Type conversions are specified with the `type` keyword argument to `add_argument()`.)
- `option_string` - The option string that was used to invoke this action. The `option_string` argument is optional, and will be absent if the action is associated with a positional argument.

An example of a custom action:

```python
>>> class FooAction(argparse.Action):
...     def __call__(self, parser, namespace, values, option_string=None):
...         print('%r %r %r' % (namespace, values, option_string))
```
16.4.3.3. nargs

ArgumentParser objects usually associate a single command-line argument with a single action to be taken. The `nargs` keyword argument associates a different number of command-line arguments with a single action. The supported values are:

- **N** (an integer). N arguments from the command line will be gathered together into a list. For example:

  ```python
  >>> parser = argparse.ArgumentParser()
  >>> parser.add_argument('--foo', nargs=2)
  >>> parser.add_argument('bar', nargs=1)
  >>> parser.parse_args('c --foo a b'.split())
  Namespace(bar=['c'], foo=['a', 'b'])
  ```

  Note that nargs=1 produces a list of one item. This is different from the default, in which the item is produced by itself.

- **?**. One argument will be consumed from the command line if possible, and produced as a single item. If no command-line argument is present, the value from `default` will be produced. Note
that for optional arguments, there is an additional case - the option string is present but not followed by a command-line argument. In this case the value from const will be produced. Some examples to illustrate this:

```python
>>> parser = argparse.ArgumentParser()
>>> parser.add_argument('--foo', nargs='?', const=None,
... default=None)
>>> parser.add_argument('bar', nargs='?', default=None)
>>> parser.parse_args('XX --foo YY'.split())
Namespace(bar='XX', foo='YY')
>>> parser.parse_args('XX --foo'.split())
Namespace(bar='XX', foo='c')
>>> parser.parse_args('').split())
Namespace(bar='d', foo='d')
```

One of the more common uses of nargs='?' is to allow optional input and output files:

```python
>>> parser = argparse.ArgumentParser()
>>> parser.add_argument('infile', nargs='?', type=...,
... default=sys.stdin)
>>> parser.add_argument('outfile', nargs='?', type=...
... default=sys.stdout)
>>> parser.parse_args(['input.txt', 'output.txt'])
Namespace(infile=<_io.TextIOWrapper name='input.txt', encoding='UTF-8'>,
... outfile=<_io.TextIOWrapper name='output.txt', encoding='UTF-8'>)
>>> parser.parse_args([])
Namespace(infile=<_io.TextIOWrapper name='<stdin>',
... outfile=<_io.TextIOWrapper name='<stdout>', encoding='UTF-8'>)
```

- **'***. All command-line arguments present are gathered into a list. Note that it generally doesn’t make much sense to have more than one positional argument with nargs='*', but multiple
optional arguments with nargs='*' is possible. For example:

```python
>>> parser = argparse.ArgumentParser()
>>> parser.add_argument('--foo', nargs='*')
>>> parser.add_argument('--bar', nargs='*')
>>> parser.add_argument('baz', nargs='*')
>>> parser.parse_args('a b --foo x y --bar 1 2').
Namespace(bar=['1', '2'], baz=['a', 'b'], foo=['x', 'y'])
```

- `'*'`. Just like `'*'`, all command-line args present are gathered into a list. Additionally, an error message will be generated if there wasn’t at least one command-line argument present. For example:

```python
>>> parser = argparse.ArgumentParser(prog='PROG')
>>> parser.add_argument('foo', nargs='+')
>>> parser.parse_args(['a b'].split())
Namespace(foo=['a', 'b'])
```

- `'*'`. Just like `'*'`, all command-line args present are gathered into a list. Additionally, an error message will be generated if there wasn’t at least one command-line argument present. For example:

```python
>>> parser = argparse.ArgumentParser()  # REMINDER
>>> parser.add_argument('--foo')  # REMINDER
>>> parser.add_argument('command')  # REMINDER
>>> parser.add_argument('args', nargs=argparse.REMAINDER)  # REMINDER
>>> print(parser.parse_args('--foo B cmd --arg1 XX ZZ'))
Namespace(args=['--arg1', 'XX', 'ZZ'], command='cmd')
```

- `argparse.REMAINDER`. All the remaining command-line arguments are gathered into a list. This is commonly useful for command line utilities that dispatch to other command line utilities:
If the `nargs` keyword argument is not provided, the number of arguments consumed is determined by the `action`. Generally this means a single command-line argument will be consumed and a single item (not a list) will be produced.

### 16.4.3.4. const

The `const` argument of `add_argument()` is used to hold constant values that are not read from the command line but are required for the various `ArgumentParser` actions. The two most common uses of it are:

- When `add_argument()` is called with `action='store_const'` or `action='append_const'`. These actions add the `const` value to one of the attributes of the object returned by `parse_args()`. See the `action` description for examples.
- When `add_argument()` is called with option strings (like `-f` or `--foo`) and `nargs='?'`. This creates an optional argument that can be followed by zero or one command-line arguments. When parsing the command line, if the option string is encountered with no command-line argument following it, the value of `const` will be assumed instead. See the `nargs` description for examples.

The `const` keyword argument defaults to `None`.

### 16.4.3.5. default

All optional arguments and some positional arguments may be omitted at the command line. The `default` keyword argument of `add_argument()`, whose value defaults to `None`, specifies what value should be used if the command-line argument is not present. For
optional arguments, the `default` value is used when the option string was not present at the command line:

```python
>>> parser = argparse.ArgumentParser()
>>> parser.add_argument('--foo', default=42)
>>> parser.parse_args('--foo 2'.split())
Namespace(foo='2')
>>> parser.parse_args('').split())
Namespace(foo=42)
```

If the `default` value is a string, the parser parses the value as if it were a command-line argument. In particular, the parser applies any `type` conversion argument, if provided, before setting the attribute on the `Namespace` return value. Otherwise, the parser uses the value as is:

```python
>>> parser = argparse.ArgumentParser()
>>> parser.add_argument('--length', default='10', type=int)
>>> parser.add_argument('--width', default=10.5, type=float)
>>> parser.parse_args()
Namespace(length=10, width=10.5)
```

For positional arguments with `nargs` equal to `?` or `*`, the `default` value is used when no command-line argument was present:

```python
>>> parser = argparse.ArgumentParser()
>>> parser.add_argument('foo', nargs='?', default=42)
>>> parser.parse_args('a'.split())
Namespace(foo='a')
>>> parser.parse_args('').split())
Namespace(foo=42)
```

Providing `default=argparse.SUPPRESS` causes no attribute to be
added if the command-line argument was not present:

```
>>> parser = argparse.ArgumentParser()
>>> parser.add_argument('--foo', default=argparse.SUPPRESS)
>>> parser.parse_args([])
Namespace()
>>> parser.parse_args([['--foo', '1']])
Namespace(foo='1')
```

16.4.3.6. type

By default, ArgumentParser objects read command-line arguments in as simple strings. However, quite often the command-line string should instead be interpreted as another type, like a float or int. The type keyword argument of add_argument() allows any necessary type-checking and type conversions to be performed. Common built-in types and functions can be used directly as the value of the type argument:

```
>>> parser = argparse.ArgumentParser()
>>> parser.add_argument('foo', type=int)
>>> parser.add_argument('bar', type=open)
>>> parser.parse_args('2 temp.txt'.split())
Namespace(bar=<_io.TextIOWrapper name='temp.txt' encoding='UTF-8'>, foo=2)
```

See the section on the default keyword argument for information on when the type argument is applied to default arguments.

To ease the use of various types of files, the argparse module provides the factory FileType which takes the mode= and bufsize= arguments of the open() function. For example, FileType('w') can be used to create a writable file:
type= can take any callable that takes a single string argument and returns the converted value:

```python
>>> def perfect_square(string):
...     value = int(string)
...     sqrt = math.sqrt(value)
...     if sqrt != int(sqrt):
...         msg = "%r is not a perfect square" % str(string)
...         raise argparse.ArgumentTypeError(msg)
...     return value
...
>>> parser = argparse.ArgumentParser(prog='PROG')
>>> parser.add_argument('foo', type=perfect_square)
>>> parser.parse_args('9'.split())
Namespace(foo=9)
>>> parser.parse_args('7'.split())
usage: PROG [-h] foo
PROG: error: argument foo: '7' is not a perfect square
```

The choices keyword argument may be more convenient for type checkers that simply check against a range of values:

```python
>>> parser = argparse.ArgumentParser(prog='PROG')
>>> parser.add_argument('foo', type=int, choices=range(5,12))
>>> parser.parse_args('7'.split())
Namespace(foo=7)
>>> parser.parse_args('11'.split())
usage: PROG [-h] {5,6,7,8,9}
PROG: error: argument foo: invalid choice: 11 (choose from 5, 6, 7, 8, 9)
```
See the choices section for more details.

16.4.3.7. choices

Some command-line arguments should be selected from a restricted set of values. These can be handled by passing a container object as the choices keyword argument to add_argument(). When the command line is parsed, argument values will be checked, and an error message will be displayed if the argument was not one of the acceptable values:

```python
>>> parser = argparse.ArgumentParser(prog='game.py')
>>> parser.add_argument('move', choices=['rock', 'paper'])
>>> parser.parse_args(['rock'])
Namespace(move='rock')
```

```python
usage: game.py [-h] {rock,paper,scissors}
game.py: error: argument move: invalid choice: 'fire' (choose from 'rock', 'paper', 'scissors')
```

Note that inclusion in the choices container is checked after any type conversions have been performed, so the type of the objects in the choices container should match the type specified:

```python
>>> parser = argparse.ArgumentParser(prog='doors.py')
>>> parser.add_argument('door', type=int, choices=range(1, 4))
>>> print(parser.parse_args([str(3)]))
Namespace(door=3)
```

```python
usage: doors.py [-h] {1,2,3}
doors.py: error: argument door: invalid choice: 4 (choose from 1, 2, 3)
```
Any object that supports the `in` operator can be passed as the `choices` value, so `dict` objects, `set` objects, custom containers, etc. are all supported.

### 16.4.3.8. required

In general, the `argparse` module assumes that flags like `-f` and `--bar` indicate `optional` arguments, which can always be omitted at the command line. To make an option `required`, `True` can be specified for the `required=` keyword argument to `add_argument()`:

```python
>>> parser = argparse.ArgumentParser()
>>> parser.add_argument('--foo', required=True)
>>> parser.parse_args(['--foo', 'BAR'])
Namespace(foo='BAR')
>>> parser.parse_args([])
argparse.py: error: option --foo is required
```

As the example shows, if an option is marked as `required`, `parse_args()` will report an error if that option is not present at the command line.

**Note:** Required options are generally considered bad form because users expect `options` to be `optional`, and thus they should be avoided when possible.

### 16.4.3.9. help

The `help` value is a string containing a brief description of the argument. When a user requests help (usually by using `-h` or `--help` at the command line), these `help` descriptions will be displayed with
each argument:

```python
>>> parser = argparse.ArgumentParser(prog='frobble')
>>> parser.add_argument('--foo', action='store_true',
... help='foo the bars before frobbling')
>>> parser.add_argument('bar', nargs='+',
... help='one of the bars to be frobbled')
>>> parser.parse_args('-h'.split())
usage: frobble [-h] [--foo] bar [bar ...]

positional arguments:
  bar       one of the bars to be frobbled

optional arguments:
  -h, --help  show this help message and exit
  --foo      foo the bars before frobbling
```

The help strings can include various format specifiers to avoid repetition of things like the program name or the argument default. The available specifiers include the program name, %(prog)s and most keyword arguments to `add_argument()`, e.g. %(default)s, %%(type)s, etc.:

```python
>>> parser = argparse.ArgumentParser(prog='frobble')
>>> parser.add_argument('bar', nargs='?', type=int,
... help='the bar to %(prog)s (default: %(default)s')
>>> parser.print_help()
usage: frobble [-h] [bar]

positional arguments:
  bar       the bar to frobble (default: 42)

optional arguments:
  -h, --help  show this help message and exit
```
As the help string supports %-formatting, if you want a literal % to appear in the help string, you must escape it as %%.

`argparse` supports silencing the help entry for certain options, by setting the help value to `argparse.SUPPRESS`:

```python
>>> parser = argparse.ArgumentParser(prog='frobble')
>>> parser.add_argument('--foo', help=argparse.SUPPRESS)
>>> parser.print_help()
usage: frobble [-h]

optional arguments:
  -h, --help    show this help message and exit
```

16.4.3.10. metavar

When `ArgumentParser` generates help messages, it needs some way to refer to each expected argument. By default, `ArgumentParser` objects use the `dest` value as the “name” of each object. By default, for positional argument actions, the `dest` value is used directly, and for optional argument actions, the `dest` value is uppercased. So, a single positional argument with `dest='bar'` will be referred to as `bar`. A single optional argument `--foo` that should be followed by a single command-line argument will be referred to as `FOO`. An example:

```python
>>> parser = argparse.ArgumentParser()
>>> parser.add_argument('--foo')
>>> parser.add_argument('bar')
>>> parser.parse_args('X --foo Y'.split())
Namespace(bar='X', foo='Y')
>>> parser.print_help()
usage: [-h] [-foo FOO] bar
```
positional arguments:
  bar

optional arguments:
  -h, --help    show this help message and exit
  --foo FOO

An alternative name can be specified with metavar:

```python
>>> parser = argparse.ArgumentParser()
>>> parser.add_argument('--foo', metavar='YYY')
>>> parser.add_argument('bar', metavar='XXX')
>>> parser.parse_args('X --foo Y'.split())
Namespace(bar='X', foo='Y')
```

```python
>>> parser.print_help()
usage: [-h] [--foo YYY] XXX
```

positional arguments:
  XXX

optional arguments:
  -h, --help    show this help message and exit
  --foo YYY

Note that metavar only changes the displayed name - the name of the attribute on the parse_args() object is still determined by the dest value.

Different values of nargs may cause the metavar to be used multiple times. Providing a tuple to metavar specifies a different display for each of the arguments:

```python
>>> parser = argparse.ArgumentParser(prog='PROG')
>>> parser.add_argument('-x', nargs=2)
>>> parser.add_argument('--foo', nargs=2, metavar=('bar', 'XXX'))
```
16.4.3.11. dest

Most `ArgumentParser` actions add some value as an attribute of the object returned by `parse_args()`. The name of this attribute is determined by the `dest` keyword argument of `add_argument()`. For positional argument actions, `dest` is normally supplied as the first argument to `add_argument()`:

```python
>>> parser = argparse.ArgumentParser()
>>> parser.add_argument('-f', '--foo-bar', '--foo')
>>> parser.parse_args('XXX'.split())
Namespace(foo='XXX')
```

For optional argument actions, the value of `dest` is normally inferred from the option strings. `ArgumentParser` generates the value of `dest` by taking the first long option string and stripping away the initial `--` string. If no long option strings were supplied, `dest` will be derived from the first short option string by stripping the initial `-` character. Any internal `-` characters will be converted to `_` characters to make sure the string is a valid attribute name. The examples below illustrate this behavior:

```python
>>> parser = argparse.ArgumentParser()
>>> parser.add_argument('-f', '--foo-bar', '--foo')
```
>>> parser.add_argument('-x', '-y')
>>> parser.parse_args('-f 1 -x 2'.split())
Namespace(foo_bar='1', x='2')
>>> parser.parse_args('--foo 1 -y 2'.split())
Namespace(foo_bar='1', x='2')

dest allows a custom attribute name to be provided:

>>> parser = argparse.ArgumentParser()
>>> parser.add_argument('--foo', dest='bar')
>>> parser.parse_args('--foo XXX'.split())
Namespace(bar='XXX')
16.4.4. The parse_args() method

ArgumentParser.parse_args(args=None, namespace=None)

Convert argument strings to objects and assign them as attributes of the namespace. Return the populated namespace.

Previous calls to add_argument() determine exactly what objects are created and how they are assigned. See the documentation for add_argument() for details.

By default, the argument strings are taken from sys.argv, and a new empty Namespace object is created for the attributes.

16.4.4.1. Option value syntax

The parse_args() method supports several ways of specifying the value of an option (if it takes one). In the simplest case, the option and its value are passed as two separate arguments:

```python
>>> parser = argparse.ArgumentParser(prog='PROG')
>>> parser.add_argument('-x')
>>> parser.add_argument('--foo')
>>> parser.parse_args('-x X'.split())
Namespace(foo=None, x='X')
>>> parser.parse_args('--foo=FOO'.split())
Namespace(foo='FOO', x=None)
```

For long options (options with names longer than a single character), the option and value can also be passed as a single command-line argument, using = to separate them:

```python
>>> parser.parse_args('--foo=FOO'.split())
```
Namespace(foo='FOO', x=None)

For short options (options only one character long), the option and its value can be concatenated:

```python
>>> parser.parse_args('-xX'.split())
Namespace(foo=None, x='X')
```

Several short options can be joined together, using only a single - prefix, as long as only the last option (or none of them) requires a value:

```python
>>> parser = argparse.ArgumentParser(prog='PROG')
>>> parser.add_argument('-x', action='store_true')
>>> parser.add_argument('-y', action='store_true')
>>> parser.add_argument('-z')
>>> parser.parse_args('-xyzZ'.split())
Namespace(x=True, y=True, z='Z')
```

16.4.4.2. Invalid arguments

While parsing the command line, `parse_args()` checks for a variety of errors, including ambiguous options, invalid types, invalid options, wrong number of positional arguments, etc. When it encounters such an error, it exits and prints the error along with a usage message:

```python
>>> parser = argparse.ArgumentParser(prog='PROG')
>>> parser.add_argument('--foo', type=int)
>>> parser.add_argument('bar', nargs='?')

>>> # invalid type
>>> parser.parse_args(['--foo', 'spam'])
usage: PROG [-h] [--foo FOO] [bar]
PROG: error: argument --foo: invalid int value: 'spam'
```
16.4.4.3. Arguments containing `-`

The `parse_args()` method attempts to give errors whenever the user has clearly made a mistake, but some situations are inherently ambiguous. For example, the command-line argument `-1` could either be an attempt to specify an option or an attempt to provide a positional argument. The `parse_args()` method is cautious here: positional arguments may only begin with `-` if they look like negative numbers and there are no options in the parser that look like negative numbers:

```python
>>> parser = argparse.ArgumentParser(prog='PROG')
>>> parser.add_argument('-x')
>>> parser.add_argument('foo', nargs='?')

>>> # no negative number options, so -1 is a positional
>>> parser.parse_args(['-x', '-1'])
Namespace(foo=None, x='-1')

>>> # no negative number options, so -1 and -5 are positions
>>> parser.parse_args(['-x', '-1', '-5'])
Namespace(foo='-5', x='-1')

>>> parser = argparse.ArgumentParser(prog='PROG')
```
If you have positional arguments that must begin with `-` and don’t look like negative numbers, you can insert the pseudo-argument `--` which tells `parse_args()` that everything after that is a positional argument:

```python
>>> parser.parse_args(['--', '-f'])
Namespace(foo='-f', one=None)
```

### 16.4.4.4. Argument abbreviations

The `parse_args()` method allows long options to be abbreviated if the abbreviation is unambiguous:
An error is produced for arguments that could produce more than one option.

### 16.4.4.5. Beyond sys.argv

Sometimes it may be useful to have an ArgumentParser parse arguments other than those of `sys.argv`. This can be accomplished by passing a list of strings to `parse_args()`. This is useful for testing at the interactive prompt:

```python
>>> parser = argparse.ArgumentParser()
>>> parser.add_argument(...
...   'integers', metavar='int', type=int, choices...
...   nargs='+', help='an integer in the range 0..9')
>>> parser.add_argument(...
...   'sum', dest='accumulate', action='store_const'...
...   default=max, help='sum the integers (default:... 
>>> parser.parse_args(['1', '2', '3', '4'])
Namespace(accumulate=<built-in function max>, integers=[1, 2, 3, 4])
>>> parser.parse_args('1 2 3 4 --sum'.split())
Namespace(accumulate=<built-in function sum>, integers=[1, 2, 3, 4])
```

### 16.4.4.6. The Namespace object

```python
class argparse.Namespace
```
Simple class used by default by `parse_args()` to create an object holding attributes and return it.

This class is deliberately simple, just an `object` subclass with a readable string representation. If you prefer to have dict-like view of the attributes, you can use the standard Python idiom, `vars()`:

```python
>>> parser = argparse.ArgumentParser()
>>> parser.add_argument('--foo')
>>> args = parser.parse_args(['--foo', 'BAR'])
>>> vars(args)
{'foo': 'BAR'}
```

It may also be useful to have an `ArgumentParser` assign attributes to an already existing object, rather than a new `Namespace` object. This can be achieved by specifying the `namespace=` keyword argument:

```python
>>> class C:
...        pass
...        ...
>>> c = C()
>>> parser = argparse.ArgumentParser()
>>> parser.add_argument('--foo')
>>> parser.parse_args(args=['--foo', 'BAR'], namespace=c)
>>> c.foo
'BAR'
```
16.4.5. Other utilities

16.4.5.1. Sub-commands

```python
ArgumentParser.add_subparsers([title][, description][, prog][, parser_class][, action][, option_string][, dest][, help][, metavar])
```

Many programs split up their functionality into a number of sub-commands, for example, the `svn` program can invoke sub-commands like `svn checkout`, `svn update`, and `svn commit`. Splitting up functionality this way can be a particularly good idea when a program performs several different functions which require different kinds of command-line arguments. `ArgumentParser` supports the creation of such sub-commands with the `add_subparsers()` method. The `add_subparsers()` method is normally called with no arguments and returns a special action object. This object has a single method, `add_parser()`, which takes a command name and any `ArgumentParser` constructor arguments, and returns an `ArgumentParser` object that can be modified as usual.

Description of parameters:

- **title** - title for the sub-parser group in help output; by default “subcommands” if description is provided, otherwise uses title for positional arguments
- **description** - description for the sub-parser group in help output, by default None
- **prog** - usage information that will be displayed with sub-command help, by default the name of the program and any positional arguments before the subparser argument
- **parser_class** - class which will be used to create sub-parser
instances, by default the class of the current parser (e.g. ArgumentParser)

- **dest** - name of the attribute under which sub-command name will be stored; by default None and no value is stored
- **help** - help for sub-parser group in help output, by default None
- **metavar** - string presenting available sub-commands in help; by default it is None and presents sub-commands in form {cmd1, cmd2, ..}

Some example usage:

```python
>>> # create the top-level parser
>>> parser = argparse.ArgumentParser(prog='PROG')
>>> parser.add_argument('--foo', action='store_true')
>>> subparsers = parser.add_subparsers(help='sub-command help')

>>> # create the parser for the "a" command
>>> parser_a = subparsers.add_parser('a', help='a help')
>>> parser_a.add_argument('bar', type=int, help='bar help')

>>> # create the parser for the "b" command
>>> parser_b = subparsers.add_parser('b', help='b help')
>>> parser_b.add_argument('--baz', choices='XYZ', help='baz help')

>>> # parse some argument lists
>>> parser.parse_args(['a', '12'])
Namespace(bar=12, foo=False)
>>> parser.parse_args(['--foo', 'b', '--baz', 'Z'])
Namespace(baz='Z', foo=True)
```

Note that the object returned by `parse_args()` will only contain attributes for the main parser and the subparser that was selected by the command line (and not any other subparsers). So in the example above, when the `a` command is specified, only the `foo`
and bar attributes are present, and when the b command is specified, only the foo and baz attributes are present.

Similarly, when a help message is requested from a subparser, only the help for that particular parser will be printed. The help message will not include parent parser or sibling parser messages. (A help message for each subparser command, however, can be given by supplying the help= argument to add_parser() as above.)

```python
>>> parser.parse_args(['--help'])
usage: PROG [-h] [--foo] {a,b} ...

positional arguments:
  {a,b}   sub-command help
    a    a help
    b    b help

optional arguments:
  -h, --help    show this help message and exit
  --foo    foo help
```
The `add_subparsers()` method also supports `title` and `description` keyword arguments. When either is present, the subparser’s commands will appear in their own group in the help output. For example:

```python
>>> parser = argparse.ArgumentParser()
>>> subparsers = parser.add_subparsers(title='subcommands',
                                                description='additional help',
                                                help='additional help')
>>> subparsers.add_parser('foo')
>>> subparsers.add_parser('bar')
>>> parser.parse_args(['-h'])
usage: [-h] {foo,bar} ...

optional arguments:
  -h, --help    show this help message and exit

subcommands:
  valid subcommands
    {foo,bar}    additional help
```

Furthermore, `add_parser` supports an additional `aliases` argument, which allows multiple strings to refer to the same subparser. This example, like `svn`, aliases `co` as a shorthand for `checkout`:

```python
>>> parser = argparse.ArgumentParser()
>>> subparsers = parser.add_subparsers()
>>> checkout = subparsers.add_parser('checkout', aliases=['co'])
>>> checkout.add_argument('foo')
>>> parser.parse_args(['co', 'bar'])
```
One particularly effective way of handling sub-commands is to combine the use of the `add_subparsers()` method with calls to `set_defaults()` so that each subparser knows which Python function it should execute. For example:

```python
def foo(args):
...   print(args.x * args.y)
...
def bar(args):
...   print('((%s))' % args.z)
...
# create the top-level parser
parser = argparse.ArgumentParser()
subparsers = parser.add_subparsers()

# create the parser for the "foo" command
parser_foo = subparsers.add_parser('foo')
parser_foo.add_argument('-x', type=int, default=None)
parser_foo.add_argument('y', type=float)
parser_foo.set_defaults(func=foo)

# create the parser for the "bar" command
parser_bar = subparsers.add_parser('bar')
parser_bar.add_argument('z')
parser_bar.set_defaults(func=bar)

# parse the args and call whatever function was selected
args = parser.parse_args('foo 1 -x 2'.split())
args.func(args)
```

```python
2.0
```
This way, you can let `parse_args()` do the job of calling the appropriate function after argument parsing is complete. Associating functions with actions like this is typically the easiest way to handle the different actions for each of your subparsers. However, if it is necessary to check the name of the subparser that was invoked, the `dest` keyword argument to the `add_subparsers()` call will work:

```python
>>> parser = argparse.ArgumentParser()
>>> subparsers = parser.add_subparsers(dest='subparser_name')
>>> subparser1 = subparsers.add_parser('1')
>>> subparser1.add_argument('-x')
>>> subparser2 = subparsers.add_parser('2')
>>> subparser2.add_argument('y')
>>> parser.parse_args(['2', 'frobble'])
Namespace(subparser_name='2', y='frobble')
```

## 16.4.5.2. FileType objects

The `argparse.FileType` factory creates objects that can be passed to the type argument of `ArgumentParser.add_argument()`. Arguments that have `FileType` objects as their type will open command-line arguments as files with the requested modes and buffer sizes:

```python
>>> parser = argparse.ArgumentParser()
>>> parser.add_argument('--output', type=argparse
```
FileType objects understand the pseudo-argument `-` and automatically convert this into `sys.stdin` for readable FileType objects and `sys.stdout` for writable FileType objects:

```python
>>> parser = argparse.ArgumentParser()
>>> parser.add_argument('infile', type=argparse.FileType())
>>> parser.parse_args(['-'])
Namespace(infile=_io.TextIOWrapper name='<stdin>')
```

16.4.5.3. Argument groups

`argparse.ArgumentParser.add_argument_group(title=None, description=None)`

By default, `ArgumentParser` groups command-line arguments into “positional arguments” and “optional arguments” when displaying help messages. When there is a better conceptual grouping of arguments than this default one, appropriate groups can be created using the `add_argument_group()` method:

```python
>>> parser = argparse.ArgumentParser(prog='PROG',
>>> group = parser.add_argument_group('group')
>>> group.add_argument('--foo', help='foo help')
>>> group.add_argument('bar', help='bar help')
>>> parser.print_help()
usage: PROG [-h] [--foo FOO] bar

group:
  bar  bar help
  --foo FOO  foo help
```
The `add_argument_group()` method returns an argument group object which has an `add_argument()` method just like a regular `ArgumentParser`. When an argument is added to the group, the parser treats it just like a normal argument, but displays the argument in a separate group for help messages. The `add_argument_group()` method accepts `title` and `description` arguments which can be used to customize this display:

```python
>>> parser = argparse.ArgumentParser(prog='PROG',
>>> group1 = parser.add_argument_group('group1',
>>> group1.add_argument('foo', help='foo help')
>>> group2 = parser.add_argument_group('group2',
>>> group2.add_argument('--bar', help='bar help')
>>> parser.print_help()
```

Usage: `PROG [--bar BAR] foo`

```
  group1:
    group1 description
    foo foo help
  group2:
    group2 description
    --bar BAR bar help
```

Note that any arguments not in your user-defined groups will end up back in the usual “positional arguments” and “optional arguments” sections.

**16.4.5.4. Mutual exclusion**
ArgumentParser.**add_mutually_exclusive_group**(\textit{requir})

Create a mutually exclusive group. \textit{argparse} will make sure that only one of the arguments in the mutually exclusive group was present on the command line:

```python
>>> parser = argparse.ArgumentParser(prog='PROG')
>>> group = parser.add_mutually_exclusive_group()
>>> group.add_argument('--foo', action='store_true')
>>> group.add_argument('--bar', action='store_false')
>>> parser.parse_args(['--foo'])
Namespace(bar=True, foo=True)
>>> parser.parse_args(['--bar'])
Namespace(bar=False, foo=False)
>>> parser.parse_args(['--foo', '--bar'])
usage: PROG [-h] [--foo | --bar]
PROG: error: argument --bar: not allowed with arg
```

The **add_mutually_exclusive_group()** method also accepts a \textit{required} argument, to indicate that at least one of the mutually exclusive arguments is required:

```python
>>> parser = argparse.ArgumentParser(prog='PROG')
>>> group = parser.add_mutually_exclusive_group(required=True)
>>> group.add_argument('--foo', action='store_true')
>>> group.add_argument('--bar', action='store_false')
>>> parser.parse_args([])
usage: PROG [-h] (--foo | --bar)
PROG: error: one of the arguments --foo --bar is required
```

Note that currently mutually exclusive argument groups do not support the \textit{title} and \textit{description} arguments of **add_argument_group()**.
16.4.5.5. Parser defaults

ArgumentParser.set_defaults(**kwargs)

Most of the time, the attributes of the object returned by parse_args() will be fully determined by inspecting the command-line arguments and the argument actions. set_defaults() allows some additional attributes that are determined without any inspection of the command line to be added:

```python
>>> parser = argparse.ArgumentParser()
>>> parser.add_argument('foo', type=int)
>>> parser.set_defaults(bar=42, baz='badger')
>>> parser.parse_args(['736'])
Namespace(bar=42, baz='badger', foo=736)
```

Note that parser-level defaults always override argument-level defaults:

```python
>>> parser = argparse.ArgumentParser()
>>> parser.add_argument('--foo', default='bar')
>>> parser.set_defaults(foo='spam')
>>> parser.parse_args([])
Namespace(foo='spam')
```

Parser-level defaults can be particularly useful when working with multiple parsers. See the add_subparsers() method for an example of this type.

ArgumentParser.get_default(dest)

Get the default value for a namespace attribute, as set by either add_argument() or by set_defaults():

```python
>>> parser = argparse.ArgumentParser()
>>> parser.add_argument('foo', type=int)
>>> parser.set_defaults(bar=42, baz='badger')
>>> parser.parse_args(['736'])
Namespace(bar=42, baz='badger', foo=736)
```
16.4.5.6. Printing help

In most typical applications, `parse_args()` will take care of formatting and printing any usage or error messages. However, several formatting methods are available:

`ArgumentParser.print_usage(file=None)`

Print a brief description of how the `ArgumentParser` should be invoked on the command line. If `file` is None, `sys.stdout` is assumed.

`ArgumentParser.print_help(file=None)`

Print a help message, including the program usage and information about the arguments registered with the `ArgumentParser`. If `file` is None, `sys.stdout` is assumed.

There are also variants of these methods that simply return a string instead of printing it:

`ArgumentParser.format_usage()`

Return a string containing a brief description of how the `ArgumentParser` should be invoked on the command line.

`ArgumentParser.format_help()`

Return a string containing a help message, including the program usage and information about the arguments registered with the
16.4.5.7. Partial parsing

ArgumentParser.parse_known_args(args=None, namespace=None)

Sometimes a script may only parse a few of the command-line arguments, passing the remaining arguments on to another script or program. In these cases, the parse_known_args() method can be useful. It works much like parse_args() except that it does not produce an error when extra arguments are present. Instead, it returns a two item tuple containing the populated namespace and the list of remaining argument strings.

```python
>>> parser = argparse.ArgumentParser()
>>> parser.add_argument('--foo', action='store_true')
>>> parser.add_argument('bar')
>>> parser.parse_known_args(['--foo', '--badger', 'BAR', 'spam'])
(Namespace(bar='BAR', foo=True), ['--badger', 'spam'])
```

16.4.5.8. Customizing file parsing

ArgumentParser.convert_arg_line_to_args(arg_line)

Arguments that are read from a file (see the fromfile_prefix_chars keyword argument to the ArgumentParser constructor) are read one argument per line. convert_arg_line_to_args() can be overridden for fancier reading.

This method takes a single argument arg_line which is a string read from the argument file. It returns a list of arguments parsed
from this string. The method is called once per line read from the argument file, in order.

A useful override of this method is one that treats each space-separated word as an argument:

```python
def convert_arg_line_to_args(self, arg_line):
    for arg in arg_line.split():
        if not arg.strip():
            continue
        yield arg
```

### 16.4.5.9. Exiting methods

ArgumentParser.**exit**(status=0, message=None)

This method terminates the program, exiting with the specified `status` and, if given, it prints a `message` before that.

ArgumentParser.**error**(message)

This method prints a usage message including the `message` to the standard error and terminates the program with a status code of 2.
16.4.6. Upgrading optparse code

Originally, the `argparse` module had attempted to maintain compatibility with `optparse`. However, `optparse` was difficult to extend transparently, particularly with the changes required to support the new `nargs=` specifiers and better usage messages. When most everything in `optparse` had either been copy-pasted over or monkey-patched, it no longer seemed practical to try to maintain the backwards compatibility.

A partial upgrade path from `optparse` to `argparse`:

- Replace all `optparse.OptionParser.add_option()` calls with `ArgumentParser.add_argument()` calls.
- Replace `(options, args) = parser.parse_args()` with `args = parser.parse_args()` and add additional `ArgumentParser.add_argument()` calls for the positional arguments. Keep in mind that what was previously called `options`, now in `argparse` context is called `args`.
- Replace callback actions and the `callback_*` keyword arguments with `type` or `action` arguments.
- Replace string names for `type` keyword arguments with the corresponding type objects (e.g. `int`, `float`, `complex`, etc).
- Replace strings with implicit arguments such as `%default` or `%prog` with the standard Python syntax to use dictionaries to format strings, that is, `%(default)s` and `%(prog)s`.
- Replace the `OptionParser` constructor `version` argument with a call to `parser.add_argument('--version',`
16.5. `optparse` — Parser for command line options

`optparse` module is deprecated and will not be developed further; development will continue with the `argparse` module.

**Source code:** `Lib/optparse.py`

`optparse` is a more convenient, flexible, and powerful library for parsing command-line options than the old `getopt` module. `optparse` uses a more declarative style of command-line parsing: you create an instance of `OptionParser`, populate it with options, and parse the command line. `optparse` allows users to specify options in the conventional GNU/POSIX syntax, and additionally generates usage and help messages for you.

Here's an example of using `optparse` in a simple script:

```python
from optparse import OptionParser

parser = OptionParser()
parser.add_option("-f", "--file", dest="filename",
                 help="write report to FILE", metavar="FILE")
parser.add_option("-q", "--quiet",
                 action="store_false", dest="verbose",
                 help="don't print status messages")

(options, args) = parser.parse_args()
```

With these few lines of code, users of your script can now do the “usual thing” on the command-line, for example:

```bash
<yourscript> --file=outfile -q
```

As it parses the command line, `optparse` sets attributes of the `options` object returned by `parse_args()` based on user-supplied command-line values. When `parse_args()` returns from parsing this command line, `options.filename` will be "outfile" and `options.verbose` will be `False`. `optparse` supports both long and short options, allows short options to be merged together, and allows options to be associated with their arguments in a variety of ways. Thus, the following command lines are all equivalent to the above example:

```bash
<yourscript> -f outfile --quiet
<yourscript> --quiet --file outfile
<yourscript> -q -f outfile
<yourscript> -qf outfile
```

Additionally, users can run one of

```bash
<yourscript> -h
<yourscript> --help
```

and `optparse` will print out a brief summary of your script's options:

```
Usage: <yourscript> [options]

Options:
- h, --help                  show this help message and exit
- f FILE, --file=FILE        write report to FILE
- q, --quiet                don't print status messages
```
where the value of `yourscript` is determined at runtime (normally from `sys.argv[0]`).
16.5.1. Background

`optparse` was explicitly designed to encourage the creation of programs with straightforward, conventional command-line interfaces. To that end, it supports only the most common command-line syntax and semantics conventionally used under Unix. If you are unfamiliar with these conventions, read this section to acquaint yourself with them.

16.5.1.1. Terminology

argument
a string entered on the command-line, and passed by the shell to `exec1()` or `execv()`. In Python, arguments are elements of `sys.argv[1:]` (`sys.argv[0]` is the name of the program being executed). Unix shells also use the term “word”.

It is occasionally desirable to substitute an argument list other than `sys.argv[1:]`, so you should read “argument” as “an element of `sys.argv[1:]`, or of some other list provided as a substitute for `sys.argv[1:]`”.

option
an argument used to supply extra information to guide or customize the execution of a program. There are many different syntaxes for options; the traditional Unix syntax is a hyphen (“-”) followed by a single letter, e.g. `-x` or `-F`. Also, traditional Unix syntax allows multiple options to be merged into a single argument, e.g. `-x` `-F` is equivalent to `-xF`. The GNU project introduced `--` followed by a series of hyphen-separated words, e.g. `--file` or `--dry-run`. These are the only two option syntaxes provided by
Some other option syntaxes that the world has seen include:

- a hyphen followed by a few letters, e.g. `--pf` (this is not the same as multiple options merged into a single argument)
- a hyphen followed by a whole word, e.g. `--file` (this is technically equivalent to the previous syntax, but they aren’t usually seen in the same program)
- a plus sign followed by a single letter, or a few letters, or a word, e.g. `+f`, `+rgb`
- a slash followed by a letter, or a few letters, or a word, e.g. `/f`, `/file`

These option syntaxes are not supported by `optparse`, and they never will be. This is deliberate: the first three are non-standard on any environment, and the last only makes sense if you’re exclusively targeting VMS, MS-DOS, and/or Windows.

**option argument**

an argument that follows an option, is closely associated with that option, and is consumed from the argument list when that option is. With `optparse`, option arguments may either be in a separate argument from their option:

```
-f foo
--file foo
```

or included in the same argument:

```
-f foo=foo
```

Typically, a given option either takes an argument or it doesn’t. Lots
of people want an “optional option arguments” feature, meaning that some options will take an argument if they see it, and won’t if they don’t. This is somewhat controversial, because it makes parsing ambiguous: if `-a` takes an optional argument and `-b` is another option entirely, how do we interpret `-ab`? Because of this ambiguity, `optparse` does not support this feature.

**positional argument**

something leftover in the argument list after options have been parsed, i.e. after options and their arguments have been parsed and removed from the argument list.

**required option**

an option that must be supplied on the command-line; note that the phrase “required option” is self-contradictory in English. `optparse` doesn’t prevent you from implementing required options, but doesn’t give you much help at it either.

For example, consider this hypothetical command-line:

```
prog -v --report report.txt foo bar
```

`-v` and `--report` are both options. Assuming that `--report` takes one argument, `report.txt` is an option argument. `foo` and `bar` are positional arguments.

### 16.5.1.2. What are options for?

Options are used to provide extra information to tune or customize the execution of a program. In case it wasn’t clear, options are usually *optional*. A program should be able to run just fine with no options whatsoever. (Pick a random program from the Unix or GNU toolsets. Can it run without any options at all and still make sense? The main
exceptions are `find`, `tar`, and `dd`—all of which are mutant oddballs that have been rightly criticized for their non-standard syntax and confusing interfaces.)

Lots of people want their programs to have “required options”. Think about it. If it's required, then it's not optional! If there is a piece of information that your program absolutely requires in order to run successfully, that's what positional arguments are for.

As an example of good command-line interface design, consider the humble `cp` utility, for copying files. It doesn’t make much sense to try to copy files without supplying a destination and at least one source. Hence, `cp` fails if you run it with no arguments. However, it has a flexible, useful syntax that does not require any options at all:

```
cp SOURCE DEST
cp SOURCE ... DEST-DIR
```

You can get pretty far with just that. Most `cp` implementations provide a bunch of options to tweak exactly how the files are copied: you can preserve mode and modification time, avoid following symlinks, ask before clobbering existing files, etc. But none of this distracts from the core mission of `cp`, which is to copy either one file to another, or several files to another directory.

### 16.5.1.3. What are positional arguments for?

Positional arguments are for those pieces of information that your program absolutely, positively requires to run.

A good user interface should have as few absolute requirements as possible. If your program requires 17 distinct pieces of information in
order to run successfully, it doesn't much matter how you get that information from the user—most people will give up and walk away before they successfully run the program. This applies whether the user interface is a command-line, a configuration file, or a GUI: if you make that many demands on your users, most of them will simply give up.

In short, try to minimize the amount of information that users are absolutely required to supply—use sensible defaults whenever possible. Of course, you also want to make your programs reasonably flexible. That's what options are for. Again, it doesn't matter if they are entries in a config file, widgets in the “Preferences” dialog of a GUI, or command-line options—the more options you implement, the more flexible your program is, and the more complicated its implementation becomes. Too much flexibility has drawbacks as well, of course; too many options can overwhelm users and make your code much harder to maintain.
While `optparse` is quite flexible and powerful, it's also straightforward to use in most cases. This section covers the code patterns that are common to any `optparse`-based program.

First, you need to import the OptionParser class; then, early in the main program, create an OptionParser instance:

```python
from optparse import OptionParser
...
parser = OptionParser()
```

Then you can start defining options. The basic syntax is:

```python
parser.add_option(opt_str, ..., attr=value, ...)
```

Each option has one or more option strings, such as `-f` or `--file`, and several option attributes that tell `optparse` what to expect and what to do when it encounters that option on the command line.

Typically, each option will have one short option string and one long option string, e.g.:

```python
parser.add_option("-f", "--file", ...)
```

You're free to define as many short option strings and as many long option strings as you like (including zero), as long as there is at least one option string overall.

The option strings passed to `OptionParser.add_option()` are effectively labels for the option defined by that call. For brevity, we will
frequently refer to *encountering an option* on the command line; in reality, *optparse* encounters *option strings* and looks up options from them.

Once all of your options are defined, instruct *optparse* to parse your program's command line:

```
(options, args) = parser.parse_args()
```

(If you like, you can pass a custom argument list to `parse_args()`, but that's rarely necessary: by default it uses `sys.argv[1:]`.)

`parse_args()` returns two values:

- **options**, an object containing values for all of your options—e.g. if `--file` takes a single string argument, then `options.file` will be the filename supplied by the user, or `None` if the user did not supply that option
- **args**, the list of positional arguments leftover after parsing options

This tutorial section only covers the four most important option attributes: *action*, *type*, *dest* (destination), and *help*. Of these, *action* is the most fundamental.

### 16.5.2.1. Understanding option actions

Actions tell *optparse* what to do when it encounters an option on the command line. There is a fixed set of actions hard-coded into *optparse*; adding new actions is an advanced topic covered in section *Extending optparse*. Most actions tell *optparse* to store a value in some variable—for example, take a string from the command
line and store it in an attribute of `options`.

If you don’t specify an option action, `optparse` defaults to `store`.

### 16.5.2.2. The store action

The most common option action is `store`, which tells `optparse` to take the next argument (or the remainder of the current argument), ensure that it is of the correct type, and store it to your chosen destination.

For example:

```python
parser.add_option("-f", "--file",
    action="store", type="string", dest="filename")
```

Now let’s make up a fake command line and ask `optparse` to parse it:

```python
args = ["-f", "foo.txt"]
(options, args) = parser.parse_args(args)
```

When `optparse` sees the option string `-f`, it consumes the next argument, `foo.txt`, and stores it in `options.filename`. So, after this call to `parse_args()`, `options.filename` is "foo.txt".

Some other option types supported by `optparse` are `int` and `float`. Here’s an option that expects an integer argument:

```python
parser.add_option("-n", type="int", dest="num")
```

Note that this option has no long option string, which is perfectly
acceptable. Also, there's no explicit action, since the default is store.

Let's parse another fake command-line. This time, we'll jam the option argument right up against the option: since -n42 (one argument) is equivalent to -n 42 (two arguments), the code

```python
(options, args) = parser.parse_args(["-n42"])
print(options.num)
```

will print 42.

If you don't specify a type, optparse assumes string. Combined with the fact that the default action is store, that means our first example can be a lot shorter:

```python
parser.add_option("-f", "--file", dest="filename")
```

If you don't supply a destination, optparse figures out a sensible default from the option strings: if the first long option string is --foo-bar, then the default destination is foo_bar. If there are no long option strings, optparse looks at the first short option string: the default destination for -f is f.

optparse also includes the built-in complex type. Adding types is covered in section Extending optparse.

16.5.2.3. Handling boolean (flag) options

Flag options—set a variable to true or false when a particular option is seen—are quite common. optparse supports them with two separate actions, store_true and store_false. For example, you might have a verbose flag that is turned on with -v and off with -q:
Here we have two different options with the same destination, which is perfectly OK. (It just means you have to be a bit careful when setting default values—see below.)

When `optparse` encounters `-v` on the command line, it sets `options.verbose` to `True`; when it encounters `-q`, `options.verbose` is set to `False`.

### 16.5.2.4. Other actions

Some other actions supported by `optparse` are:

- **"store_const"**: Store a constant value
- **"append"**: Append this option’s argument to a list
- **"count"**: Increment a counter by one
- **"callback"**: Call a specified function

These are covered in section `Reference Guide`, Reference Guide and section `Option Callbacks`.

### 16.5.2.5. Default values

All of the above examples involve setting some variable (the “destination”) when certain command-line options are seen. What
happens if those options are never seen? Since we didn’t supply any defaults, they are all set to None. This is usually fine, but sometimes you want more control. `optparse` lets you supply a default value for each destination, which is assigned before the command line is parsed.

First, consider the verbose/quiet example. If we want `optparse` to set `verbose` to True unless `-q` is seen, then we can do this:

```python
parser.add_option("-v", action="store_true", dest="verbose")
parser.add_option("-q", action="store_false", dest="verbose")
```

Since default values apply to the destination rather than to any particular option, and these two options happen to have the same destination, this is exactly equivalent:

```python
parser.add_option("-v", action="store_true", dest="verbose")
parser.add_option("-q", action="store_false", dest="verbose")
```

Consider this:

```python
parser.add_option("-v", action="store_true", dest="verbose")
parser.add_option("-q", action="store_false", dest="verbose")
```

Again, the default value for `verbose` will be True: the last default value supplied for any particular destination is the one that counts.

A clearer way to specify default values is the `set_defaults()` method of OptionParser, which you can call at any time before calling `parse_args()`:

```python
parser.set_defaults(verbos=True)
```
As before, the last value specified for a given option destination is the one that counts. For clarity, try to use one method or the other of setting default values, not both.

16.5.2.6. Generating help

`optparse`'s ability to generate help and usage text automatically is useful for creating user-friendly command-line interfaces. All you have to do is supply a `help` value for each option, and optionally a short usage message for your whole program. Here's an OptionParser populated with user-friendly (documented) options:

```python
usage = "usage: %prog [options] arg1 arg2"
parser = OptionParser(usage=usage)
parser.add_option("-v", "--verbose",
                  action="store_true", dest="verbose",
                  help="make lots of noise [default]"
               )
parser.add_option("-q", "--quiet",
                  action="store_false", dest="verbose",
                  help="be vewwy quiet (I'm hunting"
               )
parser.add_option("-f", "--filename",
                  metavar="FILE", help="write output"
               )
parser.add_option("-m", "--mode",
                  default="intermediate",
                  help="interaction mode: novice, intermediate, or expert [default: %default"
               )
```

If `optparse` encounters either `--help` on the command-line, or if you just call `parser.print_help()`, it prints the following to standard output:
Usage: <yourscript> [options] arg1 arg2

Options:
- `h`, `--help` show this help message and exit
- `v`, `--verbose` make lots of noise [default]
- `q`, `--quiet` be vewwy quiet (I'm hunting)
- `f FILE`, `--filename=FILE` write output to FILE
- `m MODE`, `--mode=MODE` interaction mode: novice, intermediate, or expert [default: intermediate]

(If the help output is triggered by a help option, optparse exits after printing the help text.)

There's a lot going on here to help optparse generate the best possible help message:

- the script defines its own usage message:

```python
usage = "usage: %prog [options] arg1 arg2"
```

optparse expands `%prog` in the usage string to the name of the current program, i.e. `os.path.basename(sys.argv[0])`. The expanded string is then printed before the detailed option help.

If you don’t supply a usage string, optparse uses a bland but sensible default: "Usage: %prog [options]", which is fine if your script doesn’t take any positional arguments.

- every option defines a help string, and doesn’t worry about line-wrapping— optparse takes care of wrapping lines and making the help output look good.

- options that take a value indicate this fact in their automatically-
generated help message, e.g. for the “mode” option:

-m MODE, --mode=MODE

Here, “MODE” is called the meta-variable: it stands for the argument that the user is expected to supply to -m/--mode. By default, optparse converts the destination variable name to uppercase and uses that for the meta-variable. Sometimes, that’s not what you want—for example, the --filename option explicitly sets metavar="FILE", resulting in this automatically-generated option description:

-f FILE, --filename=FILE

This is important for more than just saving space, though: the manually written help text uses the meta-variable FILE to clue the user in that there’s a connection between the semi-formal syntax -f FILE and the informal semantic description “write output to FILE”. This is a simple but effective way to make your help text a lot clearer and more useful for end users.

- options that have a default value can include %default in the help string—optparse will replace it with str() of the option’s default value. If an option has no default value (or the default value is None), %default expands to none.

16.5.2.6.1. Grouping Options

When dealing with many options, it is convenient to group these options for better help output. An OptionParser can contain several option groups, each of which can contain several options.
An option group is obtained using the class `OptionGroup`:

```python
class optparse.OptionGroup(parser, title, description=None)
```

where

- `parser` is the `OptionParser` instance the group will be inserted into
- `title` is the group title
- `description`, optional, is a long description of the group

`OptionGroup` inherits from `OptionContainer` (like `OptionParser`) and so the `add_option()` method can be used to add an option to the group.

Once all the options are declared, using the `OptionParser` method `add_option_group()` the group is added to the previously defined parser.

Continuing with the parser defined in the previous section, adding an `OptionGroup` to a parser is easy:

```python
group = OptionGroup(parser, "Dangerous Options",
                    "Caution: use these options at your own risk.
                    It is believed that some of them bite.")
group.add_option("-g", action="store_true", help="Group option.")
parser.add_option_group(group)
```

This would result in the following help output:

```
Usage: <yourscript> [options] arg1 arg2

Options:
  -h, --help          show this help message and exit
  -v, --verbose       make lots of noise [default]
```
-q, --quiet            be vewwy quiet (I'm hunting
-f FILE, --filename=FILE  write output to FILE
-m MODE, --mode=MODE     interaction mode: novice, inter
                       expert [default: intermediate]

Dangerous Options:
   Caution: use these options at your own risk. It
            of them bite.
   -g                      Group option.

A bit more complete example might involve using more than one group: still extending the previous example:

```python
# Dangerous Options
group = OptionGroup(parser, "Dangerous Options",
                    "Caution: use these options at your own risk. It is believed that some of them bite.")
group.add_option("-g", action="store_true", help="Group option.")
parser.add_option_group(group)

# Debug Options
group = OptionGroup(parser, "Debug Options")
group.add_option("-d", "--debug", action="store_true",
                 help="Print debug information")
group.add_option("-s", "--sql", action="store_true",
                 help="Print all SQL statements executed")
group.add_option("-e", action="store_true", help="Print every action done")
parser.add_option_group(group)
```

that results in the following output:

```
Usage: <yourscript> [options] arg1 arg2

Options:
   -h, --help            show this help message and
                          exit
```
Another interesting method, in particular when working programmatically with option groups is:

OptionParser. **get_option_group**(opt_str)

Return the **OptionGroup** to which the short or long option string opt_str (e.g. '-o' or '--option') belongs. If there's no such **OptionGroup**, return None.

### 16.5.2.7. Printing a version string

Similar to the brief usage string, optparse can also print a version string for your program. You have to supply the string as the version argument to OptionParser:
%prog is expanded just like it is in usage. Apart from that, version can contain anything you like. When you supply it, optparse automatically adds a --version option to your parser. If it encounters this option on the command line, it expands your version string (by replacing %prog), prints it to stdout, and exits.

For example, if your script is called /usr/bin/foo:

```
$ /usr/bin/foo --version
foo 1.0
```

The following two methods can be used to print and get the version string:

OptionParser.print_version(file=None)

Print the version message for the current program (self.version) to file (default stdout). As with print_usage(), any occurrence of %prog in self.version is replaced with the name of the current program. Does nothing if self.version is empty or undefined.

OptionParser.get_version()

Same as print_version() but returns the version string instead of printing it.

16.5.2.8. How optparse handles errors

There are two broad classes of errors that optparse has to worry about: programmer errors and user errors. Programmer errors are usually erroneous calls to OptionParser.add_option(), e.g. invalid option strings, unknown option attributes, missing option
attributes, etc. These are dealt with in the usual way: raise an exception (either optparse.OptionError or TypeError) and let the program crash.

Handling user errors is much more important, since they are guaranteed to happen no matter how stable your code is. optparse can automatically detect some user errors, such as bad option arguments (passing -n 4x where -n takes an integer argument), missing arguments (-n at the end of the command line, where -n takes an argument of any type). Also, you can call OptionParser.error() to signal an application-defined error condition:

```python
(options, args) = parser.parse_args()

if options.a and options.b:
    parser.error("options -a and -b are mutually exclusive")
```

In either case, optparse handles the error the same way: it prints the program's usage message and an error message to standard error and exits with error status 2.

Consider the first example above, where the user passes 4x to an option that takes an integer:

```
$ /usr/bin/foo -n 4x
Usage: foo [options]

foo: error: option -n: invalid integer value: '4x'
```

Or, where the user fails to pass a value at all:

```
$ /usr/bin/foo -n
```
Usage: foo [options]

foo: error: -n option requires an argument

optparse-generated error messages take care always to mention the option involved in the error; be sure to do the same when calling OptionParser.error() from your application code.

If optparse's default error-handling behaviour does not suit your needs, you'll need to subclass OptionParser and override its exit() and/or error() methods.

16.5.2.9. Putting it all together

Here's what optparse-based scripts usually look like:

```python
from optparse import OptionParser

[...]

def main():
    usage = 'usage: %prog [options] arg'
    parser = OptionParser(usage)
    parser.add_option('-f', '--file', dest='filename', help='read data from FILENAME')
    parser.add_option('-v', '--verbose', action='store_true', dest='verbose')
    parser.add_option('-q', '--quiet', action='store_false', dest='verbose')

    [...]
    (options, args) = parser.parse_args()
    if len(args) != 1:
        parser.error('incorrect number of arguments')
    if options.verbose:
        print('reading %s...' % options.filename)
    [...]
```
if __name__ == "__main__":
    main()
16.5.3. Reference Guide

16.5.3.1. Creating the parser

The first step in using `optparse` is to create an OptionParser instance.

```python
class optparse.OptionParser(
    ...
)
```

The OptionParser constructor has no required arguments, but a number of optional keyword arguments. You should always pass them as keyword arguments, i.e. do not rely on the order in which the arguments are declared.

```python
usage (default: "%%prog [options]")
```

The usage summary to print when your program is run incorrectly or with a help option. When `optparse` prints the usage string, it expands `%%prog` to `os.path.basename(sys.argv[0])` (or to `prog` if you passed that keyword argument). To suppress a usage message, pass the special value `optparse.SUPPRESS_USAGE`.

```python
option_list (default: [])
```

A list of Option objects to populate the parser with. The options in `option_list` are added after any options in `standard_option_list` (a class attribute that may be set by OptionParser subclasses), but before any version or help options. Deprecated; use `add_option()` after creating the parser instead.

```python
option_class (default: optparse.Option)
```

Class to use when adding options to the parser in `add_option()`.
version (default: None)
A version string to print when the user supplies a version option. If you supply a true value for version, optparse automatically adds a version option with the single option string --version. The substring %prog is expanded the same as for usage.

conflict_handler (default: "error")
Specifies what to do when options with conflicting option strings are added to the parser; see section Conflicts between options.

description (default: None)
A paragraph of text giving a brief overview of your program. optparse reformats this paragraph to fit the current terminal width and prints it when the user requests help (after usage, but before the list of options).

formatter (default: a new IndentedHelpFormatter)
An instance of optparse.HelpFormatter that will be used for printing help text. optparse provides two concrete classes for this purpose: IndentedHelpFormatter and TitledHelpFormatter.

add_help_option (default: True)
If true, optparse will add a help option (with option strings -h and --help) to the parser.

prog
The string to use when expanding %prog in usage and version instead of os.path.basename(sys.argv[0]).

epilog (default: None)
A paragraph of help text to print after the option help.

16.5.3.2. Populating the parser
There are several ways to populate the parser with options. The preferred way is by using `OptionParser.add_option()`, as shown in section *Tutorial*. `add_option()` can be called in one of two ways:

- pass it an Option instance (as returned by `make_option()`) 
- pass it any combination of positional and keyword arguments that are acceptable to `make_option()` (i.e., to the Option constructor), and it will create the Option instance for you

The other alternative is to pass a list of pre-constructed Option instances to the OptionParser constructor, as in:

```python
option_list = [
    make_option("-f", "--filename",
                action="store", type="string", dest=
    make_option("-q", "--quiet",
                action="store_false", dest="verbose"
    ]
parser = OptionParser(option_list=option_list)
```

(make_option() is a factory function for creating Option instances; currently it is an alias for the Option constructor. A future version of `optparse` may split Option into several classes, and `make_option()` will pick the right class to instantiate. Do not instantiate Option directly.)

### 16.5.3.3. Defining options

Each Option instance represents a set of synonymous command-line option strings, e.g. `-f` and `--file`. You can specify any number of short or long option strings, but you must specify at least one overall option string.
The canonical way to create an Option instance is with the add_option() method of OptionParser.

OptionParser.add_option(option)
OptionParser.add_option(*opt_str, attr=value, ...)

To define an option with only a short option string:

    parser.add_option("-f", attr=value, ...)

And to define an option with only a long option string:

    parser.add_option("--foo", attr=value, ...)

The keyword arguments define attributes of the new Option object. The most important option attribute is action, and it largely determines which other attributes are relevant or required. If you pass irrelevant option attributes, or fail to pass required ones, optparse raises an OptionError exception explaining your mistake.

An option’s action determines what optparse does when it encounters this option on the command-line. The standard option actions hard-coded into optparse are:

"store"
    store this option’s argument (default)
"store_const"
    store a constant value
"store_true"
    store a true value
"store_false"
    store a false value
"append"
  append this option's argument to a list
"append_const"
  append a constant value to a list
"count"
  increment a counter by one
"callback"
  call a specified function
"help"
  print a usage message including all options and the documentation for them

(If you don't supply an action, the default is "store". For this action, you may also supply \texttt{type} and \texttt{dest} option attributes; see \textit{Standard option actions}.)

As you can see, most actions involve storing or updating a value somewhere. \texttt{optparse} always creates a special object for this, conventionally called \texttt{options} (it happens to be an instance of \texttt{optparse.Values}). Option arguments (and various other values) are stored as attributes of this object, according to the \texttt{dest} (destination) option attribute.

For example, when you call

\begin{verbatim}
parser.parse_args()
\end{verbatim}

one of the first things \texttt{optparse} does is create the \texttt{options} object:

\begin{verbatim}
options = Values()
\end{verbatim}

If one of the options in this parser is defined with
and the command-line being parsed includes any of the following:

- `ffoo`
- `f foo`
- `--file=foo`
- `--file foo`

then `optparse`, on seeing this option, will do the equivalent of

```python
options.filename = "foo"
```

The `type` and `dest` option attributes are almost as important as `action`, but `action` is the only one that makes sense for all options.

### 16.5.3.4. Option attributes

The following option attributes may be passed as keyword arguments to `OptionParser.add_option()`. If you pass an option attribute that is not relevant to a particular option, or fail to pass a required option attribute, `optparse` raises `OptionError`.

**Option.** `action`

(default: `"store"`)  
Determines `optparse`'s behaviour when this option is seen on the command line; the available options are documented [here](#).

**Option.** `type`

(default: `"string"`)
The argument type expected by this option (e.g., "string" or "int"); the available option types are documented here.

Option. **dest**
(default: derived from option strings)

If the option's action implies writing or modifying a value somewhere, this tells `optparse` where to write it: `dest` names an attribute of the options object that `optparse` builds as it parses the command line.

Option. **default**
The value to use for this option's destination if the option is not seen on the command line. See also `OptionParser.set_defaults()`.

Option. **nargs**
(default: 1)

How many arguments of type `type` should be consumed when this option is seen. If > 1, `optparse` will store a tuple of values to `dest`.

Option. **const**
For actions that store a constant value, the constant value to store.

Option. **choices**
For options of type "choice", the list of strings the user may choose from.

Option. **callback**
For options with action "callback", the callable to call when this option is seen. See section `Option Callbacks` for detail on the
arguments passed to the callable.

Option. **callback_args**

Option. **callback_kwargs**

Additional positional and keyword arguments to pass to `callback` after the four standard callback arguments.

Option. **help**

Help text to print for this option when listing all available options after the user supplies a `help` option (such as `--help`). If no help text is supplied, the option will be listed without help text. To hide this option, use the special value `optparse.SUPPRESS_HELP`.

Option. **metavar**

(default: derived from option strings)

Stand-in for the option argument(s) to use when printing help text. See section *Tutorial* for an example.

### 16.5.3.5. Standard option actions

The various option actions all have slightly different requirements and effects. Most actions have several relevant option attributes which you may specify to guide `optparse`'s behaviour; a few have required attributes, which you must specify for any option using that action.

- **"store"** [relevant: `type`, `dest`, `nargs`, `choices`]

  The option must be followed by an argument, which is converted to a value according to `type` and stored in `dest`. If `nargs > 1`, multiple arguments will be consumed from the command line; all will be converted according to `type` and stored to `dest` as a
tuple. See the *Standard option types* section.

If *choices* is supplied (a list or tuple of strings), the type defaults to "choice".

If *type* is not supplied, it defaults to "string".

If *dest* is not supplied, *optparse* derives a destination from the first long option string (e.g., `--foo-bar` implies `foo_bar`). If there are no long option strings, *optparse* derives a destination from the first short option string (e.g., `-f` implies `f`).

Example:

```python
parser.add_option("-f")
parser.add_option("-p", type="float", nargs=3, dest="point")
```

As it parses the command line

```
-f foo.txt -p 1 -3.5 4 -fbar.txt
```

*optparse* will set

```python
options.f = "foo.txt"
options.point = (1.0, -3.5, 4.0)
options.f = "bar.txt"
```

- "store_const" [required: *const*; relevant: *dest*]

The value *const* is stored in *dest*.

Example:

```python
parser.add_option("-q", "--quiet",
```
If `--noisy` is seen, `optparse` will set

```
options.verbose = 2
```

- "store_true" [relevant: `dest`]

A special case of "store_const" that stores a true value to `dest`.

- "store_false" [relevant: `dest`]

Like "store_true", but stores a false value.

Example:

```
parser.add_option("--clobber", action="store_true"
parser.add_option("--no-clobber", action="store_true"
```

- "append" [relevant: `type, dest, nargs, choices`]

The option must be followed by an argument, which is appended to the list in `dest`. If no default value for `dest` is supplied, an empty list is automatically created when `optparse` first encounters this option on the command-line. If `nargs > 1`, multiple arguments are consumed, and a tuple of length `nargs` is appended to `dest`. 
The defaults for type and dest are the same as for the "store" action.

Example:

```python
parser.add_option("-t", "--tracks", action="append")
```

If -t3 is seen on the command-line, optparse does the equivalent of:

```python
options.tracks = []
options.tracks.append(int("3"))
```

If, a little later on, --tracks=4 is seen, it does:

```python
options.tracks.append(int("4"))
```

The append action calls the append method on the current value of the option. This means that any default value specified must have an append method. It also means that if the default value is non-empty, the default elements will be present in the parsed value for the option, with any values from the command line appended after those default values:

```python
>>> parser.add_option("--files", action="append")
>>> opts, args = parser.parse_args(["--files", 'overrides.mypkg'])
>>> opts.files
['~/.mypkg/defaults', 'overrides.mypkg']
```

- "append_const" [required: const; relevant: dest]

  Like "store_const", but the value const is appended to
\texttt{dest}; as with "\texttt{append}'s, \texttt{dest} defaults to \texttt{None}, and an empty list is automatically created the first time the option is encountered.

- "\texttt{count}" [relevant: \texttt{dest}]

  Increment the integer stored at \texttt{dest}. If no default value is supplied, \texttt{dest} is set to zero before being incremented the first time.

  Example:

  \begin{verbatim}
  parser.add_option("-v", action="count", dest="verbosity")
  \end{verbatim}

  The first time \texttt{-v} is seen on the command line, \texttt{optparse} does the equivalent of:

  \begin{verbatim}
  options.verbosity = 0
  options.verbosity += 1
  \end{verbatim}

  Every subsequent occurrence of \texttt{-v} results in

  \begin{verbatim}
  options.verbosity += 1
  \end{verbatim}

- "\texttt{callback}" [required: \texttt{callback}; relevant: \texttt{type}, \texttt{nargs}, \texttt{callback_args}, \texttt{callback_kwargs}]

  Call the function specified by \texttt{callback}, which is called as

  \begin{verbatim}
  func(option, opt_str, value, parser, *args, **kwargs)
  \end{verbatim}

  See section \textit{Option Callbacks} for more detail.
"help"

Prints a complete help message for all the options in the current option parser. The help message is constructed from the usage string passed to OptionParser's constructor and the help string passed to every option.

If no help string is supplied for an option, it will still be listed in the help message. To omit an option entirely, use the special value optparse.SUPPRESS_HELP.

optparse automatically adds a help option to all OptionParsers, so you do not normally need to create one.

Example:

```python
from optparse import OptionParser, SUPPRESS_HELP

# usually, a help option is added automatically, # be suppressed using the add_help_option argument
parser = OptionParser(add_help_option=False)

parser.add_option("-h", "--help", action="help")
parser.add_option("-v", action="store_true", dest="help", help="Be moderately verbose")
parser.add_option("--file", dest="filename", help="Input file to read data from")
parser.add_option("--secret", help=SUPPRESS_HELP)
```

If optparse sees either -h or --help on the command line, it will print something like the following help message to stdout (assuming sys.argv[0] is "foo.py"):

```
Usage: foo.py [options]
```
Options:
- h, --help  Show this help message and exit
- v  Be moderately verbose
--file=FILENAME  Input file to read data from

After printing the help message, optparse terminates your process with sys.exit(0).

- "version"

Prints the version number supplied to the OptionParser to stdout and exits. The version number is actually formatted and printed by the print_version() method of OptionParser. Generally only relevant if the version argument is supplied to the OptionParser constructor. As with help options, you will rarely create version options, since optparse automatically adds them when needed.

16.5.3.6. Standard option types

optparse has five built-in option types: "string", "int", "choice", "float" and "complex". If you need to add new option types, see section Extending optparse.

Arguments to string options are not checked or converted in any way: the text on the command line is stored in the destination (or passed to the callback) as-is.

Integer arguments (type "int") are parsed as follows:

- if the number starts with 0x, it is parsed as a hexadecimal number
- if the number starts with 0, it is parsed as an octal number
if the number starts with \texttt{0b}, it is parsed as a binary number
otherwise, the number is parsed as a decimal number

The conversion is done by calling \texttt{int()} with the appropriate base (2, 8, 10, or 16). If this fails, so will \texttt{optparse}, although with a more useful error message.

"float" and "complex" option arguments are converted directly with \texttt{float()} and \texttt{complex()}, with similar error-handling.

"choice" options are a subtype of "string" options. The \texttt{choices} option attribute (a sequence of strings) defines the set of allowed option arguments. \texttt{optparse.check_choice()} compares user-supplied option arguments against this master list and raises \texttt{OptionValueError} if an invalid string is given.

16.5.3.7. Parsing arguments

The whole point of creating and populating an OptionParser is to call its \texttt{parse_args()} method:

\begin{verbatim}
(options, args) = parser.parse_args(args=None, values=None)
\end{verbatim}

where the input parameters are

\texttt{args}
the list of arguments to process (default: \texttt{sys.argv[1:]})

\texttt{values}
a \texttt{optparse.Values} object to store option arguments in (default: a new instance of \texttt{Values}) – if you give an existing object, the option defaults will not be initialized on it
and the return values are

options
  the same object that was passed in as values, or the
optparse.Values instance created by optparse

args
  the leftover positional arguments after all options have been
  processed

The most common usage is to supply neither keyword argument. If you supply values, it will be modified with repeated setattr() calls (roughly one for every option argument stored to an option destination) and returned by parse_args().

If parse_args() encounters any errors in the argument list, it calls the OptionParser's error() method with an appropriate end-user error message. This ultimately terminates your process with an exit status of 2 (the traditional Unix exit status for command-line errors).

16.5.3.8. Querying and manipulating your option parser

The default behavior of the option parser can be customized slightly, and you can also poke around your option parser and see what's there. OptionParser provides several methods to help you out:

OptionParser.disable_interspersed_args()
  Set parsing to stop on the first non-option. For example, if -a and -b are both simple options that take no arguments, optparse normally accepts this syntax:

  prog -a arg1 -b arg2
and treats it as equivalent to

```
prog -a -b arg1 arg2
```

To disable this feature, call `disable_interspersed_args()`. This restores traditional Unix syntax, where option parsing stops with the first non-option argument.

Use this if you have a command processor which runs another command which has options of its own and you want to make sure these options don’t get confused. For example, each command might have a different set of options.

**OptionParser.** `enable_interspersed_args()`  
Set parsing to not stop on the first non-option, allowing interspersing switches with command arguments. This is the default behavior.

**OptionParser.** `get_option(opt_str)`  
Returns the Option instance with the option string `opt_str`, or None if no options have that option string.

**OptionParser.** `has_option(opt_str)`  
Return true if the OptionParser has an option with option string `opt_str` (e.g., `-q` or `--verbose`).

**OptionParser.** `remove_option(opt_str)`  
If the OptionParser has an option corresponding to `opt_str`, that option is removed. If that option provided any other option strings, all of those option strings become invalid. If `opt_str` does not occur in any option belonging to this OptionParser, raises `ValueError`. 
16.5.3.9. Conflicts between options

If you're not careful, it's easy to define options with conflicting option strings:

```python
parser.add_option("-n", "--dry-run", ...)
[...]
parsed.add_option("-n", "--noisy", ...)
```

(This is particularly true if you've defined your own OptionParser subclass with some standard options.)

Every time you add an option, `optparse` checks for conflicts with existing options. If it finds any, it invokes the current conflict-handling mechanism. You can set the conflict-handling mechanism either in the constructor:

```python
parser = OptionParser(..., conflict_handler=handler)
```

or with a separate call:

```python
parser.set_conflict_handler(handler)
```

The available conflict handlers are:

- "error" (default)
  - assume option conflicts are a programming error and raise `OptionConflictError`
- "resolve"
  - resolve option conflicts intelligently (see below)

As an example, let's define an `OptionParser` that resolves conflicts intelligently and add conflicting options to it:
At this point, `optparse` detects that a previously-added option is already using the `-n` option string. Since `conflict_handler` is "resolve", it resolves the situation by removing `-n` from the earlier option’s list of option strings. Now `--dry-run` is the only way for the user to activate that option. If the user asks for help, the help message will reflect that:

Options:
- `--dry-run`  do no harm
  ...
- `-n`, `--noisy`  be noisy

It’s possible to whittle away the option strings for a previously-added option until there are none left, and the user has no way of invoking that option from the command-line. In that case, `optparse` removes that option completely, so it doesn’t show up in help text or anywhere else. Carrying on with our existing OptionParser:

```
parser.add_option("--dry-run", ..., help="new dry-run option")
```

At this point, the original `-n/--dry-run` option is no longer accessible, so `optparse` removes it, leaving this help text:

Options:
- `-n`, `--noisy`  be noisy
- `--dry-run`  new dry-run option
16.5.3.10. Cleanup

OptionParser instances have several cyclic references. This should not be a problem for Python's garbage collector, but you may wish to break the cyclic references explicitly by calling destroy() on your OptionParser once you are done with it. This is particularly useful in long-running applications where large object graphs are reachable from your OptionParser.

16.5.3.11. Other methods

OptionParser supports several other public methods:

OptionParser.set_usage(usage)

Set the usage string according to the rules described above for the usage constructor keyword argument. Passing None sets the default usage string; use optparse.SUPPRESS_USAGE to suppress a usage message.

OptionParser.print_usage(file=None)

Print the usage message for the current program (self.usage) to file (default stdout). Any occurrence of the string %prog in self.usage is replaced with the name of the current program. Does nothing if self.usage is empty or not defined.

OptionParser.get_usage()

Same as print_usage() but returns the usage string instead of printing it.

OptionParser.set_defaults(dest=value,...)

Set default values for several option destinations at once. Using
**set_defaults()** is the preferred way to set default values for options, since multiple options can share the same destination. For example, if several “mode” options all set the same destination, any one of them can set the default, and the last one wins:

```python
parser.add_option("--advanced", action="store_const", dest="mode", const="advanced", default="novice") # overridden
parser.add_option("--novice", action="store_const", dest="mode", const="novice", default="advanced") # override
```

To avoid this confusion, use **set_defaults()**:

```python
parser.set_defaults(mode="advanced")
parser.add_option("--advanced", action="store_const", dest="mode", const="advanced")
parser.add_option("--novice", action="store_const", dest="mode", const="novice")
```
16.5.4. Option Callbacks

When `optparse`'s built-in actions and types aren't quite enough for your needs, you have two choices: extend `optparse` or define a callback option. Extending `optparse` is more general, but overkill for a lot of simple cases. Quite often a simple callback is all you need.

There are two steps to defining a callback option:

- define the option itself using the "callback" action
- write the callback; this is a function (or method) that takes at least four arguments, as described below

16.5.4.1. Defining a callback option

As always, the easiest way to define a callback option is by using the `OptionParser.add_option()` method. Apart from `action`, the only option attribute you must specify is `callback`, the function to call:

```
parser.add_option("-c", action="callback", callback=\n```

`callback` is a function (or other callable object), so you must have already defined `my_callback()` when you create this callback option. In this simple case, `optparse` doesn't even know if `-c` takes any arguments, which usually means that the option takes no arguments—the mere presence of `-c` on the command-line is all it needs to know. In some circumstances, though, you might want your callback to consume an arbitrary number of command-line arguments. This is where writing callbacks gets tricky; it's covered later in this
section.

**optparse** always passes four particular arguments to your callback, and it will only pass additional arguments if you specify them via `callback_args` and `callback_kwargs`. Thus, the minimal callback function signature is:

```python
def my_callback(option, opt, value, parser):
```

The four arguments to a callback are described below.

There are several other option attributes that you can supply when you define a callback option:

- **type**
  - has its usual meaning: as with the "store" or "append" actions, it instructs **optparse** to consume one argument and convert it to `type`. Rather than storing the converted value(s) anywhere, though, **optparse** passes it to your callback function.

- **nargs**
  - also has its usual meaning: if it is supplied and > 1, **optparse** will consume `nargs` arguments, each of which must be convertible to `type`. It then passes a tuple of converted values to your callback.

- **callback_args**
  - a tuple of extra positional arguments to pass to the callback

- **callback_kwargs**
  - a dictionary of extra keyword arguments to pass to the callback

### 16.5.4.2. How callbacks are called

All callbacks are called as follows:
where

**option**

is the Option instance that's calling the callback

**opt_str**

is the option string seen on the command-line that's triggering the callback. (If an abbreviated long option was used, **opt_str** will be the full, canonical option string—e.g. if the user puts **--foo** on the command-line as an abbreviation for **--foobar**, then **opt_str** will be "**--foobar**".)

**value**

is the argument to this option seen on the command-line. [optparse] will only expect an argument if **type** is set; the type of value will be the type implied by the option's type. If **type** for this option is None (no argument expected), then **value** will be None. If **nargs** > 1, **value** will be a tuple of values of the appropriate type.

**parser**

is the OptionParser instance driving the whole thing, mainly useful because you can access some other interesting data through its instance attributes:

**parser.largs**

the current list of leftover arguments, i.e. arguments that have been consumed but are neither options nor option arguments. Feel free to modify **parser.largs**, e.g. by adding more arguments to it. (This list will become **args**, the second return value of parse_args().)

**parser.rargs**
the current list of remaining arguments, ie. with \texttt{opt_str} and \texttt{value} (if applicable) removed, and only the arguments following them still there. Feel free to modify \texttt{parser.rargs}, e.g. by consuming more arguments.

\texttt{parser.values}

the object where option values are by default stored (an instance of \texttt{optparse.OptionValues}). This lets callbacks use the same mechanism as the rest of \texttt{optparse} for storing option values; you don’t need to mess around with globals or closures. You can also access or modify the value(s) of any options already encountered on the command-line.

\texttt{args}

is a tuple of arbitrary positional arguments supplied via the \texttt{callback_args} option attribute.

\texttt{kwargs}

is a dictionary of arbitrary keyword arguments supplied via \texttt{callback_kwargs}.

16.5.4.3. Raising errors in a callback

The callback function should raise \texttt{OptionValueError} if there are any problems with the option or its argument(s). \texttt{optparse} catches this and terminates the program, printing the error message you supply to stderr. Your message should be clear, concise, accurate, and mention the option at fault. Otherwise, the user will have a hard time figuring out what he did wrong.

16.5.4.4. Callback example 1: trivial callback

Here’s an example of a callback option that takes no arguments, and simply records that the option was seen:
Of course, you could do that with the "store_true" action.

16.5.4.5. Callback example 2: check option order

Here’s a slightly more interesting example: record the fact that `-a` is seen, but blow up if it comes after `-b` in the command-line.

```python
def check_order(option, opt_str, value, parser):
    if parser.values.b:
        raise OptionValueError("can't use -a after -b")
    parser.values.a = 1
```

16.5.4.6. Callback example 3: check option order (generalized)

If you want to re-use this callback for several similar options (set a flag, but blow up if `-b` has already been seen), it needs a bit of work: the error message and the flag that it sets must be generalized.

```python
def check_order(option, opt_str, value, parser):
    if parser.values.b:
        raise OptionValueError("can't use %s after -b")
        setattr(parser.values, option.dest, 1)
```
16.5.4.7. Callback example 4: check arbitrary condition

Of course, you could put any condition in there—you're not limited to checking the values of already-defined options. For example, if you have options that should not be called when the moon is full, all you have to do is this:

```python
def check_moon(option, opt_str, value, parser):
    if is_moon_full():
        raise OptionValueError("%s option invalid when %s option is full")
    setattr(parser.values, option.dest, 1)
```

(The definition of `is_moon_full()` is left as an exercise for the reader.)

16.5.4.8. Callback example 5: fixed arguments

Things get slightly more interesting when you define callback options that take a fixed number of arguments. Specifying that a callback option takes arguments is similar to defining a "store" or "append" option: if you define `type`, then the option takes one argument that must be convertible to that type; if you further define `nargs`, then the
option takes \texttt{nargs} arguments.

Here's an example that just emulates the standard \texttt{"store"} action:

```python
def store_value(option, opt_str, value, parser):
    setattr(parser.values, option.dest, value)

[...]
parser.add_option("--foo",
    action="callback",
    callback=store_value,
    type="int",
    nargs=3,
    dest="foo")
```

Note that \texttt{optparse} takes care of consuming 3 arguments and converting them to integers for you; all you have to do is store them. (Or whatever; obviously you don't need a callback for this example.)

16.5.4.9. Callback example 6: variable arguments

Things get hairy when you want an option to take a variable number of arguments. For this case, you must write a callback, as \texttt{optparse} doesn't provide any built-in capabilities for it. And you have to deal with certain intricacies of conventional Unix command-line parsing that \texttt{optparse} normally handles for you. In particular, callbacks should implement the conventional rules for bare \texttt{--} and \texttt{-} arguments:

- either \texttt{--} or \texttt{-} can be option arguments
- bare \texttt{--} (if not the argument to some option): halt command-line processing and discard the \texttt{--}
- bare \texttt{-} (if not the argument to some option): halt command-line processing but keep the \texttt{-} (append it to \texttt{parser.largs})

If you want an option that takes a variable number of arguments, there are several subtle, tricky issues to worry about. The exact
implementation you choose will be based on which trade-offs you're willing to make for your application (which is why `optparse` doesn't support this sort of thing directly).

Nevertheless, here's a stab at a callback for an option with variable arguments:

```python
def vararg_callback(option, opt_str, value, parser):
    assert value is None
    value = []

    def floatable(str):
        try:
            float(str)
            return True
        except ValueError:
            return False

    for arg in parser.rargs:
        # stop on --foo like options
        if arg[:2] == "--" and len(arg) > 2:
            break
        # stop on -a, but not on -3 or -3.0
        if arg[:1] == "-" and len(arg) > 1 and not
            break
    value.append(arg)

    del parser.rargs[:len(value)]
    setattr(parser.values, option.dest, value)

[...] parser.add_option("-c", "--callback", dest="vararg_attr",
    action="callback", callback=vararg_callback)
```
16.5.5. Extending optparse

Since the two major controlling factors in how optparse interprets command-line options are the action and type of each option, the most likely direction of extension is to add new actions and new types.

16.5.5.1. Adding new types

To add new types, you need to define your own subclass of optparse's Option class. This class has a couple of attributes that define optparse's types: TYPES and TYPE_CHECKER.

**Option. TYPES**

A tuple of type names; in your subclass, simply define a new tuple TYPES that builds on the standard one.

**Option. TYPE_CHECKER**

A dictionary mapping type names to type-checking functions. A type-checking function has the following signature:

```python
def check_mytype(option, opt, value)
```

where option is an Option instance, opt is an option string (e.g., -f), and value is the string from the command line that must be checked and converted to your desired type. check_mytype() should return an object of the hypothetical type mytype. The value returned by a type-checking function will wind up in the OptionValues instance returned by OptionParser.parse_args(), or be passed to a callback as the value parameter.
Your type-checking function should raise `OptionValueError` if it encounters any problems. `OptionValueError` takes a single string argument, which is passed as-is to `OptionParser`'s `error()` method, which in turn prepends the program name and the string "error:" and prints everything to stderr before terminating the process.

Here's a silly example that demonstrates adding a "complex" option type to parse Python-style complex numbers on the command line. (This is even sillier than it used to be, because `optparse` 1.3 added built-in support for complex numbers, but never mind.)

First, the necessary imports:

```python
from copy import copy
from optparse import Option, OptionValueError
```

You need to define your type-checker first, since it's referred to later (in the `TYPE_CHECKER` class attribute of your Option subclass):

```python
def check_complex(option, opt, value):
    try:
        return complex(value)
    except ValueError:
        raise OptionValueError("option %s: invalid complex value: %r" %
```

Finally, the Option subclass:

```python
class MyOption(Option):
    TYPES = Option.TYPES + ("complex",)
    TYPE_CHECKER = copy(Option.TYPE_CHECKER)
    TYPE_CHECKER["complex"] = check_complex
```
(If we didn’t make a `copy()` of `Option.TYPE_CHECKER`, we would end up modifying the `TYPE_CHECKER` attribute of `optparse`’s Option class. This being Python, nothing stops you from doing that except good manners and common sense.)

That’s it! Now you can write a script that uses the new option type just like any other `optparse`-based script, except you have to instruct your `OptionParser` to use `MyOption` instead of `Option`:

```python
parser = OptionParser(option_class=MyOption)
parsed.add_option("-c", type="complex")
```

Alternately, you can build your own option list and pass it to `OptionParser`; if you don’t use `add_option()` in the above way, you don’t need to tell `OptionParser` which option class to use:

```python
option_list = [MyOption("-c", action="store", type="complex")
parser = OptionParser(option_list=option_list)
```

### 16.5.5.2. Adding new actions

Adding new actions is a bit trickier, because you have to understand that `optparse` has a couple of classifications for actions:

**“store” actions**

actions that result in `optparse` storing a value to an attribute of the current `OptionValues` instance; these options require a `dest` attribute to be supplied to the Option constructor.

**“typed” actions**

actions that take a value from the command line and expect it to be of a certain type; or rather, a string that can be converted to a certain type. These options require a `type` attribute to the Option
These are overlapping sets: some default “store” actions are "store", "store_const", "append", and "count", while the default “typed” actions are "store", "append", and "callback".

When you add an action, you need to categorize it by listing it in at least one of the following class attributes of Option (all are lists of strings):

Option. **ACTIONS**

All actions must be listed in ACTIONS.

Option. **STORE_ACTIONS**

"store" actions are additionally listed here.

Option. **TYPED_ACTIONS**

"typed" actions are additionally listed here.

Option. **ALWAYS_TYPED_ACTIONS**

Actions that always take a type (i.e. whose options always take a value) are additionally listed here. The only effect of this is that optparse assigns the default type, "string", to options with no explicit type whose action is listed in **ALWAYS_TYPED_ACTIONS**.

In order to actually implement your new action, you must override Option's `take_action()` method and add a case that recognizes your action.

For example, let's add an "extend" action. This is similar to the standard "append" action, but instead of taking a single value from the command-line and appending it to an existing list, "extend" will take multiple values in a single comma-delimited string, and extend an
existing list with them. That is, if `--names` is an "extend" option of type "string", the command line

```
--names=foo,bar --names blah --names ding,dong
```

would result in a list

```
["foo", "bar", "blah", "ding", "dong"]
```

Again we define a subclass of Option:

```python
class MyOption(Option):

    ACTIONS = Option.ACTIONS + ("extend",)
    STORE_ACTIONS = Option.STORE_ACTIONS + ("extend")
    TYPED_ACTIONS = Option.TYPED_ACTIONS + ("extend")
    ALWAYS_TYPED_ACTIONS = Option.ALWAYS_TYPED_ACTIONS

    def take_action(self, action, dest, opt, value, value=
        if action == "extend":
            lvalue = value.split(",")
            values.ensure_value(dest, []).extend(lvalue)
        else: self, action, dest, opt, value, value,
```

Features of note:

- "extend" both expects a value on the command-line and stores that value somewhere, so it goes in both `STORE_ACTIONS` and `TYPED_ACTIONS`.

- to ensure that `optparse` assigns the default type of "string" to "extend" actions, we put the "extend" action in
ALWAYS_TYPED_ACTIONS as well.

- MyOption.take_action() implements just this one new action, and passes control back to Option.take_action() for the standard optparse actions.

- values is an instance of the optparse_parser.Values class, which provides the very useful ensure_value() method. ensure_value() is essentially getattr() with a safety valve; it is called as

```python
values.ensure_value(attr, value)
```

If the attr attribute of values doesn't exist or is None, then ensure_value() first sets it to value, and then returns 'value. This is very handy for actions like "extend", "append", and "count", all of which accumulate data in a variable and expect that variable to be of a certain type (a list for the first two, an integer for the latter). Using ensure_value() means that scripts using your action don't have to worry about setting a default value for the option destinations in question; they can just leave the default as None and ensure_value() will take care of getting it right when it's needed.
16.6. **getopt** — C-style parser for command line options

**Source code:** Lib/getopt.py

---

**Note:** The `getopt` module is a parser for command line options whose API is designed to be familiar to users of the C `getopt()` function. Users who are unfamiliar with the C `getopt()` function or who would like to write less code and get better help and error messages should consider using the `argparse` module instead.

This module helps scripts to parse the command line arguments in `sys.argv`. It supports the same conventions as the Unix `getopt()` function (including the special meanings of arguments of the form `-` and `--`). Long options similar to those supported by GNU software may be used as well via an optional third argument.

This module provides two functions and an exception:

```python
getopt.getopt(args, shortopts, longopts=[])
```

Parses command line options and parameter list. `args` is the argument list to be parsed, without the leading reference to the running program. Typically, this means `sys.argv[1:]`. `shortopts` is the string of option letters that the script wants to recognize, with options that require an argument followed by a colon (`':'`; i.e., the same format that Unix `getopt()` uses).

**Note:** Unlike GNU `getopt()`, after a non-option argument, all further arguments are considered also non-options. This is similar
to the way non-GNU Unix systems work.

`longopts`, if specified, must be a list of strings with the names of the long options which should be supported. The leading `--` characters should not be included in the option name. Long options which require an argument should be followed by an equal sign (`='). Optional arguments are not supported. To accept only long options, `shortopts` should be an empty string. Long options on the command line can be recognized so long as they provide a prefix of the option name that matches exactly one of the accepted options. For example, if `longopts` is `['foo', 'frob']`, the option `--fo` will match as `--foo`, but `--f` will not match uniquely, so `GetoptError` will be raised.

The return value consists of two elements: the first is a list of `(option, value)` pairs; the second is the list of program arguments left after the option list was stripped (this is a trailing slice of `args`). Each option-and-value pair returned has the option as its first element, prefixed with a hyphen for short options (e.g., `-x`) or two hyphens for long options (e.g., `--long-option`), and the option argument as its second element, or an empty string if the option has no argument. The options occur in the list in the same order in which they were found, thus allowing multiple occurrences. Long and short options may be mixed.

`getopt`'s `gnu_getopt(args, shortopts, longopts=[])`

This function works like `getopt()`, except that GNU style scanning mode is used by default. This means that option and non-option arguments may be intermixed. The `getopt()` function stops processing options as soon as a non-option argument is encountered.
If the first character of the option string is `+`, or if the environment variable POSIXLY_CORRECT is set, then option processing stops as soon as a non-option argument is encountered.

**exception getopt. GetoptError**

This is raised when an unrecognized option is found in the argument list or when an option requiring an argument is given none. The argument to the exception is a string indicating the cause of the error. For long options, an argument given to an option which does not require one will also cause this exception to be raised. The attributes msg and opt give the error message and related option; if there is no specific option to which the exception relates, opt is an empty string.

**exception getopt. error**

Alias for GetoptError; for backward compatibility.

An example using only Unix style options:

```python
>>> import getopt
>>> args = '-a -b -cfoo -d bar a1 a2'.split()
>>> args
['-a', '-b', '-cfoo', '-d', 'bar', 'a1', 'a2']
>>> optlist, args = getopt.getopt(args, 'abc:d:')
>>> optlist
[('-a', ''), ('-b', ''), ('-c', 'foo'), ('-d', 'bar')]
>>> args
['a1', 'a2']
```

Using long option names is equally easy:

```python
>>> s = '--condition=foo --testing --output-file abc'
```
In a script, typical usage is something like this:

```python
import getopt, sys

def main():
    try:
        opts, args = getopt.getopt(sys.argv[1:], "ho:v")
    except getopt.GetoptError as err:
        # print help information and exit:
        print(err)  # will print something like "option -a not recognized"
        usage()
        sys.exit(2)
    output = None
    verbose = False
    for o, a in opts:
        if o == "-v":
            verbose = True
        elif o in ("-h", "--help"):
            usage()
            sys.exit()
        elif o in ("-o", "--output"):
            output = a
        else:
            assert False, "unhandled option"
    # ...
```
if __name__ == "__main__":
    main()

Note that an equivalent command line interface could be produced with less code and more informative help and error messages by using the argparse module:

```python
import argparse

if __name__ == '__main__':
    parser = argparse.ArgumentParser()
    parser.add_argument('-o', '--output')
    parser.add_argument('-v', dest='verbose', action='store_true')
    args = parser.parse_args()
    # ... do something with args.output ...
    # ... do something with args.verbose ..
```

**Module argparse**

Alternative command line option and argument parsing library.
16.7. **logging** — Logging facility for Python

**Source code:** Lib/logging/__init__.py

This module defines functions and classes which implement a flexible event logging system for applications and libraries.

The key benefit of having the logging API provided by a standard library module is that all Python modules can participate in logging, so your application log can include your own messages integrated with messages from third-party modules.

The module provides a lot of functionality and flexibility. If you are unfamiliar with logging, the best way to get to grips with it is to see the tutorials (see the links on the right).

The basic classes defined by the module, together with their functions, are listed below.

- Loggers expose the interface that application code directly uses.
- Handlers send the log records (created by loggers) to the appropriate destination.
- Filters provide a finer grained facility for determining which log records to output.
- Formatters specify the layout of log records in the final output.
16.7.1. Logger Objects

Loggers have the following attributes and methods. Note that Loggers are never instantiated directly, but always through the module-level function `logging.getLogger(name)`. Multiple calls to `getLogger()` with the same name will always return a reference to the same Logger object.

The name is potentially a period-separated hierarchical value, like `foo.bar.baz` (though it could also be just plain `foo`, for example). Loggers that are further down in the hierarchical list are children of loggers higher up in the list. For example, given a logger with a name of `foo`, loggers with names of `foo.bar`, `foo.bar.baz`, and `foo.bam` are all descendants of `foo`. The logger name hierarchy is analogous to the Python package hierarchy, and identical to it if you organise your loggers on a per-module basis using the recommended construction `logging.getLogger(__name__)`. That’s because in a module, `__name__` is the module’s name in the Python package namespace.

```python
class logging.Logger

Logger.propagate
```

If this evaluates to true, events logged to this logger will be passed to the handlers of higher level (ancestor) loggers, in addition to any handlers attached to this logger. Messages are passed directly to the ancestor loggers’ handlers - neither the level nor filters of the ancestor loggers in question are considered.

If this evaluates to false, logging messages are not passed to the handlers of ancestor loggers.
The constructor sets this attribute to True.

**Note:** If you attach a handler to a logger *and* one or more of its ancestors, it may emit the same record multiple times. In general, you should not need to attach a handler to more than one logger - if you just attach it to the appropriate logger which is highest in the logger hierarchy, then it will see all events logged by all descendant loggers, provided that their propagate setting is left set to True. A common scenario is to attach handlers only to the root logger, and to let propagation take care of the rest.

**Logger** . `setLevel(lvl)`

Sets the threshold for this logger to `lvl`. Logging messages which are less severe than `lvl` will be ignored. When a logger is created, the level is set to `NOTSET` (which causes all messages to be processed when the logger is the root logger, or delegation to the parent when the logger is a non-root logger). Note that the root logger is created with level `WARNING`.

The term ‘delegation to the parent’ means that if a logger has a level of `NOTSET`, its chain of ancestor loggers is traversed until either an ancestor with a level other than `NOTSET` is found, or the root is reached.

If an ancestor is found with a level other than `NOTSET`, then that ancestor’s level is treated as the effective level of the logger where the ancestor search began, and is used to determine how a logging event is handled.

If the root is reached, and it has a level of `NOTSET`, then all messages will be processed. Otherwise, the root’s level will be used as the effective level.
Changed in version 3.2: The \textit{lvl} parameter now accepts a string representation of the level such as ‘INFO’ as an alternative to the integer constants such as INFO.

**Logger.\texttt{isEnabledFor(lvl)}**

Indicates if a message of severity \textit{lvl} would be processed by this logger. This method checks first the module-level level set by \texttt{logging.disable(lvl)} and then the logger’s effective level as determined by \texttt{getEffectiveLevel()}.

**Logger.\texttt{getEffectiveLevel()}**

Indicates the effective level for this logger. If a value other than NOTSET has been set using \texttt{setLevel()}, it is returned. Otherwise, the hierarchy is traversed towards the root until a value other than NOTSET is found, and that value is returned.

**Logger.\texttt{getChild(suffix)}**

Returns a logger which is a descendant to this logger, as determined by the suffix. Thus, \texttt{logging.getLogger('abc').getChild('def.ghi')} would return the same logger as would be returned by \texttt{logging.getLogger('abc.def.ghi')}. This is a convenience method, useful when the parent logger is named using e.g. \_\_\texttt{name}\_\_ rather than a literal string.

\textit{New in version 3.2.}

**Logger.\texttt{debug(msg, *args, **kwargs)}**

Logs a message with level DEBUG on this logger. The \textit{msg} is the message format string, and the \textit{args} are the arguments which are merged into \textit{msg} using the string formatting operator. (Note that this means that you can use keywords in the format string, together
with a single dictionary argument.)

There are three keyword arguments in `kwargs` which are inspected: `exc_info` which, if it does not evaluate as false, causes exception information to be added to the logging message. If an exception tuple (in the format returned by `sys.exc_info()`) is provided, it is used; otherwise, `sys.exc_info()` is called to get the exception information.

The second optional keyword argument is `stack_info`, which defaults to False. If specified as True, stack information is added to the logging message, including the actual logging call. Note that this is not the same stack information as that displayed through specifying `exc_info`: The former is stack frames from the bottom of the stack up to the logging call in the current thread, whereas the latter is information about stack frames which have been unwound, following an exception, while searching for exception handlers.

You can specify `stack_info` independently of `exc_info`, e.g. to just show how you got to a certain point in your code, even when no exceptions were raised. The stack frames are printed following a header line which says:

```
Stack (most recent call last):
```

This mimics the Traceback (most recent call last): which is used when displaying exception frames.

The third keyword argument is `extra` which can be used to pass a dictionary which is used to populate the `__dict__` of the LogRecord created for the logging event with user-defined attributes. These custom attributes can then be used as you like. For example, they could be incorporated into logged messages. For example:
FORMAT = '%(asctime)-15s %(clientip)s %(user)-8s %(message)s'
logging.basicConfig(format=FORMAT)
d = {'clientip': '192.168.0.1', 'user': 'fbloggs'}
logger = logging.getLogger('tcpserver')
logger.warning('Protocol problem: %s', 'connection reset')

would print something like

2006-02-08 22:20:02,165 192.168.0.1 fbloggs Protocol

The keys in the dictionary passed in extra should not clash with the keys used by the logging system. (See the Formatter documentation for more information on which keys are used by the logging system.)

If you choose to use these attributes in logged messages, you need to exercise some care. In the above example, for instance, the Formatter has been set up with a format string which expects ‘clientip’ and ‘user’ in the attribute dictionary of the LogRecord. If these are missing, the message will not be logged because a string formatting exception will occur. So in this case, you always need to pass the extra dictionary with these keys.

While this might be annoying, this feature is intended for use in specialized circumstances, such as multi-threaded servers where the same code executes in many contexts, and interesting conditions which arise are dependent on this context (such as remote client IP address and authenticated user name, in the above example). In such circumstances, it is likely that specialized Formatters would be used with particular Handlers.

New in version 3.2: The stack_info parameter was added.
Logger.info(msg, *args, **kwargs)

Logs a message with level INFO on this logger. The arguments are interpreted as for debug().

Logger.warning(msg, *args, **kwargs)

Logs a message with level WARNING on this logger. The arguments are interpreted as for debug().

Note: There is an obsolete method warn which is functionally identical to warning. As warn is deprecated, please do not use it - use warning instead.

Logger.error(msg, *args, **kwargs)

Logs a message with level ERROR on this logger. The arguments are interpreted as for debug().

Logger.critical(msg, *args, **kwargs)

Logs a message with level CRITICAL on this logger. The arguments are interpreted as for debug().

Logger.log(lvl, msg, *args, **kwargs)

Logs a message with integer level lvl on this logger. The other arguments are interpreted as for debug().

Logger.exception(msg, *args)

Logs a message with level ERROR on this logger. The arguments are interpreted as for debug(). Exception info is added to the logging message. This method should only be called from an exception handler.

Logger.addFilter(filt)
Adds the specified filter \textit{filt} to this logger.

\texttt{Logger.removeFilter(filt)}

Removes the specified filter \textit{filt} from this logger.

\texttt{Logger.filter(record)}

Applies this logger's filters to the record and returns a true value if the record is to be processed. The filters are consulted in turn, until one of them returns a false value. If none of them return a false value, the record will be processed (passed to handlers). If one returns a false value, no further processing of the record occurs.

\texttt{Logger.addHandler(hdlr)}

Adds the specified handler \textit{hdlr} to this logger.

\texttt{Logger.removeHandler(hdlr)}

Removes the specified handler \textit{hdlr} from this logger.

\texttt{Logger.findCaller(stack_info=False)}

Finds the caller's source filename and line number. Returns the filename, line number, function name and stack information as a 4-element tuple. The stack information is returned as \textit{None} unless \textit{stack_info} is \textit{True}.

\texttt{Logger.handle(record)}

Handles a record by passing it to all handlers associated with this logger and its ancestors (until a false value of \textit{propagate} is found). This method is used for unpickled records received from a socket, as well as those created locally. Logger-level filtering is applied using \texttt{filter()}.

\texttt{Logger.makeRecord(name, lvl, fn, lno, msg, args, exc_info, func=None, extra=None, sinfo=None)}
This is a factory method which can be overridden in subclasses to create specialized LogRecord instances.

Logger . hasHandlers()

Checks to see if this logger has any handlers configured. This is done by looking for handlers in this logger and its parents in the logger hierarchy. Returns True if a handler was found, else False. The method stops searching up the hierarchy whenever a logger with the ‘propagate’ attribute set to False is found - that will be the last logger which is checked for the existence of handlers.

New in version 3.2.
16.7.2. Handler Objects

Handlers have the following attributes and methods. Note that Handler is never instantiated directly; this class acts as a base for more useful subclasses. However, the `__init__()` method in subclasses needs to call `Handler.__init__()`.

**Handler.** `__init__(level=NOTSET)`

Initializes the Handler instance by setting its level, setting the list of filters to the empty list and creating a lock (using `createLock()`) for serializing access to an I/O mechanism.

**Handler.** `createLock()`

Initializes a thread lock which can be used to serialize access to underlying I/O functionality which may not be threadsafe.

**Handler.** `acquire()`

Acquires the thread lock created with `createLock()`.

**Handler.** `release()`

Releases the thread lock acquired with `acquire()`.

**Handler.** `setLevel(lvl)`

Sets the threshold for this handler to `lvl`. Logging messages which are less severe than `lvl` will be ignored. When a handler is created, the level is set to NOTSET (which causes all messages to be processed).

`Changed in version 3.2:` The `lvl` parameter now accepts a string representation of the level such as ‘INFO’ as an alternative to the integer constants such as INFO.
Handler . **setFormatter**(form)

Sets the **Formatter** for this handler to **form**.

Handler . **addFilter**(filt)

Adds the specified filter **filt** to this handler.

Handler . **removeFilter**(filt)

Removes the specified filter **filt** from this handler.

Handler . **filter**(record)

Applies this handler’s filters to the record and returns a true value if the record is to be processed. The filters are consulted in turn, until one of them returns a false value. If none of them return a false value, the record will be emitted. If one returns a false value, the handler will not emit the record.

Handler . **flush**()

Ensure all logging output has been flushed. This version does nothing and is intended to be implemented by subclasses.

Handler . **close**()

Tidy up any resources used by the handler. This version does no output but removes the handler from an internal list of handlers which is closed when **shutdown()** is called. Subclasses should ensure that this gets called from overridden **close()** methods.

Handler . **handle**(record)

Conditionally emits the specified logging record, depending on filters which may have been added to the handler. Wraps the actual emission of the record with acquisition/release of the I/O thread lock.
Handler. **handleError** (*record*)

This method should be called from handlers when an exception is encountered during an **emit()** call. If the module-level attribute `raiseExceptions` is False, exceptions get silently ignored. This is what is mostly wanted for a logging system - most users will not care about errors in the logging system, they are more interested in application errors. You could, however, replace this with a custom handler if you wish. The specified record is the one which was being processed when the exception occurred. (The default value of `raiseExceptions` is True, as that is more useful during development).

Handler. **format** (*record*)

Do formatting for a record - if a formatter is set, use it. Otherwise, use the default formatter for the module.

Handler. **emit** (*record*)

Do whatever it takes to actually log the specified logging record. This version is intended to be implemented by subclasses and so raises a **NotImplementedError**.

For a list of handlers included as standard, see **logging.handlers**.
16.7.3. Formatter Objects

Formatter objects have the following attributes and methods. They are responsible for converting a LogRecord to (usually) a string which can be interpreted by either a human or an external system. The base Formatter allows a formatting string to be specified. If none is supplied, the default value of '%(message)s' is used.

A Formatter can be initialized with a format string which makes use of knowledge of the LogRecord attributes - such as the default value mentioned above making use of the fact that the user’s message and arguments are pre-formatted into a LogRecord’s message attribute. This format string contains standard Python %-style mapping keys. See section printf-style String Formatting for more information on string formatting.

The useful mapping keys in a LogRecord are given in the section on LogRecord attributes.

```python
class logging.Formatter(fmt=None, datefmt=None, style='%')
```

Returns a new instance of the Formatter class. The instance is initialized with a format string for the message as a whole, as well as a format string for the date/time portion of a message. If no fmt is specified, '%(message)s' is used. If no datefmt is specified, the ISO8601 date format is used.

The style parameter can be one of ‘%’, ‘{‘ or ‘$’ and determines how the format string will be merged with its data: using one of %-formatting, str.format() or string.Template.

Changed in version 3.2: The style parameter was added.
format(record)

The record's attribute dictionary is used as the operand to a string formatting operation. Returns the resulting string. Before formatting the dictionary, a couple of preparatory steps are carried out. The message attribute of the record is computed using msg % args. If the formatting string contains '(asctime)', formatTime() is called to format the event time. If there is exception information, it is formatted using formatException() and appended to the message. Note that the formatted exception information is cached in attribute exc_text. This is useful because the exception information can be pickled and sent across the wire, but you should be careful if you have more than one Formatter subclass which customizes the formatting of exception information. In this case, you will have to clear the cached value after a formatter has done its formatting, so that the next formatter to handle the event doesn't use the cached value but recalculates it afresh.

If stack information is available, it's appended after the exception information, using formatStack() to transform it if necessary.

formatTime(record, datefmt=None)

This method should be called from format() by a formatter which wants to make use of a formatted time. This method can be overridden in formatters to provide for any specific requirement, but the basic behavior is as follows: if datefmt (a string) is specified, it is used with time.strftime() to format the creation time of the record. Otherwise, the ISO8601 format is used. The resulting string is returned.

This function uses a user-configurable function to convert the
creation time to a tuple. By default, `time.localtime()` is used; to change this for a particular formatter instance, set the `converter` attribute to a function with the same signature as `time.localtime()` or `time.gmtime()`. To change it for all formatters, for example if you want all logging times to be shown in GMT, set the `converter` attribute in the `Formatter` class.

*Changed in version 3.3:* Previously, the default ISO 8601 format was hard-coded as in this example: 2010-09-06 22:38:15,292 where the part before the comma is handled by a strftime format string (`'%Y-%m-%d %H:%M:%S'`), and the part after the comma is a millisecond value. Because strftime does not have a format placeholder for milliseconds, the millisecond value is appended using another format string, `'%s,%03d'` – and both of these format strings have been hardcoded into this method. With the change, these strings are defined as class-level attributes which can be overridden at the instance level when desired. The names of the attributes are `default_time_format` (for the strftime format string) and `default_msec_format` (for appending the millisecond value).

`formatException(exc_info)`

Formats the specified exception information (a standard exception tuple as returned by `sys.exc_info()`) as a string. This default implementation just uses `traceback.print_exception()`. The resulting string is returned.

`formatStack(stack_info)`
Formats the specified stack information (a string as returned by \texttt{traceback.print_stack()}, but with the last newline removed) as a string. This default implementation just returns the input value.
16.7.4. Filter Objects

Filters can be used by Handlers and Loggers for more sophisticated filtering than is provided by levels. The base filter class only allows events which are below a certain point in the logger hierarchy. For example, a filter initialized with ‘A.B’ will allow events logged by loggers ‘A.B’, ‘A.B.C’, ‘A.B.C.D’, ‘A.B.D’ etc. but not ‘A.BB’, ‘B.A.B’ etc. If initialized with the empty string, all events are passed.

class logging.Filter(name="")

Returns an instance of the Filter class. If name is specified, it names a logger which, together with its children, will have its events allowed through the filter. If name is the empty string, allows every event.

filter(record)

Is the specified record to be logged? Returns zero for no, nonzero for yes. If deemed appropriate, the record may be modified in-place by this method.

Note that filters attached to handlers are consulted before an event is emitted by the handler, whereas filters attached to loggers are consulted whenever an event is logged (using debug(), info(), etc.), before sending an event to handlers. This means that events which have been generated by descendant loggers will not be filtered by a logger’s filter setting, unless the filter has also been applied to those descendant loggers.

You don’t actually need to subclass Filter: you can pass any instance which has a filter method with the same semantics.

Changed in version 3.2: You don’t need to create specialized Filter
classes, or use other classes with a \texttt{filter} method: you can use a function (or other callable) as a filter. The filtering logic will check to see if the filter object has a \texttt{filter} attribute: if it does, it's assumed to be a \texttt{Filter} and its \texttt{filter()} method is called. Otherwise, it's assumed to be a callable and called with the record as the single parameter. The returned value should conform to that returned by \texttt{filter()}.

Although filters are used primarily to filter records based on more sophisticated criteria than levels, they get to see every record which is processed by the handler or logger they're attached to: this can be useful if you want to do things like counting how many records were processed by a particular logger or handler, or adding, changing or removing attributes in the LogRecord being processed. Obviously changing the LogRecord needs to be done with some care, but it does allow the injection of contextual information into logs (see \textit{Using Filters to impart contextual information}).
16.7.5. LogRecord Objects

LogRecord instances are created automatically by the Logger every time something is logged, and can be created manually via makeLogRecord() (for example, from a pickled event received over the wire).

```python
class logging.LogRecord(name, level, pathname, lineno, msg, args, exc_info, func=None, sinfo=None)
```

Contains all the information pertinent to the event being logged.

The primary information is passed in msg and args, which are combined using `msg % args` to create the message field of the record.

**Parameters:**

- **name** – The name of the logger used to log the event represented by this LogRecord. Note that this name will always have this value, even though it may be emitted by a handler attached to a different (ancestor) logger.
- **level** – The numeric level of the logging event (one of DEBUG, INFO etc.) Note that this is converted to two attributes of the LogRecord: levelno for the numeric value andlevelname for the corresponding level name.
- **pathname** – The full pathname of the source file where the logging call was made.
- **lineno** – The line number in the source file where the logging call was made.
- **msg** – The event description message, possibly a format string with placeholders for variable data.
• **args** – Variable data to merge into the `msg` argument to obtain the event description.
• **exc_info** – An exception tuple with the current exception information, or `None` if no exception information is available.
• **func** – The name of the function or method from which the logging call was invoked.
• **sinfo** – A text string representing stack information from the base of the stack in the current thread, up to the logging call.

**getMessage()**

Returns the message for this LogRecord instance after merging any user-supplied arguments with the message. If the user-supplied message argument to the logging call is not a string, `str()` is called on it to convert it to a string. This allows use of user-defined classes as messages, whose `__str__` method can return the actual format string to be used.

*Changed in version 3.2:* The creation of a LogRecord has been made more configurable by providing a factory which is used to create the record. The factory can be set using `getLogRecordFactory()` and `setLogRecordFactory()` (see this for the factory's signature).

This functionality can be used to inject your own values into a LogRecord at creation time. You can use the following pattern:

```python
old_factory = logging.getLogRecordFactory()

def record_factory(*args, **kwargs):
    record = old_factory(*args, **kwargs)
    record.custom_attribute = 0xdecafbad
    return record
```
With this pattern, multiple factories could be chained, and as long as they don’t overwrite each other’s attributes or unintentionally overwrite the standard attributes listed above, there should be no surprises.
16.7.6. LogRecord attributes

The LogRecord has a number of attributes, most of which are derived from the parameters to the constructor. (Note that the names do not always correspond exactly between the LogRecord constructor parameters and the LogRecord attributes.) These attributes can be used to merge data from the record into the format string. The following table lists (in alphabetical order) the attribute names, their meanings and the corresponding placeholder in a %-style format string.

If you are using {}-formatting (str.format()), you can use {attrname} as the placeholder in the format string. If you are using $-formatting (string.Template), use the form ${attrname}. In both cases, of course, replace attrname with the actual attribute name you want to use.

In the case of {}-formatting, you can specify formatting flags by placing them after the attribute name, separated from it with a colon. For example: a placeholder of {msecs:03d} would format a millisecond value of 4 as 004. Refer to the str.format() documentation for full details on the options available to you.

*Changed in version 3.1: processName was added.*
16.7.7. LoggerAdapter Objects

LoggerAdapter instances are used to conveniently pass contextual information into logging calls. For a usage example, see the section on adding contextual information to your logging output.

class logging.LoggerAdapter(logger, extra)

Returns an instance of LoggerAdapter initialized with an underlying Logger instance and a dict-like object.

process(msg, kwargs)

Modifies the message and/or keyword arguments passed to a logging call in order to insert contextual information. This implementation takes the object passed as extra to the constructor and adds it to kwargs using key ‘extra’. The return value is a (msg, kwargs) tuple which has the (possibly modified) versions of the arguments passed in.

In addition to the above, LoggerAdapter supports the following methods of Logger, i.e. debug(), info(), warning(), error(), exception(), critical(), log(), isEnabledFor(), getEffectiveLevel(), setLevel(), hasHandlers(). These methods have the same signatures as their counterparts in Logger, so you can use the two types of instances interchangeably.

Changed in version 3.2: The isEnabledFor(), getEffectiveLevel(), setLevel() and hasHandlers() methods were added to LoggerAdapter. These methods delegate to the underlying logger.
16.7.8. Thread Safety

The logging module is intended to be thread-safe without any special work needing to be done by its clients. It achieves this though using threading locks; there is one lock to serialize access to the module's shared data, and each handler also creates a lock to serialize access to its underlying I/O.

If you are implementing asynchronous signal handlers using the `signal` module, you may not be able to use logging from within such handlers. This is because lock implementations in the `threading` module are not always re-entrant, and so cannot be invoked from such signal handlers.
16.7.9. Module-Level Functions

In addition to the classes described above, there are a number of module-level functions.

**logging.getLogger** *(name=None)*

Return a logger with the specified name or, if name is None, return a logger which is the root logger of the hierarchy. If specified, the name is typically a dot-separated hierarchical name like ‘a’, ‘a.b’ or ‘a.b.c.d’. Choice of these names is entirely up to the developer who is using logging.

All calls to this function with a given name return the same logger instance. This means that logger instances never need to be passed between different parts of an application.

**logging.getLoggerClass()**

Return either the standard Logger class, or the last class passed to setLoggerClass(). This function may be called from within a new class definition, to ensure that installing a customised Logger class will not undo customisations already applied by other code. For example:

```python
class MyLogger(logging.getLoggerClass()):
    # ... override behaviour here
```

**logging.getLogRecordFactory()**

Return a callable which is used to create a LogRecord.

*New in version 3.2:* This function has been provided, along with setLogRecordFactory(), to allow developers more control
over how the `LogRecord` representing a logging event is constructed.

See `setLogRecordFactory()` for more information about the how the factory is called.

```
logging.debug(msg, *args, **kwargs)
```

Logs a message with level DEBUG on the root logger. The `msg` is the message format string, and the `args` are the arguments which are merged into `msg` using the string formatting operator. (Note that this means that you can use keywords in the format string, together with a single dictionary argument.)

There are three keyword arguments in `kwargs` which are inspected: `exc_info` which, if it does not evaluate as false, causes exception information to be added to the logging message. If an exception tuple (in the format returned by `sys.exc_info()`) is provided, it is used; otherwise, `sys.exc_info()` is called to get the exception information.

The second optional keyword argument is `stack_info`, which defaults to False. If specified as True, stack information is added to the logging message, including the actual logging call. Note that this is not the same stack information as that displayed through specifying `exc_info`: The former is stack frames from the bottom of the stack up to the logging call in the current thread, whereas the latter is information about stack frames which have been unwound, following an exception, while searching for exception handlers.

You can specify `stack_info` independently of `exc_info`, e.g. to just show how you got to a certain point in your code, even when no exceptions were raised. The stack frames are printed following a header line which says:
Stack (most recent call last):

This mimics the Traceback (most recent call last): which is used when displaying exception frames.

The third optional keyword argument is extra which can be used to pass a dictionary which is used to populate the __dict__ of the LogRecord created for the logging event with user-defined attributes. These custom attributes can then be used as you like. For example, they could be incorporated into logged messages. For example:

```python
FORMAT = '%(asctime)-15s %(clientip)s %(user)-8s %(message)s'
logging.basicConfig(format=FORMAT)
d = {'clientip': '192.168.0.1', 'user': 'fbloggs'}
logging.warning('Protocol problem: %s', 'connection reset')
```

would print something like:

```
2006-02-08 22:20:02,165 192.168.0.1 fbloggs Protocol
```

The keys in the dictionary passed in extra should not clash with the keys used by the logging system. (See the Formatter documentation for more information on which keys are used by the logging system.)

If you choose to use these attributes in logged messages, you need to exercise some care. In the above example, for instance, the Formatter has been set up with a format string which expects ‘clientip’ and ‘user’ in the attribute dictionary of the LogRecord. If these are missing, the message will not be logged because a string formatting exception will occur. So in this case,
you always need to pass the *extra* dictionary with these keys.

While this might be annoying, this feature is intended for use in specialized circumstances, such as multi-threaded servers where the same code executes in many contexts, and interesting conditions which arise are dependent on this context (such as remote client IP address and authenticated user name, in the above example). In such circumstances, it is likely that specialized *Formatter*s would be used with particular *Handlers*.

*New in version 3.2:* The *stack_info* parameter was added.

```python
logging.info(msg, *args, **kwargs)
```
Logs a message with level INFO on the root logger. The arguments are interpreted as for `debug()`.

```python
logging.warning(msg, *args, **kwargs)
```
Logs a message with level WARNING on the root logger. The arguments are interpreted as for `debug()`.

**Note:** There is an obsolete function `warn` which is functionally identical to `warning`. As `warn` is deprecated, please do not use it - use `warning` instead.

```python
logging.error(msg, *args, **kwargs)
```
Logs a message with level ERROR on the root logger. The arguments are interpreted as for `debug()`.

```python
logging.critical(msg, *args, **kwargs)
```
Logs a message with level CRITICAL on the root logger. The arguments are interpreted as for `debug()`.
logging.**exception**(msg, *args)

Logs a message with level ERROR on the root logger. The arguments are interpreted as for debug(). Exception info is added to the logging message. This function should only be called from an exception handler.

logging.**log**(level, msg, *args, **kwargs)

Logs a message with level *level* on the root logger. The other arguments are interpreted as for debug().

**Note:** The above module-level functions which delegate to the root logger should *not* be used in threads, in versions of Python earlier than 2.7.1 and 3.2, unless at least one handler has been added to the root logger *before* the threads are started. These convenience functions call basicConfig() to ensure that at least one handler is available; in earlier versions of Python, this can (under rare circumstances) lead to handlers being added multiple times to the root logger, which can in turn lead to multiple messages for the same event.

logging.**disable**(lvl)

Provides an overriding level *lvl* for all loggers which takes precedence over the logger’s own level. When the need arises to temporarily throttle logging output down across the whole application, this function can be useful. Its effect is to disable all logging calls of severity *lvl* and below, so that if you call it with a value of INFO, then all INFO and DEBUG events would be discarded, whereas those of severity WARNING and above would be processed according to the logger’s effective level. To undo the effect of a call to logging.disable(lvl), call logging.disable(logging.NOTSET).
logging.addLevelName(lvl, levelName)

Associates level lvl with text levelName in an internal dictionary, which is used to map numeric levels to a textual representation, for example when a Formatter formats a message. This function can also be used to define your own levels. The only constraints are that all levels used must be registered using this function, levels should be positive integers and they should increase in increasing order of severity.

**Note:** If you are thinking of defining your own levels, please see the section on Custom Levels.

logging.getName(lvl)

Returns the textual representation of logging level lvl. If the level is one of the predefined levels CRITICAL, ERROR, WARNING, INFO or DEBUG then you get the corresponding string. If you have associated levels with names using addLevelName() then the name you have associated with lvl is returned. If a numeric value corresponding to one of the defined levels is passed in, the corresponding string representation is returned. Otherwise, the string 'Level %s' % lvl is returned.

logging.makeLogRecord(attrdict)

Creates and returns a new LogRecord instance whose attributes are defined by attrdict. This function is useful for taking a pickled LogRecord attribute dictionary, sent over a socket, and reconstituting it as a LogRecord instance at the receiving end.

logging.basicConfig(**kwargs)

Does basic configuration for the logging system by creating a StreamHandler with a default Formatter and adding it to the
The functions `debug()`, `info()`, `warning()`, `error()` and `critical()` will call `basicConfig()` automatically if no handlers are defined for the root logger.

This function does nothing if the root logger already has handlers configured for it.

**Note:** This function should be called from the main thread before other threads are started. In versions of Python prior to 2.7.1 and 3.2, if this function is called from multiple threads, it is possible (in rare circumstances) that a handler will be added to the root logger more than once, leading to unexpected results such as messages being duplicated in the log.

The following keyword arguments are supported.

<table>
<thead>
<tr>
<th>Format</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>filename</td>
<td>Specifies that a FileHandler be created, using the specified filename, rather than a StreamHandler.</td>
</tr>
<tr>
<td>filemode</td>
<td>Specifies the mode to open the file, if filename is specified (if filemode is unspecified, it defaults to ‘a’).</td>
</tr>
<tr>
<td>format</td>
<td>Use the specified format string for the handler.</td>
</tr>
<tr>
<td>datefmt</td>
<td>Use the specified date/time format.</td>
</tr>
<tr>
<td>style</td>
<td>If format is specified, use this style for the format string. One of ‘%’, ‘{’ or ‘$’ for %-formatting, <code>str.format()</code> or <code>string.Template</code> respectively, and defaulting to ‘%’ if not specified.</td>
</tr>
<tr>
<td>level</td>
<td>Set the root logger level to the specified level.</td>
</tr>
<tr>
<td></td>
<td>Use the specified stream to initialize the root logger.</td>
</tr>
</tbody>
</table>
StreamHandler. Note that this argument is incompatible with ‘filename’ - if both are present, a `ValueError` is raised.

If specified, this should be an iterable of already created handlers to add to the root logger. Any handlers which don’t already have a formatter set will be assigned the default formatter created in this function. Note that this argument is incompatible with ‘filename’ or ‘stream’ - if both are present, a `ValueError` is raised.

*Changed in version 3.2:* The `style` argument was added.

*Changed in version 3.3:* The `handlers` argument was added. Additional checks were added to catch situations where incompatible arguments are specified (e.g. `handlers` together with `stream` or `filename`, or `stream` together with `filename`).

**logging.shutdown()**

Informs the logging system to perform an orderly shutdown by flushing and closing all handlers. This should be called at application exit and no further use of the logging system should be made after this call.

**logging.setLoggerClass(klass)**

Tells the logging system to use the class `klass` when instantiating a logger. The class should define `__init__()`, such that only a name argument is required, and the `__init__()` should call `Logger.__init__()`. This function is typically called before any loggers are instantiated by applications which need to use custom logger behavior.

**logging.setLogRecordFactory(factory)**
Set a callable which is used to create a LogRecord.

### Parameters:

<table>
<thead>
<tr>
<th>parameter</th>
<th>description</th>
</tr>
</thead>
<tbody>
<tr>
<td><strong>factory</strong></td>
<td>The factory callable to be used to instantiate a log record.</td>
</tr>
</tbody>
</table>

*New in version 3.2*: This function has been provided, along with `getLogRecordFactory()`, to allow developers more control over how the LogRecord representing a logging event is constructed.

The factory has the following signature:

```python
factory(name, level, fn, lno, msg, args, exc_info, func=None, sinfo=None, **kwargs)
```

<table>
<thead>
<tr>
<th>parameter</th>
<th>description</th>
</tr>
</thead>
<tbody>
<tr>
<td>name</td>
<td>The logger name.</td>
</tr>
<tr>
<td>level</td>
<td>The logging level (numeric).</td>
</tr>
<tr>
<td>fn</td>
<td>The full pathname of the file where the logging call was made.</td>
</tr>
<tr>
<td>lno</td>
<td>The line number in the file where the logging call was made.</td>
</tr>
<tr>
<td>msg</td>
<td>The logging message.</td>
</tr>
<tr>
<td>args</td>
<td>The arguments for the logging message.</td>
</tr>
<tr>
<td>exc_info</td>
<td>An exception tuple, or None.</td>
</tr>
<tr>
<td>func</td>
<td>The name of the function or method which invoked the logging call.</td>
</tr>
<tr>
<td>sinfo</td>
<td>A stack traceback such as is provided by <code>traceback.print_stack()</code>, showing the call hierarchy.</td>
</tr>
<tr>
<td>kwargs</td>
<td>Additional keyword arguments.</td>
</tr>
</tbody>
</table>
16.7.10. Module-Level Attributes

logging.lastResort

A “handler of last resort” is available through this attribute. This is a StreamHandler writing to sys.stderr with a level of WARNING, and is used to handle logging events in the absence of any logging configuration. The end result is to just print the message to sys.stderr. This replaces the earlier error message saying that “no handlers could be found for logger XYZ”. If you need the earlier behaviour for some reason, lastResort can be set to None.

New in version 3.2.
16.7.11. Integration with the warnings module

The `captureWarnings()` function can be used to integrate logging with the `warnings` module.

```python
logging.captureWarnings(capture)
```

This function is used to turn the capture of warnings by logging on and off.

If `capture` is True, warnings issued by the `warnings` module will be redirected to the logging system. Specifically, a warning will be formatted using `warnings.formatwarning()` and the resulting string logged to a logger named `'py.warnings'` with a severity of WARNING.

If `capture` is False, the redirection of warnings to the logging system will stop, and warnings will be redirected to their original destinations (i.e. those in effect before `captureWarnings(True)` was called).

Useful handlers included with the logging module.

**PEP 282 - A Logging System**

The proposal which described this feature for inclusion in the Python standard library.
Original Python logging package

This is the original source for the `logging` package. The version of the package available from this site is suitable for use with Python 1.5.2, 2.1.x and 2.2.x, which do not include the `logging` package in the standard library.
16.8. `logging.config` — Logging configuration

**Source code:** Lib/logging/config.py

This section describes the API for configuring the logging module.

**Important**

This page contains only reference information. For tutorials, please see

- *Basic Tutorial*
- *Advanced Tutorial*
- *Logging Cookbook*
16.8.1. Configuration functions

The following functions configure the logging module. They are located in the `logging.config` module. Their use is optional — you can configure the logging module using these functions or by making calls to the main API (defined in `logging` itself) and defining handlers which are declared either in `logging` or `logging.handlers`.

`logging.config.dictConfig(config)`

Takes the logging configuration from a dictionary. The contents of this dictionary are described in *Configuration dictionary schema* below.

If an error is encountered during configuration, this function will raise a `ValueError`, `TypeError`, `AttributeError` or `ImportError` with a suitably descriptive message. The following is a (possibly incomplete) list of conditions which will raise an error:

- A `level` which is not a string or which is a string not corresponding to an actual logging level.
- A `propagate` value which is not a boolean.
- An id which does not have a corresponding destination.
- A non-existent handler id found during an incremental call.
- An invalid logger name.
- Inability to resolve to an internal or external object.

Parsing is performed by the `DictConfigurator` class, whose constructor is passed the dictionary used for configuration, and has a `configure()` method. The `logging.config` module has a callable attribute
dictConfigClass which is initially set to DictConfigurator. You can replace the value of dictConfigClass with a suitable implementation of your own.

dictConfig() calls dictConfigClass passing the specified dictionary, and then calls the configure() method on the returned object to put the configuration into effect:

```python
def dictConfig(config):
    dictConfigClass(config).configure()
```

For example, a subclass of DictConfigurator could call DictConfigurator.__init__() in its own __init__(), then set up custom prefixes which would be usable in the subsequent configure() call. dictConfigClass would be bound to this new subclass, and then dictConfig() could be called exactly as in the default, uncustomized state.

*New in version 3.2.*

logging.config.fileConfig(fname, defaults=None, disable_existing_loggers=True)

Reads the logging configuration from a configparser-format file named `fname`. This function can be called several times from an application, allowing an end user to select from various pre-canned configurations (if the developer provides a mechanism to present the choices and load the chosen configuration).

- **defaults** – Defaults to be passed to the ConfigParser can be specified in this argument.
**Parameters:**

- **disable_existing_loggers** – If specified as False, loggers which exist when this call is made are left alone. The default is True because this enables old behaviour in a backward-compatible way. This behaviour is to disable any existing loggers unless they or their ancestors are explicitly named in the logging configuration.

`logging.config.listen(port=DEFAULT_LOGGING_CONFIG_PORT)`

Starts up a socket server on the specified port, and listens for new configurations. If no port is specified, the module's default `DEFAULT_LOGGING_CONFIG_PORT` is used. Logging configurations will be sent as a file suitable for processing by `fileConfig()`. Returns a `Thread` instance on which you can call `start()` to start the server, and which you can `join()` when appropriate. To stop the server, call `stopListening()`.

To send a configuration to the socket, read in the configuration file and send it to the socket as a string of bytes preceded by a four-byte length string packed in binary using `struct.pack('>L', n)`.

**Note:** Because portions of the configuration are passed through `eval()`, use of this function may open its users to a security risk. While the function only binds to a socket on `localhost`, and so does not accept connections from remote machines, there are scenarios where untrusted code could be run under the account of the process which calls `listen()`. Specifically, if the process calling `listen()` runs on a multi-user machine where users cannot trust each other, then a malicious user could arrange to run essentially arbitrary code in a victim user's
process, simply by connecting to the victim’s `listen()` socket and sending a configuration which runs whatever code the attacker wants to have executed in the victim’s process. This is especially easy to do if the default port is used, but not hard even if a different port is used).

```
logging.config.stopListening()
```

Stops the listening server which was created with a call to `listen()`. This is typically called before calling `join()` on the return value from `listen()`. 
16.8.2. Configuration dictionary schema

Describing a logging configuration requires listing the various objects to create and the connections between them; for example, you may create a handler named ‘console’ and then say that the logger named ‘startup’ will send its messages to the ‘console’ handler. These objects aren’t limited to those provided by the logging module because you might write your own formatter or handler class. The parameters to these classes may also need to include external objects such as sys.stderr. The syntax for describing these objects and connections is defined in Object connections below.

16.8.2.1. Dictionary Schema Details

The dictionary passed to dictConfig() must contain the following keys:

- **version** - to be set to an integer value representing the schema version. The only valid value at present is 1, but having this key allows the schema to evolve while still preserving backwards compatibility.

All other keys are optional, but if present they will be interpreted as described below. In all cases below where a ‘configuring dict’ is mentioned, it will be checked for the special '(' key to see if a custom instantiation is required. If so, the mechanism described in User-defined objects below is used to create an instance; otherwise, the context is used to determine what to instantiate.

- **formatters** - the corresponding value will be a dict in which each key is a formatter id and each value is a dict describing how to
configure the corresponding **Formatter** instance.

The configuring dict is searched for keys `format` and `datefmt` (with defaults of None) and these are used to construct a **Formatter** instance.

- **filters** - the corresponding value will be a dict in which each key is a filter id and each value is a dict describing how to configure the corresponding Filter instance.

  The configuring dict is searched for the key `name` (defaulting to the empty string) and this is used to construct a **logging.Filter** instance.

- **handlers** - the corresponding value will be a dict in which each key is a handler id and each value is a dict describing how to configure the corresponding Handler instance.

  The configuring dict is searched for the following keys:

  - `class` (mandatory). This is the fully qualified name of the handler class.
  - `level` (optional). The level of the handler.
  - `formatter` (optional). The id of the formatter for this handler.
  - `filters` (optional). A list of ids of the filters for this handler.

  All *other* keys are passed through as keyword arguments to the handler's constructor. For example, given the snippet:

```python
def snippet:
    handlers:
        console:
            class : logging.StreamHandler
            formatter: brief
```
the handler with id console is instantiated as a `logging.StreamHandler`, using `sys.stdout` as the underlying stream. The handler with id file is instantiated as a `logging.handlers.RotatingFileHandler` with the keyword arguments `filename='logconfig.log', maxBytes=1024, backupCount=3`.

- **loggers** - the corresponding value will be a dict in which each key is a logger name and each value is a dict describing how to configure the corresponding Logger instance.

The configuring dict is searched for the following keys:

- **level** (optional). The level of the logger.
- **propagate** (optional). The propagation setting of the logger.
- **filters** (optional). A list of ids of the filters for this logger.
- **handlers** (optional). A list of ids of the handlers for this logger.

The specified loggers will be configured according to the level, propagation, filters and handlers specified.

- **root** - this will be the configuration for the root logger. Processing of the configuration will be as for any logger, except that the
propagate setting will not be applicable.

- **incremental** - whether the configuration is to be interpreted as incremental to the existing configuration. This value defaults to False, which means that the specified configuration replaces the existing configuration with the same semantics as used by the existing `fileConfig()` API.

  If the specified value is True, the configuration is processed as described in the section on *Incremental Configuration*.

- **disable_existing_loggers** - whether any existing loggers are to be disabled. This setting mirrors the parameter of the same name in `fileConfig()`. If absent, this parameter defaults to True. This value is ignored if *incremental* is True.

### 16.8.2.2. Incremental Configuration

It is difficult to provide complete flexibility for incremental configuration. For example, because objects such as filters and formatters are anonymous, once a configuration is set up, it is not possible to refer to such anonymous objects when augmenting a configuration.

Furthermore, there is not a compelling case for arbitrarily altering the object graph of loggers, handlers, filters, formatters at run-time, once a configuration is set up; the verbosity of loggers and handlers can be controlled just by setting levels (and, in the case of loggers, propagation flags). Changing the object graph arbitrarily in a safe way is problematic in a multi-threaded environment; while not impossible, the benefits are not worth the complexity it adds to the implementation.

Thus, when the **incremental** key of a configuration dict is present
and is True, the system will completely ignore any formatters and filters entries, and process only the level settings in the handlers entries, and the level and propagate settings in the loggers and root entries.

Using a value in the configuration dict lets configurations to be sent over the wire as pickled dicts to a socket listener. Thus, the logging verbosity of a long-running application can be altered over time with no need to stop and restart the application.

16.8.2.3. Object connections

The schema describes a set of logging objects - loggers, handlers, formatters, filters - which are connected to each other in an object graph. Thus, the schema needs to represent connections between the objects. For example, say that, once configured, a particular logger has attached to it a particular handler. For the purposes of this discussion, we can say that the logger represents the source, and the handler the destination, of a connection between the two. Of course in the configured objects this is represented by the logger holding a reference to the handler. In the configuration dict, this is done by giving each destination object an id which identifies it unambiguously, and then using the id in the source object’s configuration to indicate that a connection exists between the source and the destination object with that id.

So, for example, consider the following YAML snippet:

```yaml
formatters:
  brief:
    # configuration for formatter with id 'brief' goes here
  precise:
    # configuration for formatter with id 'precise'
```
handlers:
  h1: #This is an id
      # configuration of handler with id 'h1' goes here
      formatter: brief
  h2: #This is another id
      # configuration of handler with id 'h2' goes here
      formatter: precise

loggers:
  foo.bar.baz:
    # other configuration for logger 'foo.bar.baz'
    handlers: [h1, h2]

(Note: YAML used here because it's a little more readable than the equivalent Python source form for the dictionary.)

The ids for loggers are the logger names which would be used programmatically to obtain a reference to those loggers, e.g. foo.bar.baz. The ids for Formatters and Filters can be any string value (such as brief, precise above) and they are transient, in that they are only meaningful for processing the configuration dictionary and used to determine connections between objects, and are not persisted anywhere when the configuration call is complete.

The above snippet indicates that logger named foo.bar.baz should have two handlers attached to it, which are described by the handler ids h1 and h2. The formatter for h1 is that described by id brief, and the formatter for h2 is that described by id precise.

16.8.2.4. User-defined objects

The schema supports user-defined objects for handlers, filters and formatters. (Loggers do not need to have different types for different instances, so there is no support in this configuration schema for user-
defined logger classes.)

Objects to be configured are described by dictionaries which detail their configuration. In some places, the logging system will be able to infer from the context how an object is to be instantiated, but when a user-defined object is to be instantiated, the system will not know how to do this. In order to provide complete flexibility for user-defined object instantiation, the user needs to provide a ‘factory’ - a callable which is called with a configuration dictionary and which returns the instantiated object. This is signalled by an absolute import path to the factory being made available under the special key `[:]`. Here’s a concrete example:

```yaml
formatters:
  brief:
    format: '%(message)s'
  default:
    format: '%(asctime)s %(levelname)-8s %(name)-15s %(message)s'
    datefmt: '%Y-%m-%d %H:%M:%S'
  custom:
    (): my.package.customFormatterFactory
    bar: baz
    spam: 99.9
    answer: 42
```

The above YAML snippet defines three formatters. The first, with id `brief`, is a standard `logging.Formatter` instance with the specified format string. The second, with id `default`, has a longer format and also defines the time format explicitly, and will result in a `logging.Formatter` initialized with those two format strings. Shown in Python source form, the `brief` and `default` formatters have configuration sub-dictionaries:
respectively, and as these dictionaries do not contain the special key '__()', the instantiation is inferred from the context: as a result, standard logging.Formatter instances are created. The configuration sub-dictionary for the third formatter, with id custom, is:

```python
{
    '__()' : 'my.package.customFormatterFactory',
    'bar' : 'baz',
    'spam' : 99.9,
    'answer' : 42
}
```

and this contains the special key '__()', which means that user-defined instantiation is wanted. In this case, the specified factory callable will be used. If it is an actual callable it will be used directly - otherwise, if you specify a string (as in the example) the actual callable will be located using normal import mechanisms. The callable will be called with the remaining items in the configuration sub-dictionary as keyword arguments. In the above example, the formatter with id custom will be assumed to be returned by the call:

```
my.package.customFormatterFactory(bar='baz', spam=99.9)
```
The key 

() 

has been used as the special key because it is not a valid keyword parameter name, and so will not clash with the names of the keyword arguments used in the call. The 

() 

also serves as a mnemonic that the corresponding value is a callable.

16.8.2.5. Access to external objects

There are times where a configuration needs to refer to objects external to the configuration, for example 

sys.stderr 

. If the configuration dict is constructed using Python code, this is straightforward, but a problem arises when the configuration is provided via a text file (e.g. JSON, YAML). In a text file, there is no standard way to distinguish 

sys.stderr 

from the literal string 

'sys.stderr'. To facilitate this distinction, the configuration system looks for certain special prefixes in string values and treat them specially. For example, if the literal string 

'ext://sys.stderr' 

is provided as a value in the configuration, then the 

ext:// 

will be stripped off and the remainder of the value processed using normal import mechanisms.

The handling of such prefixes is done in a way analogous to protocol handling: there is a generic mechanism to look for prefixes which match the regular expression 

^(?P<prefix>[a-z]+)://(?P<suffix>.*$) 

whereby, if the prefix is recognised, the suffix is processed in a prefix-dependent manner and the result of the processing replaces the string value. If the prefix is not recognised, then the string value will be left as-is.

16.8.2.6. Access to internal objects
As well as external objects, there is sometimes also a need to refer to objects in the configuration. This will be done implicitly by the configuration system for things that it knows about. For example, the string value 'DEBUG' for a level in a logger or handler will automatically be converted to the value `logging.DEBUG`, and the handlers, filters and formatter entries will take an object id and resolve to the appropriate destination object.

However, a more generic mechanism is needed for user-defined objects which are not known to the `logging` module. For example, consider `logging.handlers.MemoryHandler`, which takes a target argument which is another handler to delegate to. Since the system already knows about this class, then in the configuration, the given target just needs to be the object id of the relevant target handler, and the system will resolve to the handler from the id. If, however, a user defines a `my.package.MyHandler` which has an alternate handler, the configuration system would not know that the alternate referred to a handler. To cater for this, a generic resolution system allows the user to specify:

```yaml
handlers:
  file:
    # configuration of file handler goes here

custom:
  (): my.package.MyHandler
  alternate: cfg://handlers.file
```

The literal string `cfg://handlers.file` will be resolved in an analogous way to strings with the `ext://` prefix, but looking in the configuration itself rather than the import namespace. The mechanism allows access by dot or by index, in a similar way to that provided by
Given the following snippet:

```python
handlers:
    email:
        class: logging.handlers.SMTPHandler
        mailhost: localhost
        fromaddr: my_app@domain.tld
        toaddrs:
            - support_team@domain.tld
            - dev_team@domain.tld
        subject: Houston, we have a problem.
```

in the configuration, the string `cfg://handlers` would resolve to the dict with key `handlers`, the string `cfg://handlers.email` would resolve to the dict with key `email` in the handlers dict, and so on. The string `cfg://handlers.email.toaddrs[1]` would resolve to `'dev_team.domain.tld'` and the string `cfg://handlers.email.toaddrs[0]` would resolve to the value `'support_team@domain.tld'`. The subject value could be accessed using either `cfg://handlers.email.subject` or, equivalently, `cfg://handlers.email[subject]`. The latter form only needs to be used if the key contains spaces or non-alphanumeric characters. If an index value consists only of decimal digits, access will be attempted using the corresponding integer value, falling back to the string value if needed.

Given a string `cfg://handlers.myhandler.mykey.123`, this will resolve to `config_dict['handlers']['myhandler']['mykey']['123']`. If the string is specified as `cfg://handlers.myhandler.mykey[123]`, the system will attempt to retrieve the value from `config_dict['handlers']['myhandler']['mykey'][123]`, and fall back to
if that fails.

16.8.2.7. Import resolution and custom importers

Import resolution, by default, uses the built-in `__import__()` function to do its importing. You may want to replace this with your own importing mechanism: if so, you can replace the `importer` attribute of the `DictConfigurator` or its superclass, the `BaseConfigurator` class. However, you need to be careful because of the way functions are accessed from classes via descriptors. If you are using a Python callable to do your imports, and you want to define it at class level rather than instance level, you need to wrap it with `staticmethod()`. For example:

```python
from importlib import import_module
from logging.config import BaseConfigurator

BaseConfigurator.importer = staticmethod(import_module)
```

You don’t need to wrap with `staticmethod()` if you’re setting the import callable on a configurator instance.
16.8.3. Configuration file format

The configuration file format understood by `fileConfig()` is based on `configparser` functionality. The file must contain sections called `[loggers]`, `[handlers]` and `[formatters]` which identify by name the entities of each type which are defined in the file. For each such entity, there is a separate section which identifies how that entity is configured. Thus, for a logger named `log01` in the `[loggers]` section, the relevant configuration details are held in a section `[logger_log01]`. Similarly, a handler called `hand01` in the `[handlers]` section will have its configuration held in a section called `[handler_hand01]`, while a formatter called `form01` in the `[formatters]` section will have its configuration specified in a section called `[formatter_form01]`. The root logger configuration must be specified in a section called `[logger_root]`.

Examples of these sections in the file are given below.

```
[loggers]
keys=root,log02,log03,log04,log05,log06,log07

[handlers]
keys=hand01,hand02,hand03,hand04,hand05,hand06,hand07

[formatters]
keys=form01/form02/form03/form04/form05/form06/form07
```

The root logger must specify a level and a list of handlers. An example of a root logger section is given below.

```
[logger_root]
```
The `level` entry can be one of `DEBUG`, `INFO`, `WARNING`, `ERROR`, `CRITICAL` or `NOTSET`. For the root logger only, `NOTSET` means that all messages will be logged. Level values are evaluated in the context of the `logging` package’s namespace.

The `handlers` entry is a comma-separated list of handler names, which must appear in the `[handlers]` section. These names must appear in the `[handlers]` section and have corresponding sections in the configuration file.

For loggers other than the root logger, some additional information is required. This is illustrated by the following example.

```
[logger_parser]
level=DEBUG
handlers=hand01
propagate=1
qualname=compiler.parser
```

The `level` and `handlers` entries are interpreted as for the root logger, except that if a non-root logger’s level is specified as `NOTSET`, the system consults loggers higher up the hierarchy to determine the effective level of the logger. The `propagate` entry is set to 1 to indicate that messages must propagate to handlers higher up the logger hierarchy from this logger, or 0 to indicate that messages are not propagated to handlers up the hierarchy. The `qualname` entry is the hierarchical channel name of the logger, that is to say the name used by the application to get the logger.

Sections which specify handler configuration are exemplified by the
The class entry indicates the handler's class (as determined by \texttt{eval()} in the \texttt{logging} package's namespace). The level is interpreted as for loggers, and \texttt{NOTSET} is taken to mean 'log everything'.

The formatter entry indicates the key name of the formatter for this handler. If blank, a default formatter (\texttt{logging._defaultFormatter}) is used. If a name is specified, it must appear in the [formatters] section and have a corresponding section in the configuration file.

The args entry, when \texttt{eval()}uated in the context of the \texttt{logging} package's namespace, is the list of arguments to the constructor for the handler class. Refer to the constructors for the relevant handlers, or to the examples below, to see how typical entries are constructed.
args=('localhost', handlers.DEFAULT_TCP_LOGGING_PORT)

[handler_hand04]
class=handlers.DatagramHandler
level=WARN
formatter=form04
args=('localhost', handlers.DEFAULT_UDP_LOGGING_PORT)

[handler_hand05]
class=handlers.SysLogHandler
level=ERROR
formatter=form05
args=('localhost', handlers.SYSLOG_UDP_PORT),

[handler_hand06]
class=handlers.NTEventLogHandler
level=CRITICAL
formatter=form06
args=('Python Application', '', 'Application')

[handler_hand07]
class=handlers.SMTPHandler
level=WARN
formatter=form07
args=('localhost', 'from@abc', ['user1@abc', 'user2@xyz'])

[handler_hand08]
class=handlers.MemoryHandler
level=NOTSET
formatter=form08
target=
args=(10, ERROR)

[handler_hand09]
class=handlers.HTTPHandler
level=NOTSET
formatter=form09
Sections which specify formatter configuration are typified by the following.

```
[formatter_form01]
format=F1 %(asctime)s %(levelname)s %(message)s
datefmt=
class=logging.Formatter
```

The `format` entry is the overall format string, and the `datefmt` entry is the `strftime()`-compatible date/time format string. If empty, the package substitutes ISO8601 format date/times, which is almost equivalent to specifying the date format string `'%Y-%m-%d %H:%M:%S'`. The ISO8601 format also specifies milliseconds, which are appended to the result of using the above format string, with a comma separator. An example time in ISO8601 format is `2003-01-23 00:29:50,411`.

The `class` entry is optional. It indicates the name of the formatter's class (as a dotted module and class name.) This option is useful for instantiating a `Formatter` subclass. Subclasses of `Formatter` can present exception tracebacks in an expanded or condensed format.

**Note:** Due to the use of `eval()` as described above, there are potential security risks which result from using the `listen()` to send and receive configurations via sockets. The risks are limited to where multiple users with no mutual trust run code on the same machine; see the `listen()` documentation for more information.

**See also:**
Module **logging**

API reference for the logging module.

Module **logging.handlers**

Useful handlers included with the logging module.
16.9. logging.handlers — Logging handlers

Source code: Lib/logging/handlers.py

The following useful handlers are provided in the package. Note that three of the handlers (StreamHandler, FileHandler and NullHandler) are actually defined in the logging module itself, but have been documented here along with the other handlers.
16.9.1. StreamHandler

The **StreamHandler** class, located in the core **logging** package, sends logging output to streams such as `sys.stdout`, `sys.stderr` or any file-like object (or, more precisely, any object which supports `write()` and `flush()` methods).

```python
class logging.StreamHandler(stream=None)
    Returns a new instance of the StreamHandler class. If `stream` is specified, the instance will use it for logging output; otherwise, `sys.stderr` will be used.
```

**emit**(record)

If a formatter is specified, it is used to format the record. The record is then written to the stream with a terminator. If exception information is present, it is formatted using `traceback.print_exception()` and appended to the stream.

**flush()

Flushes the stream by calling its `flush()` method. Note that the close() method is inherited from Handler and so does no output, so an explicit `flush()` call may be needed at times.

*Changed in version 3.2:* The **StreamHandler** class now has a `terminator` attribute, default value `'
'`, which is used as the terminator when writing a formatted record to a stream. If you don’t want this newline termination, you can set the handler instance’s `terminator` attribute to the empty string. In earlier versions, the terminator was hardcoded as `\n`. 

16.9.2. FileHandler

The **FileHandler** class, located in the core **logging** package, sends logging output to a disk file. It inherits the output functionality from **StreamHandler**.

```python
class logging.FileHandler(filename, mode='a', encoding=None, delay=False)
```

Returns a new instance of the **FileHandler** class. The specified file is opened and used as the stream for logging. If `mode` is not specified, 'a' is used. If `encoding` is not `None`, it is used to open the file with that encoding. If `delay` is true, then file opening is deferred until the first call to **emit()**. By default, the file grows indefinitely.

**close()**

Closes the file.

**emit(record)**

Outputs the record to the file.
16.9.3. NullHandler

New in version 3.1.

The `NullHandler` class, located in the core `logging` package, does not do any formatting or output. It is essentially a ‘no-op’ handler for use by library developers.

```python
class logging.NullHandler
    Returns a new instance of the NullHandler class.

    `emit(record)`
    This method does nothing.

    `handle(record)`
    This method does nothing.

    `createLock()`
    This method returns None for the lock, since there is no underlying I/O to which access needs to be serialized.
```

See *Configuring Logging for a Library* for more information on how to use `NullHandler`.
16.9.4. WatchedFileHandler

The `WatchedFileHandler` class, located in the `logging.handlers` module, is a `FileHandler` which watches the file it is logging to. If the file changes, it is closed and reopened using the file name.

A file change can happen because of usage of programs such as `newsyslog` and `logrotate` which perform log file rotation. This handler, intended for use under Unix/Linux, watches the file to see if it has changed since the last emit. (A file is deemed to have changed if its device or inode have changed.) If the file has changed, the old file stream is closed, and the file opened to get a new stream.

This handler is not appropriate for use under Windows, because under Windows open log files cannot be moved or renamed - logging opens the files with exclusive locks - and so there is no need for such a handler. Furthermore, `ST_INO` is not supported under Windows; `stat()` always returns zero for this value.

class logging.handlers.WatchedFileHandler(filename[, mode[, encoding[, delay]]])

Returns a new instance of the `WatchedFileHandler` class. The specified file is opened and used as the stream for logging. If `mode` is not specified, 'a' is used. If `encoding` is not `None`, it is used to open the file with that encoding. If `delay` is true, then file opening is deferred until the first call to `emit()`. By default, the file grows indefinitely.

`emit(record)`

Outputs the record to the file, but first checks to see if the file
has changed. If it has, the existing stream is flushed and closed and the file opened again, before outputting the record to the file.
16.9.5. BaseRotatingHandler

The `BaseRotatingHandler` class, located in the `logging.handlers` module, is the base class for the rotating file handlers, `RotatingFileHandler` and `TimedRotatingFileHandler`. You should not need to instantiate this class, but it has attributes and methods you may need to override.

```python
class logging.handlers.BaseRotatingHandler(filename, mode, encoding=None, delay=False)
```

The parameters are as for `FileHandler`. The attributes are:

**namer**

If this attribute is set to a callable, the `rotation_filename()` method delegates to this callable. The parameters passed to the callable are those passed to `rotation_filename()`.

**Note:** The namer function is called quite a few times during rollover, so it should be as simple and as fast as possible. It should also return the same output every time for a given input, otherwise the rollover behaviour may not work as expected.

`New in version 3.3.`

**rotator**

If this attribute is set to a callable, the `rotate()` method delegates to this callable. The parameters passed to the callable are those passed to `rotate()`.

`New in version 3.3.`
rotation_filename(default_name)
Modify the filename of a log file when rotating.

This is provided so that a custom filename can be provided.

The default implementation calls the ‘namer’ attribute of the handler, if it's callable, passing the default name to it. If the attribute isn't callable (the default is None), the name is returned unchanged.

| Parameters: | default_name – The default name for the log file. |

*New in version 3.3.*

rotate(source, dest)
When rotating, rotate the current log.

The default implementation calls the ‘rotator’ attribute of the handler, if it's callable, passing the source and dest arguments to it. If the attribute isn't callable (the default is None), the source is simply renamed to the destination.

| Parameters: | • source – The source filename. This is normally the base filename, e.g. ‘test.log’
• dest – The destination filename. This is normally what the source is rotated to, e.g. ‘test.log.1’ |

*New in version 3.3.*

The reason the attributes exist is to save you having to subclass - you can use the same callables for instances of RotatingFileHandler and TimedRotatingFileHandler. If either the namer or rotator
callable raises an exception, this will be handled in the same way as any other exception during an emit() call, i.e. via the handleError() method of the handler.

If you need to make more significant changes to rotation processing, you can override the methods.

For an example, see Using a rotator and namer to customise log rotation processing.
16.9.6. RotatingFileHandler

The RotatingFileHandler class, located in the logging.handlers module, supports rotation of disk log files.

class logging.handlers.RotatingFileHandler(filename, mode='a', maxBytes=0, backupCount=0, encoding=None, delay=0)

Returns a new instance of the RotatingFileHandler class. The specified file is opened and used as the stream for logging. If mode is not specified, 'a' is used. If encoding is not None, it is used to open the file with that encoding. If delay is true, then file opening is deferred until the first call to emit(). By default, the file grows indefinitely.

You can use the maxBytes and backupCount values to allow the file to rollover at a predetermined size. When the size is about to be exceeded, the file is closed and a new file is silently opened for output. Rollover occurs whenever the current log file is nearly maxBytes in length; if maxBytes is zero, rollover never occurs. If backupCount is non-zero, the system will save old log files by appending the extensions `.1`, `.2` etc., to the filename. For example, with a backupCount of 5 and a base file name of app.log, you would get app.log, app.log.1, app.log.2, up to app.log.5. The file being written to is always app.log. When this file is filled, it is closed and renamed to app.log.1, and if files app.log.1, app.log.2, etc. exist, then they are renamed to app.log.2, app.log.3 etc. respectively.

doRollover()

Does a rollover, as described above.
**emit**(*record*)

Outputs the record to the file, catering for rollover as described previously.
16.9.7. TimedRotatingFileHandler

The `TimedRotatingFileHandler` class, located in the `logging.handlers` module, supports rotation of disk log files at certain timed intervals.

class
logging.handlers.TimedRotatingFileHandler(filename, when='h', interval=1, backupCount=0, encoding=None, delay=False, utc=False)

Returns a new instance of the `TimedRotatingFileHandler` class. The specified file is opened and used as the stream for logging. On rotating it also sets the filename suffix. Rotating happens based on the product of `when` and `interval`.

You can use the `when` to specify the type of `interval`. The list of possible values is below. Note that they are not case sensitive.

<table>
<thead>
<tr>
<th>Value</th>
<th>Type of interval</th>
</tr>
</thead>
<tbody>
<tr>
<td>'S'</td>
<td>Seconds</td>
</tr>
<tr>
<td>'M'</td>
<td>Minutes</td>
</tr>
<tr>
<td>'H'</td>
<td>Hours</td>
</tr>
<tr>
<td>'D'</td>
<td>Days</td>
</tr>
<tr>
<td>'W0'-'W6'</td>
<td>Weekday</td>
</tr>
<tr>
<td></td>
<td>(0=Monday)</td>
</tr>
<tr>
<td>'midnight'</td>
<td>Roll over at midnight</td>
</tr>
</tbody>
</table>

When using weekday-based rotation, specify ‘W0’ for Monday, ‘W1’ for Tuesday, and so on up to ‘W6’ for Sunday. In this case, the value passed for `interval` isn’t used.
The system will save old log files by appending extensions to the filename. The extensions are date-and-time based, using the strftime format \%Y-\%m-\%d\_%H-\%M-\%S or a leading portion thereof, depending on the rollover interval.

When computing the next rollover time for the first time (when the handler is created), the last modification time of an existing log file, or else the current time, is used to compute when the next rotation will occur.

If the \texttt{utc} argument is true, times in UTC will be used; otherwise local time is used.

If \texttt{backupCount} is nonzero, at most \texttt{backupCount} files will be kept, and if more would be created when rollover occurs, the oldest one is deleted. The deletion logic uses the interval to determine which files to delete, so changing the interval may leave old files lying around.

If \texttt{delay} is true, then file opening is deferred until the first call to \texttt{emit()}.

\textbf{doRollover()}

Does a rollover, as described above.

\textbf{emit(record)}

Outputs the record to the file, catering for rollover as described above.
16.9.8. SocketHandler

The **SocketHandler** class, located in the `logging.handlers` module, sends logging output to a network socket. The base class uses a TCP socket.

```python
class logging.handlers.SocketHandler(host, port)
```

Returns a new instance of the `SocketHandler` class intended to communicate with a remote machine whose address is given by `host` and `port`.

**close()**
Closes the socket.

**emit()**
Pickles the record's attribute dictionary and writes it to the socket in binary format. If there is an error with the socket, silently drops the packet. If the connection was previously lost, re-establishes the connection. To unpickle the record at the receiving end into a LogRecord, use the `makeLogRecord()` function.

**handleError()**
Handles an error which has occurred during `emit()`. The most likely cause is a lost connection. Closes the socket so that we can retry on the next event.

**makeSocket()**
This is a factory method which allows subclasses to define the precise type of socket they want. The default implementation creates a TCP socket (`socket.SOCK_STREAM`).
**makePickle**(record)

Pickles the record's attribute dictionary in binary format with a length prefix, and returns it ready for transmission across the socket.

Note that pickles aren't completely secure. If you are concerned about security, you may want to override this method to implement a more secure mechanism. For example, you can sign pickles using HMAC and then verify them on the receiving end, or alternatively you can disable unpickling of global objects on the receiving end.

**send**(packet)

Send a pickled string *packet* to the socket. This function allows for partial sends which can happen when the network is busy.

**createSocket**()

Tries to create a socket; on failure, uses an exponential back-off algorithm. On intial failure, the handler will drop the message it was trying to send. When subsequent messages are handled by the same instance, it will not try connecting until some time has passed. The default parameters are such that the initial delay is one second, and if after that delay the connection still can't be made, the handler will double the delay each time up to a maximum of 30 seconds.

This behaviour is controlled by the following handler attributes:

- **retryStart** (initial delay, defaulting to 1.0 seconds).
- **retryFactor** (multiplier, defaulting to 2.0).
- **retryMax** (maximum delay, defaulting to 30.0 seconds).

This means that if the remote listener starts up *after* the handler
has been used, you could lose messages (since the handler won't even attempt a connection until the delay has elapsed, but just silently drop messages during the delay period).
16.9.9. DatagramHandler

The DatagramHandler class, located in the logging.handlers module, inherits from SocketHandler to support sending logging messages over UDP sockets.

class logging.handlers.DatagramHandler(host, port)

Returns a new instance of the DatagramHandler class intended to communicate with a remote machine whose address is given by host and port.

emit()

Pickles the record’s attribute dictionary and writes it to the socket in binary format. If there is an error with the socket, silently drops the packet. To unpickle the record at the receiving end into a LogRecord, use the makeLogRecord() function.

makeSocket()

The factory method of SocketHandler is here overridden to create a UDP socket (socket.SOCK_DGRAM).

send(s)

Send a pickled string to a socket.
16.9.10. SysLogHandler

The `SysLogHandler` class, located in the `logging.handlers` module, supports sending logging messages to a remote or local Unix syslog.

```python
class logging.handlers.SysLogHandler(address=('localhost', SYSLOG_UDP_PORT), facility=LOG_USER, socktype=socket.SOCK_DGRAM)
```

Returns a new instance of the `SysLogHandler` class intended to communicate with a remote Unix machine whose address is given by `address` in the form of a `(host, port)` tuple. If `address` is not specified, (`'localhost', 514`) is used. The address is used to open a socket. An alternative to providing a `(host, port)` tuple is providing an address as a string, for example `'/dev/log'`. In this case, a Unix domain socket is used to send the message to the syslog. If `facility` is not specified, LOG_USER is used. The type of socket opened depends on the `socktype` argument, which defaults to `socket.SOCK_DGRAM` and thus opens a UDP socket. To open a TCP socket (for use with the newer syslog daemons such as rsyslog), specify a value of `socket.SOCK_STREAM`.

Note that if your server is not listening on UDP port 514, `SysLogHandler` may appear not to work. In that case, check what address you should be using for a domain socket - it’s system dependent. For example, on Linux it’s usually `'/dev/log'` but on OS/X it’s `'/var/run/syslog'`. You’ll need to check your platform and use the appropriate address (you may need to do this check at runtime if your application needs to run on several platforms). On Windows, you pretty much have to use the UDP option.

Changed in version 3.2: socktype was added.

**close()**

Closes the socket to the remote host.

**emit(record)**

The record is formatted, and then sent to the syslog server. If exception information is present, it is *not* sent to the server.

*Changed in version 3.2.1:* (See: issue 12168.) In earlier versions, the message sent to the syslog daemons was always terminated with a NUL byte, because early versions of these daemons expected a NUL terminated message - even though it's not in the relevant specification (RF 5424). More recent versions of these daemons don’t expect the NUL byte but strip it off if it's there, and even more recent daemons (which adhere more closely to RFC 5424) pass the NUL byte on as part of the message.

To enable easier handling of syslog messages in the face of all these differing daemon behaviours, the appending of the NUL byte has been made configurable, through the use of a class-level attribute, append_nul. This defaults to True (preserving the existing behaviour) but can be set to False on a SysLogHandler instance in order for that instance to *not* append the NUL terminator.

*Changed in version 3.3:* (See: issue 12419.) In earlier versions, there was no facility for an “ident” or “tag” prefix to identify the source of the message. This can now be specified using a class-level attribute, defaulting to "" to preserve existing behaviour, but which can be overridden on a SysLogHandler
instance in order for that instance to prepend the ident to every message handled. Note that the provided ident must be text, not bytes, and is prepended to the message exactly as is.

**encodePriority**(facility, priority)
Encodes the facility and priority into an integer. You can pass in strings or integers - if strings are passed, internal mapping dictionaries are used to convert them to integers.

The symbolic LOG_ values are defined in `SysLogHandler` and mirror the values defined in the `sys/syslog.h` header file.

### Priorities

<td>LOG_LOCAL7</td>
</tr>
</tbody>
</table>

**mapPriority**(*levelname*)

Maps a logging level name to a syslog priority name. You may need to override this if you are using custom levels, or if the default algorithm is not suitable for your needs. The default algorithm maps `DEBUG`, `INFO`, `WARNING`, `ERROR` and `CRITICAL` to the equivalent syslog names, and all other level names to 'warning'.
16.9.11. NTEventLogHandler

The NTEventLogHandler class, located in the logging.handlers module, supports sending logging messages to a local Windows NT, Windows 2000 or Windows XP event log. Before you can use it, you need Mark Hammond’s Win32 extensions for Python installed.

class logging.handlers.NTEventLogHandler(appname, dllname=None, logtype='Application')

Returns a new instance of the NTEventLogHandler class. The appname is used to define the application name as it appears in the event log. An appropriate registry entry is created using this name. The dllname should give the fully qualified pathname of a .dll or .exe which contains message definitions to hold in the log (if not specified, 'win32service.pyd' is used - this is installed with the Win32 extensions and contains some basic placeholder message definitions. Note that use of these placeholders will make your event logs big, as the entire message source is held in the log. If you want slimmer logs, you have to pass in the name of your own .dll or .exe which contains the message definitions you want to use in the event log). The logtype is one of 'Application', 'System' or 'Security', and defaults to 'Application'.

close()

At this point, you can remove the application name from the registry as a source of event log entries. However, if you do this, you will not be able to see the events as you intended in the Event Log Viewer - it needs to be able to access the registry to get the .dll name. The current version does not do this.
emit(record)
Determines the message ID, event category and event type, and then logs the message in the NT event log.

getEventCategory(record)
Returns the event category for the record. Override this if you want to specify your own categories. This version returns 0.

getEventType(record)
Returns the event type for the record. Override this if you want to specify your own types. This version does a mapping using the handler’s typemap attribute, which is set up in __init__() to a dictionary which contains mappings for DEBUG, INFO, WARNING, ERROR and CRITICAL. If you are using your own levels, you will either need to override this method or place a suitable dictionary in the handler’s typemap attribute.

getMessageID(record)
Returns the message ID for the record. If you are using your own messages, you could do this by having the msg passed to the logger being an ID rather than a format string. Then, in here, you could use a dictionary lookup to get the message ID. This version returns 1, which is the base message ID in win32service.pyd.
16.9.12. SMTPHandler

The `SMTPHandler` class, located in the `logging.handlers` module, supports sending logging messages to an email address via SMTP.

class logging.handlers.SMTPHandler(mailhost, fromaddr, toaddrs, subject, credentials=None, secure=None, timeout=1.0)

Returns a new instance of the `SMTPHandler` class. The instance is initialized with the from and to addresses and subject line of the email. The `toaddrs` should be a list of strings. To specify a non-standard SMTP port, use the (host, port) tuple format for the `mailhost` argument. If you use a string, the standard SMTP port is used. If your SMTP server requires authentication, you can specify a (username, password) tuple for the `credentials` argument.

To specify the use of a secure protocol (TLS), pass in a tuple to the `secure` argument. This will only be used when authentication credentials are supplied. The tuple should be either an empty tuple, or a single-value tuple with the name of a keyfile, or a 2-value tuple with the names of the keyfile and certificate file. (This tuple is passed to the `smtplib.SMTP.starttls()` method.)

A timeout can be specified for communication with the SMTP server using the `timeout` argument.

*New in version 3.3:* The `timeout` argument was added.

`emit(record)`

Formats the record and sends it to the specified addressees.

`getSubject(record)`
If you want to specify a subject line which is record-dependent, override this method.
16.9.13. MemoryHandler

The MemoryHandler class, located in the logging.handlers module, supports buffering of logging records in memory, periodically flushing them to a target handler. Flushing occurs whenever the buffer is full, or when an event of a certain severity or greater is seen.

MemoryHandler is a subclass of the more general BufferingHandler, which is an abstract class. This buffers logging records in memory. Whenever each record is added to the buffer, a check is made by calling shouldFlush() to see if the buffer should be flushed. If it should, then flush() is expected to do the flushing.

```
class logging.handlers.BufferingHandler(capacity)
    Initializes the handler with a buffer of the specified capacity.

    emit(record)
        Appends the record to the buffer. If shouldFlush() returns true, calls flush() to process the buffer.

    flush()
        You can override this to implement custom flushing behavior. This version just zaps the buffer to empty.

    shouldFlush(record)
        Returns true if the buffer is up to capacity. This method can be overridden to implement custom flushing strategies.
```

```
class logging.handlers.MemoryHandler(capacity, flushLevel=ERROR, target=None)
    Returns a new instance of the MemoryHandler class. The
instance is initialized with a buffer size of capacity. If flushLevel is not specified, ERROR is used. If no target is specified, the target will need to be set using setTarget() before this handler does anything useful.

**close()**

Calls flush(), sets the target to None and clears the buffer.

**flush()**

For a MemoryHandler, flushing means just sending the buffered records to the target, if there is one. The buffer is also cleared when this happens. Override if you want different behavior.

**setTarget(target)**

Sets the target handler for this handler.

**shouldFlush(record)**

Checks for buffer full or a record at the flushLevel or higher.
16.9.14. HTTPHandler

The HTTPHandler class, located in the logging.handlers module, supports sending logging messages to a Web server, using either GET or POST semantics.

class logging.handlers.HTTPHandler(host, url, method='GET', secure=False, credentials=None)

Returns a new instance of the HTTPHandler class. The host can be of the form host:port, should you need to use a specific port number. If no method is specified, GET is used. If secure is True, an HTTPS connection will be used. If credentials is specified, it should be a 2-tuple consisting of userid and password, which will be placed in an HTTP ‘Authorization’ header using Basic authentication. If you specify credentials, you should also specify secure=True so that your userid and password are not passed in cleartext across the wire.

emit(record)

Sends the record to the Web server as a percent-encoded dictionary.
16.9.15. QueueHandler

New in version 3.2.

The `QueueHandler` class, located in the `logging.handlers` module, supports sending logging messages to a queue, such as those implemented in the `queue` or `multiprocessing` modules.

Along with the `QueueListener` class, `QueueHandler` can be used to let handlers do their work on a separate thread from the one which does the logging. This is important in Web applications and also other service applications where threads servicing clients need to respond as quickly as possible, while any potentially slow operations (such as sending an email via `SMTPHandler`) are done on a separate thread.

```python
class logging.handlers.QueueHandler(queue)
    Returns a new instance of the QueueHandler class. The instance is initialized with the queue to send messages to. The queue can be any queue-like object; it's used as-is by the `enqueue()` method, which needs to know how to send messages to it.

    `emit(record)`
    Enqueues the result of preparing the LogRecord.

    `prepare(record)`
    Prepares a record for queuing. The object returned by this method is enqueued.

    The base implementation formats the record to merge the message and arguments, and removes unpickleable items from the record in-place.
```
You might want to override this method if you want to convert the record to a dict or JSON string, or send a modified copy of the record while leaving the original intact.

**enqueue**(record)

Enqueues the record on the queue using `put_nowait()`; you may want to override this if you want to use blocking behaviour, or a timeout, or a customised queue implementation.
16.9.16. QueueListener

New in version 3.2.

The QueueListener class, located in the logging.handlers module, supports receiving logging messages from a queue, such as those implemented in the queue or multiprocessing modules. The messages are received from a queue in an internal thread and passed, on the same thread, to one or more handlers for processing. While QueueListener is not itself a handler, it is documented here because it works hand-in-hand with QueueHandler.

Along with the QueueHandler class, QueueListener can be used to let handlers do their work on a separate thread from the one which does the logging. This is important in Web applications and also other service applications where threads servicing clients need to respond as quickly as possible, while any potentially slow operations (such as sending an email via SMTPHandler) are done on a separate thread.

```python
class logging.handlers.QueueListener(queue, *handlers)
    Returns a new instance of the QueueListener class. The instance is initialized with the queue to send messages to and a list of handlers which will handle entries placed on the queue. The queue can be any queue-like object; it’s passed as-is to the dequeue() method, which needs to know how to get messages from it.

    dequeue(block)
        Dequeues a record and return it, optionally blocking.
```

The base implementation uses get(). You may want to
override this method if you want to use timeouts or work with custom queue implementations.

**prepare**(record)
Prepare a record for handling.

This implementation just returns the passed-in record. You may want to override this method if you need to do any custom marshalling or manipulation of the record before passing it to the handlers.

**handle**(record)
Handle a record.

This just loops through the handlers offering them the record to handle. The actual object passed to the handlers is that which is returned from **prepare()**.

**start()**
Starts the listener.

This starts up a background thread to monitor the queue for LogRecords to process.

**stop()**
Stops the listener.

This asks the thread to terminate, and then waits for it to do so. Note that if you don’t call this before your application exits, there may be some records still left on the queue, which won’t be processed.

**enqueue_sentinel()**
Writes a sentinel to the queue to tell the listener to quit. This implementation uses `put_nowait()`. You may want to override this method if you want to use timeouts or work with custom queue implementations.

*New in version 3.3.*

  Configuration API for the logging module.
16.10. getpass — Portable password input

The `getpass` module provides two functions:

`getpass.getpass(prompt='Password: ', stream=None)`

Prompt the user for a password without echoing. The user is prompted using the string `prompt`, which defaults to `'Password: '`. On Unix, the prompt is written to the file-like object `stream`. `stream` defaults to the controlling terminal (`/dev/tty`) or if that is unavailable to `sys.stderr` (this argument is ignored on Windows).

If echo free input is unavailable `getpass()` falls back to printing a warning message to `stream` and reading from `sys.stdin` and issuing a `GetPassWarning`.

Availability: Macintosh, Unix, Windows.

**Note:** If you call `getpass` from within IDLE, the input may be done in the terminal you launched IDLE from rather than the idle window itself.

**exception** `getpass.GetPassWarning`

A `UserWarning` subclass issued when password input may be echoed.

`getpass.getuser()`

Return the “login name” of the user. Availability: Unix, Windows.
This function checks the environment variables LOGNAME, USER, LNAME and USERNAME, in order, and returns the value of the first one which is set to a non-empty string. If none are set, the login name from the password database is returned on systems which support the `pwd` module, otherwise, an exception is raised.
16.11. **curses** — Terminal handling for character-cell displays

*Platforms:* Unix

The *curses* module provides an interface to the curses library, the de-facto standard for portable advanced terminal handling.

While curses is most widely used in the Unix environment, versions are available for DOS, OS/2, and possibly other systems as well. This extension module is designed to match the API of ncurses, an open-source curses library hosted on Linux and the BSD variants of Unix.

**Note:** Since version 5.4, the ncurses library decides how to interpret non-ASCII data using the `nl_langinfo` function. That means that you have to call `locale.setlocale()` in the application and encode Unicode strings using one of the system's available encodings. This example uses the system's default encoding:

```python
import locale
locale.setlocale(locale.LC_ALL, '')
code = locale.getpreferredencoding()
```

Then use *code* as the encoding for `str.encode()` calls.

**See also:**

**Module** [curses.ascii](#)  
Utilities for working with ASCII characters, regardless of your locale settings.
**Module curses.panel**

A panel stack extension that adds depth to curses windows.

**Module curses.textpad**

Editable text widget for curses supporting Emacs-like bindings.

**Curses Programming with Python**

Tutorial material on using curses with Python, by Andrew Kuchling and Eric Raymond.

The Tools/demo/ directory in the Python source distribution contains some example programs using the curses bindings provided by this module.
16.11.1. Functions

The module `curses` defines the following exception:

`exception curses.error`

Exception raised when a curses library function returns an error.

**Note:** Whenever `x` or `y` arguments to a function or a method are optional, they default to the current cursor location. Whenever `attr` is optional, it defaults to `A_NORMAL`.

The module `curses` defines the following functions:

`curses.baudrate()`

Return the output speed of the terminal in bits per second. On software terminal emulators it will have a fixed high value. Included for historical reasons; in former times, it was used to write output loops for time delays and occasionally to change interfaces depending on the line speed.

`curses.beep()`

Emit a short attention sound.

`curses.can_change_color()`

Return True or False, depending on whether the programmer can change the colors displayed by the terminal.

`curses.cbreak()`

Enter cbreak mode. In cbreak mode (sometimes called “rare” mode) normal tty line buffering is turned off and characters are available to be read one by one. However, unlike raw mode,
special characters (interrupt, quit, suspend, and flow control) retain their effects on the tty driver and calling program. Calling first `raw()` then `cbreak()` leaves the terminal in cbreak mode.

curses.color_content(color_number)
Return the intensity of the red, green, and blue (RGB) components in the color `color_number`, which must be between 0 and COLORS. A 3-tuple is returned, containing the R,G,B values for the given color, which will be between 0 (no component) and 1000 (maximum amount of component).

curses.color_pair(color_number)
Return the attribute value for displaying text in the specified color. This attribute value can be combined with A_STANDOUT, A_REVERSE, and the other A_* attributes. `pair_number()` is the counterpart to this function.

curses.curs_set(visibility)
Set the cursor state. `visibility` can be set to 0, 1, or 2, for invisible, normal, or very visible. If the terminal supports the visibility requested, the previous cursor state is returned; otherwise, an exception is raised. On many terminals, the “visible” mode is an underline cursor and the “very visible” mode is a block cursor.

curses.def_prog_mode()
Save the current terminal mode as the “program” mode, the mode when the running program is using curses. (Its counterpart is the “shell” mode, for when the program is not in curses.) Subsequent calls to `reset_prog_mode()` will restore this mode.

curses.def_shell_mode()
Save the current terminal mode as the “shell” mode, the mode
when the running program is not using curses. (Its counterpart is the “program” mode, when the program is using curses capabilities.) Subsequent calls to reset_shell_mode() will restore this mode.

**curses.delay_output**(*ms*)

Insert an *ms* millisecond pause in output.

**curses.doupdate()**

Update the physical screen. The curses library keeps two data structures, one representing the current physical screen contents and a virtual screen representing the desired next state. The doupdate() ground updates the physical screen to match the virtual screen.

The virtual screen may be updated by a noutrefresh() call after write operations such as addstr() have been performed on a window. The normal refresh() call is simply noutrefresh() followed by doupdate(); if you have to update multiple windows, you can speed performance and perhaps reduce screen flicker by issuing noutrefresh() calls on all windows, followed by a single doupdate().

**curses.echo()**

Enter echo mode. In echo mode, each character input is echoed to the screen as it is entered.

**curses.endwin()**

De-initialize the library, and return terminal to normal status.

**curses.erasechar()**

Return the user’s current erase character. Under Unix operating
systems this is a property of the controlling tty of the curses program, and is not set by the curses library itself.

curses.filter()
The filter() routine, if used, must be called before initscr() is called. The effect is that, during those calls, LINES is set to 1; the capabilities clear, cup, cud, cud1, cuu1, cuu, vpa are disabled; and the home string is set to the value of cr. The effect is that the cursor is confined to the current line, and so are screen updates. This may be used for enabling character-at-a-time line editing without touching the rest of the screen.

curses.flash()
Flash the screen. That is, change it to reverse-video and then change it back in a short interval. Some people prefer such as ‘visible bell’ to the audible attention signal produced by beep().

curses.flushinp()
Flush all input buffers. This throws away any typeahead that has been typed by the user and has not yet been processed by the program.

curses.getmouse()
After getch() returns KEY_MOUSE to signal a mouse event, this method should be call to retrieve the queued mouse event, represented as a 5-tuple (id, x, y, z, bstate). id is an ID value used to distinguish multiple devices, and x, y, z are the event's coordinates. (z is currently unused.) bstate is an integer value whose bits will be set to indicate the type of event, and will be the bitwise OR of one or more of the following constants, where n is the button number from 1 to 4: BUTTONn_PRESSED, BUTTONn_RELEASED, BUTTONn_CLICKED,
BUTTONn_DOUBLE_CLICKED, BUTTONn_TRIPLE_CLICKED,
BUTTON_SHIFT, BUTTON_CTRL, BUTTON_ALT.

curses.getsyx()
Return the current coordinates of the virtual screen cursor in y and x. If leaveok is currently true, then -1,-1 is returned.

curses.getwin(file)
Read window related data stored in the file by an earlier putwin() call. The routine then creates and initializes a new window using that data, returning the new window object.

curses.has_colors()
Return True if the terminal can display colors; otherwise, return False.

curses.has_ic()
Return True if the terminal has insert- and delete-character capabilities. This function is included for historical reasons only, as all modern software terminal emulators have such capabilities.

curses.has_il()
Return True if the terminal has insert- and delete-line capabilities, or can simulate them using scrolling regions. This function is included for historical reasons only, as all modern software terminal emulators have such capabilities.

curses.has_key(ch)
Take a key value ch, and return True if the current terminal type recognizes a key with that value.

curses.halfdelay(tenths)
Used for half-delay mode, which is similar to cbreak mode in that characters typed by the user are immediately available to the program. However, after blocking for \textit{tenths} tenths of seconds, an exception is raised if nothing has been typed. The value of \textit{tenths} must be a number between 1 and 255. Use \texttt{nocbreak()} to leave half-delay mode.

\texttt{curses.init\_color(color\_number, r, g, b)}

Change the definition of a color, taking the number of the color to be changed followed by three RGB values (for the amounts of red, green, and blue components). The value of \textit{color\_number} must be between 0 and COLORS. Each of \textit{r}, \textit{g}, \textit{b}, must be a value between 0 and 1000. When \texttt{init\_color()} is used, all occurrences of that color on the screen immediately change to the new definition. This function is a no-op on most terminals; it is active only if \texttt{can\_change\_color()} returns 1.

\texttt{curses.init\_pair(pair\_number, fg, bg)}

Change the definition of a color-pair. It takes three arguments: the number of the color-pair to be changed, the foreground color number, and the background color number. The value of \textit{pair\_number} must be between 1 and COLOR\_PAIRS - 1 (the 0 color pair is wired to white on black and cannot be changed). The value of \textit{fg} and \textit{bg} arguments must be between 0 and COLORS. If the color-pair was previously initialized, the screen is refreshed and all occurrences of that color-pair are changed to the new definition.

\texttt{curses.initscr()}  

Initialize the library. Return a \texttt{Window\_Object} which represents the whole screen.

\textbf{Note}: If there is an error opening the terminal, the underlying
curses library may cause the interpreter to exit.

curses. `is_term_resized`(nlines, ncols)
Return True if resize_term() would modify the window structure, False otherwise.

curses. `isendwin`()
Return True if endwin() has been called (that is, the curses library has been deinitialized).

curses. `keyname`(k)
Return the name of the key numbered k. The name of a key generating printable ASCII character is the key's character. The name of a control-key combination is a two-character string consisting of a caret followed by the corresponding printable ASCII character. The name of an alt-key combination (128-255) is a string consisting of the prefix ‘M-‘ followed by the name of the corresponding ASCII character.

curses. `killchar`()
Return the user's current line kill character. Under Unix operating systems this is a property of the controlling tty of the curses program, and is not set by the curses library itself.

curses. `longname`()
Return a string containing the terminfo long name field describing the current terminal. The maximum length of a verbose description is 128 characters. It is defined only after the call to `initscr()`.

curses. `meta`(yes)
If yes is 1, allow 8-bit characters to be input. If yes is 0, allow only 7-bit chars.
curses.

**mouseinterval(interval)**

Set the maximum time in milliseconds that can elapse between press and release events in order for them to be recognized as a click, and return the previous interval value. The default value is 200 msec, or one fifth of a second.

**mousemask(mousemask)**

Set the mouse events to be reported, and return a tuple (availmask, oldmask). *availmask* indicates which of the specified mouse events can be reported; on complete failure it returns 0. *oldmask* is the previous value of the given window's mouse event mask. If this function is never called, no mouse events are ever reported.

**napms(ms)**

Sleep for *ms* milliseconds.

**newpad(nlines, ncols)**

Create and return a pointer to a new pad data structure with the given number of lines and columns. A pad is returned as a window object.

A pad is like a window, except that it is not restricted by the screen size, and is not necessarily associated with a particular part of the screen. Pads can be used when a large window is needed, and only a part of the window will be on the screen at one time. Automatic refreshes of pads (such as from scrolling or echoing of input) do not occur. The `refresh()` and `noutrefresh()` methods of a pad require 6 arguments to specify the part of the pad to be displayed and the location on the screen to be used for the display. The arguments are `pminrow, pmincol, sminrow, smincol, smaxrow, smaxcol`; the `p` arguments refer to the upper left
corner of the pad region to be displayed and the s arguments define a clipping box on the screen within which the pad region is to be displayed.

curses.**newwin**(begin_y, begin_x)
curses.**newwin**(nlines, ncols, begin_y, begin_x)

Return a new window, whose left-upper corner is at (begin_y, begin_x), and whose height/width is nlines/ncols.

By default, the window will extend from the specified position to the lower right corner of the screen.

curses.**nl**()
Enter newline mode. This mode translates the return key into newline on input, and translates newline into return and line-feed on output. Newline mode is initially on.

curses.**nocbreak**()
Leave cbreak mode. Return to normal “cooked” mode with line buffering.

curses.**noecho**()
Leave echo mode. Echoing of input characters is turned off.

curses.**nonl**()
Leave newline mode. Disable translation of return into newline on input, and disable low-level translation of newline into newline/return on output (but this does not change the behavior of `addch('\n')`, which always does the equivalent of return and line feed on the virtual screen). With translation off, curses can sometimes speed up vertical motion a little; also, it will be able to detect the return key on input.
curses.\texttt{noqiflush()}

When the \texttt{noqiflush()} routine is used, normal flush of input and output queues associated with the INTR, QUIT and SUSP characters will not be done. You may want to call \texttt{noqiflush()} in a signal handler if you want output to continue as though the interrupt had not occurred, after the handler exits.

curses.\texttt{noraw()}

Leave raw mode. Return to normal “cooked” mode with line buffering.

curses.\texttt{pair\_content(pair\_number)}

Return a tuple \((\texttt{fg}, \texttt{bg})\) containing the colors for the requested color pair. The value of \texttt{pair\_number} must be between \texttt{1} and \texttt{COLOR\_PAIRS - 1}.

curses.\texttt{pair\_number(attr)}

Return the number of the color-pair set by the attribute value \texttt{attr}. \texttt{color\_pair()} is the counterpart to this function.

curses.\texttt{putp(string)}

Equivalent to \texttt{tputs(str, 1, putchar)}; emit the value of a specified terminfo capability for the current terminal. Note that the output of \texttt{putp()} always goes to standard output.

curses.\texttt{qiflush([flag])}

If \texttt{flag} is False, the effect is the same as calling \texttt{noqiflush()}. If \texttt{flag} is True, or no argument is provided, the queues will be flushed when these control characters are read.

curses.\texttt{raw()}
Enter raw mode. In raw mode, normal line buffering and processing of interrupt, quit, suspend, and flow control keys are turned off; characters are presented to curses input functions one by one.

curses.\texttt{reset\_prog\_mode()}  
restore the terminal to “program” mode, as previously saved by \texttt{def\_prog\_mode()}.  

curses.\texttt{reset\_shell\_mode()}  
Restore the terminal to “shell” mode, as previously saved by \texttt{def\_shell\_mode()}.  

curses.\texttt{resetty()}  
Restore the state of the terminal modes to what it was at the last call to \texttt{savetty()}.  

curses.\texttt{resize\_term(nlines, ncols)}  
backend function used by \texttt{resizeterm()}, performing most of the work; when resizing the windows, \texttt{resize\_term()} blank-fills the areas that are extended. The calling application should fill in these areas with appropriate data. The \texttt{resize\_term()} function attempts to resize all windows. However, due to the calling convention of pads, it is not possible to resize these without additional interaction with the application.  

curses.\texttt{resizeterm(nlines, ncols)}  
Resize the standard and current windows to the specified dimensions, and adjusts other bookkeeping data used by the curses library that record the window dimensions (in particular the SIGWINCH handler).  

curses.\texttt{savetty()}
Save the current state of the terminal modes in a buffer, usable by `resetty()`.

**curses.setsyx(y, x)**

Set the virtual screen cursor to `y`, `x`. If `y` and `x` are both -1, then `leaveok` is set.

**curses.setupterm([termstr, fd])**

Initialize the terminal. `termstr` is a string giving the terminal name; if omitted, the value of the TERM environment variable will be used. `fd` is the file descriptor to which any initialization sequences will be sent; if not supplied, the file descriptor for `sys.stdout` will be used.

**curses.start_color()**

Must be called if the programmer wants to use colors, and before any other color manipulation routine is called. It is good practice to call this routine right after `initscr()`.

`start_color()` initializes eight basic colors (black, red, green, yellow, blue, magenta, cyan, and white), and two global variables in the `curses` module, `COLORS` and `COLOR_PAIRS`, containing the maximum number of colors and color-pairs the terminal can support. It also restores the colors on the terminal to the values they had when the terminal was just turned on.

**curses.terminal()**

Return a logical OR of all video attributes supported by the terminal. This information is useful when a curses program needs complete control over the appearance of the screen.
Return the value of the environment variable TERM, truncated to 14 characters.

curses.tigetflag(capname)

Return the value of the Boolean capability corresponding to the terminfo capability name capname. The value -1 is returned if capname is not a Boolean capability, or 0 if it is canceled or absent from the terminal description.

curses.tigetnum(capname)

Return the value of the numeric capability corresponding to the terminfo capability name capname. The value -2 is returned if capname is not a numeric capability, or -1 if it is canceled or absent from the terminal description.

curses.tigetstr(capname)

Return the value of the string capability corresponding to the terminfo capability name capname. None is returned if capname is not a string capability, or is canceled or absent from the terminal description.

curses.tparm(str[, ...])

Instantiate the string str with the supplied parameters, where str should be a parameterized string obtained from the terminfo database. E.g. tparm(tigetstr("cup"), 5, 3) could result in b'\033[6;4H', the exact result depending on terminal type.

curses.typeahead(fd)

Specify that the file descriptor fd be used for typeahead checking. If fd is -1, then no typeahead checking is done.

The curses library does "line-breakout optimization" by looking for
typeahead periodically while updating the screen. If input is found, and it is coming from a tty, the current update is postponed until refresh or doupdate is called again, allowing faster response to commands typed in advance. This function allows specifying a different file descriptor for typeahead checking.

curses.*unctrl*(ch)
Return a string which is a printable representation of the character ch. Control characters are displayed as a caret followed by the character, for example as `^C`. Printing characters are left as they are.

curses.*ungetch*(ch)
PUSH ch so the next getch() will return it.

**Note:** Only one ch can be pushed before getch() is called.

**curses.*unget_wch*(ch)**
PUSH ch so the next get_wch() will return it.

**Note:** Only one ch can be pushed before get_wch() is called.

*New in version 3.3.*

curses.*ungetmouse*(id, x, y, z, bstate)
Push a KEY_MOUSE event onto the input queue, associating the given state data with it.

curses.*use_env*(flag)
If used, this function should be called before initscr() or newterm are called. When flag is False, the values of lines and columns specified in the terminfo database will be used, even if
environment variables LINES and COLUMNS (used by default) are set, or if curses is running in a window (in which case default behavior would be to use the window size if LINES and COLUMNS are not set).

curses.use_default_colors()

Allow use of default values for colors on terminals supporting this feature. Use this to support transparency in your application. The default color is assigned to the color number -1. After calling this function, init_pair(x, curses.COLOR_RED, -1) initializes, for instance, color pair x to a red foreground color on the default background.

curses.wrapper(func, ...)

Initialize curses and call another callable object, func, which should be the rest of your curses-using application. If the application raises an exception, this function will restore the terminal to a sane state before re-raising the exception and generating a traceback. The callable object func is then passed the main window ‘stdscr’ as its first argument, followed by any other arguments passed to wrapper(). Before calling func, wrapper() turns on cbreak mode, turns off echo, enables the terminal keypad, and initializes colors if the terminal has color support. On exit (whether normally or by exception) it restores cooked mode, turns on echo, and disables the terminal keypad.
16.11.2. Window Objects

Window objects, as returned by `initscr()` and `newwin()` above, have the following methods and attributes:

```python
window.addch(ch[, attr])
window.addch(y, x, ch[, attr])
```

**Note:** A character means a C character (an ASCII code), rather than a Python character (a string of length 1). (This note is true whenever the documentation mentions a character.) The built-in `ord()` is handy for conveying strings to codes.

Paint character `ch` at `(y, x)` with attributes `attr`, overwriting any character previously painter at that location. By default, the character position and attributes are the current settings for the window object.

```python
window.addnstr(str[, attr])
window.addnstr(y, x, str[, attr])
```

Paint at most `n` characters of the string `str` at `(y, x)` with attributes `attr`, overwriting anything previously on the display.

```python
window.addstr(str[, attr])
window.addstr(y, x, str[, attr])
```

Paint the string `str` at `(y, x)` with attributes `attr`, overwriting anything previously on the display.

```python
window.attroff(attr)
```

Remove attribute `attr` from the “background” set applied to all writes to the current window.
**window.ATTRON(attr)**
Add attribute *attr* from the “background” set applied to all writes to the current window.

**window.ATTRSET(attr)**
Set the “background” set of attributes to *attr*. This set is initially 0 (no attributes).

**window.BKGD(ch[, attr])**
Set the background property of the window to the character *ch*, with attributes *attr*. The change is then applied to every character position in that window:

- The attribute of every character in the window is changed to the new background attribute.
- Wherever the former background character appears, it is changed to the new background character.

**window.BKGDS SET(ch[, attr])**
Set the window's background. A window's background consists of a character and any combination of attributes. The attribute part of the background is combined (OR'ed) with all non-blank characters that are written into the window. Both the character and attribute parts of the background are combined with the blank characters. The background becomes a property of the character and moves with the character through any scrolling and insert/delete line/character operations.

**window.BORDER([ls[, rs[, ts[, bs[, tl[, tr[, bl[, br]]]]]]]])**
Draw a border around the edges of the window. Each parameter specifies the character to use for a specific part of the border; see the table below for more details. The characters can be specified
as integers or as one-character strings.

**Note:** A 0 value for any parameter will cause the default character to be used for that parameter. Keyword parameters can *not* be used. The defaults are listed in this table:

<table>
<thead>
<tr>
<th>Parameter</th>
<th>Description</th>
<th>Default value</th>
</tr>
</thead>
<tbody>
<tr>
<td><code>ls</code></td>
<td>Left side</td>
<td>ACS_VLINE</td>
</tr>
<tr>
<td><code>rs</code></td>
<td>Right side</td>
<td>ACS_VLINE</td>
</tr>
<tr>
<td><code>ts</code></td>
<td>Top</td>
<td>ACS_HLINE</td>
</tr>
<tr>
<td><code>bs</code></td>
<td>Bottom</td>
<td>ACS_HLINE</td>
</tr>
<tr>
<td><code>tl</code></td>
<td>Upper-left corner</td>
<td>ACS_ULCORNER</td>
</tr>
<tr>
<td><code>tr</code></td>
<td>Upper-right corner</td>
<td>ACS_URCORNER</td>
</tr>
<tr>
<td><code>bl</code></td>
<td>Bottom-left corner</td>
<td>ACS_LLCORNER</td>
</tr>
<tr>
<td><code>br</code></td>
<td>Bottom-right corner</td>
<td>ACS_LRCORNER</td>
</tr>
</tbody>
</table>

`window.box([[vertch, horch]])`

Similar to `border()`, but both `ls` and `rs` are `vertch` and both `ts` and `bs` are `horch`. The default corner characters are always used by this function.

`window.chgat(attr)`
`window.chgat(num, attr)`
`window.chgat(y, x, attr)`
`window.chgat(y, x, num, attr)`

Set the attributes of `num` characters at the current cursor position, or at position `(y, x)` if supplied. If no value of `num` is given or `num = -1`, the attribute will be set on all the characters to the end of the line. This function does not move the cursor. The changed line
will be touched using the `touchline()` method so that the contents will be redisplayed by the next window refresh.

```cpp
window.clear()
```
Like `erase()`, but also cause the whole window to be repainted upon next call to `refresh()`.

```cpp
window.clearok(yes)
```
If `yes` is 1, the next call to `refresh()` will clear the window completely.

```cpp
window.clrtobot()
```
Erase from cursor to the end of the window: all lines below the cursor are deleted, and then the equivalent of `clrtoeol()` is performed.

```cpp
window.clrtoeol()
```
Erase from cursor to the end of the line.

```cpp
window.cursyncup()
```
Update the current cursor position of all the ancestors of the window to reflect the current cursor position of the window.

```cpp
window.delch([y, x])
```
Delete any character at \((y, x)\).

```cpp
window.deleteln()
```
Delete the line under the cursor. All following lines are moved up by one line.

```cpp
window.derwin(begin_y, begin_x)
window.derwin(nlines, ncols, begin_y, begin_x)
```
An abbreviation for “derive window”, \texttt{derwin()} is the same as calling \texttt{subwin()}, except that \texttt{begin\_y} and \texttt{begin\_x} are relative to the origin of the window, rather than relative to the entire screen. Return a window object for the derived window.

\texttt{window.echochar(\texttt{ch}[, \texttt{attr}])}
Add character \texttt{ch} with attribute \texttt{attr}, and immediately call \texttt{refresh()} on the window.

\texttt{window.enclose(\texttt{y}, \texttt{x})}
Test whether the given pair of screen-relative character-cell coordinates are enclosed by the given window, returning True or False. It is useful for determining what subset of the screen windows enclose the location of a mouse event.

\texttt{window.encoding}
Encoding used to encode method arguments (Unicode strings and characters). The encoding attribute is inherited from the parent window when a subwindow is created, for example with \texttt{window.subwin()}. By default, the locale encoding is used (see \texttt{locale.getpreferredencoding()}).

\textit{New in version 3.3.}

\texttt{window.erase()}
Clear the window.

\texttt{window.getbegyx()}
Return a tuple \texttt{(y, x)} of co-ordinates of upper-left corner.

\texttt{window.getbkgd()}
Return the given window's current background character/attribute
window.\texttt{getch([y, x])}

Get a character. Note that the integer returned does \textit{not} have to be in ASCII range: function keys, keypad keys and so on return numbers higher than 256. In no-delay mode, \texttt{-1} is returned if there is no input, else \texttt{getch()} waits until a key is pressed.

\texttt{New in version 3.3.}

window.\texttt{get_wch([y, x])}

Get a wide character. Return a character for most keys, or an integer for function keys, keypad keys, and other special keys.

\texttt{New in version 3.3.}

window.\texttt{getkey([y, x])}

Get a character, returning a string instead of an integer, as \texttt{getch()} does. Function keys, keypad keys and other special keys return a multibyte string containing the key name. In no-delay mode, an exception is raised if there is no input.

window.\texttt{getmaxyx()}

Return a tuple \((y, x)\) of the height and width of the window.

window.\texttt{getparyx()}

Return the beginning coordinates of this window relative to its parent window into two integer variables \(y\) and \(x\). Return \(-1, -1\) if this window has no parent.

window.\texttt{getstr([y, x])}

Read a string from the user, with primitive line editing capacity.

window.\texttt{getyx()}

pair.
Return a tuple \((y, x)\) of current cursor position relative to the window's upper-left corner.

```
window. hline(ch, n)
```

```
window. hline(y, x, ch, n)
```

Display a horizontal line starting at \((y, x)\) with length \(n\) consisting of the character \(ch\).

```
window. idcok(flag)
```

If \(flag\) is False, curses no longer considers using the hardware insert/delete character feature of the terminal; if \(flag\) is True, use of character insertion and deletion is enabled. When curses is first initialized, use of character insert/delete is enabled by default.

```
window. idlok(yes)
```

If called with \(yes\) equal to 1, curses will try and use hardware line editing facilities. Otherwise, line insertion/deletion are disabled.

```
window. immedok(flag)
```

If \(flag\) is True, any change in the window image automatically causes the window to be refreshed; you no longer have to call \(refresh()\) yourself. However, it may degrade performance considerably, due to repeated calls to \(wrefresh\). This option is disabled by default.

```
window. inch([y, x])
```

Return the character at the given position in the window. The bottom 8 bits are the character proper, and upper bits are the attributes.

```
window. insch(ch[, attr])
```

```
window. insch(y, x, ch[, attr])
```
Paint character \( ch \) at \((y, x)\) with attributes \( attr \), moving the line from position \( x \) right by one character.

**window.insdelln(nlines)**

Insert \( nlines \) lines into the specified window above the current line. The \( nlines \) bottom lines are lost. For negative \( nlines \), delete \( nlines \) lines starting with the one under the cursor, and move the remaining lines up. The bottom \( nlines \) lines are cleared. The current cursor position remains the same.

**window.insertln()**

Insert a blank line under the cursor. All following lines are moved down by one line.

**window.insnstr(str, n[, attr])**  
**window.insnstr(y, x, str, n[, attr])**

Insert a character string (as many characters as will fit on the line) before the character under the cursor, up to \( n \) characters. If \( n \) is zero or negative, the entire string is inserted. All characters to the right of the cursor are shifted right, with the rightmost characters on the line being lost. The cursor position does not change (after moving to \( y, x \), if specified).

**window.insstr(str[, attr])**  
**window.insstr(y, x, str[, attr])**

Insert a character string (as many characters as will fit on the line) before the character under the cursor. All characters to the right of the cursor are shifted right, with the rightmost characters on the line being lost. The cursor position does not change (after moving to \( y, x \), if specified).
window\.instr\([n]\)

window\.instr\((y, x[, n])\)

Return a string of characters, extracted from the window starting at the current cursor position, or at \(y, x\) if specified. Attributes are stripped from the characters. If \(n\) is specified, `instr()` returns a string at most \(n\) characters long (exclusive of the trailing NUL).

window\.is_linetouched\(line\)

Return True if the specified line was modified since the last call to `refresh()`; otherwise return False. Raise a `curses.error` exception if \(line\) is not valid for the given window.

window\.is_wintouched()

Return True if the specified window was modified since the last call to `refresh()`; otherwise return False.

window\.keypad\(yes\)

If \(yes\) is 1, escape sequences generated by some keys (keypad, function keys) will be interpreted by `curses`. If \(yes\) is 0, escape sequences will be left as is in the input stream.

window\.leaveok\(yes\)

If \(yes\) is 1, cursor is left where it is on update, instead of being at “cursor position.” This reduces cursor movement where possible. If possible the cursor will be made invisible.

If \(yes\) is 0, cursor will always be at “cursor position” after an update.

window\.move\(new\_y, new\_x\)

Move cursor to \((new\_y, new\_x)\).

window\.mvderwin\((y, x)\)
Move the window inside its parent window. The screen-relative parameters of the window are not changed. This routine is used to display different parts of the parent window at the same physical position on the screen.

\texttt{window.mvwin(new\_y, new\_x)}

Move the window so its upper-left corner is at \((new\_y, new\_x)\).

\texttt{window.nodelay(yes)}

If \textit{yes} is \texttt{1}, \texttt{getch()} will be non-blocking.

\texttt{window.notimeout(yes)}

If \textit{yes} is \texttt{1}, escape sequences will not be timed out.

\texttt{window.noutrefresh()}

Mark for refresh but wait. This function updates the data structure representing the desired state of the window, but does not force an update of the physical screen. To accomplish that, call \texttt{doupdate()}.

\texttt{window.overlay(destwin[, sminrow, smincol, dminrow, dmincol, dmaxrow, dmaxcol])}

Overlay the window on top of \textit{destwin}. The windows need not be the same size, only the overlapping region is copied. This copy is non-destructive, which means that the current background character does not overwrite the old contents of \textit{destwin}.

To get fine-grained control over the copied region, the second form of \texttt{overlay()} can be used. \texttt{sminrow} and \texttt{smincol} are the upper-
left coordinates of the source window, and the other variables mark a rectangle in the destination window.

```c
window.overwrite(destwin[, sminrow, smincol, dminrow, dmincol, dmaxrow, dmaxcol])
```

Overwrite the window on top of `destwin`. The windows need not be the same size, in which case only the overlapping region is copied. This copy is destructive, which means that the current background character overwrites the old contents of `destwin`.

To get fine-grained control over the copied region, the second form of `overwrite()` can be used. `sminrow` and `smincol` are the upper-left coordinates of the source window, the other variables mark a rectangle in the destination window.

```c
window.putwin(file)
```

Write all data associated with the window into the provided file object. This information can be later retrieved using the `getwin()` function.

```c
window.redrawln(beg, num)
```

Indicate that the `num` screen lines, starting at line `beg`, are corrupted and should be completely redrawn on the next `refresh()` call.

```c
window.redrawwin()
```

Touch the entire window, causing it to be completely redrawn on the next `refresh()` call.

```c
window.refresh([pminrow, pmincol, sminrow, smincol, smaxrow, smaxcol])
```

Update the display immediately (sync actual screen with previous
The 6 optional arguments can only be specified when the window is a pad created with `newpad()`. The additional parameters are needed to indicate what part of the pad and screen are involved. `pminrow` and `pmincol` specify the upper left-hand corner of the rectangle to be displayed in the pad. `sminrow`, `smincol`, `smaxrow`, and `smaxcol` specify the edges of the rectangle to be displayed on the screen. The lower right-hand corner of the rectangle to be displayed in the pad is calculated from the screen coordinates, since the rectangles must be the same size. Both rectangles must be entirely contained within their respective structures. Negative values of `pminrow`, `pmincol`, `sminrow`, or `smincol` are treated as if they were zero.

**window. resize(nlines, ncols)**

Reallocate storage for a curses window to adjust its dimensions to the specified values. If either dimension is larger than the current values, the window's data is filled with blanks that have the current background rendition (as set by `bkgdset()`) merged into them.

**window. scroll([lines=1])**

Scroll the screen or scrolling region upward by `lines` lines.

**window. scrollok(flag)**

Control what happens when the cursor of a window is moved off the edge of the window or scrolling region, either as a result of a newline action on the bottom line, or typing the last character of the last line. If `flag` is false, the cursor is left on the bottom line. If `flag` is true, the window is scrolled up one line. Note that in order to get the physical scrolling effect on the terminal, it is also necessary to call `idlok()`.
window.setscrreg(top, bottom)
Set the scrolling region from line top to line bottom. All scrolling actions will take place in this region.

window.standend()
Turn off the standout attribute. On some terminals this has the side effect of turning off all attributes.

window.standout()
Turn on attribute A_STANDOUT.

window.subpad(begin_y, begin_x)
window.subpad(nlines, ncols, begin_y, begin_x)
Return a sub-window, whose upper-left corner is at (begin_y, begin_x), and whose width/height is ncols/nlines.

window.subwin(begin_y, begin_x)
window.subwin(nlines, ncols, begin_y, begin_x)
Return a sub-window, whose upper-left corner is at (begin_y, begin_x), and whose width/height is ncols/nlines.

By default, the sub-window will extend from the specified position to the lower right corner of the window.

window.syncdown()
Touch each location in the window that has been touched in any of its ancestor windows. This routine is called by refresh(), so it should almost never be necessary to call it manually.

window.syncok(flag)
If called with flag set to True, then syncup() is called automatically whenever there is a change in the window.
window. **syncup()**
Touch all locations in ancestors of the window that have been changed in the window.

window. **timeout**(delay)
Set blocking or non-blocking read behavior for the window. If *delay* is negative, blocking read is used (which will wait indefinitely for input). If *delay* is zero, then non-blocking read is used, and -1 will be returned by **getch()** if no input is waiting. If *delay* is positive, then **getch()** will block for *delay* milliseconds, and return -1 if there is still no input at the end of that time.

window. **touchline**(start, count[, changed])
Pretend *count* lines have been changed, starting with line *start*. If *changed* is supplied, it specifies whether the affected lines are marked as having been changed (*changed*=1) or unchanged (*changed*=0).

window. **touchwin()**
Pretend the whole window has been changed, for purposes of drawing optimizations.

window. **untouchwin()**
Mark all lines in the window as unchanged since the last call to **refresh()**.

window. **vline**(ch, n)
window. **vline**(y, x, ch, n)
Display a vertical line starting at \((y, x)\) with length *n* consisting of the character *ch*. 
16.11.3. Constants

The `curses` module defines the following data members:

**curses.ERR**
Some curses routines that return an integer, such as `getch()`, return `ERR` upon failure.

**curses.OK**
Some curses routines that return an integer, such as `napms()`, return `OK` upon success.

**curses.version**
A string representing the current version of the module. Also available as `__version__`.

Several constants are available to specify character cell attributes:

<table>
<thead>
<tr>
<th>Attribute</th>
<th>Meaning</th>
</tr>
</thead>
<tbody>
<tr>
<td>A_ALTCHARSET</td>
<td>Alternate character set mode.</td>
</tr>
<tr>
<td>A_BLINK</td>
<td>Blink mode.</td>
</tr>
<tr>
<td>A_BOLD</td>
<td>Bold mode.</td>
</tr>
<tr>
<td>A_DIM</td>
<td>Dim mode.</td>
</tr>
<tr>
<td>A_NORMAL</td>
<td>Normal attribute.</td>
</tr>
<tr>
<td>A_REVERSE</td>
<td>Reverse background and foreground colors.</td>
</tr>
<tr>
<td>A_STANDOUT</td>
<td>Standout mode.</td>
</tr>
<tr>
<td>A_UNDERLINE</td>
<td>Underline mode.</td>
</tr>
</tbody>
</table>
Keys are referred to by integer constants with names starting with `KEY_`. The exact keycaps available are system dependent.

<table>
<thead>
<tr>

</tr>
</tbody>
</table>

On VT100s and their software emulations, such as X terminal emulators, there are normally at least four function keys (KEY_F1,
KEY_F2, KEY_F3, KEY_F4) available, and the arrow keys mapped to KEY_UP, KEY_DOWN, KEY_LEFT and KEY_RIGHT in the obvious way. If your machine has a PC keyboard, it is safe to expect arrow keys and twelve function keys (older PC keyboards may have only ten function keys); also, the following keypad mappings are standard:

<table>
<thead>
<tr>
<th>Keycap</th>
<th>Constant</th>
</tr>
</thead>
<tbody>
<tr>
<td>Insert</td>
<td>KEY_IC</td>
</tr>
<tr>
<td>Delete</td>
<td>KEY_DC</td>
</tr>
<tr>
<td>Home</td>
<td>KEY_HOME</td>
</tr>
<tr>
<td>End</td>
<td>KEY_END</td>
</tr>
<tr>
<td>Page Up</td>
<td>KEY_NPAGE</td>
</tr>
<tr>
<td>Page Down</td>
<td>KEY_PPAGE</td>
</tr>
</tbody>
</table>

The following table lists characters from the alternate character set. These are inherited from the VT100 terminal, and will generally be available on software emulations such as X terminals. When there is no graphic available, curses falls back on a crude printable ASCII approximation.

**Note:** These are available only after `initscr()` has been called.

<table>

</table>
16.12. **curses.textpad** — Text input widget for curses programs

The **curses.textpad** module provides a **Textbox** class that handles elementary text editing in a curses window, supporting a set of keybindings resembling those of Emacs (thus, also of Netscape Navigator, BBedit 6.x, FrameMaker, and many other programs). The module also provides a rectangle-drawing function useful for framing text boxes or for other purposes.

The module **curses.textpad** defines the following function:

**curses.textpad.rectangle**(win, uly, ulx, lry, lrx)

Draw a rectangle. The first argument must be a window object; the remaining arguments are coordinates relative to that window. The second and third arguments are the \( y \) and \( x \) coordinates of the upper left hand corner of the rectangle to be drawn; the fourth and fifth arguments are the \( y \) and \( x \) coordinates of the lower right hand corner. The rectangle will be drawn using VT100/IBM PC forms characters on terminals that make this possible (including xterm and most other software terminal emulators). Otherwise it will be drawn with ASCII dashes, vertical bars, and plus signs.
16.12.1. Textbox objects

You can instantiate a `Textbox` object as follows:

```python
class curses.textpad.Textbox(win)
```

Return a textbox widget object. The `win` argument should be a `curses` `WindowObject` in which the textbox is to be contained. The edit cursor of the textbox is initially located at the upper left hand corner of the containing window, with coordinates `(0, 0)`. The instance's `stripspaces` flag is initially on.

`Textbox` objects have the following methods:

**edit([validator])**

This is the entry point you will normally use. It accepts editing keystrokes until one of the termination keystrokes is entered. If `validator` is supplied, it must be a function. It will be called for each keystroke entered with the keystroke as a parameter; command dispatch is done on the result. This method returns the window contents as a string; whether blanks in the window are included is affected by the `stripspaces` attribute.

**do_command(ch)**

Process a single command keystroke. Here are the supported special keystrokes:

<table>
<thead>
<tr>
<th>Keystroke</th>
<th>Action</th>
</tr>
</thead>
<tbody>
<tr>
<td>Control-A</td>
<td>Go to left edge of window.</td>
</tr>
<tr>
<td>Control-B</td>
<td>Cursor left, wrapping to previous line if appropriate.</td>
</tr>
</tbody>
</table>
**Control-D**  Delete character under cursor.

**Control-E**  Go to right edge (stripspaces off) or end of line (stripspaces on).

**Control-F**  Cursor right, wrapping to next line when appropriate.

**Control-G**  Terminate, returning the window contents.

**Control-H**  Delete character backward.

**Control-J**  Terminate if the window is 1 line, otherwise insert newline.

**Control-K**  If line is blank, delete it, otherwise clear to end of line.

**Control-L**  Refresh screen.

**Control-N**  Cursor down; move down one line.

**Control-O**  Insert a blank line at cursor location.

**Control-P**  Cursor up; move up one line.

Move operations do nothing if the cursor is at an edge where the movement is not possible. The following synonyms are supported where possible:

<table>
<thead>
<tr>
<th>Constant</th>
<th>Keystore</th>
</tr>
</thead>
<tbody>
<tr>

<td>KEY_UP</td>
<td>Control-P</td>
</tr>
<tr>
<td>KEY_DOWN</td>
<td>Control-N</td>
</tr>
<tr>
<td>KEY_BACKSPACE</td>
<td>Control-h</td>
</tr>
</tbody>
</table>

All other keystrokes are treated as a command to insert the given character and move right (with line wrapping).
**gather()**

Return the window contents as a string; whether blanks in the window are included is affected by the `stripspaces` member.

**stripspaces**

This attribute is a flag which controls the interpretation of blanks in the window. When it is on, trailing blanks on each line are ignored; any cursor motion that would land the cursor on a trailing blank goes to the end of that line instead, and trailing blanks are stripped when the window contents are gathered.
The `curses.ascii` module supplies name constants for ASCII characters and functions to test membership in various ASCII character classes. The constants supplied are names for control characters as follows:

<table>

</tbody>
</table>

Note that many of these have little practical significance in modern usage. The mnemonics derive from teleprinter conventions that predate digital computers.

The module supplies the following functions, patterned on those in the
standard C library:

```c
#include <curses.h>
```

- **curses.ascii.isalnum(c)**
  Checks for an ASCII alphanumeric character; it is equivalent to `isalpha(c)` or `isdigit(c)`.

- **curses.ascii.isalpha(c)**
  Checks for an ASCII alphabetic character; it is equivalent to `isupper(c)` or `islower(c)`.

- **curses.ascii.isascii(c)**
  Checks for a character value that fits in the 7-bit ASCII set.

- **curses.ascii.isblank(c)**
  Checks for an ASCII whitespace character.

- **curses.ascii.iscntrl(c)**
  Checks for an ASCII control character (in the range 0x00 to 0x1f).

- **curses.ascii.isdigit(c)**
  Checks for an ASCII decimal digit, '0' through '9'. This is equivalent to `c in string.digits`.

- **curses.ascii.isgraph(c)**
  Checks for ASCII any printable character except space.

- **curses.ascii.islower(c)**
  Checks for an ASCII lower-case character.

- **curses.ascii.isprint(c)**
  Checks for any ASCII printable character including space.

- **curses.ascii.ispunct(c)**
Checks for any printable ASCII character which is not a space or an alphanumeric character.

curses.ascii\texttt{.isspace}(c)
Checks for ASCII white-space characters; space, line feed, carriage return, form feed, horizontal tab, vertical tab.

curses.ascii\texttt{.isupper}(c)
Checks for an ASCII uppercase letter.

curses.ascii\texttt{.isxdigit}(c)
Checks for an ASCII hexadecimal digit. This is equivalent to \texttt{c in string.hexdigits}.

curses.ascii\texttt{.isctrl}(c)
Checks for an ASCII control character (ordinal values 0 to 31).

curses.ascii\texttt{.ismeta}(c)
Checks for a non-ASCII character (ordinal values 0x80 and above).

These functions accept either integers or strings; when the argument is a string, it is first converted using the built-in function \texttt{ord(\text{\par

Note that all these functions check ordinal bit values derived from the first character of the string you pass in; they do not actually know anything about the host machine's character encoding. For functions that know about the character encoding (and handle internationalization properly) see the \texttt{string} module.

The following two functions take either a single-character string or integer byte value; they return a value of the same type.

curses.ascii\texttt{.ascii}(c)\par
Return the ASCII value corresponding to the low 7 bits of c.

curses.ascii.ctrl(c)

Return the control character corresponding to the given character (the character bit value is bitwise-anded with 0x1f).

curses.ascii.alt(c)

Return the 8-bit character corresponding to the given ASCII character (the character bit value is bitwise-ored with 0x80).

The following function takes either a single-character string or integer value; it returns a string.

curses.ascii.unctrl(c)

Return a string representation of the ASCII character c. If c is printable, this string is the character itself. If the character is a control character (0x00-0x1f) the string consists of a caret ('^') followed by the corresponding uppercase letter. If the character is an ASCII delete (0x7f) the string is '^?'. If the character has its meta bit (0x80) set, the meta bit is stripped, the preceding rules applied, and '!' prepended to the result.

curses.ascii.controlnames

A 33-element string array that contains the ASCII mnemonics for the thirty-two ASCII control characters from 0 (NUL) to 0x1f (US), in order, plus the mnemonic SP for the space character.
16.14. `curses.panel` — A panel stack extension for curses

Panels are windows with the added feature of depth, so they can be stacked on top of each other, and only the visible portions of each window will be displayed. Panels can be added, moved up or down in the stack, and removed.
16.14.1. Functions

The module `curses.panel` defines the following functions:

- **curses.panel.bottom_panel()**
  
  Returns the bottom panel in the panel stack.

- **curses.panel.new_panel(win)**
  
  Returns a panel object, associating it with the given window `win`. Be aware that you need to keep the returned panel object referenced explicitly. If you don't, the panel object is garbage collected and removed from the panel stack.

- **curses.panel.top_panel()**
  
  Returns the top panel in the panel stack.

- **curses.panel.update_panels()**
  
  Updates the virtual screen after changes in the panel stack. This does not call `curses.doupdate()`, so you'll have to do this yourself.
16.14.2. Panel Objects

Panel objects, as returned by `new_panel()` above, are windows with a stacking order. There’s always a window associated with a panel which determines the content, while the panel methods are responsible for the window’s depth in the panel stack.

Panel objects have the following methods:

Panel. **above()**
   Returns the panel above the current panel.

Panel. **below()**
   Returns the panel below the current panel.

Panel. **bottom()**
   Push the panel to the bottom of the stack.

Panel. **hidden()**
   Returns true if the panel is hidden (not visible), false otherwise.

Panel. **hide()**
   Hide the panel. This does not delete the object, it just makes the window on screen invisible.

Panel. **move(y, x)**
   Move the panel to the screen coordinates \((y, x)\).

Panel. **replace(win)**
   Change the window associated with the panel to the window \(win\).

Panel. **set_userptr(obj)**
Set the panel's user pointer to \texttt{obj}. This is used to associate an arbitrary piece of data with the panel, and can be any Python object.

\texttt{Panel.show()}

Display the panel (which might have been hidden).

\texttt{Panel.top()}

Push panel to the top of the stack.

\texttt{Panel.userptr()}

Returns the user pointer for the panel. This might be any Python object.

\texttt{Panel.window()}

Returns the window object associated with the panel.
16.15. `platform` — Access to underlying platform’s identifying data

**Source code:** `Lib/platform.py`

**Note:** Specific platforms listed alphabetically, with Linux included in the Unix section.
16.15.1. Cross Platform

```
platform.architecture(executable=sys.executable, bits='', linkage='')
```

Queries the given executable (defaults to the Python interpreter binary) for various architecture information.

Returns a tuple (bits, linkage) which contain information about the bit architecture and the linkage format used for the executable. Both values are returned as strings.

Values that cannot be determined are returned as given by the parameter presets. If bits is given as '', the `sizeof(pointer)` (or `sizeof(long)` on Python version < 1.5.2) is used as indicator for the supported pointer size.

The function relies on the system's `file` command to do the actual work. This is available on most if not all Unix platforms and some non-Unix platforms and then only if the executable points to the Python interpreter. Reasonable defaults are used when the above needs are not met.

**Note:** On Mac OS X (and perhaps other platforms), executable files may be universal files containing multiple architectures. To get at the “64-bitness” of the current interpreter, it is more reliable to query the `sys.maxsize` attribute:

```
is_64bits = sys.maxsize > 2**32
```

```
platform.machine()
```

Returns the machine type, e.g. 'i386'. An empty string is
returned if the value cannot be determined.

**platform.node()**

Returns the computer’s network name (may not be fully qualified!). An empty string is returned if the value cannot be determined.

**platform.platform(aliased=0, terse=0)**

Returns a single string identifying the underlying platform with as much useful information as possible.

The output is intended to be *human readable* rather than machine parseable. It may look different on different platforms and this is intended.

If *aliased* is true, the function will use aliases for various platforms that report system names which differ from their common names, for example SunOS will be reported as Solaris. The *system_alias()* function is used to implement this.

Setting *terse* to true causes the function to return only the absolute minimum information needed to identify the platform.

**platform.processor()**

Returns the (real) processor name, e.g. *'amdk6'*.

An empty string is returned if the value cannot be determined. Note that many platforms do not provide this information or simply return the same value as for *machine()*. NetBSD does this.

**platform.python_build()**

Returns a tuple *(buildno, builddate)* stating the Python build number and date as strings.
platform. `python_compiler()`
Returns a string identifying the compiler used for compiling Python.

platform. `python_branch()`
Returns a string identifying the Python implementation SCM branch.

platform. `python_implementation()`

platform. `python_revision()`
Returns a string identifying the Python implementation SCM revision.

platform. `python_version()`
Returns the Python version as string 'major.minor.patchlevel'

Note that unlike the Python `sys.version`, the returned value will always include the patchlevel (it defaults to 0).

platform. `python_version_tuple()`
Returns the Python version as tuple (major, minor, patchlevel) of strings.

Note that unlike the Python `sys.version`, the returned value will always include the patchlevel (it defaults to '0').

platform. `release()`
Returns the system’s release, e.g. '2.2.0' or 'NT' An empty string is returned if the value cannot be determined.
platform.\texttt{system}()

Returns the system/OS name, e.g. 'Linux', 'Windows', or 'Java'. An empty string is returned if the value cannot be determined.

platform.\texttt{system\_alias}(system, release, version)

Returns (system, release, version) aliased to common marketing names used for some systems. It also does some reordering of the information in some cases where it would otherwise cause confusion.

platform.\texttt{version}()

Returns the system's release version, e.g. '#3 on degas'. An empty string is returned if the value cannot be determined.

platform.\texttt{uname}()

Fairly portable uname interface. Returns a \texttt{namedtuple()} containing six attributes: system, node, release, version, machine, and processor.

Note that this adds a sixth attribute (processor) not present in the \texttt{os.uname()} result. Also, the attribute names are different for the first two attributes; \texttt{os.uname()} names them sysname and nodename.

Entries which cannot be determined are set to ''. 

\textit{Changed in version} 3.3: Result changed from a tuple to a namedtuple.
16.15.2. Java Platform

```
platform.java_ver(release='', vendor='', vminfo=('', '', ''), osinfo=( '', '', '' ))
```

Version interface for Jython.

Returns a tuple (release, vendor, vminfo, osinfo) with vminfo being a tuple (vm_name, vm_release, vm_vendor) and osinfo being a tuple (os_name, os_version, os_arch). Values which cannot be determined are set to the defaults given as parameters (which all default to ' ').
16.15.3. Windows Platform

platform.\texttt{win32\_ver}(\textit{release=\''}, \textit{version=\''}, \textit{csd=\''}, \textit{ptype=\''})

Get additional version information from the Windows Registry and return a tuple \texttt{(release, version, csd, ptype)} referring to OS release, version number, CSD level (service pack) and OS type (multi/single processor).

As a hint: \textit{ptype} is 'Uniprocessor Free' on single processor NT machines and 'Multiprocessor Free' on multi processor machines. The 'Free' refers to the OS version being free of debugging code. It could also state 'Checked' which means the OS version uses debugging code, i.e. code that checks arguments, ranges, etc.

\begin{shaded}
\textbf{Note:} This function works best with Mark Hammond's \texttt{win32all} package installed, but also on Python 2.3 and later (support for this was added in Python 2.6). It obviously only runs on Win32 compatible platforms.
\end{shaded}

16.15.3.1. Win95/98 specific

platform.\texttt{popen}(\textit{cmd, mode='r', bufsize=-1})

Portable \texttt{popen()} interface. Find a working popen implementation preferring \texttt{win32pipe.popen()}. On Windows NT, \texttt{win32pipe.popen()} should work; on Windows 9x it hangs due to bugs in the MS C library.

\begin{shaded}
\textit{Deprecated since version 3.3:} This function is obsolete. Use the \texttt{subprocess} module. Check especially the \textit{Replacing Older}
\end{shaded}
Functions with the subprocess Module section.
16.15.4. Mac OS Platform

platform.mac_ver(release='', versioninfo=( '', '', ''), machine='')

Get Mac OS version information and return it as tuple (release, versioninfo, machine) with versioninfo being a tuple (version, dev_stage, non_release_version).

Entries which cannot be determined are set to ''. All tuple entries are strings.
16.15.5. Unix Platforms

platform.dist(distname='', version='', id='', supported_dists=('SuSE', 'debian', 'redhat', 'mandrake', ...))

This is another name for linux_distribution().

platform.linux_distribution(distname='', version='', id='', supported_dists=('SuSE', 'debian', 'redhat', 'mandrake', ...), full_distribution_name=1)

Tries to determine the name of the Linux OS distribution name.

supported_dists may be given to define the set of Linux distributions to look for. It defaults to a list of currently supported Linux distributions identified by their release file name.

If full_distribution_name is true (default), the full distribution read from the OS is returned. Otherwise the short name taken from supported_dists is used.

Returns a tuple (distname, version, id) which defaults to the args given as parameters. id is the item in parentheses after the version number. It is usually the version codename.

platform.libc_ver(executable=sys.executable, lib='', version='', chunksize=2048)

Tries to determine the libc version against which the file executable (defaults to the Python interpreter) is linked. Returns a tuple of strings (lib, version) which default to the given parameters in case the lookup fails.

Note that this function has intimate knowledge of how different libc versions add symbols to the executable is probably only usable for
executables compiled using \texttt{gcc}.

The file is read and scanned in chunks of \textit{chunksize} bytes.
16.16. **errno** — Standard errno system symbols

This module makes available standard `errno` system symbols. The value of each symbol is the corresponding integer value. The names and descriptions are borrowed from `linux/include/errno.h`, which should be pretty all-inclusive.

`errno.errorcode`

Dictionary providing a mapping from the `errno` value to the string name in the underlying system. For instance, `errno.errorcode[errno.EPERM]` maps to `'EPERM'`.

To translate a numeric error code to an error message, use `os.strerror()`.

Of the following list, symbols that are not used on the current platform are not defined by the module. The specific list of defined symbols is available as `errno.errorcode.keys()`. Symbols available can include:

`errno.EPERM`  
Operation not permitted

`errno.ENOENT`  
No such file or directory

`errno.ESRCH`  
No such process

`errno.EINTR`
Interrupted system call

**errno. EIO**
I/O error

**errno. ENXIO**
No such device or address

**errno. E2BIG**
Arg list too long

**errno. ENOEXEC**
Exec format error

**errno. EBADF**
Bad file number

**errno. ECHILD**
No child processes

**errno. EAGAIN**
Try again

**errno. ENOMEM**
Out of memory

**errno. EACCES**
Permission denied

**errno. EFAULT**
Bad address

**errno. ENOTBLK**
Block device required
errno. **EBUSY**
    Device or resource busy

errno. **EEXIST**
    File exists

errno. **EXDEV**
    Cross-device link

errno. **ENODEV**
    No such device

errno. **ENOTDIR**
    Not a directory

errno. **EISDIR**
    Is a directory

errno. **EINVAL**
    Invalid argument

errno. **ENFILE**
    File table overflow

errno. **EMFILE**
    Too many open files

errno. **ENOTTY**
    Not a typewriter

errno. **ETXTBSY**
    Text file busy

errno. **EFBIG**
File too large

`errno. ENOSPC`
No space left on device

`errno. ESPIPE`
Illegal seek

`errno. EROFS`
Read-only file system

`errno. EMLINK`
Too many links

`errno. EPIPE`
Broken pipe

`errno. EDOM`
Math argument out of domain of func

`errno. ERANGE`
Math result not representable

`errno. EDEADLK`
Resource deadlock would occur

`errno. ENAMETOOLONG`
File name too long

`errno. ENOLCK`
No record locks available

`errno. ENOSYS`
Function not implemented
errno. **ENOTEMPTY**  
Directory not empty

errno. **ELOOP**  
Too many symbolic links encountered

errno. **EWOULDBLOCK**  
Operation would block

errno. **ENOMSG**  
No message of desired type

errno. **EIDRM**  
Identifier removed

errno. **ECHRNG**  
Channel number out of range

errno. **EL2NSYNC**  
Level 2 not synchronized

errno. **EL3HLT**  
Level 3 halted

errno. **EL3RST**  
Level 3 reset

errno. **ELNRNG**  
Link number out of range

errno. **EUNATCH**  
Protocol driver not attached

errno. **ENOCSI**
No CSI structure available

errno. **EL2HLT**
Level 2 halted

errno. **EBADE**
Invalid exchange

errno. **EBADR**
Invalid request descriptor

errno. **EXFULL**
Exchange full

errno. **ENOANO**
No anode

errno. **EBADRQC**
Invalid request code

errno. **EBADSLT**
Invalid slot

errno. **EDEADLOCK**
File locking deadlock error

errno. **EBFONT**
Bad font file format

errno. **ENOSTR**
Device not a stream

errno. **ENODATA**
No data available
errno. **ETIME**  
Timer expired

errno. **ENOSR**  
Out of streams resources

errno. **ENONET**  
Machine is not on the network

errno. **ENOPKG**  
Package not installed

errno. **EREMOTE**  
Object is remote

errno. **ENOLINK**  
Link has been severed

errno. **EADV**  
Advertise error

errno. **ESRMNT**  
Srmount error

errno. **ECOMM**  
Communication error on send

errno. **EPROTO**  
Protocol error

errno. **EMULTIhop**  
Multihop attempted

errno. **EDOTDOT**
RFS specific error

errno. **EBADMSG**
Not a data message

errno. **EOVERFLOW**
Value too large for defined data type

errno. **ENOTUNIQ**
Name not unique on network

errno. **EBADFD**
File descriptor in bad state

errno. **EREMCHG**
Remote address changed

errno. **ELIBACC**
Can not access a needed shared library

errno. **ELIBBAD**
Accessing a corrupted shared library

errno. **ELIBSCN**
.lib section in a.out corrupted

errno. **ELIBMAX**
Attempting to link in too many shared libraries

errno. **ELIBEXEC**
Cannot exec a shared library directly

errno. **EILSEQ**
Illegal byte sequence
errno. **ERESTART**
   Interrupted system call should be restarted

errno. **ESTRPIPE**
   Streams pipe error

errno. **EUSERS**
   Too many users

errno. **ENOTSOCK**
   Socket operation on non-socket

errno. **EDESTADDRREQ**
   Destination address required

errno. **EMSGSIZE**
   Message too long

errno. **EPROTOTYPE**
   Protocol wrong type for socket

errno. **ENOPROTOOPT**
   Protocol not available

errno. **EPROTONOSUPPORT**
   Protocol not supported

errno. **ESOCKETNOSUPPORT**
   Socket type not supported

errno. **EOPNOTSUPP**
   Operation not supported on transport endpoint

errno. **EPFNOSUPPORT**
Protocol family not supported

errno. **EAFNOSUPPORT**
Address family not supported by protocol

errno. **EADDRINUSE**
Address already in use

errno. **EADDRNOTAVAIL**
Cannot assign requested address

errno. **ENETDOWN**
Network is down

errno. **ENETUNREACH**
Network is unreachable

errno. **ENETRESET**
Network dropped connection because of reset

errno. **ECONNABORTED**
Software caused connection abort

errno. **ECONNRESET**
Connection reset by peer

errno. **ENOBUFS**
No buffer space available

errno. **EISCONN**
Transport endpoint is already connected

errno. **ENOTCONN**
Transport endpoint is not connected
errno. **ESHUTDOWN**  
Cannot send after transport endpoint shutdown

errno. **ETOOMANYREFS**  
Too many references: cannot splice

errno. **ETIMEDOUT**  
Connection timed out

errno. **ECONNREFUSED**  
Connection refused

errno. **EHOSTDOWN**  
Host is down

errno. **EHOSTUNREACH**  
No route to host

errno. **EALREADY**  
Operation already in progress

errno. **EINPROGRESS**  
Operation now in progress

errno. **ESTALE**  
Stale NFS file handle

errno. **EUCLEAN**  
Structure needs cleaning

errno. **ENOTNAM**  
Not a XENIX named type file

errno. **ENAVAIL**
No XENIX semaphores available

errno. **EISNAM**
Is a named type file

errno. **EREMOTEIO**
Remote I/O error

errno. **EDQUOT**
Quota exceeded
16.17. ctypes — A foreign function library for Python

ctypes is a foreign function library for Python. It provides C compatible data types, and allows calling functions in DLLs or shared libraries. It can be used to wrap these libraries in pure Python.
16.17.1. ctypes tutorial

Note: The code samples in this tutorial use doctest to make sure that they actually work. Since some code samples behave differently under Linux, Windows, or Mac OS X, they contain doctest directives in comments.

Note: Some code samples reference the ctypes c_int type. This type is an alias for the c_long type on 32-bit systems. So, you should not be confused if c_long is printed if you would expect c_int — they are actually the same type.

16.17.1.1. Loading dynamic link libraries

ctypes exports the cdll, and on Windows windll and oledll objects, for loading dynamic link libraries.

You load libraries by accessing them as attributes of these objects. cdll loads libraries which export functions using the standard cdecl calling convention, while windll libraries call functions using the stdcall calling convention. oledll also uses the stdcall calling convention, and assumes the functions return a Windows HRESULT error code. The error code is used to automatically raise a OSError exception when the function call fails.

*Changed in version 3.3:* Windows errors used to raise WindowsError, which is now an alias of OSError.

Here are some examples for Windows. Note that msvcrtn is the MS standard C library containing most standard C functions, and uses the cdecl calling convention:
Windows appends the usual `.dll` file suffix automatically.

On Linux, it is required to specify the filename *including* the extension to load a library, so attribute access can not be used to load libraries. Either the `LoadLibrary()` method of the dll loaders should be used, or you should load the library by creating an instance of `CDLL` by calling the constructor:

```python
>>> cdll.LoadLibrary("libc.so.6")  
<CDLL 'libc.so.6', handle ... at ...>  
>>> libc = CDLL("libc.so.6")  
>>> libc  
<CDLL 'libc.so.6', handle ... at ...>
```

**16.17.1.2. Accessing functions from loaded dlls**

Functions are accessed as attributes of dll objects:

```python
>>> from ctypes import *  
>>> libc.printf  
<_FuncPtr object at 0x...>  
>>> print(windll.kernel32.GetModuleHandleA)  
<_FuncPtr object at 0x...>  
>>> print(windll.kernel32.MyOwnFunction)  
Traceback (most recent call last):
```
Note that win32 system dlls like kernel32 and user32 often export ANSI as well as UNICODE versions of a function. The UNICODE version is exported with an \texttt{W} appended to the name, while the ANSI version is exported with an \texttt{A} appended to the name. The win32 GetModuleHandle function, which returns a module handle for a given module name, has the following C prototype, and a macro is used to expose one of them as \texttt{GetModuleHandle} depending on whether UNICODE is defined or not:

\begin{Verbatim}
/* ANSI version */
HMODULE GetModuleHandleA(LPCSTR lpModuleName);

/* UNICODE version */
HMODULE GetModuleHandleW(LPCWSTR lpModuleName);
\end{Verbatim}

\texttt{windll} does not try to select one of them by magic, you must access the version you need by specifying \texttt{GetModuleHandleA} or \texttt{GetModuleHandleW} explicitly, and then call it with bytes or string objects respectively.

Sometimes, dlls export functions with names which aren't valid Python identifiers, like "??2@YAPAXI@Z". In this case you have to use \texttt{getattr()} to retrieve the function:

\begin{Verbatim}
>>> getattr(cdll.msvcrt, "??2@YAPAXI@Z")
<_FuncPtr object at 0x...>

>>> 
\end{Verbatim}
On Windows, some dlls export functions not by name but by ordinal. These functions can be accessed by indexing the dll object with the ordinal number:

```python
>>> cdll.kernel32[1]
<_FuncPtr object at 0x...>
>>> cdll.kernel32[0]
Traceback (most recent call last):
  File "<stdin>", line 1, in ?
  File "ctypes.py", line 310, in __getitem__
    func = _StdcallFuncPtr(name, self)
AttributeError: function ordinal 0 not found
```.

16.17.1.3. Calling functions

You can call these functions like any other Python callable. This example uses the `time()` function, which returns system time in seconds since the Unix epoch, and the `GetModuleHandleA()` function, which returns a win32 module handle.

This example calls both functions with a NULL pointer (None should be used as the NULL pointer):

```python
>>> print(libc.time(None))
1150640792
>>> print(hex(windll.kernel32.GetModuleHandleA(None)))
0x1d000000
```.

`ctypes` tries to protect you from calling functions with the wrong number of arguments or the wrong calling convention. Unfortunately this only works on Windows. It does this by examining the stack after
the function returns, so although an error is raised the function has been called:

```python
>>> windll.kernel32.GetModuleHandleA()
Traceback (most recent call last):
  File "<stdin>", line 1, in ?
ValueError: Procedure probably called with not enough arguments (4 bytes missing)
```

The same exception is raised when you call an `stdcall` function with the `cdecl` calling convention, or vice versa:

```python
>>> cdll.kernel32.GetModuleHandleA(\None)
Traceback (most recent call last):
  File "<stdin>", line 1, in ?
ValueError: Procedure probably called with not enough arguments (4 bytes missing)
```

```python
>>> windll.msvcrt.printf(b"spam")
Traceback (most recent call last):
  File "<stdin>", line 1, in ?
ValueError: Procedure probably called with too many arguments (4 bytes in excess)
```

To find out the correct calling convention you have to look into the C header file or the documentation for the function you want to call.

On Windows, `ctypes` uses win32 structured exception handling to prevent crashes from general protection faults when functions are called with invalid argument values:
There are, however, enough ways to crash Python with `ctypes`, so you should be careful anyway. The `faulthandler` module can be helpful in debugging crashes (e.g. from segmentation faults produced by erroneous C library calls).

None, integers, bytes objects and (unicode) strings are the only native Python objects that can directly be used as parameters in these function calls. None is passed as a C `NULL` pointer, bytes objects and strings are passed as pointer to the memory block that contains their data (char * or wchar_t *). Python integers are passed as the platforms default C int type, their value is masked to fit into the C type.

Before we move on calling functions with other parameter types, we have to learn more about `ctypes` data types.

### 16.17.1.4. Fundamental data types

`ctypes` defines a number of primitive C compatible data types:

<table>
<thead>
<tr>
<th>ctypes type</th>
<th>C type</th>
<th>Python type</th>
</tr>
</thead>
<tbody>
<tr>
<td>c_bool</td>
<td>_Bool</td>
<td>bool (1)</td>
</tr>
<tr>
<td>c_char</td>
<td>char</td>
<td>1-character bytes object</td>
</tr>
<tr>
<td>c_wchar</td>
<td>wchar_t</td>
<td>1-character string</td>
</tr>
<tr>
<td>Type</td>
<td>Description</td>
<td>Type</td>
</tr>
<tr>
<td>---------------------</td>
<td>--------------------------------------------------</td>
<td>------------</td>
</tr>
<tr>
<td>c_byte</td>
<td>char</td>
<td>int</td>
</tr>
<tr>
<td>c_ubyte</td>
<td>unsigned char</td>
<td>int</td>
</tr>
<tr>
<td>c_short</td>
<td>short</td>
<td>int</td>
</tr>
<tr>
<td>c_ushort</td>
<td>unsigned short</td>
<td>int</td>
</tr>
<tr>
<td>c_int</td>
<td>int</td>
<td>int</td>
</tr>
<tr>
<td>c_uint</td>
<td>unsigned int</td>
<td>int</td>
</tr>
<tr>
<td>c_long</td>
<td>long</td>
<td>int</td>
</tr>
<tr>
<td>c_ulong</td>
<td>unsigned long</td>
<td>int</td>
</tr>
<tr>
<td>c_longlong</td>
<td>__int64 or long</td>
<td>int</td>
</tr>
<tr>
<td>c_ulonglong</td>
<td>unsigned __int64 or unsigned long</td>
<td>int</td>
</tr>
<tr>
<td>c_size_t</td>
<td>size_t</td>
<td>int</td>
</tr>
<tr>
<td>c_ssize_t</td>
<td>ssize_t or Py_ssize_t</td>
<td>int</td>
</tr>
<tr>
<td>c_float</td>
<td>float</td>
<td>float</td>
</tr>
<tr>
<td>c_double</td>
<td>double</td>
<td>float</td>
</tr>
<tr>
<td>c_longdouble</td>
<td>long double</td>
<td>float</td>
</tr>
<tr>
<td>c_char_p</td>
<td>char * (NULL terminated)</td>
<td>bytes object or None</td>
</tr>
<tr>
<td>c_wchar_p</td>
<td>wchar_t * (NULL terminated)</td>
<td>string or None</td>
</tr>
<tr>
<td>c_void_p</td>
<td>void *</td>
<td>int or None</td>
</tr>
</tbody>
</table>

1. The constructor accepts any object with a truth value.

All these types can be created by calling them with an optional initializer of the correct type and value:

```python
>>> c_int()
```
c_long(0)
>>> c_wchar_p("Hello, World")
c_wchar_p('Hello, World')
>>> c_ushort(-3)
c_ushort(65533)
>>>

Since these types are mutable, their value can also be changed afterwards:

>>> i = c_int(42)
>>> print(i)
c_long(42)
>>> print(i.value)
42
>>> i.value = -99
>>> print(i.value)
-99
>>>

Assigning a new value to instances of the pointer types c_char_p, c_wchar_p, and c_void_p changes the memory location they point to, not the contents of the memory block (of course not, because Python bytes objects are immutable):

>>> s = "Hello, World"
>>> c_s = c_wchar_p(s)
>>> print(c_s)
c_wchar_p('Hello, World')
>>> c_s.value = "Hi, there"
>>> print(c_s)
c_wchar_p('Hi, there')
>>> print(s)
Hello, World
>>> # first object is unchanged
You should be careful, however, not to pass them to functions expecting pointers to mutable memory. If you need mutable memory blocks, ctypes has a `create_string_buffer()` function which creates these in various ways. The current memory block contents can be accessed (or changed) with the `raw` property; if you want to access it as NUL terminated string, use the `value` property:

```python
>>> from ctypes import *  
>>> p = create_string_buffer(3)  # create
3 b'\x00\x00\x00'
>>> p = create_string_buffer(b"Hello")  # create
6 b'Hello\x00'
>>> print(repr(p.value))
'b'Hello'
>>> p = create_string_buffer(b"Hello", 10)  # create
10 b'Hello\x00\x00\x00\x00\x00\x00\x00\x00\x00'
>>> p.value = b"Hi"
>>> print(repr(p.value))
'Hi\x00\x00\x00\x00\x00\x00\x00\x00\x00'
```

The `create_string_buffer()` function replaces the `c_buffer()` function (which is still available as an alias), as well as the `c_string()` function from earlier ctypes releases. To create a mutable memory block containing unicode characters of the C type `wchar_t` use the `create_unicode_buffer()` function.

### 16.17.1.5. Calling functions, continued

Note that printf prints to the real standard output channel, *not* to
**sys.stdout**, so these examples will only work at the console prompt, not from within *IDLE* or *PythonWin*:

```python
>>> printf = libc.printf
>>> printf(b"Hello, %s\n", b"World!")
Hello, World!
14
>>> printf(b"Hello, %S\n", "World!")
Hello, World!
14
>>> printf(b"%d bottles of beer\n", 42)
42 bottles of beer
19
>>> printf(b"%f bottles of beer\n", 42.5)
Traceback (most recent call last):
  File "<stdin>", line 1, in ?
ArgumentError: argument 2: exceptions.TypeError: Don
```  

As has been mentioned before, all Python types except integers, strings, and bytes objects have to be wrapped in their corresponding *ctypes* type, so that they can be converted to the required C data type:

```python
>>> printf(b"An int %d, a double %f\n", 1234, c_double(3.14))
An int 1234, a double 3.140000
31
```  

16.17.1.6. Calling functions with your own custom data types

You can also customize *ctypes* argument conversion to allow
instances of your own classes be used as function arguments. 
`ctypes` looks for an `_as_parameter_` attribute and uses this as the function argument. Of course, it must be one of integer, string, or bytes:

```python
>>> class Bottles:
...     def __init__(self, number):
...         self._as_parameter_ = number
...
>>> bottles = Bottles(42)
>>> printf(b"%d bottles of beer\n", bottles)
42 bottles of beer
19
```

If you don't want to store the instance's data in the `_as_parameter_` instance variable, you could define a `property` which makes the attribute available on request.

16.17.1.7. Specifying the required argument types (function prototypes)

It is possible to specify the required argument types of functions exported from DLLs by setting the `argtypes` attribute.

`argtypes` must be a sequence of C data types (the `printf` function is probably not a good example here, because it takes a variable number and different types of parameters depending on the format string, on the other hand this is quite handy to experiment with this feature):

```python
>>> printf.argtypes = [c_char_p, c_char_p, c_int, c_
>>> printf(b"String '%s', Int %d, Double %f\n", b"Hi"
Specifying a format protects against incompatible argument types (just as a prototype for a C function), and tries to convert the arguments to valid types:

```python
>>> printf(b"%d %d %d", 1, 2, 3)
Traceback (most recent call last):
  File "<stdin>", line 1, in 
ArgumentError: argument 2: exceptions.TypeError: wrong type

>>> printf(b"%s %d %f\n", b"X", 2, 3)
X 2 3.000000
13
```

If you have defined your own classes which you pass to function calls, you have to implement a `from_param()` class method for them to be able to use them in the `argtypes` sequence. The `from_param()` class method receives the Python object passed to the function call, it should do a type check or whatever is needed to make sure this object is acceptable, and then return the object itself, its `_as_parameter_` attribute, or whatever you want to pass as the C function argument in this case. Again, the result should be an integer, string, bytes, a `ctypes` instance, or an object with an `_as_parameter_` attribute.

16.17.1.8. Return types

By default functions are assumed to return the C `int` type. Other return types can be specified by setting the `restype` attribute of the function object.
Here is a more advanced example, it uses the `strchr` function, which expects a string pointer and a char, and returns a pointer to a string:

```python
>>> strchr = libc.strchr
>>> strchr(b"abcdef", ord("d"))
8059983
>>> strchr.retype = c_char_p  # c_char_p is a pointer
>>> strchr(b"abcdef", ord("d"))
'b\'def\'
>>> print(strchr(b"abcdef", ord("x")))
None
```

If you want to avoid the `ord("x")` calls above, you can set the `argtypes` attribute, and the second argument will be converted from a single character Python bytes object into a C char:

```python
>>> strchr.retype = c_char_p
>>> strchr.argtypes = [c_char_p, c_char]
>>> strchr(b"abcdef", b"d")
'\'def\'
>>> strchr(b"abcdef", b"def")
Traceback (most recent call last):
  File "<stdin>", line 1, in 
ArgumentError: argument 2: exceptions.TypeError: one

>>> print(strchr(b"abcdef", b"x"))
None
>>> strchr(b"abcdef", b"d")
'\'def\'
```

You can also use a callable Python object (a function or a class for example) as the restype attribute, if the foreign function returns an integer. The callable will be called with the `integer` the C function
returns, and the result of this call will be used as the result of your function call. This is useful to check for error return values and automatically raise an exception:

```python
>>> GetModuleHandle = windll.kernel32.GetModuleHandle
>>> def ValidHandle(value):
...     if value == 0:
...         raise WinError()
...     return value
...
>>> GetModuleHandle.restype = ValidHandle
>>> GetModuleHandle(None)
486539264
>>> GetModuleHandle("something silly")
Traceback (most recent call last):
  File "<stdin>", line 1, in ?
  File "<stdin>", line 3, in ValidHandle
OSError: [Errno 126] The specified module could not
```

WinError is a function which will call Windows FormatMessage() api to get the string representation of an error code, and returns an exception. WinError takes an optional error code parameter, if no one is used, it calls GetLastError() to retrieve it.

Please note that a much more powerful error checking mechanism is available through the errcheck attribute; see the reference manual for details.

16.17.1.9. Passing pointers (or: passing parameters by reference)
Sometimes a C api function expects a *pointer* to a data type as parameter, probably to write into the corresponding location, or if the data is too large to be passed by value. This is also known as *passing parameters by reference*.

`ctypes` exports the `byref()` function which is used to pass parameters by reference. The same effect can be achieved with the `pointer()` function, although `pointer()` does a lot more work since it constructs a real pointer object, so it is faster to use `byref()` if you don’t need the pointer object in Python itself:

```python
>>> i = c_int()
>>> f = c_float()
>>> s = create_string_buffer(b'\000' * 32)
>>> print(i.value, f.value, repr(s.value))
0 0.0 b''
>>> libc sscanf(b'1 3.14 Hello', b'%d %f %s',
             byref(i), byref(f), s)
3
>>> print(i.value, f.value, repr(s.value))
1 3.1400001049 b'Hello'
```

16.17.1.10. Structures and unions

Structures and unions must derive from the `Structure` and `Union` base classes which are defined in the `ctypes` module. Each subclass must define a `_fields_` attribute. `_fields_` must be a list of 2-tuples, containing a *field name* and a *field type*.

The field type must be a `ctypes` type like `c_int`, or any other derived `ctypes` type: structure, union, array, pointer.
Here is a simple example of a POINT structure, which contains two integers named \(x\) and \(y\), and also shows how to initialize a structure in the constructor:

```python
>>> from ctypes import *
>>> class POINT(Structure):
...     _fields_ = [("x", c_int),
...                 ("y", c_int)]
...     point = POINT(10, 20)
>>> print(point.x, point.y)
10 20
>>> point = POINT(y=5)
>>> print(point.x, point.y)
0 5
>>> POINT(1, 2, 3)
Traceback (most recent call last):
  File "<stdin>" , line 1, in ?
ValueError: too many initializers
```

You can, however, build much more complicated structures. A structure can itself contain other structures by using a structure as a field type.

Here is a RECT structure which contains two POINTs named upperleft and lowerright:

```python
>>> class RECT(Structure):
...     _fields_ = [("upperleft", POINT),
...                 ("lowerright", POINT)]
...     rc = RECT(point)
>>> print(rc.upperleft.x, rc.upperleft.y)
0 5
>>> print(rc.lowerright.x, rc.lowerright.y)
```
Nested structures can also be initialized in the constructor in several ways:

```python
>>> r = RECT(POINT(1, 2), POINT(3, 4))
>>> r = RECT((1, 2), (3, 4))
```

Field descriptors can be retrieved from the class, they are useful for debugging because they can provide useful information:

```python
>>> print(POINT.x)
<Field type=c_long, ofs=0, size=4>
>>> print(POINT.y)
<Field type=c_long, ofs=4, size=4>
```

**Warning:** `ctypes` does not support passing unions or structures with bit-fields to functions by value. While this may work on 32-bit x86, it’s not guaranteed by the library to work in the general case. Unions and structures with bit-fields should always be passed to functions by pointer.

### 16.17.1.11. Structure/union alignment and byte order

By default, Structure and Union fields are aligned in the same way the C compiler does it. It is possible to override this behavior by specifying a `_pack_` class attribute in the subclass definition. This must be set to a positive integer and specifies the maximum alignment for the fields. This is what `#pragma pack(n)` also does in MSVC.
**ctypes** uses the native byte order for Structures and Unions. To build structures with non-native byte order, you can use one of the `BigEndianStructure`, `LittleEndianStructure`, `BigEndianUnion`, and `LittleEndianUnion` base classes. These classes cannot contain pointer fields.

### 16.17.1.12. Bit fields in structures and unions

It is possible to create structures and unions containing bit fields. Bit fields are only possible for integer fields, the bit width is specified as the third item in the `_fields_` tuples:

```python
>>> class Int(Structure):
...     _fields_ = [('first_16', c_int, 16),
...                ('second_16', c_int, 16)]
... >>> print(Int.first_16)
<Field type=c_long, ofs=0:0, bits=16>
>>> print(Int.second_16)
<Field type=c_long, ofs=0:16, bits=16>
```

### 16.17.1.13. Arrays

Arrays are sequences, containing a fixed number of instances of the same type.

The recommended way to create array types is by multiplying a data type with a positive integer:

```python
TenPointsArrayType = POINT * 10
```

Here is an example of an somewhat artificial data type, a structure
containing 4 POINTs among other stuff:

```python
>>> from ctypes import *
>>> class POINT(Structure):
...     _fields_ = ("x", c_int), ("y", c_int)
...
>>> class MyStruct(Structure):
...     _fields_ = [("a", c_int),
...                 ("b", c_float),
...                 ("point_array", POINT * 4)]
>>> print(len(MyStruct().point_array))
4
>>> print(arr)
```

Instances are created in the usual way, by calling the class:

```python
arr = TenPointsArrayType()
for pt in arr:
    print(pt.x, pt.y)
```

The above code print a series of 0 0 lines, because the array contents is initialized to zeros.

Initializers of the correct type can also be specified:

```python
>>> from ctypes import *
>>> TenIntegers = c_int * 10
>>> ii = TenIntegers(1, 2, 3, 4, 5, 6, 7, 8, 9, 10)
>>> print(ii)
<c_long_Array_10 object at 0x...>
>>> for i in ii: print(i, end=" ")
... 1 2 3 4 5 6 7 8 9 10
>>> 
```

Pointer instances are created by calling the `pointer()` function on a `ctypes` type:

```python
>>> from ctypes import *
>>> i = c_int(42)
>>> pi = pointer(i)

>>> pi
<ctypes._Pointer object at 0x7f0000000000>
```

Pointer instances have a `contents` attribute which returns the object to which the pointer points, the `i` object above:

```python
>>> pi.contents
<ctypes.c_long object at 0x7f0000000000>
```

Note that `ctypes` does not have OOR (original object return), it constructs a new, equivalent object each time you retrieve an attribute:

```python
>>> pi.contents is i
False
>>> pi.contents is pi.contents
False
```

Assigning another `c_int` instance to the pointer’s `contents` attribute would cause the pointer to point to the memory location where this is stored:

```python
>>> i = c_int(99)
>>> pi.contents = i
>>> pi
<ctypes._Pointer object at 0x7f0000000000>
```

```python
>>> pi.contents
<ctypes.c_long object at 0x7f0000000000>
```
Pointer instances can also be indexed with integers:

```python
>>> pi[0]
99
```

Assigning to an integer index changes the pointed to value:

```python
>>> print(i)
c_long(99)
>>> pi[0] = 22
>>> print(i)
c_long(22)
```

It is also possible to use indexes different from 0, but you must know what you’re doing, just as in C: You can access or change arbitrary memory locations. Generally you only use this feature if you receive a pointer from a C function, and you know that the pointer actually points to an array instead of a single item.

Behind the scenes, the `pointer()` function does more than simply create pointer instances, it has to create pointer types first. This is done with the `POINTER()` function, which accepts any `ctypes` type, and returns a new type:

```python
>>> PI = POINTER(c_int)
>>> PI
<class 'ctypes.LP_c_long'>
>>> PI(42)
Traceback (most recent call last):
  File "<stdin>", line 1, in ?
TypeError: expected c_long instead of int
```
Calling the pointer type without an argument creates a NULL pointer. NULL pointers have a False boolean value:

```python
>>> null_ptr = POINTER(c_int)()
>>> print(bool(null_ptr))
False
```  

`ctypes` checks for NULL when dereferencing pointers (but dereferencing invalid non-NULL pointers would crash Python):

```python
>>> null_ptr[0]
Traceback (most recent call last):
  ....
ValueError: NULL pointer access

>>> null_ptr[0] = 1234
>>> null_ptr[0] = 1234
Traceback (most recent call last):
  ....
ValueError: NULL pointer access
```  

### 16.17.1.15. Type conversions

Usually, ctypes does strict type checking. This means, if you have `POINTER(c_int)` in the argtypes list of a function or as the type of a member field in a structure definition, only instances of exactly the same type are accepted. There are some exceptions to this rule, where ctypes accepts other objects. For example, you can pass
compatible array instances instead of pointer types. So, for `POINTER(c_int)`, ctypes accepts an array of `c_int`:

```python
>>> class Bar(Structure):
...     _fields_ = [("count", c_int), ("values", POINTER(c_int))]
... >>> bar = Bar()
>>> bar.values = (c_int * 3)(1, 2, 3)
>>> bar.count = 3
>>> for i in range(bar.count):
...     print(bar.values[i])
... 1
 2
 3
```

In addition, if a function argument is explicitly declared to be a pointer type (such as `POINTER(c_int)`) in argtypes, an object of the pointed type (`c_int` in this case) can be passed to the function. ctypes will apply the required `byref()` conversion in this case automatically.

To set a `POINTER` type field to `NULL`, you can assign `None`:

```python
>>> bar.values = None
```

Sometimes you have instances of incompatible types. In C, you can cast one type into another type. `ctypes` provides a `cast()` function which can be used in the same way. The `Bar` structure defined above accepts `POINTER(c_int)` pointers or `c_int` arrays for its `values` field, but not instances of other types:
For these cases, the `cast()` function is handy.

The `cast()` function can be used to cast a ctypes instance into a pointer to a different ctypes data type. `cast()` takes two parameters, a ctypes object that is or can be converted to a pointer of some kind, and a ctypes pointer type. It returns an instance of the second argument, which references the same memory block as the first argument:

```python
>>> a = (c_byte * 4)()
>>> cast(a, POINTER(c_int))
<ctypes.LP_c_long object at ...>

So, `cast()` can be used to assign to the `values` field of `Bar` the structure:

```python
>>> bar = Bar()
>>> bar.values = cast((c_byte * 4)(), POINTER(c_int))
>>> print(bar.values[0])
0
```

16.17.1.16. Incomplete Types

Incomplete Types are structures, unions or arrays whose members are
not yet specified. In C, they are specified by forward declarations, which are defined later:

```c
struct cell; /* forward declaration */

struct cell {
    char *name;
    struct cell *next;
};
```

The straightforward translation into ctypes code would be this, but it does not work:

```python
>>> class cell(Structure):
...     _fields_ = ["name", c_char_p],
...                 ("next", POINTER(cell))]
... Traceback (most recent call last):
  File "<stdin>", line 1, in ?
  File "<stdin>", line 2, in cell
NameError: name 'cell' is not defined

>>> from ctypes import *
>>> class cell(Structure):
...     pass
... cell._fields_ = ["name", c_char_p],
...                 ("next", POINTER(cell))]
>>> 
```

because the new `class cell` is not available in the class statement itself. In `ctypes`, we can define the `cell` class and set the `_fields_` attribute later, after the class statement:

```python
>>> from ctypes import *
>>> class cell(Structure):
...     pass
... cell._fields_ = ["name", c_char_p],
...                 ("next", POINTER(cell))]
>>> 
```
Lets try it. We create two instances of `cell`, and let them point to each other, and finally follow the pointer chain a few times:

```python
>>> c1 = cell()
>>> c1.name = "foo"
>>> c2 = cell()
>>> c2.name = "bar"
>>> c1.next = pointer(c2)
>>> c2.next = pointer(c1)
>>> p = c1
>>> for i in range(8):
...     print(p.name, end=" ")
...     p = p.next[0]
...
foo bar foo bar foo bar foo bar
```

### 16.17.1.17. Callback functions

`ctypes` allows to create C callable function pointers from Python callables. These are sometimes called *callback functions*.

First, you must create a class for the callback function. The class knows the calling convention, the return type, and the number and types of arguments this function will receive.

The `CFUNCTYPE()` factory function creates types for callback functions using the *cdecl* calling convention. On Windows, the `WINFUNCTYPE()` factory function creates types for callback functions using the *stdcall* calling convention.

Both of these factory functions are called with the result type as first argument, and the callback functions expected argument types as the remaining arguments.
I will present an example here which uses the standard C library’s `qsort()` function, that is used to sort items with the help of a callback function. `qsort()` will be used to sort an array of integers:

```python
>>> IntArray5 = c_int * 5
>>> ia = IntArray5(5, 1, 7, 33, 99)
>>> qsort = libc.qsort
>>> qsort.restype = None

`qsort()` must be called with a pointer to the data to sort, the number of items in the data array, the size of one item, and a pointer to the comparison function, the callback. The callback will then be called with two pointers to items, and it must return a negative integer if the first item is smaller than the second, a zero if they are equal, and a positive integer otherwise.

So our callback function receives pointers to integers, and must return an integer. First we create the type for the callback function:

```python
>>> CMPFUNC = CFUNCTYPE(c_int, POINTER(c_int), POINTER(c_int))

To get started, here is a simple callback that shows the values it gets passed:

```python
>>> def py_cmp_func(a, b):
...     print("py_cmp_func", a[0], b[0])
...     return 0
...
>>> cmp_func = CMPFUNC(py_cmp_func)

```
The result:

```python
>>> qsort(ia, len(ia), sizeof(c_int), cmp_func)
py_cmp_func 5 1
py_cmp_func 33 99
py_cmp_func 7 33
py_cmp_func 5 7
py_cmp_func 1 7
>>> py_cmp_func 5 1
py_cmp_func 33 99
py_cmp_func 7 33
py_cmp_func 1 7
py_cmp_func 5 7
```
they are used from C code. \texttt{ctypes} doesn't, and if you don't, they may be garbage collected, crashing your program when a callback is made.

16.17.1.18. Accessing values exported from dlls

Some shared libraries not only export functions, they also export variables. An example in the Python library itself is the \texttt{Py\_OptimizeFlag}, an integer set to 0, 1, or 2, depending on the \texttt{-O} or \texttt{-OO} flag given on startup.

\texttt{ctypes} can access values like this with the \texttt{in\_dll()} class methods of the type. \texttt{pythonapi} is a predefined symbol giving access to the Python C api:

\begin{verbatim}
>>> opt_flag = c_int.in_dll(pythonapi, "Py\_OptimizeFlag")
>>> print(opt_flag)
0

If the interpreter would have been started with \texttt{-O}, the sample would have printed \texttt{c\_long(1)}, or \texttt{c\_long(2)} if \texttt{-OO} would have been specified.

An extended example which also demonstrates the use of pointers accesses the \texttt{PyImport\_FrozenModules} pointer exported by Python.

Quoting the docs for that value:

This pointer is initialized to point to an array of struct \_frozen records, terminated by one whose members are all \texttt{NULL} or zero. When a frozen module is imported, it is searched in this table.
Third-party code could play tricks with this to provide a dynamically created collection of frozen modules.

So manipulating this pointer could even prove useful. To restrict the example size, we show only how this table can be read with *ctypes*:

```python
>>> from ctypes import *
>>> class struct_frozen(Structure):
...     _fields_ = [('name', c_char_p),
...                 ('code', POINTER(c_ubyte)),
...                 ('size', c_int)]
```

We have defined the `struct_frozen` data type, so we can get the pointer to the table:

```python
>>> FrozenTable = POINTER(struct_frozen)
>>> table = FrozenTable.in_dll(pythonapi, "PyImport_FrozenModules")
```

Since `table` is a pointer to the array of `struct_frozen` records, we can iterate over it, but we just have to make sure that our loop terminates, because pointers have no size. Sooner or later it would probably crash with an access violation or whatever, so it's better to break out of the loop when we hit the NULL entry:

```python
>>> for item in table:
...     print(item.name, item.size)
...     if item.name is None:
...         break
...__hello__ 104
The fact that standard Python has a frozen module and a frozen package (indicated by the negative size member) is not well known, it is only used for testing. Try it out with import __hello__ for example.

16.17.1.19. Surprises

There are some edges in ctypes where you might expect something other than what actually happens.

Consider the following example:

```python
cpython
>>> from ctypes import *
>>> class POINT(Structure):
...     _fields_ = ("x", c_int), ("y", c_int)
...
>>> class RECT(Structure):
...     _fields_ = ("a", POINT), ("b", POINT)
...
>>> p1 = POINT(1, 2)
>>> p2 = POINT(3, 4)
>>> rc = RECT(p1, p2)
>>> print(rc.a.x, rc.a.y, rc.b.x, rc.b.y)
1 2 3 4
>>> # now swap the two points
>>> rc.a, rc.b = rc.b, rc.a
>>> print(rc.a.x, rc.a.y, rc.b.x, rc.b.y)
3 4 3 4
>>>```
Hm. We certainly expected the last statement to print 3 4 1 2. What happened? Here are the steps of the \texttt{rc.a, rc.b = rc.b, rc.a} line above:

\begin{verbatim}
>>> temp0, temp1 = rc.b, rc.a
>>> rc.a = temp0
>>> rc.b = temp1
\end{verbatim}

Note that \texttt{temp0} and \texttt{temp1} are objects still using the internal buffer of the \texttt{rc} object above. So executing \texttt{rc.a = temp0} copies the buffer contents of \texttt{temp0} into \texttt{rc} 's buffer. This, in turn, changes the contents of \texttt{temp1}. So, the last assignment \texttt{rc.b = temp1}, doesn't have the expected effect.

Keep in mind that retrieving sub-objects from Structure, Unions, and Arrays doesn't \texttt{copy} the sub-object, instead it retrieves a wrapper object accessing the root-object's underlying buffer.

Another example that may behave different from what one would expect is this:

\begin{verbatim}
>>> s = c_char_p()
>>> s.value = "abc def ghi"
>>> s.value
'abc def ghi'
>>> s.value is s.value
False
\end{verbatim}

Why is it printing \texttt{False}? ctypes instances are objects containing a memory block plus some \texttt{descriptors} accessing the contents of the memory. Storing a Python object in the memory block does not store the object itself, instead the \texttt{contents} of the object is stored.
Accessing the contents again constructs a new Python object each time!

16.17.1.20. Variable-sized data types

cypes provides some support for variable-sized arrays and structures.

The resize() function can be used to resize the memory buffer of an existing ctypes object. The function takes the object as first argument, and the requested size in bytes as the second argument. The memory block cannot be made smaller than the natural memory block specified by the objects type, a ValueError is raised if this is tried:

```python
>>> short_array = (c_short * 4)()
>>> print(sizeof(short_array))
8
>>> resize(short_array, 4)
Traceback (most recent call last):
  ... ValueError: minimum size is 8
>>> resize(short_array, 32)
>>> sizeof(short_array)
32
>>> sizeof(type(short_array))
8
```

This is nice and fine, but how would one access the additional elements contained in this array? Since the type still only knows about 4 elements, we get errors accessing other elements:

```python
>>> short_array[:]
```
Another way to use variable-sized data types with `ctypes` is to use the dynamic nature of Python, and (re-)define the data type after the required size is already known, on a case by case basis.
16.17.2. ctypes reference

16.17.2.1. Finding shared libraries

When programming in a compiled language, shared libraries are accessed when compiling/linking a program, and when the program is run.

The purpose of the `find_library()` function is to locate a library in a way similar to what the compiler does (on platforms with several versions of a shared library the most recent should be loaded), while the ctypes library loaders act like when a program is run, and call the runtime loader directly.

The `ctypes.util` module provides a function which can help to determine the library to load.

`ctypes.util.find_library(name)`

Try to find a library and return a pathname. `name` is the library name without any prefix like `lib`, suffix like `.so`, `.dylib` or version number (this is the form used for the posix linker option `-l`). If no library can be found, returns None.

The exact functionality is system dependent.

On Linux, `find_library()` tries to run external programs (`/sbin/ldconfig`, `gcc`, and `objdump`) to find the library file. It returns the filename of the library file. Here are some examples:

```python
>>> from ctypes.util import find_library
>>> find_library("m")
'libm.so.6'
>>> find_library("c")
```
On OS X, `find_library()` tries several predefined naming schemes and paths to locate the library, and returns a full pathname if successful:

```python
>>> from ctypes.util import find_library
>>> find_library("c")
'/usr/lib/libc.dylib'
>>> find_library("m")
'/usr/lib/libm.dylib'
>>> find_library("bz2")
'/usr/lib/libbz2.dylib'
>>> find_library("AGL")
'/System/Library/Frameworks/AGL.framework/AGL'

```

On Windows, `find_library()` searches along the system search path, and returns the full pathname, but since there is no predefined naming scheme a call like `find_library("c")` will fail and return `None`

If wrapping a shared library with `ctypes`, it may be better to determine the shared library name at development time, and hardcode that into the wrapper module instead of using `find_library()` to locate the library at runtime.

### 16.17.2.2. Loading shared libraries

There are several ways to loaded shared libraries into the Python process. One way is to instantiate one of the following classes:
**class ctypes.CDLL**(name, mode=DEFAULT_MODE, handle=None, use_errno=False, use_last_error=False)

Instances of this class represent loaded shared libraries. Functions in these libraries use the standard C calling convention, and are assumed to return int.

**class ctypes.OleDLL**(name, mode=DEFAULT_MODE, handle=None, use_errno=False, use_last_error=False)

Windows only: Instances of this class represent loaded shared libraries, functions in these libraries use the stdcall calling convention, and are assumed to return the windows specific HRESULT code. HRESULT values contain information specifying whether the function call failed or succeeded, together with additional error code. If the return value signals a failure, an OSError is automatically raised.

*Changed in version 3.3: WindowsError used to be raised.*

**class ctypes.WinDLL**(name, mode=DEFAULT_MODE, handle=None, use_errno=False, use_last_error=False)

Windows only: Instances of this class represent loaded shared libraries, functions in these libraries use the stdcall calling convention, and are assumed to return int by default.

On Windows CE only the standard calling convention is used, for convenience the WinDLL and OleDLL use the standard calling convention on this platform.

The Python `global interpreter lock` is released before calling any function exported by these libraries, and reacquired afterwards.

**class ctypes.PyDLL**(name, mode=DEFAULT_MODE,
Instances of this class behave like CDLL instances, except that the Python GIL is *not* released during the function call, and after the function execution the Python error flag is checked. If the error flag is set, a Python exception is raised.

Thus, this is only useful to call Python C api functions directly.

All these classes can be instantiated by calling them with at least one argument, the pathname of the shared library. If you have an existing handle to an already loaded shared library, it can be passed as the `handle` named parameter, otherwise the underlying platforms `dlopen` or `LoadLibrary` function is used to load the library into the process, and to get a handle to it.

The `mode` parameter can be used to specify how the library is loaded. For details, consult the `dlopen(3)` manpage, on Windows, `mode` is ignored.

The `use_errno` parameter, when set to True, enables a ctypes mechanism that allows to access the system `errno` error number in a safe way. ctypes maintains a thread-local copy of the systems `errno` variable; if you call foreign functions created with `use_errno=True` then the `errno` value before the function call is swapped with the ctypes private copy, the same happens immediately after the function call.

The function `ctypes.get_errno()` returns the value of the ctypes private copy, and the function `ctypes.set_errno()` changes the ctypes private copy to a new value and returns the former value.

The `use_last_error` parameter, when set to True, enables the same mechanism for the Windows error code which is managed by the

```python
handle=None)
```
GetLastError() and SetLastError() Windows API functions; ctypes.get_last_error() and ctypes.set_last_error() are used to request and change the ctypes private copy of the windows error code.

ctypes.RTLD_GLOBAL
Flag to use as mode parameter. On platforms where this flag is not available, it is defined as the integer zero.

ctypes.RTLD_LOCAL
Flag to use as mode parameter. On platforms where this is not available, it is the same as RTLD_GLOBAL.

ctypes.DEFAULT_MODE
The default mode which is used to load shared libraries. On OSX 10.3, this is RTLD_GLOBAL, otherwise it is the same as RTLD_LOCAL.

Instances of these classes have no public methods, however __getattr__() and __getitem__() have special behavior: functions exported by the shared library can be accessed as attributes of by index. Please note that both __getattr__() and __getitem__() cache their result, so calling them repeatedly returns the same object each time.

The following public attributes are available, their name starts with an underscore to not clash with exported function names:

PyDLL._handle
The system handle used to access the library.

PyDLL._name
The name of the library passed in the constructor.
Shared libraries can also be loaded by using one of the prefabricated objects, which are instances of the `LibraryLoader` class, either by calling the `LoadLibrary()` method, or by retrieving the library as attribute of the loader instance.

```python
class ctypes.LibraryLoader(dlltype):
    Class which loads shared libraries. `dlltype` should be one of the CDLL, PyDLL, WinDLL, or OleDLL types.

    __getattr__() has special behavior: It allows to load a shared library by accessing it as attribute of a library loader instance. The result is cached, so repeated attribute accesses return the same library each time.

    LoadLibrary(name)
    Load a shared library into the process and return it. This method always returns a new instance of the library.
```

These prefabricated library loaders are available:

```python
c types.cdll
    Creates CDLL instances.

c types.windll
    Windows only: Creates WinDLL instances.

c types.oledll
    Windows only: Creates OleDLL instances.

c types.pydll
    Creates PyDLL instances.
```

For accessing the C Python api directly, a ready-to-use Python shared
library object is available:

```python
ctypes.pythonapi
```

An instance of `PyDLL` that exposes Python C API functions as attributes. Note that all these functions are assumed to return C `int`, which is of course not always the truth, so you have to assign the correct `restype` attribute to use these functions.

### 16.17.2.3. Foreign functions

As explained in the previous section, foreign functions can be accessed as attributes of loaded shared libraries. The function objects created in this way by default accept any number of arguments, accept any `ctypes` data instances as arguments, and return the default result type specified by the library loader. They are instances of a private class:

```python
class ctypes._FuncPtr
```

Base class for C callable foreign functions.

Instances of foreign functions are also C compatible data types; they represent C function pointers.

This behavior can be customized by assigning to special attributes of the foreign function object.

```python
restype
```

Assign a `ctypes` type to specify the result type of the foreign function. Use `None` for `void`, a function not returning anything.

It is possible to assign a callable Python object that is not a `ctypes` type, in this case the function is assumed to return a C `int`, and the callable will be called with this integer, allowing to
do further processing or error checking. Using this is deprecated, for more flexible post processing or error checking use a ctypes data type as `restype` and assign a callable to the `errcheck` attribute.

**argtypes**

Assign a tuple of ctypes types to specify the argument types that the function accepts. Functions using the `stdcall` calling convention can only be called with the same number of arguments as the length of this tuple; functions using the C calling convention accept additional, unspecified arguments as well.

When a foreign function is called, each actual argument is passed to the `from_param()` class method of the items in the `argtypes` tuple, this method allows to adapt the actual argument to an object that the foreign function accepts. For example, a `c_char_p` item in the `argtypes` tuple will convert a string passed as argument into a bytes object using ctypes conversion rules.

New: It is now possible to put items in argtypes which are not ctypes types, but each item must have a `from_param()` method which returns a value usable as argument (integer, string, ctypes instance). This allows to define adapters that can adapt custom objects as function parameters.

**errcheck**

Assign a Python function or another callable to this attribute. The callable will be called with three or more arguments:

```
callable(result, func, arguments)
```
result is what the foreign function returns, as specified by the restype attribute.

func is the foreign function object itself, this allows to reuse the same callable object to check or post process the results of several functions.

arguments is a tuple containing the parameters originally passed to the function call, this allows to specialize the behavior on the arguments used.

The object that this function returns will be returned from the foreign function call, but it can also check the result value and raise an exception if the foreign function call failed.

exception ctypes.ArgumentError
This exception is raised when a foreign function call cannot convert one of the passed arguments.

16.17.2.4. Function prototypes

Foreign functions can also be created by instantiating function prototypes. Function prototypes are similar to function prototypes in C; they describe a function (return type, argument types, calling convention) without defining an implementation. The factory functions must be called with the desired result type and the argument types of the function.

ctypes.CFUNCTYPE(restype, *argtypes, use_errno=False, use_last_error=False)
The returned function prototype creates functions that use the standard C calling convention. The function will release the GIL during the call. If use_errno is set to True, the ctypes private copy
of the system \texttt{errno} variable is exchanged with the real \texttt{errno} value before and after the call; \texttt{use\_last\_error} does the same for the Windows error code.

\texttt{ctypes.WINFUNCTYPE}(\texttt{restype, *argtypes, use\_errno=False, use\_last\_error=False})

Windows only: The returned function prototype creates functions that use the \texttt{stdcall} calling convention, except on Windows CE where \texttt{WINFUNCTYPE()} is the same as \texttt{CFUNCTYPE()}(). The function will release the GIL during the call. \texttt{use\_errno} and \texttt{use\_last\_error} have the same meaning as above.

\texttt{ctypes.PYFUNCTYPE}(\texttt{restype, *argtypes})

The returned function prototype creates functions that use the Python calling convention. The function will \textit{not} release the GIL during the call.

Function prototypes created by these factory functions can be instantiated in different ways, depending on the type and number of the parameters in the call:

\begin{itemize}
  \item \texttt{prototype}(\texttt{address})
    \begin{itemize}
      \item Returns a foreign function at the specified address which must be an integer.
    \end{itemize}
  \item \texttt{prototype}(\texttt{callable})
    \begin{itemize}
      \item Create a C callable function (a callback function) from a Python \texttt{callable}.
    \end{itemize}
  \item \texttt{prototype}(\texttt{func\_spec[, paramflags]})
    \begin{itemize}
      \item Returns a foreign function exported by a shared library. \texttt{func\_spec} must be a 2-tuple \texttt{(name\_or\_ordinal,}
    \end{itemize}
\end{itemize}
The first item is the name of the exported function as string, or the ordinal of the exported function as small integer. The second item is the shared library instance.

`prototype(vtbl_index, name[, paramflags[, iid]])`

Returns a foreign function that will call a COM method. `vtbl_index` is the index into the virtual function table, a small non-negative integer. `name` is name of the COM method. `iid` is an optional pointer to the interface identifier which is used in extended error reporting.

COM methods use a special calling convention: They require a pointer to the COM interface as first argument, in addition to those parameters that are specified in the `argtypes` tuple.

The optional `paramflags` parameter creates foreign function wrappers with much more functionality than the features described above.

`paramflags` must be a tuple of the same length as `argtypes`.

Each item in this tuple contains further information about a parameter, it must be a tuple containing one, two, or three items.

The first item is an integer containing a combination of direction flags for the parameter:

1
   Specifies an input parameter to the function.
2
   Output parameter. The foreign function fills in a value.
4
   Input parameter which defaults to the integer zero.
The optional second item is the parameter name as string. If this is specified, the foreign function can be called with named parameters.

The optional third item is the default value for this parameter.

This example demonstrates how to wrap the Windows MessageBoxA function so that it supports default parameters and named arguments. The C declaration from the windows header file is this:

```c
WINUSERAPI int WINAPI MessageBoxA(
    HWND hWnd, 
    LPCSTR lpText, 
    LPCSTR lpCaption, 
    UINT uType);
```

Here is the wrapping with `ctypes`:

```python
from ctypes import c_int, WINFUNCTYPE, windll
from ctypes.wintypes import HWND, LPCSTR, UINT
prototype = WINFUNCTYPE(c_int, HWND, LPCSTR, LPCSTR, UINT)
paramflags = (1, "hwnd", 0), (1, "text", "Hi"),
MessageBox = prototype("
```

The MessageBox foreign function can now be called in these ways:

```python
>>> MessageBox()
>>> MessageBox(text="Spam, spam, spam")
>>> MessageBox(flags=2, text="foo bar")
```

A second example demonstrates output parameters. The win32
GetWindowRect function retrieves the dimensions of a specified window by copying them into RECT structure that the caller has to supply. Here is the C declaration:

```c
WINUSERAPI BOOL WINAPI GetWindowRect( HWND hWnd, LPRECT lpRect);
```

Here is the wrapping with `ctypes`:

```python
>>> from ctypes import POINTER, WINFUNCTYPE, windll, 
>>> from ctypes.wintypes import BOOL, HWND, RECT 
>>> prototype = WINFUNCTYPE(BOOL, HWND, POINTER(RECT)) 
>>> paramflags = (1, "hwnd"), (2, "lprect") 
>>> GetWindowRect = prototype("GetWindowRect", windll).
```

Functions with output parameters will automatically return the output parameter value if there is a single one, or a tuple containing the output parameter values when there are more than one, so the GetWindowRect function now returns a RECT instance, when called.

Output parameters can be combined with the `errcheck` protocol to do further output processing and error checking. The win32 GetWindowRect api function returns a BOOL to signal success or failure, so this function could do the error checking, and raises an exception when the api call failed:

```python
>>> def errcheck(result, func, args):
...     if not result:
...         raise WinError()
...     return args
...```
If the errcheck function returns the argument tuple it receives unchanged, `ctypes` continues the normal processing it does on the output parameters. If you want to return a tuple of window coordinates instead of a `RECT` instance, you can retrieve the fields in the function and return them instead, the normal processing will no longer take place:

```python
>>> def errcheck(result, func, args):
...     if not result:
...         raise WinError()
...     rc = args[1]
...     return rc.left, rc.top, rc.bottom, rc.right

>>> GetWindowRect.errcheck = errcheck
```

16.17.2.5. Utility functions

`ctypes.addressof(obj)`

Returns the address of the memory buffer as integer. `obj` must be an instance of a ctypes type.

`ctypes.alignment(obj_or_type)`

Returns the alignment requirements of a ctypes type. `obj_or_type` must be a ctypes type or instance.

`ctypes.byref(obj[, offset])`

Returns a light-weight pointer to `obj`, which must be an instance of a ctypes type. `offset` defaults to zero, and must be an integer that will be added to the internal pointer value.
byref(obj, offset) corresponds to this C code:

```c
(((char *)&obj) + offset)
```

The returned object can only be used as a foreign function call parameter. It behaves similar to pointer(obj), but the construction is a lot faster.

**ctypes.cast(obj, type)**

This function is similar to the cast operator in C. It returns a new instance of type which points to the same memory block as obj. type must be a pointer type, and obj must be an object that can be interpreted as a pointer.

**ctypes.create_string_buffer(init_or_size, size=None)**

This function creates a mutable character buffer. The returned object is a ctypes array of c_char.

init_or_size must be an integer which specifies the size of the array, or a bytes object which will be used to initialize the array items.

If a bytes object is specified as first argument, the buffer is made one item larger than its length so that the last element in the array is a NUL termination character. An integer can be passed as second argument which allows to specify the size of the array if the length of the bytes should not be used.

**ctypes.create_unicode_buffer(init_or_size, size=None)**

This function creates a mutable unicode character buffer. The returned object is a ctypes array of c_wchar.

init_or_size must be an integer which specifies the size of the
array, or a string which will be used to initialize the array items.

If a string is specified as first argument, the buffer is made one item larger than the length of the string so that the last element in the array is a NUL termination character. An integer can be passed as second argument which allows to specify the size of the array if the length of the string should not be used.

ctypes.\texttt{DllCanUnloadNow}()
Windows only: This function is a hook which allows to implement in-process COM servers with ctypes. It is called from the DllCanUnloadNow function that the _ctypes extension dll exports.

ctypes.\texttt{DllGetClassObject}()
Windows only: This function is a hook which allows to implement in-process COM servers with ctypes. It is called from the DllGetClassObject function that the _ctypes extension dll exports.

ctypes.util.\texttt{find_library}(\textit{name})
Try to find a library and return a pathname. \textit{name} is the library name without any prefix like \texttt{lib}, suffix like \texttt{.so}, \texttt{.dylib} or version number (this is the form used for the posix linker option -l). If no library can be found, returns None.

The exact functionality is system dependent.

ctypes.util.\texttt{find_msvcr}()
Windows only: return the filename of the VC runtype library used by Python, and by the extension modules. If the name of the library cannot be determined, None is returned.

If you need to free memory, for example, allocated by an extension module with a call to the \texttt{free(void *)}, it is important that you
use the function in the same library that allocated the memory.

cetypes.\texttt{FormatError([code])}

Windows only: Returns a textual description of the error code \texttt{code}. If no error code is specified, the last error code is used by calling the Windows api function GetLastError.

cetypes.\texttt{GetLastError()}

Windows only: Returns the last error code set by Windows in the calling thread. This function calls the Windows \texttt{GetLastError()} function directly, it does not return the ctypes-private copy of the error code.

cetypes.\texttt{get_errno()}

Returns the current value of the ctypes-private copy of the system \texttt{errno} variable in the calling thread.

cetypes.\texttt{get_last_error()}

Windows only: returns the current value of the ctypes-private copy of the system \texttt{LastErrorCode} variable in the calling thread.

cetypes.\texttt{memmove(dst, src, count)}

Same as the standard C \texttt{memmove} library function: copies \texttt{count} bytes from \texttt{src} to \texttt{dst}. \texttt{dst} and \texttt{src} must be integers or ctypes instances that can be converted to pointers.

cetypes.\texttt{memset(dst, c, count)}

Same as the standard C \texttt{memset} library function: fills the memory block at address \texttt{dst} with \texttt{count} bytes of value \texttt{c}. \texttt{dst} must be an integer specifying an address, or a ctypes instance.

cetypes.\texttt{POINTER(type)}
This factory function creates and returns a new ctypes pointer type. Pointer types are cached and reused internally, so calling this function repeatedly is cheap. `type` must be a ctypes type.

```python
ctypes.pointer(obj)
```

This function creates a new pointer instance, pointing to `obj`. The returned object is of the type `POINTER(type(obj))`.

Note: If you just want to pass a pointer to an object to a foreign function call, you should use `byref(obj)` which is much faster.

```python
ctypes.resize(obj, size)
```

This function resizes the internal memory buffer of `obj`, which must be an instance of a ctypes type. It is not possible to make the buffer smaller than the native size of the objects type, as given by `sizeof(type(obj))`, but it is possible to enlarge the buffer.

```python
ctypes.set_errno(value)
```

Set the current value of the ctypes-private copy of the system `errno` variable in the calling thread to `value` and return the previous value.

```python
ctypes.set_last_error(value)
```

Windows only: set the current value of the ctypes-private copy of the system `LastError` variable in the calling thread to `value` and return the previous value.

```python
ctypes.sizeof(obj_or_type)
```

Returns the size in bytes of a ctypes type or instance memory buffer. Does the same as the C `sizeof` operator.

```python
ctypes.string_at(address, size=-1)
```
This function returns the C string starting at memory address `address` as a bytes object. If size is specified, it is used as size, otherwise the string is assumed to be zero-terminated.

```python
ctypes.WinError(code=None, descr=None)
```

Windows only: this function is probably the worst-named thing in ctypes. It creates an instance of OSError. If `code` is not specified, `GetLastError` is called to determine the error code. If `descr` is not specified, `FormatError()` is called to get a textual description of the error.

*Changed in version 3.3:* An instance of `WindowsError` used to be created.

```python
ctypes.wstring_at(address, size=-1)
```

This function returns the wide character string starting at memory address `address` as a string. If `size` is specified, it is used as the number of characters of the string, otherwise the string is assumed to be zero-terminated.

### 16.17.2.6. Data types

```python
class ctypes._CData
```

This non-public class is the common base class of all ctypes data types. Among other things, all ctypes type instances contain a memory block that hold C compatible data; the address of the memory block is returned by the `addressof()` helper function. Another instance variable is exposed as `_objects`; this contains other Python objects that need to be kept alive in case the memory block contains pointers.

Common methods of ctypes data types, these are all class
methods (to be exact, they are methods of the \texttt{metaclass}):

\texttt{from\_buffer}(source[,\ offset])

This method returns a ctypes instance that shares the buffer of the \texttt{source} object. The \texttt{source} object must support the writeable buffer interface. The optional \texttt{offset} parameter specifies an offset into the source buffer in bytes; the default is zero. If the source buffer is not large enough a \texttt{ValueError} is raised.

\texttt{from\_buffer\_copy}(source[,\ offset])

This method creates a ctypes instance, copying the buffer from the \texttt{source} object buffer which must be readable. The optional \texttt{offset} parameter specifies an offset into the source buffer in bytes; the default is zero. If the source buffer is not large enough a \texttt{ValueError} is raised.

\texttt{from\_address}(address)

This method returns a ctypes type instance using the memory specified by \texttt{address} which must be an integer.

\texttt{from\_param}(obj)

This method adapts \texttt{obj} to a ctypes type. It is called with the actual object used in a foreign function call when the type is present in the foreign function’s \texttt{argtypes} tuple; it must return an object that can be used as a function call parameter.

All ctypes data types have a default implementation of this classmethod that normally returns \texttt{obj} if that is an instance of the type. Some types accept other objects as well.

\texttt{in\_dll}(library, name)

This method returns a ctypes type instance exported by a
shared library. *name* is the name of the symbol that exports the data, *library* is the loaded shared library.

Common instance variables of ctypes data types:

```
_b_base_
```

Sometimes ctypes data instances do not own the memory block they contain, instead they share part of the memory block of a base object. The *b_base* read-only member is the root ctypes object that owns the memory block.

```
_b_needsfree_
```

This read-only variable is true when the ctypes data instance has allocated the memory block itself, false otherwise.

```
_objects
```

This member is either None or a dictionary containing Python objects that need to be kept alive so that the memory block contents is kept valid. This object is only exposed for debugging; never modify the contents of this dictionary.

16.17.2.7. Fundamental data types

```
class ctypes._SimpleCData
```

This non-public class is the base class of all fundamental ctypes data types. It is mentioned here because it contains the common attributes of the fundamental ctypes data types. *SimpleCData* is a subclass of *CData*, so it inherits their methods and attributes. ctypes data types that are not and do not contain pointers can now be pickled.

Instances have a single attribute:
value

This attribute contains the actual value of the instance. For integer and pointer types, it is an integer, for character types, it is a single character bytes object or string, for character pointer types it is a Python bytes object or string.

When the value attribute is retrieved from a ctypes instance, usually a new object is returned each time. ctypes does not implement original object return, always a new object is constructed. The same is true for all other ctypes object instances.

Fundamental data types, when returned as foreign function call results, or, for example, by retrieving structure field members or array items, are transparently converted to native Python types. In other words, if a foreign function has a restype of c_char_p, you will always receive a Python bytes object, not a c_char_p instance.

Subclasses of fundamental data types do not inherit this behavior. So, if a foreign functions restype is a subclass of c_void_p, you will receive an instance of this subclass from the function call. Of course, you can get the value of the pointer by accessing the value attribute.

These are the fundamental ctypes data types:

class ctypes.c_byte

Represents the C signed char datatype, and interprets the value as small integer. The constructor accepts an optional integer initializer; no overflow checking is done.

class ctypes.c_char

Represents the C char datatype, and interprets the value as a single character. The constructor accepts an optional string
initializer, the length of the string must be exactly one character.

class ctypes.\texttt{c\_char\_p}
Represents the C char * datatype when it points to a zero-terminated string. For a general character pointer that may also point to binary data, \texttt{POINTER(c\_char)} must be used. The constructor accepts an integer address, or a bytes object.

class ctypes.\texttt{c\_double}
Represents the C double datatype. The constructor accepts an optional float initializer.

class ctypes.\texttt{c\_longdouble}
Represents the C long double datatype. The constructor accepts an optional float initializer. On platforms where \texttt{sizeof(long\ double) == sizeof(double)} it is an alias to \texttt{c\_double}.

class ctypes.\texttt{c\_float}
Represents the C float datatype. The constructor accepts an optional float initializer.

class ctypes.\texttt{c\_int}
Represents the C signed int datatype. The constructor accepts an optional integer initializer; no overflow checking is done. On platforms where \texttt{sizeof(int) == sizeof(long)} it is an alias to \texttt{c\_long}.

class ctypes.\texttt{c\_int8}
Represents the C 8-bit signed int datatype. Usually an alias for \texttt{c\_byte}.
class ctypes.c_int16
    Represents the C 16-bit signed int datatype. Usually an alias for c_short.

class ctypes.c_int32
    Represents the C 32-bit signed int datatype. Usually an alias for c_int.

class ctypes.c_int64
    Represents the C 64-bit signed int datatype. Usually an alias for c_longlong.

class ctypes.c_long
    Represents the C signed long datatype. The constructor accepts an optional integer initializer; no overflow checking is done.

class ctypes.c_longlong
    Represents the C signed long long datatype. The constructor accepts an optional integer initializer; no overflow checking is done.

class ctypes.c_short
    Represents the C signed short datatype. The constructor accepts an optional integer initializer; no overflow checking is done.

class ctypes.c_size_t
    Represents the C size_t datatype.

class ctypes.c_ssize_t
    Represents the C ssize_t datatype.

    New in version 3.2.

class ctypes.c_ubyte
 Represents the C unsigned char datatype, it interprets the value as small integer. The constructor accepts an optional integer initializer; no overflow checking is done.

class ctypes.c_uint
 Represents the C unsigned int datatype. The constructor accepts an optional integer initializer; no overflow checking is done. On platforms where sizeof(int) == sizeof(long) it is an alias for c_ulong.

class ctypes.c_uint8
 Represents the C 8-bit unsigned int datatype. Usually an alias for c_ubyte.

class ctypes.c_uint16
 Represents the C 16-bit unsigned int datatype. Usually an alias for c_ushort.

class ctypes.c_uint32
 Represents the C 32-bit unsigned int datatype. Usually an alias for c_uint.

class ctypes.c_uint64
 Represents the C 64-bit unsigned int datatype. Usually an alias for c_ulonglong.

class ctypes.c_ulong
 Represents the C unsigned long datatype. The constructor accepts an optional integer initializer; no overflow checking is done.

class ctypes.c_ulonglong
 Represents the C unsigned long long datatype. The
constructor accepts an optional integer initializer; no overflow checking is done.

class ctypes.c_ushort
Represents the C unsigned short datatype. The constructor accepts an optional integer initializer; no overflow checking is done.

class ctypes.c_void_p
Represents the C void * type. The value is represented as integer. The constructor accepts an optional integer initializer.

class ctypes.c_wchar
Represents the C wchar_t datatype, and interprets the value as a single character unicode string. The constructor accepts an optional string initializer, the length of the string must be exactly one character.

class ctypes.c_wchar_p
Represents the C wchar_t * datatype, which must be a pointer to a zero-terminated wide character string. The constructor accepts an integer address, or a string.

class ctypes.c_bool
Represent the C bool datatype (more accurately, _Bool from C99). Its value can be True or False, and the constructor accepts any object that has a truth value.

class ctypes.HRESULT
Windows only: Represents a HRESULT value, which contains success or error information for a function or method call.

class ctypes.py_object
Represents the C PyObject * datatype. Calling this without an
argument creates a NULL PyObject * pointer.

The ctypes.wintypes module provides quite some other Windows specific data types, for example HWND, WPARAM, or DWORD. Some useful structures like MSG or RECT are also defined.

### 16.17.2.8. Structured data types

```python
class ctypes.Union(*args, **kw)
    Abstract base class for unions in native byte order.

class ctypes.BigEndianStructure(*args, **kw)
    Abstract base class for structures in big endian byte order.

class ctypes.LittleEndianStructure(*args, **kw)
    Abstract base class for structures in little endian byte order.
```

Structures with non-native byte order cannot contain pointer type fields, or any other data types containing pointer type fields.

```python
class ctypes.Structure(*args, **kw)
    Abstract base class for structures in native byte order.
```

Concrete structure and union types must be created by subclassing one of these types, and at least define a `_fields_` class variable. ctypes will create descriptors which allow reading and writing the fields by direct attribute accesses. These are the `_fields_`:

A sequence defining the structure fields. The items must be 2-tuples or 3-tuples. The first item is the name of the field, the second item specifies the type of the field; it can be any ctypes
data type.

For integer type fields like `c_int`, a third optional item can be given. It must be a small positive integer defining the bit width of the field.

Field names must be unique within one structure or union. This is not checked, only one field can be accessed when names are repeated.

It is possible to define the `_fields_` class variable after the class statement that defines the Structure subclass, this allows to create data types that directly or indirectly reference themselves:

```python
class List(Structure):
    pass
List._fields_ = ["pnext", POINTER(List),
                 ...
]
```

The `_fields_` class variable must, however, be defined before the type is first used (an instance is created, `sizeof()` is called on it, and so on). Later assignments to the `_fields_` class variable will raise an AttributeError.

Structure and union subclass constructors accept both positional and named arguments. Positional arguments are used to initialize the fields in the same order as they appear in the `_fields_` definition, named arguments are used to initialize the fields with the corresponding name.

It is possible to defined sub-subclasses of structure types, they
inherit the fields of the base class plus the _fields_ defined in the sub-subclass, if any.

_pack_
An optional small integer that allows to override the alignment of structure fields in the instance. _pack_ must already be defined when _fields_ is assigned, otherwise it will have no effect.

_anonymous_
An optional sequence that lists the names of unnamed (anonymous) fields. _anonymous_ must be already defined when _fields_ is assigned, otherwise it will have no effect.

The fields listed in this variable must be structure or union type fields. ctypes will create descriptors in the structure type that allows to access the nested fields directly, without the need to create the structure or union field.

Here is an example type (Windows):

```python
class _U(Union):
    _fields_ = [(
        "lptdesc", POINTER(TYPEDESC)),
        ("lpadesc", POINTER(ARRAYDESC)),
        ("hreftype", HREFTYPE)]

class TYPEDESC(Structure):
    _anonymous_ = ("u",)
    _fields_ = [(
        "u", _U),
        ("vt", VARTYPE)]
```

The TYPEDESC structure describes a COM data type, the vt field specifies which one of the union fields is valid. Since the u
field is defined as anonymous field, it is now possible to access
the members directly off the TYPEDESC instance. `td.lptdesc` and `td.u.lptdesc` are equivalent, but the
former is faster since it does not need to create a temporary
union instance:

```python
td = TYPEDESC()
td.vt = VT_PTR
td.lptdesc = POINTER(some_type)
td.u.lptdesc = POINTER(some_type)
```

It is possible to defined sub-subclasses of structures, they inherit
the fields of the base class. If the subclass definition has a
separate `_fields_` variable, the fields specified in this are
appended to the fields of the base class.

Structure and union constructors accept both positional and
keyword arguments. Positional arguments are used to initialize
member fields in the same order as they are appear in `_fields_`.  
Keyword arguments in the constructor are interpreted as attribute
assignments, so they will initialize `_fields_` with the same name,
or create new attributes for names not present in `_fields_`.

### 16.17.2.9. Arrays and pointers

Not yet written - please see the sections *Pointers* and section *Arrays* in
the tutorial.
17. Concurrent Execution

The modules described in this chapter provide support for concurrent execution of code. The appropriate choice of tool will depend on the task to be executed (CPU bound vs IO bound) and preferred style of development (event driven cooperative multitasking vs preemptive multitasking). Here’s an overview:

- **17.1. threading — Thread-based parallelism**
  - 17.1.1. Thread-Local Data
  - 17.1.2. Thread Objects
  - 17.1.3. Lock Objects
  - 17.1.4. RLock Objects
  - 17.1.5. Condition Objects
  - 17.1.6. Semaphore Objects
    - 17.1.6.1. Semaphore Example
  - 17.1.7. Event Objects
  - 17.1.8. Timer Objects
  - 17.1.9. Barrier Objects
  - 17.1.10. Using locks, conditions, and semaphores in the with statement

- **17.2. multiprocessing — Process-based parallelism**
  - 17.2.1. Introduction
    - 17.2.1.1. The Process class
    - 17.2.1.2. Exchanging objects between processes
    - 17.2.1.3. Synchronization between processes
    - 17.2.1.4. Sharing state between processes
    - 17.2.1.5. Using a pool of workers
  - 17.2.2. Reference
    - 17.2.2.1. Process and exceptions
    - 17.2.2.2. Pipes and Queues
    - 17.2.2.3. Miscellaneous
- **17.2.2.4.** Connection Objects
- **17.2.2.5.** Synchronization primitives
- **17.2.2.6.** Shared ctypes Objects
  - **17.2.2.6.1.** The `multiprocessing.sharedctypes` module
- **17.2.2.7.** Managers
  - **17.2.2.7.1.** Namespace objects
  - **17.2.2.7.2.** Customized managers
  - **17.2.2.7.3.** Using a remote manager
- **17.2.2.8.** Proxy Objects
  - **17.2.2.8.1.** Cleanup
- **17.2.2.9.** Process Pools
- **17.2.2.10.** Listeners and Clients
  - **17.2.2.10.1.** Address Formats
- **17.2.2.11.** Authentication keys
- **17.2.2.12.** Logging
- **17.2.2.13.** The `multiprocessing.dummy` module
- **17.2.3.** Programming guidelines
  - **17.2.3.1.** All platforms
  - **17.2.3.2.** Windows
- **17.2.4.** Examples
- **17.3.** The `concurrent` package
- **17.4.** `concurrent.futures` — Launching parallel tasks
  - **17.4.1.** Executor Objects
  - **17.4.2.** ThreadPoolExecutor
    - **17.4.2.1.** ThreadPoolExecutor Example
  - **17.4.3.** ProcessPoolExecutor
    - **17.4.3.1.** ProcessPoolExecutor Example
  - **17.4.4.** Future Objects
  - **17.4.5.** Module Functions
  - **17.4.6.** Exception classes
- **17.5.** `subprocess` — Subprocess management
  - **17.5.1.** Using the `subprocess` Module
    - **17.5.1.1.** Frequently Used Arguments
17.5.1.2. Popen Constructor
17.5.1.3. Exceptions
17.5.1.4. Security
- 17.5.2. Popen Objects
- 17.5.3. Windows Popen Helpers
  - 17.5.3.1. Constants
- 17.5.4. Replacing Older Functions with the subprocess Module
  - 17.5.4.1. Replacing /bin/sh shell backquote
  - 17.5.4.2. Replacing shell pipeline
  - 17.5.4.3. Replacing os.system()
  - 17.5.4.4. Replacing the os.spawn family
  - 17.5.4.5. Replacing os.popen(), os.popen2(), os.popen3()
  - 17.5.4.6. Replacing functions from the popen2 module
- 17.5.5. Legacy Shell Invocation Functions
- 17.5.6. Notes
  - 17.5.6.1. Converting an argument sequence to a string on Windows
- 17.6. sched — Event scheduler
  - 17.6.1. Scheduler Objects
- 17.7. queue — A synchronized queue class
  - 17.7.1. Queue Objects
- 17.8. select — Waiting for I/O completion
  - 17.8.1. /dev/poll Polling Objects
  - 17.8.2. Edge and Level Trigger Polling (epoll) Objects
  - 17.8.3. Polling Objects
  - 17.8.4. Kqueue Objects
  - 17.8.5. Kevent Objects

The following are support modules for some of the above services:

- 17.9. dummy_threading — Drop-in replacement for the threading module
17.10. _thread — Low-level threading API
17.11. _dummy_thread — Drop-in replacement for the _thread module
17.1. **threading** — Thread-based parallelism

**Source code:** Lib/threading.py

This module constructs higher-level threading interfaces on top of the lower level `_thread` module. See also the `queue` module.

The `dummy_threading` module is provided for situations where `threading` cannot be used because `_thread` is missing.

**Note:** While they are not listed below, the camelCase names used for some methods and functions in this module in the Python 2.x series are still supported by this module.

This module defines the following functions:

```python
threading.active_count()
```

Return the number of `Thread` objects currently alive. The returned count is equal to the length of the list returned by `enumerate()`.

```python
threading.current_thread()
```

Return the current `Thread` object, corresponding to the caller’s thread of control. If the caller’s thread of control was not created through the `threading` module, a dummy thread object with limited functionality is returned.

```python
threading.get_ident()
```

Return the ‘thread identifier’ of the current thread. This is a nonzero
integer. Its value has no direct meaning; it is intended as a magic cookie to be used e.g. to index a dictionary of thread-specific data. Thread identifiers may be recycled when a thread exits and another thread is created.

*New in version 3.3.*

**threading.enumerate()**

Return a list of all `Thread` objects currently alive. The list includes daemonic threads, dummy thread objects created by `current_thread()`, and the main thread. It excludes terminated threads and threads that have not yet been started.

**threading.settrace(func)**

Set a trace function for all threads started from the `threading` module. The *func* will be passed to `sys.settrace()` for each thread, before its `run()` method is called.

**threading.setprofile(func)**

Set a profile function for all threads started from the `threading` module. The *func* will be passed to `sys.setprofile()` for each thread, before its `run()` method is called.

**threading.stack_size([size])**

Return the thread stack size used when creating new threads. The optional *size* argument specifies the stack size to be used for subsequently created threads, and must be 0 (use platform or configured default) or a positive integer value of at least 32,768 (32 KiB). If changing the thread stack size is unsupported, a `RuntimeError` is raised. If the specified stack size is invalid, a `ValueError` is raised and the stack size is unmodified. 32 KiB is currently the minimum supported stack size value to guarantee
sufficient stack space for the interpreter itself. Note that some platforms may have particular restrictions on values for the stack size, such as requiring a minimum stack size > 32 KiB or requiring allocation in multiples of the system memory page size - platform documentation should be referred to for more information (4 KiB pages are common; using multiples of 4096 for the stack size is the suggested approach in the absence of more specific information).

Availability: Windows, systems with POSIX threads.

This module also defines the following constant:

```
threading.TIMEOUT_MAX
```

The maximum value allowed for the `timeout` parameter of blocking functions (``Lock.acquire()``, ``RLock.acquire()``, ``Condition.wait()``, etc.). Specifying a timeout greater than this value will raise an `OverflowError`.

`New in version 3.2`.

This module defines a number of classes, which are detailed in the sections below.

The design of this module is loosely based on Java's threading model. However, where Java makes locks and condition variables basic behavior of every object, they are separate objects in Python. Python's `Thread` class supports a subset of the behavior of Java's `Thread` class; currently, there are no priorities, no thread groups, and threads cannot be destroyed, stopped, suspended, resumed, or interrupted. The static methods of Java's `Thread` class, when implemented, are mapped to module-level functions.

All of the methods described below are executed atomically.
17.1.1. Thread-Local Data

Thread-local data is data whose values are thread specific. To manage thread-local data, just create an instance of `local` (or a subclass) and store attributes on it:

```python
mydata = threading.local()
mydata.x = 1
```

The instance’s values will be different for separate threads.

```class threading.Library
```

A class that represents thread-local data.

For more details and extensive examples, see the documentation string of the `_threading_local` module.
17.1.2. Thread Objects

The **Thread** class represents an activity that is run in a separate thread of control. There are two ways to specify the activity: by passing a callable object to the constructor, or by overriding the `run()` method in a subclass. No other methods (except for the constructor) should be overridden in a subclass. In other words, *only* override the `__init__() and `run()` methods of this class.

Once a thread object is created, its activity must be started by calling the thread's `start()` method. This invokes the `run()` method in a separate thread of control.

Once the thread's activity is started, the thread is considered ‘alive’. It stops being alive when its `run()` method terminates – either normally, or by raising an unhandled exception. The `is_alive()` method tests whether the thread is alive.

Other threads can call a thread's `join()` method. This blocks the calling thread until the thread whose `join()` method is called is terminated.

A thread has a name. The name can be passed to the constructor, and read or changed through the `name` attribute.

A thread can be flagged as a “daemon thread”. The significance of this flag is that the entire Python program exits when only daemon threads are left. The initial value is inherited from the creating thread. The flag can be set through the `daemon` property or the `daemon` constructor argument.

*Note:* Daemon threads are abruptly stopped at shutdown. Their
resources (such as open files, database transactions, etc.) may not be released properly. If you want your threads to stop gracefully, make them non-daemonic and use a suitable signalling mechanism such as an Event.

There is a “main thread” object; this corresponds to the initial thread of control in the Python program. It is not a daemon thread.

There is the possibility that “dummy thread objects” are created. These are thread objects corresponding to “alien threads”, which are threads of control started outside the threading module, such as directly from C code. Dummy thread objects have limited functionality; they are always considered alive and daemonic, and cannot be join()ed. They are never deleted, since it is impossible to detect the termination of alien threads.

class threading.Thread(group=None, target=None, name=None, args=(), kwarsgs={}, *, daemon=None)

    This constructor should always be called with keyword arguments. Arguments are:

    group should be None; reserved for future extension when a ThreadGroup class is implemented.

    target is the callable object to be invoked by the run() method. Defaults to None, meaning nothing is called.

    name is the thread name. By default, a unique name is constructed of the form “Thread-N” where N is a small decimal number.

    args is the argument tuple for the target invocation. Defaults to ( ).

    kwargs is a dictionary of keyword arguments for the target
invocation. Defaults to `{}`.

If not None, `daemon` explicitly sets whether the thread is daemonic. If None (the default), the daemonic property is inherited from the current thread.

If the subclass overrides the constructor, it must make sure to invoke the base class constructor (`Thread.__init__()`) before doing anything else to the thread.

*Changed in version 3.3:* Added the `daemon` argument.

**start()**

Start the thread's activity.

It must be called at most once per thread object. It arranges for the object's `run()` method to be invoked in a separate thread of control.

This method will raise a `RuntimeError` if called more than once on the same thread object.

**run()**

Method representing the thread's activity.

You may override this method in a subclass. The standard `run()` method invokes the callable object passed to the object's constructor as the `target` argument, if any, with sequential and keyword arguments taken from the `args` and `kwargs` arguments, respectively.

**join(timeout=None)**

Wait until the thread terminates. This blocks the calling thread
until the thread whose `join()` method is called terminates – either normally or through an unhandled exception –, or until the optional timeout occurs.

When the `timeout` argument is present and not None, it should be a floating point number specifying a timeout for the operation in seconds (or fractions thereof). As `join()` always returns None, you must call `is_alive()` after `join()` to decide whether a timeout happened – if the thread is still alive, the `join()` call timed out.

When the `timeout` argument is not present or None, the operation will block until the thread terminates.

A thread can be `join()`ed many times.

`join()` raises a `RuntimeError` if an attempt is made to join the current thread as that would cause a deadlock. It is also an error to `join()` a thread before it has been started and attempts to do so raise the same exception.

**name**

A string used for identification purposes only. It has no semantics. Multiple threads may be given the same name. The initial name is set by the constructor.

**getName()**
**setName()**

Old getter/setter API for `name`; use it directly as a property instead.

**ident**

The ‘thread identifier’ of this thread or None if the thread has
not been started. This is a nonzero integer. See the _thread.get_ident() function. Thread identifiers may be recycled when a thread exits and another thread is created. The identifier is available even after the thread has exited.

**is_alive()**

Return whether the thread is alive.

This method returns True just before the run() method starts until just after the run() method terminates. The module function enumerate() returns a list of all alive threads.

**daemon**

A boolean value indicating whether this thread is a daemon thread (True) or not (False). This must be set before start() is called, otherwise RuntimeError is raised. Its initial value is inherited from the creating thread; the main thread is not a daemon thread and therefore all threads created in the main thread default to daemon = False.

The entire Python program exits when no alive non-daemon threads are left.

**isDaemon()**

**setDaemon()**

Old getter/setter API for daemon; use it directly as a property instead.

**CPython implementation detail:** In CPython, due to the Global Interpreter Lock, only one thread can execute Python code at once (even though certain performance-oriented libraries might overcome this limitation). If you want your application to make better use of the
computational resources of multi-core machines, you are advised to use `multiprocessing` or `concurrent.futures.ProcessPoolExecutor`. However, threading is still an appropriate model if you want to run multiple I/O-bound tasks simultaneously.
17.1.3. Lock Objects

A primitive lock is a synchronization primitive that is not owned by a particular thread when locked. In Python, it is currently the lowest level synchronization primitive available, implemented directly by the _thread extension module.

A primitive lock is in one of two states, “locked” or “unlocked”. It is created in the unlocked state. It has two basic methods, acquire() and release(). When the state is unlocked, acquire() changes the state to locked and returns immediately. When the state is locked, acquire() blocks until a call to release() in another thread changes it to unlocked, then the acquire() call resets it to locked and returns. The release() method should only be called in the locked state; it changes the state to unlocked and returns immediately. If an attempt is made to release an unlocked lock, a RuntimeError will be raised.

Locks also support the context manager protocol.

When more than one thread is blocked in acquire() waiting for the state to turn to unlocked, only one thread proceeds when a release() call resets the state to unlocked; which one of the waiting threads proceeds is not defined, and may vary across implementations.

All methods are executed atomically.

class threading.Lock

The class implementing primitive lock objects. Once a thread has acquired a lock, subsequent attempts to acquire it block, until it is released; any thread may release it.
*Changed in version 3.3:* Changed from a factory function to a class.

**acquire**(blocking=True, timeout=-1)

Acquire a lock, blocking or non-blocking.

When invoked with the *blocking* argument set to True (the default), block until the lock is unlocked, then set it to locked and return True.

When invoked with the *blocking* argument set to False, do not block. If a call with *blocking* set to True would block, return False immediately; otherwise, set the lock to locked and return True.

When invoked with the floating-point *timeout* argument set to a positive value, block for at most the number of seconds specified by *timeout* and as long as the lock cannot be acquired. A *timeout* argument of -1 specifies an unbounded wait. It is forbidden to specify a *timeout* when *blocking* is false.

The return value is True if the lock is acquired successfully, False if not (for example if the *timeout* expired).

*Changed in version 3.2:* The *timeout* parameter is new.

*Changed in version 3.2:* Lock acquires can now be interrupted by signals on POSIX.

**release()

Release a lock. This can be called from any thread, not only the thread which has acquired the lock.
When the lock is locked, reset it to unlocked, and return. If any other threads are blocked waiting for the lock to become unlocked, allow exactly one of them to proceed.

When invoked on an unlocked lock, a `RuntimeError` is raised.

There is no return value.
17.1.4. RLock Objects

A reentrant lock is a synchronization primitive that may be acquired multiple times by the same thread. Internally, it uses the concepts of “owning thread” and “recursion level” in addition to the locked/unlocked state used by primitive locks. In the locked state, some thread owns the lock; in the unlocked state, no thread owns it.

To lock the lock, a thread calls its `acquire()` method; this returns once the thread owns the lock. To unlock the lock, a thread calls its `release()` method. `acquire()/release()` call pairs may be nested; only the final `release()` (the `release()` of the outermost pair) resets the lock to unlocked and allows another thread blocked in `acquire()` to proceed.

Reentrant locks also support the `context manager protocol`.

class threading. RLock

This class implements reentrant lock objects. A reentrant lock must be released by the thread that acquired it. Once a thread has acquired a reentrant lock, the same thread may acquire it again without blocking; the thread must release it once for each time it has acquired it.

Note that `RLock` is actually a factory function which returns an instance of the most efficient version of the concrete RLock class that is supported by the platform.

`acquire(blocking=True, timeout=-1)`

Acquire a lock, blocking or non-blocking.

When invoked without arguments: if this thread already owns
the lock, increment the recursion level by one, and return immediately. Otherwise, if another thread owns the lock, block until the lock is unlocked. Once the lock is unlocked (not owned by any thread), then grab ownership, set the recursion level to one, and return. If more than one thread is blocked waiting until the lock is unlocked, only one at a time will be able to grab ownership of the lock. There is no return value in this case.

When invoked with the blocking argument set to true, do the same thing as when called without arguments, and return true.

When invoked with the blocking argument set to false, do not block. If a call without an argument would block, return false immediately; otherwise, do the same thing as when called without arguments, and return true.

When invoked with the floating-point timeout argument set to a positive value, block for at most the number of seconds specified by timeout and as long as the lock cannot be acquired. Return true if the lock has been acquired, false if the timeout has elapsed.

*Changed in version 3.2:* The timeout parameter is new.

**release()**

Release a lock, decrementing the recursion level. If after the decrement it is zero, reset the lock to unlocked (not owned by any thread), and if any other threads are blocked waiting for the lock to become unlocked, allow exactly one of them to proceed. If after the decrement the recursion level is still nonzero, the lock remains locked and owned by the calling thread.

Only call this method when the calling thread owns the lock. A
RuntimeError is raised if this method is called when the lock is unlocked.

There is no return value.
17.1.5. Condition Objects

A condition variable is always associated with some kind of lock; this can be passed in or one will be created by default. Passing one in is useful when several condition variables must share the same lock. The lock is part of the condition object: you don’t have to track it separately.

A condition variable obeys the context manager protocol: using the with statement acquires the associated lock for the duration of the enclosed block. The acquire() and release() methods also call the corresponding methods of the associated lock.

Other methods must be called with the associated lock held. The wait() method releases the lock, and then blocks until another thread awakens it by calling notify() or notify_all(). Once awakened, wait() re-acquires the lock and returns. It is also possible to specify a timeout.

The notify() method wakes up one of the threads waiting for the condition variable, if any are waiting. The notify_all() method wakes up all threads waiting for the condition variable.

Note: the notify() and notify_all() methods don’t release the lock; this means that the thread or threads awakened will not return from their wait() call immediately, but only when the thread that called notify() or notify_all() finally relinquishes ownership of the lock.

The typical programming style using condition variables uses the lock to synchronize access to some shared state; threads that are
interested in a particular change of state call `wait()` repeatedly until they see the desired state, while threads that modify the state call `notify()` or `notify_all()` when they change the state in such a way that it could possibly be a desired state for one of the waiters. For example, the following code is a generic producer-consumer situation with unlimited buffer capacity:

```python
# Consume one item
with cv:
    while not an_item_is_available():
        cv.wait()
        get_an_available_item()

# Produce one item
with cv:
    make_an_item_available()
    cv.notify()
```

The `while` loop checking for the application’s condition is necessary because `wait()` can return after an arbitrary long time, and the condition which prompted the `notify()` call may no longer hold true. This is inherent to multi-threaded programming. The `wait_for()` method can be used to automate the condition checking, and eases the computation of timeouts:

```python
# Consume an item
with cv:
    cv.wait_for(an_item_is_available)
    get_an_available_item()
```

To choose between `notify()` and `notify_all()`, consider whether one state change can be interesting for only one or several waiting threads. E.g. in a typical producer-consumer situation, adding
one item to the buffer only needs to wake up one consumer thread.

```python
class threading.Condition(lock=None)
    This class implements condition variable objects. A condition variable allows one or more threads to wait until they are notified by another thread.

    If the lock argument is given and not None, it must be a Lock or RLock object, and it is used as the underlying lock. Otherwise, a new RLock object is created and used as the underlying lock.

    Changed in version 3.3: changed from a factory function to a class.

    acquire(*args)
        Acquire the underlying lock. This method calls the corresponding method on the underlying lock; the return value is whatever that method returns.

    release()
        Release the underlying lock. This method calls the corresponding method on the underlying lock; there is no return value.

    wait(timeout=None)
        Wait until notified or until a timeout occurs. If the calling thread has not acquired the lock when this method is called, a RuntimeError is raised.

        This method releases the underlying lock, and then blocks until it is awakened by a notify() or notify_all() call for the same condition variable in another thread, or until the optional timeout occurs. Once awakened or timed out, it re-acquires the lock and returns.
```
When the *timeout* argument is present and not `None`, it should be a floating point number specifying a timeout for the operation in seconds (or fractions thereof).

When the underlying lock is an `RLock`, it is not released using its `release()` method, since this may not actually unlock the lock when it was acquired multiple times recursively. Instead, an internal interface of the `RLock` class is used, which really unlocks it even when it has been recursively acquired several times. Another internal interface is then used to restore the recursion level when the lock is reacquired.

The return value is `True` unless a given *timeout* expired, in which case it is `False`.

*Changed in version 3.2*: Previously, the method always returned `None`.

**wait_for**(`predicate`, *timeout=None*)

Wait until a condition evaluates to `True`. *predicate* should be a callable which result will be interpreted as a boolean value. A *timeout* may be provided giving the maximum time to wait.

This utility method may call `wait()` repeatedly until the predicate is satisfied, or until a timeout occurs. The return value is the last return value of the predicate and will evaluate to `False` if the method timed out.

Ignoring the timeout feature, calling this method is roughly equivalent to writing:

```python
while not predicate():
    cv.wait()
```
Therefore, the same rules apply as with `wait()`: The lock must be held when called and is re-acquired on return. The predicate is evaluated with the lock held.

*New in version 3.2.*

**notify\((n=1)\)**

By default, wake up one thread waiting on this condition, if any. If the calling thread has not acquired the lock when this method is called, a `RuntimeError` is raised.

This method wakes up at most \(n\) of the threads waiting for the condition variable; it is a no-op if no threads are waiting.

The current implementation wakes up exactly \(n\) threads, if at least \(n\) threads are waiting. However, it's not safe to rely on this behavior. A future, optimized implementation may occasionally wake up more than \(n\) threads.

Note: an awakened thread does not actually return from its `wait()` call until it can reacquire the lock. Since `notify()` does not release the lock, its caller should.

**notify_all()**

Wake up all threads waiting on this condition. This method acts like `notify()`, but wakes up all waiting threads instead of one. If the calling thread has not acquired the lock when this method is called, a `RuntimeError` is raised.
17.1.6. Semaphore Objects

This is one of the oldest synchronization primitives in the history of computer science, invented by the early Dutch computer scientist Edsger W. Dijkstra (he used the names P() and V() instead of acquire() and release()).

A semaphore manages an internal counter which is decremented by each acquire() call and incremented by each release() call. The counter can never go below zero; when acquire() finds that it is zero, it blocks, waiting until some other thread calls release().

Semaphores also support the context manager protocol.

class threading.Semaphore(value=1)

This class implements semaphore objects. A semaphore manages a counter representing the number of release() calls minus the number of acquire() calls, plus an initial value. The acquire() method blocks if necessary until it can return without making the counter negative. If not given, value defaults to 1.

The optional argument gives the initial value for the internal counter; it defaults to 1. If the value given is less than 0, ValueError is raised.

Changed in version 3.3: changed from a factory function to a class.

acquire(blocking=True, timeout=None)

Acquire a semaphore.

When invoked without arguments: if the internal counter is larger than zero on entry, decrement it by one and return
immediately. If it is zero on entry, block, waiting until some other thread has called \texttt{release()} to make it larger than zero. This is done with proper interlocking so that if multiple \texttt{acquire()} calls are blocked, \texttt{release()} will wake exactly one of them up. The implementation may pick one at random, so the order in which blocked threads are awakened should not be relied on. Returns true (or blocks indefinitely).

When invoked with \textit{blocking} set to false, do not block. If a call without an argument would block, return false immediately; otherwise, do the same thing as when called without arguments, and return true.

When invoked with a \textit{timeout} other than None, it will block for at most \textit{timeout} seconds. If \texttt{acquire} does not complete successfully in that interval, return false. Return true otherwise.

\emph{Changed in version 3.2: The \textit{timeout} parameter is new.}

\textbf{release()}

Release a semaphore, incrementing the internal counter by one. When it was zero on entry and another thread is waiting for it to become larger than zero again, wake up that thread.

\textbf{class \texttt{threading.BoundedSemaphore}(value=1)}

Class implementing bounded semaphore objects. A bounded semaphore checks to make sure its current value doesn’t exceed its initial value. If it does, \texttt{ValueError} is raised. In most situations semaphores are used to guard resources with limited capacity. If the semaphore is released too many times it’s a sign of a bug. If not given, \textit{value} defaults to 1.

\emph{Changed in version 3.3: changed from a factory function to a class.}
17.1.6.1. **Semaphore** Example

Semaphores are often used to guard resources with limited capacity, for example, a database server. In any situation where the size of the resource is fixed, you should use a bounded semaphore. Before spawning any worker threads, your main thread would initialize the semaphore:

```python
maxconnections = 5
# ...
pool_sema = BoundedSemaphore(value=maxconnections)
```

Once spawned, worker threads call the semaphore’s acquire and release methods when they need to connect to the server:

```python
with pool_sema:
    conn = connectdb()
    try:
        # ... use connection ...
    finally:
        conn.close()
```

The use of a bounded semaphore reduces the chance that a programming error which causes the semaphore to be released more than it’s acquired will go undetected.
17.1.7. Event Objects

This is one of the simplest mechanisms for communication between threads: one thread signals an event and other threads wait for it.

An event object manages an internal flag that can be set to true with the `set()` method and reset to false with the `clear()` method. The `wait()` method blocks until the flag is true.

```python
class threading.Event
    Class implementing event objects. An event manages a flag that can be set to true with the `set()` method and reset to false with the `clear()` method. The `wait()` method blocks until the flag is true. The flag is initially false.

    Changed in version 3.3: changed from a factory function to a class.

    is_set()
        Return true if and only if the internal flag is true.

    set()
        Set the internal flag to true. All threads waiting for it to become true are awakened. Threads that call `wait()` once the flag is true will not block at all.

    clear()
        Reset the internal flag to false. Subsequently, threads calling `wait()` will block until `set()` is called to set the internal flag to true again.

    wait(timeout=None)
        Block until the internal flag is true. If the internal flag is true on
entry, return immediately. Otherwise, block until another thread calls \texttt{set()}\ to set the flag to true, or until the optional timeout occurs.

When the timeout argument is present and not \texttt{None}, it should be a floating point number specifying a timeout for the operation in seconds (or fractions thereof).

This method returns true if and only if the internal flag has been set to true, either before the wait call or after the wait starts, so it will always return \texttt{True} except if a timeout is given and the operation times out.

\textit{Changed in version 3.1:} Previously, the method always returned \texttt{None}. 
17.1.8. Timer Objects

This class represents an action that should be run only after a certain amount of time has passed — a timer. Timer is a subclass of Thread and as such also functions as an example of creating custom threads.

Timers are started, as with threads, by calling their start() method. The timer can be stopped (before its action has begun) by calling the cancel() method. The interval the timer will wait before executing its action may not be exactly the same as the interval specified by the user.

For example:

```python
def hello():
    print("hello, world")

t = Timer(30.0, hello)
t.start() # after 30 seconds, "hello, world" will be
```

```python
class threading.Timer(interval, function, args=None, kwargs=None)

    Create a timer that will run function with arguments args and keyword arguments kwargs, after interval seconds have passed. If args is None (the default) then an empty list will be used. If kwargs is None (the default) then an empty dict will be used.

    Changed in version 3.3: changed from a factory function to a class.

    cancel()

    Stop the timer, and cancel the execution of the timer's action. This will only work if the timer is still in its waiting stage.
```
17.1.9. Barrier Objects

*New in version 3.2.*

This class provides a simple synchronization primitive for use by a fixed number of threads that need to wait for each other. Each of the threads tries to pass the barrier by calling the `wait()` method and will block until all of the threads have made the call. At this points, the threads are released simultaneously.

The barrier can be reused any number of times for the same number of threads.

As an example, here is a simple way to synchronize a client and server thread:

```python
b = Barrier(2, timeout=5)

def server():
    start_server()
    b.wait()
    while True:
        connection = accept_connection()
        process_server_connection(connection)

def client():
    b.wait()
    while True:
        connection = make_connection()
        process_client_connection(connection)
```

```python
class threading.Barrier(parties, action=None, timeout=None)
```

Create a barrier object for `parties` number of threads. An `action`, when provided, is a callable to be called by one of the threads.
when they are released. *timeout* is the default timeout value if none is specified for the *wait()* method.

**wait**(timeout=None)

Pass the barrier. When all the threads party to the barrier have called this function, they are all released simultaneously. If a *timeout* is provided, it is used in preference to any that was supplied to the class constructor.

The return value is an integer in the range 0 to *parties* – 1, different for each thread. This can be used to select a thread to do some special housekeeping, e.g.:

```python
i = barrier.wait()
if i == 0:
    # Only one thread needs to print this
    print("passed the barrier")
```

If an *action* was provided to the constructor, one of the threads will have called it prior to being released. Should this call raise an error, the barrier is put into the broken state.

If the call times out, the barrier is put into the broken state.

This method may raise a *BrokenBarrierError* exception if the barrier is broken or reset while a thread is waiting.

**reset()**

Return the barrier to the default, empty state. Any threads waiting on it will receive the *BrokenBarrierError* exception.

Note that using this function may can require some external synchronization if there are other threads whose state is unknown. If a barrier is broken it may be better to just leave it
and create a new one.

**abort()**
Put the barrier into a broken state. This causes any active or future calls to `wait()` to fail with the `BrokenBarrierError`. Use this for example if one of the needs to abort, to avoid deadlocking the application.

It may be preferable to simply create the barrier with a sensible `timeout` value to automatically guard against one of the threads going awry.

**parties**
The number of threads required to pass the barrier.

**n_waiting**
The number of threads currently waiting in the barrier.

**broken**
A boolean that is `True` if the barrier is in the broken state.

**exception** `threading.BrokenBarrierError`
This exception, a subclass of `RuntimeError`, is raised when the `Barrier` object is reset or broken.
17.1.10. Using locks, conditions, and semaphores in the `with` statement

All of the objects provided by this module that have `acquire()` and `release()` methods can be used as context managers for a `with` statement. The `acquire()` method will be called when the block is entered, and `release()` will be called when the block is exited. Hence, the following snippet:

```python
with some_lock:
    # do something...
```

is equivalent to:

```python
some_lock.acquire()
try:
    # do something...
finally:
    some_lock.release()
```

Currently, `Lock`, `RLock`, `Condition`, `Semaphore`, and `BoundedSemaphore` objects may be used as `with` statement context managers.
17.2. multiprocessing —
Process-based parallelism
17.2.1. Introduction

`multiprocessing` is a package that supports spawning processes using an API similar to the `threading` module. The `multiprocessing` package offers both local and remote concurrency, effectively side-stepping the *Global Interpreter Lock* by using subprocesses instead of threads. Due to this, the `multiprocessing` module allows the programmer to fully leverage multiple processors on a given machine. It runs on both Unix and Windows.

**Note:** Some of this package's functionality requires a functioning shared semaphore implementation on the host operating system. Without one, the `multiprocessing.synchronize` module will be disabled, and attempts to import it will result in an `ImportError`. See issue 3770 for additional information.

**Note:** Functionality within this package requires that the `__main__` module be importable by the children. This is covered in *Programming guidelines* however it is worth pointing out here. This means that some examples, such as the `multiprocessing.pool.Pool` examples will not work in the interactive interpreter. For example:

```python
>>> from multiprocessing import Pool
>>> p = Pool(5)
>>> def f(x):
...     return x**x
... >>> p.map(f, [1,2,3])
Process PoolWorker-1:
Process PoolWorker-2:
```
(If you try this it will actually output three full tracebacks interleaved in a semi-random fashion, and then you may have to stop the master process somehow.)

17.2.1.1. The Process class

In multiprocessing, processes are spawned by creating a Process object and then calling its start() method. Process follows the API of threading.Thread. A trivial example of a multiprocess program is

```python
from multiprocessing import Process

def f(name):
    print('hello', name)

if __name__ == '__main__':
    p = Process(target=f, args=('bob',))
    p.start()
    p.join()
```

To show the individual process IDs involved, here is an expanded example:

```python
from multiprocessing import Process
import os
```
For an explanation of why (on Windows) the if __name__ == '__main__' part is necessary, see Programming guidelines.

17.2.1.2. Exchanging objects between processes

multiprocessing supports two types of communication channel between processes:

Queues

The Queue class is a near clone of queue.Queue. For example:

def f(q):
    q.put([42, None, 'hello'])
if __name__ == '__main__':
    q = Queue()
    p = Process(target=f, args=(q,))
    p.start()
    print(q.get())  # prints "[42, None, 'hello']"
    p.join(

Queues are thread and process safe.

Pipes

The `Pipe()` function returns a pair of connection objects connected by a pipe which by default is duplex (two-way). For example:

```python
from multiprocessing import Process, Pipe

def f(conn):
    conn.send([42, None, 'hello'])
    conn.close()

if __name__ == '__main__':
    parent_conn, child_conn = Pipe()
    p = Process(target=f, args=(child_conn,))
    p.start()
    print(parent_conn.recv())  # prints "[42, None, 'hello']"
    p.join()
```

The two connection objects returned by `Pipe()` represent the two ends of the pipe. Each connection object has `send()` and `recv()` methods (among others). Note that data in a pipe may become corrupted if two processes (or threads) try to read from or write to the same end of the pipe at the same time. Of course there is no risk of corruption from processes using different ends
of the pipe at the same time.

17.2.1.3. Synchronization between processes

`multiprocessing` contains equivalents of all the synchronization primitives from `threading`. For instance one can use a lock to ensure that only one process prints to standard output at a time:

```python
from multiprocessing import Process, Lock

def f(l, i):
    l.acquire()
    print('hello world', i)
    l.release()

if __name__ == '__main__':
    lock = Lock()

    for num in range(10):
        Process(target=f, args=(lock, num)).start()
```

Without using the lock output from the different processes is liable to get all mixed up.

17.2.1.4. Sharing state between processes

As mentioned above, when doing concurrent programming it is usually best to avoid using shared state as far as possible. This is particularly true when using multiple processes.

However, if you really do need to use some shared data then `multiprocessing` provides a couple of ways of doing so.
Shared memory

Data can be stored in a shared memory map using `Value` or `Array`. For example, the following code

```python
def f(n, a):
    n.value = 3.1415927
    for i in range(len(a)):
        a[i] = -a[i]

if __name__ == '__main__':
    num = Value('d', 0.0)
    arr = Array('i', range(10))
    p = Process(target=f, args=(num, arr))
    p.start()
    p.join()
    print(num.value)
    print(arr[:])
```

will print

```
3.1415927
[0, -1, -2, -3, -4, -5, -6, -7, -8, -9]
```

The 'd' and 'i' arguments used when creating `num` and `arr` are typecodes of the kind used by the `array` module: 'd' indicates a double precision float and 'i' indicates a signed integer. These shared objects will be process and thread-safe.

For more flexibility in using shared memory one can use the
The `multiprocessing.sharedctypes` module supports the creation of arbitrary ctypes objects allocated from shared memory.

### Server process

A manager object returned by `Manager()` controls a server process which holds Python objects and allows other processes to manipulate them using proxies.

A manager returned by `Manager()` will support types `list`, `dict`, `Namespace`, `Lock`, `RLock`, `Semaphore`, `BoundedSemaphore`, `Condition`, `Event`, `Barrier`, `Queue`, `Value` and `Array`. For example,

```python
from multiprocessing import Process, Manager

def f(d, l):
    d[1] = '1'
    d['2'] = 2
    d[0.25] = None
    l.reverse()

if __name__ == '__main__':
    with Manager() as manager:
        d = manager.dict()
        l = manager.list(range(10))

        p = Process(target=f, args=(d, l))
        p.start()
        p.join()

        print(d)
        print(l)
```

will print
Server process managers are more flexible than using shared memory objects because they can be made to support arbitrary object types. Also, a single manager can be shared by processes on different computers over a network. They are, however, slower than using shared memory.

17.2.1.5. Using a pool of workers

The Pool class represents a pool of worker processes. It has methods which allows tasks to be offloaded to the worker processes in a few different ways.

For example:

```python
from multiprocessing import Pool

def f(x):
    return x*x

if __name__ == '__main__':
    with Pool(processes=4) as pool:
        result = pool.apply_async(f, [10])  # evaluate "f(10)" asynchronously
        print(result.get(timeout=1))  # prints "100" unless your computer is *very* slow
        print(pool.map(f, range(10)))  # prints 
```

Note that the methods of a pool should only ever be used by the process which created it.
17.2.2. Reference

The `multiprocessing` package mostly replicates the API of the `threading` module.

17.2.2.1. `Process` and exceptions

```python
class multiprocessing.Process(group=None, target=None, name=None, args=(), kwargs={}, *, daemon=None)
```

Process objects represent activity that is run in a separate process. The `Process` class has equivalents of all the methods of `threading.Thread`.

The constructor should always be called with keyword arguments. `group` should always be `None`; it exists solely for compatibility with `threading.Thread`. `target` is the callable object to be invoked by the `run()` method. It defaults to `None`, meaning nothing is called. `name` is the process name (see `name` for more details). `args` is the argument tuple for the target invocation. `kwargs` is a dictionary of keyword arguments for the target invocation. If provided, the keyword-only `daemon` argument sets the process `daemon` flag to `True` or `False`. If `None` (the default), this flag will be inherited from the creating process.

By default, no arguments are passed to `target`.

If a subclass overrides the constructor, it must make sure it invokes the base class constructor (`Process.__init__()`)) before doing anything else to the process.

*Changed in version 3.3:* Added the `daemon` argument.
run()
Method representing the process’s activity.

You may override this method in a subclass. The standard run() method invokes the callable object passed to the object’s constructor as the target argument, if any, with sequential and keyword arguments taken from the args and kwargs arguments, respectively.

start()
Start the process’s activity.

This must be called at most once per process object. It arranges for the object’s run() method to be invoked in a separate process.

join([timeout])
If the optional argument timeout is None (the default), the method blocks until the process whose join() method is called terminates. If timeout is a positive number, it blocks at most timeout seconds.

A process can be joined many times.

A process cannot join itself because this would cause a deadlock. It is an error to attempt to join a process before it has been started.

ame
The process’s name. The name is a string used for identification purposes only. It has no semantics. Multiple processes may be given the same name.
The initial name is set by the constructor. If no explicit name is provided to the constructor, a name of the form ‘Process-N_1:N_2:...:N_k’ is constructed, where each N_k is the N-th child of its parent.

**is_alive()**

Return whether the process is alive.

Roughly, a process object is alive from the moment the start() method returns until the child process terminates.

**daemon**

The process’s daemon flag, a Boolean value. This must be set before start() is called.

The initial value is inherited from the creating process.

When a process exits, it attempts to terminate all of its daemonic child processes.

Note that a daemonic process is not allowed to create child processes. Otherwise a daemonic process would leave its children orphaned if it gets terminated when its parent process exits. Additionally, these are **not** Unix daemons or services, they are normal processes that will be terminated (and not joined) if non-daemonic processes have exited.

In addition to the threading.Thread API, Process objects also support the following attributes and methods:

**pid**

Return the process ID. Before the process is spawned, this will be None.
**exitcode**

The child’s exit code. This will be None if the process has not yet terminated. A negative value -N indicates that the child was terminated by signal $N$.

**authkey**

The process’s authentication key (a byte string).

When `multiprocessing` is initialized the main process is assigned a random string using `os.urandom()`.

When a `Process` object is created, it will inherit the authentication key of its parent process, although this may be changed by setting `authkey` to another byte string.

See *Authentication keys*.

**sentinel**

A numeric handle of a system object which will become “ready” when the process ends.

You can use this value if you want to wait on several events at once using `multiprocessing.connection.wait()`. Otherwise calling `join()` is simpler.

On Windows, this is an OS handle usable with the `WaitForSingleObject` and `WaitForMultipleObjects` family of API calls. On Unix, this is a file descriptor usable with primitives from the `select` module.

*New in version 3.3.*

**terminate()**
Terminate the process. On Unix this is done using the `SIGTERM` signal; on Windows `TerminateProcess()` is used. Note that exit handlers and finally clauses, etc., will not be executed.

Note that descendant processes of the process will not be terminated – they will simply become orphaned.

**Warning:** If this method is used when the associated process is using a pipe or queue then the pipe or queue is liable to become corrupted and may become unusable by other process. Similarly, if the process has acquired a lock or semaphore etc. then terminating it is liable to cause other processes to deadlock.

Note that the `start()`, `join()`, `is_alive()`, `terminate()` and `exitcode` methods should only be called by the process that created the process object.

Example usage of some of the methods of `Process`:

```python
>>> import multiprocessing, time, signal
>>> p = multiprocessing.Process(target=time.sleep
... print(p, p.is_alive())
<Process(Process-1, initial)> False
>>> p.start()
>>> print(p, p.is_alive())
<Process(Process-1, started)> True
>>> p.terminate()
>>> time.sleep(0.1)
>>> print(p, p.is_alive())
<Process(Process-1, stopped[SIGTERM])> False
>>> p.exitcode == -signal.SIGTERM
True
```
exception multiprocessing.ProcessError
    The base class of all multiprocessing exceptions.

exception multiprocessing.BufferTooShort
    Exception raised by Connection.recv_bytes_into() when the supplied buffer object is too small for the message read.

    If e is an instance of BufferTooShort then e.args[0] will give the message as a byte string.

exception multiprocessing.AuthenticationError
    Raised when there is an authentication error.

exception multiprocessing.TimeoutError
    Raised by methods with a timeout when the timeout expires.

17.2.2.2. Pipes and Queues

When using multiple processes, one generally uses message passing for communication between processes and avoids having to use any synchronization primitives like locks.

For passing messages one can use Pipe() (for a connection between two processes) or a queue (which allows multiple producers and consumers).

The Queue, SimpleQueue and JoinableQueue types are multi-producer, multi-consumer FIFO queues modelled on the queue.Queue class in the standard library. They differ in that Queue lacks the task_done() and join() methods introduced into Python 2.5's queue.Queue class.

    If you use JoinableQueue then you must call
JoinableQueue.task_done() for each task removed from the queue or else the semaphore used to count the number of unfinished tasks may eventually overflow, raising an exception.

Note that one can also create a shared queue by using a manager object – see Managers.

**Note:** multiprocessing uses the usual queue.Empty and queue.Full exceptions to signal a timeout. They are not available in the multiprocessing namespace so you need to import them from queue.

**Note:** When an object is put on a queue, the object is pickled and a background thread later flushes the pickled data to an underlying pipe. This has some consequences which are a little surprising, but should not cause any practical difficulties – if they really bother you then you can instead use a queue created with a manager.

1. After putting an object on an empty queue there may be an infinitesimal delay before the queue's empty() method returns False and get_nowait() can return without raising queue.Empty.
2. If multiple processes are enqueuing objects, it is possible for the objects to be received at the other end out-of-order. However, objects enqueued by the same process will always be in the expected order with respect to each other.

**Warning:** If a process is killed using Process.terminate() or os.kill() while it is trying to use a Queue, then the data in the queue is likely to become corrupted. This may cause any other process to get an exception when it tries to use the queue later on.
**Warning:** As mentioned above, if a child process has put items on a queue (and it has not used `JoinableQueue.cancel_join_thread`), then that process will not terminate until all buffered items have been flushed to the pipe.

This means that if you try joining that process you may get a deadlock unless you are sure that all items which have been put on the queue have been consumed. Similarly, if the child process is non-daemonic then the parent process may hang on exit when it tries to join all its non-daemonic children.

Note that a queue created using a manager does not have this issue. See *Programming guidelines*.

For an example of the usage of queues for interprocess communication see *Examples*.

```python
multiprocessing.Pipe([duplex])
```

Returns a pair `(conn1, conn2)` of `Connection` objects representing the ends of a pipe.

If `duplex` is `True` (the default) then the pipe is bidirectional. If `duplex` is `False` then the pipe is unidirectional: `conn1` can only be used for receiving messages and `conn2` can only be used for sending messages.

```python
class multiprocessing.Queue([maxsize])
```

Returns a process shared queue implemented using a pipe and a few locks/semaphores. When a process first puts an item on the queue a feeder thread is started which transfers objects from a buffer into the pipe.
The usual `queue.Empty` and `queue.Full` exceptions from the standard library's `queue` module are raised to signal timeouts.

`Queue` implements all the methods of `queue.Queue` except for `task_done()` and `join()`.

`qsize()`
Return the approximate size of the queue. Because of multithreading/multiprocessing semantics, this number is not reliable.

Note that this may raise `NotImplementedError` on Unix platforms like Mac OS X where `sem_getvalue()` is not implemented.

`empty()`
Return True if the queue is empty, False otherwise. Because of multithreading/multiprocessing semantics, this is not reliable.

`full()`
Return True if the queue is full, False otherwise. Because of multithreading/multiprocessing semantics, this is not reliable.

`put(obj[, block[, timeout]])`
Put obj into the queue. If the optional argument `block` is True (the default) and `timeout` is None (the default), block if necessary until a free slot is available. If `timeout` is a positive number, it blocks at most `timeout` seconds and raises the `queue.Full` exception if no free slot was available within that time. Otherwise (`block` is False), put an item on the queue if a free slot is immediately available, else raise the `queue.Full` exception (`timeout` is ignored in that case).
**put_nowait**(obj)
Equivalent to `put(obj, False)`.

**get**([`block`, `timeout`])
Remove and return an item from the queue. If optional args `block` is True (the default) and `timeout` is None (the default), block if necessary until an item is available. If `timeout` is a positive number, it blocks at most `timeout` seconds and raises the `queue.Empty` exception if no item was available within that time. Otherwise (block is False), return an item if one is immediately available, else raise the `queue.Empty` exception (`timeout` is ignored in that case).

**get_nowait()**
Equivalent to `get(False)`.

`multiprocessing.Queue` has a few additional methods not found in `queue.Queue`. These methods are usually unnecessary for most code:

**close()**
Indicate that no more data will be put on this queue by the current process. The background thread will quit once it has flushed all buffered data to the pipe. This is called automatically when the queue is garbage collected.

**join_thread()**
Join the background thread. This can only be used after `close()` has been called. It blocks until the background thread exits, ensuring that all data in the buffer has been flushed to the pipe.
By default if a process is not the creator of the queue then on exit it will attempt to join the queue's background thread. The process can call `cancel_join_thread()` to make `join_thread()` do nothing.

`cancel_join_thread()`
Prevent `join_thread()` from blocking. In particular, this prevents the background thread from being joined automatically when the process exits – see `join_thread()`.

A better name for this method might be `allow_exit_without_flush()`. It is likely to cause enqueued data to lost, and you almost certainly will not need to use it. It is really only there if you need the current process to exit immediately without waiting to flush enqueued data to the underlying pipe, and you don’t care about lost data.

`class multiprocessing.SimpleQueue`
It is a simplified `Queue` type, very close to a locked `Pipe`.

`empty()`
Return `True` if the queue is empty, `False` otherwise.

`get()`
Remove and return an item from the queue.

`put(item)`
Put `item` into the queue.

`class multiprocessing.JoinableQueue([maxsize])`
`JoinableQueue`, a `Queue` subclass, is a queue which additionally has `task_done()` and `join()` methods.
**task_done()**

Indicate that a formerly enqueued task is complete. Used by queue consumers. For each `get()` used to fetch a task, a subsequent call to `task_done()` tells the queue that the processing on the task is complete.

If a `join()` is currently blocking, it will resume when all items have been processed (meaning that a `task_done()` call was received for every item that had been `put()` into the queue).

Raises a `ValueError` if called more times than there were items placed in the queue.

**join()**

Block until all items in the queue have been gotten and processed.

The count of unfinished tasks goes up whenever an item is added to the queue. The count goes down whenever a consumer calls `task_done()` to indicate that the item was retrieved and all work on it is complete. When the count of unfinished tasks drops to zero, `join()` unblocks.

### 17.2.2.3. Miscellaneous

**multiprocessing.active_children()**

Return list of all live children of the current process.

Calling this has the side affect of “joining” any processes which have already finished.

**multiprocessing.cpu_count()**
Return the number of CPUs in the system. May raise `NotImplementedError`.

```
multiprocessing.current_process()

Return the `Process` object corresponding to the current process.

An analogue of `threading.current_thread()`.
```

```
multiprocessing.freeze_support()

Add support for when a program which uses `multiprocessing` has been frozen to produce a Windows executable. (Has been tested with `py2exe`, `PyInstaller` and `cx_Freeze`.)

One needs to call this function straight after the `if __name__ == '__main__'` line of the main module. For example:

```python
from multiprocessing import Process, freeze_support

def f():
    print('hello world!')

if __name__ == '__main__':
    freeze_support()
    Process(target=f).start()
```

If the `freeze_support()` line is omitted then trying to run the frozen executable will raise `RuntimeError`.

If the module is being run normally by the Python interpreter then `freeze_support()` has no effect.

```
multiprocessing.set_executable()

Sets the path of the Python interpreter to use when starting a child
process. (By default `sys.executable` is used). Embedders will probably need to do some thing like

```python
def set_executable(path):
    os.environ['PATH'] = path
```

before they can create child processes. (Windows only)

**Note:** `multiprocessing` contains no analogues of `threading.active_count()`, `threading.enumerate()`, `threading.settrace()`, `threading.setprofile()`, `threading.Timer`, or `threading.local`.

### 17.2.2.4. Connection Objects

Connection objects allow the sending and receiving of picklable objects or strings. They can be thought of as message oriented connected sockets.

Connection objects are usually created using `Pipe()` – see also *Listeners and Clients*.

```python
class multiprocessing.Connection
    send(obj)
        Send an object to the other end of the connection which should be read using `recv()`.

        The object must be picklable. Very large pickles (approximately 32 MB+, though it depends on the OS) may raise a ValueError exception.

    recv()
        Return an object sent from the other end of the connection
```
using `send()`. Blocks until there is something to receive. Raises `EOFError` if there is nothing left to receive and the other end was closed.

**fileno()**

Return the file descriptor or handle used by the connection.

**close()**

Close the connection.

This is called automatically when the connection is garbage collected.

**poll([timeout])**

Return whether there is any data available to be read.

If `timeout` is not specified then it will return immediately. If `timeout` is a number then this specifies the maximum time in seconds to block. If `timeout` is None then an infinite timeout is used.

Note that multiple connection objects may be polled at once by using `multiprocessing.connection.wait()`.

**send_bytes(buffer[, offset[, size]])**

Send byte data from a `bytes-like object` as a complete message.

If `offset` is given then data is read from that position in `buffer`. If `size` is given then that many bytes will be read from buffer. Very large buffers (approximately 32 MB+, though it depends on the OS) may raise a `ValueError` exception.
recv_bytes([maxlength])

Return a complete message of byte data sent from the other end of the connection as a string. Blocks until there is something to receive. Raises EOFError if there is nothing left to receive and the other end has closed.

If maxlength is specified and the message is longer than maxlength then OSError is raised and the connection will no longer be readable.

*Changed in version 3.3:* This function used to raise a IOError, which is now an alias of OSError.

recv_bytes_into(buffer[, offset])

Read into buffer a complete message of byte data sent from the other end of the connection and return the number of bytes in the message. Blocks until there is something to receive. Raises EOFError if there is nothing left to receive and the other end was closed.

buffer must be a writable bytes-like object. If offset is given then the message will be written into the buffer from that position. Offset must be a non-negative integer less than the length of buffer (in bytes).

If the buffer is too short then a BufferTooShort exception is raised and the complete message is available as e.args[0] where e is the exception instance.

*Changed in version 3.3:* Connection objects themselves can now be transferred between processes using Connection.send() and Connection.recv().
New in version 3.3: Connection objects now support the context manager protocol – see Context Manager Types. __enter__() returns the connection object, and __exit__() calls close().

For example:

```python
>>> from multiprocessing import Pipe
>>> a, b = Pipe()
>>> a.send([1, 'hello', None])
>>> b.recv()
[1, 'hello', None]
>>> b.send_bytes(b'thank you')
>>> a.recv_bytes()
b'thank you'
```
it may become impossible to be sure where the message boundaries lie.

17.2.2.5. Synchronization primitives

Generally synchronization primitives are not as necessary in a multiprocess program as they are in a multithreaded program. See the documentation for threading module.

Note that one can also create synchronization primitives by using a manager object – see Managers.

class multiprocessing.Barrier([parties[, action[, timeout]]])

A barrier object: a clone of threading.Barrier.

*New in version 3.3.*

class multiprocessing.BoundedSemaphore([value])

(On Mac OS X, this is indistinguishable from Semaphore because sem_getvalue() is not implemented on that platform).

class multiprocessing.Condition([lock])

If lock is specified then it should be a Lock or RLock object from multiprocessing.

*Changed in version 3.3:* The wait_for() method was added.

class multiprocessing.Event
A clone of `threading.Event`.

```python
class multiprocessing.Lock
    A non-recursive lock object: a clone of `threading.Lock`.

class multiprocessing.RLock
    A recursive lock object: a clone of `threading.RLock`.

class multiprocessing.Semaphore([value])
    A semaphore object: a clone of `threading.Semaphore`.
```

**Note:** The `acquire()` and `wait()` methods of each of these types treat negative timeouts as zero timeouts. This differs from `threading` where, since version 3.2, the equivalent `acquire()` methods treat negative timeouts as infinite timeouts.

On Mac OS X, `sem_timedwait` is unsupported, so calling `acquire()` with a timeout will emulate that function's behavior using a sleeping loop.

**Note:** If the SIGINT signal generated by Ctrl-C arrives while the main thread is blocked by a call to `BoundedSemaphore.acquire()`, `Lock.acquire()`, `RLock.acquire()`, `Semaphore.acquire()`, `Condition.acquire()` or `Condition.wait()` then the call will be immediately interrupted and `KeyboardInterrupt` will be raised.

This differs from the behaviour of `threading` where SIGINT will be ignored while the equivalent blocking calls are in progress.
17.2.2.6. Shared ctypes Objects

It is possible to create shared objects using shared memory which can be inherited by child processes.

multiprocessing.**Value**(**code_or_type**, *args, **lock**=**True**)  
Return a ctypes object allocated from shared memory. By default the return value is actually a synchronized wrapper for the object. The object itself can be accessed via the *value* attribute of a Value.

**code_or_type** determines the type of the returned object: it is either a ctypes type or a one character typecode of the kind used by the array module. *args* is passed on to the constructor for the type.

If **lock** is True (the default) then a new lock object is created to synchronize access to the value. If **lock** is a Lock or RLock object then that will be used to synchronize access to the value. If **lock** is False then access to the returned object will not be automatically protected by a lock, so it will not necessarily be “process-safe”.

Note that **lock** is a keyword-only argument.

multiprocessing.**Array**(**code_or_type**, **size_or_initializer**, *, **lock**=**True**)  
Return a ctypes array allocated from shared memory. By default the return value is actually a synchronized wrapper for the array.

**code_or_type** determines the type of the elements of the returned array: it is either a ctypes type or a one character typecode of the kind used by the array module. If
size_or_initializer is an integer, then it determines the length of the array, and the array will be initially zeroed. Otherwise, size_or_initializer is a sequence which is used to initialize the array and whose length determines the length of the array.

If lock is True (the default) then a new lock object is created to synchronize access to the value. If lock is a Lock or RLock object then that will be used to synchronize access to the value. If lock is False then access to the returned object will not be automatically protected by a lock, so it will not necessarily be “process-safe”.

Note that lock is a keyword only argument.

Note that an array of ctypes.c_char has value and raw attributes which allow one to use it to store and retrieve strings.

17.2.2.6.1. The multiprocessing.sharedctypes module

The multiprocessing.sharedctypes module provides functions for allocating ctypes objects from shared memory which can be inherited by child processes.

**Note:** Although it is possible to store a pointer in shared memory remember that this will refer to a location in the address space of a specific process. However, the pointer is quite likely to be invalid in the context of a second process and trying to dereference the pointer from the second process may cause a crash.

multiprocessing.sharedctypes.RawArray(typecode_or_type size_or_initializer)

Return a ctypes array allocated from shared memory.
typecode_or_type determines the type of the elements of the returned array: it is either a ctypes type or a one character typecode of the kind used by the array module. If size_or_initializer is an integer then it determines the length of the array, and the array will be initially zeroed. Otherwise size_or_initializer is a sequence which is used to initialize the array and whose length determines the length of the array.

Note that setting and getting an element is potentially non-atomic – use Array() instead to make sure that access is automatically synchronized using a lock.

multiprocessing.sharedctypes.RawValue(typecode_or_type, *args)

Return a ctypes object allocated from shared memory.

typecode_or_type determines the type of the returned object: it is either a ctypes type or a one character typecode of the kind used by the array module. *args is passed on to the constructor for the type.

Note that setting and getting the value is potentially non-atomic – use Value() instead to make sure that access is automatically synchronized using a lock.

Note that an array of ctypes.c_char has value and raw attributes which allow one to use it to store and retrieve strings – see documentation for ctypes.

multiprocessing.sharedctypes.Array(typecode_or_type, size_or_initializer, *, lock=True)

The same as RawArray() except that depending on the value of lock a process-safe synchronization wrapper may be returned
instead of a raw ctypes array.

If lock is True (the default) then a new lock object is created to synchronize access to the value. If lock is a Lock or RLock object then that will be used to synchronize access to the value. If lock is False then access to the returned object will not be automatically protected by a lock, so it will not necessarily be “process-safe”.

Note that lock is a keyword-only argument.

```
multiprocessing.sharedctypes.Value(typecode_or_type, *args, lock=True)
```

The same as RawValue() except that depending on the value of lock a process-safe synchronization wrapper may be returned instead of a raw ctypes object.

If lock is True (the default) then a new lock object is created to synchronize access to the value. If lock is a Lock or RLock object then that will be used to synchronize access to the value. If lock is False then access to the returned object will not be automatically protected by a lock, so it will not necessarily be “process-safe”.

Note that lock is a keyword-only argument.

```
multiprocessing.sharedctypes.copy(obj)
```

Return a ctypes object allocated from shared memory which is a copy of the ctypes object obj.

```
multiprocessing.sharedctypes.synchronized(obj[, lock])
```

Return a process-safe wrapper object for a ctypes object which uses lock to synchronize access. If lock is None (the default) then a multiprocessing.RLock object is created automatically.
A synchronized wrapper will have two methods in addition to those of the object it wraps: get_obj() returns the wrapped object and get_lock() returns the lock object used for synchronization.

Note that accessing the ctypes object through the wrapper can be a lot slower than accessing the raw ctypes object.

The table below compares the syntax for creating shared ctypes objects from shared memory with the normal ctypes syntax. (In the table MyStruct is some subclass of ctypes.Structure.)

<table>
<thead>
<tr>
<th>ctypes</th>
<th>sharedctypes using type</th>
<th>sharedctypes using typecode</th>
</tr>
</thead>
<tbody>
<tr>
<td>c_double(2.4)</td>
<td>RawValue(c_double, 2.4)</td>
<td>RawValue('d', 2.4)</td>
</tr>
<tr>
<td>MyStruct(4, 6)</td>
<td>RawValue(MyStruct, 4, 6)</td>
<td></td>
</tr>
<tr>
<td>(c_short * 7)()</td>
<td>RawArray(c_short, 7)</td>
<td>RawArray('h', 7)</td>
</tr>
<tr>
<td>(c_int * 3)(9, 2, 8)</td>
<td>RawArray(c_int, (9, 2, 8))</td>
<td>RawArray('i', (9, 2, 8))</td>
</tr>
</tbody>
</table>

Below is an example where a number of ctypes objects are modified by a child process:

```python
from multiprocessing import Process, Lock
from multiprocessing.sharedctypes import Value, Array
from ctypes import Structure, c_double

class Point(Structure):
    _fields_ = [('x', c_double), ('y', c_double)]

def modify(n, x, s, A):
    n.value **= 2
```
x.value **= 2
s.value = s.value.upper()
for a in A:
a.x **= 2
a.y **= 2

if __name__ == '__main__':
    lock = Lock()

    n = Value('i', 7)
x = Value(c_double, 1.0/3.0, lock=False)
s = Array('c', b'hello world', lock=lock)
A = Array(Point, [(1.875, -6.25), (-5.75, 2.0)], (2

    p = Process(target=modify, args=(n, x, s, A))
p.start()
p.join()

    print(n.value)
    print(x.value)
    print(s.value)
    print([(a.x, a.y) for a in A])

The results printed are

49
0.1111111111111111
HELLO WORLD
[(3.515625, 39.0625), (33.0625, 4.0), (5.640625, 90.

17.2.2.7. Managers

Managers provide a way to create data which can be shared between different processes, including sharing over a network between
processes running on different machines. A manager object controls a server process which manages *shared objects*. Other processes can access the shared objects by using proxies.

**multiprocessing.Manager()**

Returns a started *SyncManager* object which can be used for sharing objects between processes. The returned manager object corresponds to a spawned child process and has methods which will create shared objects and return corresponding proxies.

Manager processes will be shutdown as soon as they are garbage collected or their parent process exits. The manager classes are defined in the `multiprocessing.managers` module:

```python
class multiprocessing.managers.BaseManager([address[, authkey]])
```

Create a BaseManager object.

Once created one should call `start()` or `get_server().serve_forever()` to ensure that the manager object refers to a started manager process.

*address* is the address on which the manager process listens for new connections. If *address* is None then an arbitrary one is chosen.

*authkey* is the authentication key which will be used to check the validity of incoming connections to the server process. If *authkey* is None then `current_process().authkey` is used. Otherwise *authkey* is used and it must be a byte string.

```python
start([initializer[, initargs]])
```
Start a subprocess to start the manager. If `initializer` is not None then the subprocess will call `initializer(*initargs)` when it starts.

get_server()

Returns a Server object which represents the actual server under the control of the Manager. The Server object supports the `serve_forever()` method:

```python
>>> from multiprocessing.managers import BaseManager
>>> manager = BaseManager(address=('', 50000),
>>> server = manager.get_server()
>>> server.serve_forever()
```

Server additionally has an `address` attribute.

connect()

Connect a local manager object to a remote manager process:

```python
>>> from multiprocessing.managers import BaseManager
>>> m = BaseManager(address=('127.0.0.1', 5000))
>>> m.connect()
```

shutdown()

Stop the process used by the manager. This is only available if `start()` has been used to start the server process.

This can be called multiple times.

register(`typeid`, `callable`, `proxytype`, `exposed`, `method_to_typeid`, `create_method`)

A classmethod which can be used for registering a type or
callable with the manager class.

typeid is a “type identifier” which is used to identify a particular type of shared object. This must be a string.

callable is a callable used for creating objects for this type identifier. If a manager instance will be connected to the server using the connect() method, or if the create_method argument is False then this can be left as None.

proxytype is a subclass of BaseProxy which is used to create proxies for shared objects with this typeid. If None then a proxy class is created automatically.

exposed is used to specify a sequence of method names which proxies for this typeid should be allowed to access using BaseProxy._callMethod(). (If exposed is None then proxytype._exposed_ is used instead if it exists.) In the case where no exposed list is specified, all “public methods” of the shared object will be accessible. (Here a “public method” means any attribute which has a __call__() method and whose name does not begin with '_'.)

method_to_typeid is a mapping used to specify the return type of those exposed methods which should return a proxy. It maps method names to typeid strings. (If method_to_typeid is None then proxytype._method_to_typeid_ is used instead if it exists.) If a method's name is not a key of this mapping or if the mapping is None then the object returned by the method will be copied by value.

create_method determines whether a method should be created with name typeid which can be used to tell the server
process to create a new shared object and return a proxy for it. By default it is True.

**BaseManager** instances also have one read-only property:

**address**

The address used by the manager.

*Changed in version 3.3:* Manager objects support the context manager protocol – see *Context Manager Types.* **__enter__()** starts the server process (if it has not already started) and then returns the manager object. **__exit__()** calls **shutdown()**.

In previous versions **__enter__()** did not start the manager’s server process if it was not already started.

**class multiprocessing.managers.SyncManager**

A subclass of **BaseManager** which can be used for the synchronization of processes. Objects of this type are returned by **multiprocessing.Manager()**.

It also supports creation of shared lists and dictionaries.

**Barrier**(parties[, action[, timeout]])

Create a shared **threading.Barrier** object and return a proxy for it.

*New in version 3.3.*

**BoundedSemaphore**(value)

Create a shared **threading.BoundedSemaphore** object and return a proxy for it.
**Condition**([lock])

Create a shared `threading.Condition` object and return a proxy for it.

If *lock* is supplied then it should be a proxy for a `threading.Lock` or `threading.RLock` object.

*Changed in version 3.3:* The `wait_for()` method was added.

**Event()**

Create a shared `threading.Event` object and return a proxy for it.

**Lock()**

Create a shared `threading.Lock` object and return a proxy for it.

**Namespace()**

Create a shared `Namespace` object and return a proxy for it.

**Queue([maxsize])**

Create a shared `queue.Queue` object and return a proxy for it.

**RLock()**

Create a shared `threading.RLock` object and return a proxy for it.

**Semaphore([value])**

Create a shared `threading.Semaphore` object and return a proxy for it.

**Array**(typecode, sequence)
Create an array and return a proxy for it.

**Value**(*typecode, value*)
Create an object with a writable `value` attribute and return a proxy for it.

`dict()`
`dict(mapping)`
`dict(sequence)`
Create a shared `dict` object and return a proxy for it.

`list()`
`list(sequence)`
Create a shared `list` object and return a proxy for it.

**Note:** Modifications to mutable values or items in `dict` and `list` proxies will not be propagated through the manager, because the proxy has no way of knowing when its values or items are modified. To modify such an item, you can re-assign the modified object to the container proxy:

```python
# create a list proxy and append a mutable object
lproxy = manager.list()
lproxy.append({})
# now mutate the dictionary
d = lproxy[0]
d['a'] = 1
d['b'] = 2
# at this point, the changes to d are not yet sync'd
# reassigning the dictionary, the proxy is notified
lproxy[0] = d
```
17.2.2.7.1. Namespace objects

A namespace object has no public methods, but does have writable attributes. Its representation shows the values of its attributes.

However, when using a proxy for a namespace object, an attribute beginning with '___' will be an attribute of the proxy and not an attribute of the referent:

```python
>>> manager = multiprocessing.Manager()
>>> Global = manager.Namespace()
>>> Global.x = 10
>>> Global.y = 'hello'
>>> Global._z = 12.3  # this is an attribute of the proxy
>>> print(Global)
Namespace(x=10, y='hello')
```

17.2.2.7.2. Customized managers

To create one's own manager, one creates a subclass of `BaseManager` and uses the `register()` classmethod to register new types or callables with the manager class. For example:

```python
from multiprocessing.managers import BaseManager

class MathsClass:
    def add(self, x, y):
        return x + y
    def mul(self, x, y):
        return x * y

class MyManager(BaseManager):
    pass
```
MyManager.register('Maths', MathsClass)

if __name__ == '__main__':
    with MyManager() as manager:
        maths = manager.Maths()
        print(maths.add(4, 3))  # prints 7
        print(maths.mul(7, 8))  # prints 56

17.2.2.7.3. Using a remote manager

It is possible to run a manager server on one machine and have clients use it from other machines (assuming that the firewalls involved allow it).

Running the following commands creates a server for a single shared queue which remote clients can access:

```python
>>> from multiprocessing.managers import BaseManager
>>> import queue
>>> queue = queue.Queue()
>>> class QueueManager(BaseManager): pass
>>> QueueManager.register('get_queue', callable=lambda: queue)
>>> m = QueueManager(address=('', 50000), authkey=b'abracadabra')
>>> s = m.get_server()
>>> s.serve_forever()
```

One client can access the server as follows:

```python
>>> from multiprocessing.managers import BaseManager
>>> class QueueManager(BaseManager): pass
>>> QueueManager.register('get_queue')
>>> m = QueueManager(address=('foo.bar.org', 50000),)
>>> m.connect()
>>> queue = m.get_queue()
>>> queue.put('hello')
```
Another client can also use it:

```python
>>> from multiprocessing.managers import BaseManager
>>> class QueueManager(BaseManager): pass
>>> QueueManager.register('get_queue')
>>> m = QueueManager(address=('', 50000),
>>> m.connect()
>>> queue = m.get_queue()
>>> queue.get()
'hello'
```

Local processes can also access that queue, using the code from above on the client to access it remotely:

```python
>>> from multiprocessing import Process, Queue
>>> from multiprocessing.managers import BaseManager
>>> class Worker(Process):
...     def __init__(self, q):
...         self.q = q
...     super(Worker, self).__init__()
...     def run(self):
...         self.q.put('local hello')
...
>>> queue = Queue()
>>> w = Worker(queue)
>>> w.start()
>>> class QueueManager(BaseManager): pass
...     def register(self, name, callable=lambda: None):
...         self._registration[name] = callable
...     def get_server(self, _=None):
...         return self._server
...
>>> QueueManager.register('get_queue', callable=lambda: None)
>>> m = QueueManager(address=('localhost', 50000), authkey=b'abracadabra')
>>> s = m.get_server()
>>> s.serve_forever()
```
17.2.2.8. Proxy Objects

A proxy is an object which refers to a shared object which lives (presumably) in a different process. The shared object is said to be the referent of the proxy. Multiple proxy objects may have the same referent.

A proxy object has methods which invoke corresponding methods of its referent (although not every method of the referent will necessarily be available through the proxy). A proxy can usually be used in most of the same ways that its referent can:

```python
>>> from multiprocessing import Manager
>>> manager = Manager()
>>> l = manager.list([i*i for i in range(10)])
>>> print(l)
[0, 1, 4, 9, 16, 25, 36, 49, 64, 81]
>>> print(repr(l))
<ListProxy object, typeid 'list' at 0x...>
>>> l[4]
16
>>> l[2:5]
[4, 9, 16]
```

Notice that applying `str()` to a proxy will return the representation of the referent, whereas applying `repr()` will return the representation of the proxy.

An important feature of proxy objects is that they are picklable so they can be passed between processes. Note, however, that if a proxy is sent to the corresponding manager’s process then unpickling it will produce the referent itself. This means, for example, that one shared object can contain a second:
```python
>>> a = manager.list()
>>> b = manager.list()
>>> a.append(b)  # referent of a now contains referent of b
>>> print(a, b)
[[], []]
>>> b.append('hello')
>>> print(a, b)
[['hello'], ['hello']]
```

**Note:** The proxy types in *multiprocessing* do nothing to support comparisons by value. So, for instance, we have:

```python
>>> manager.list([1, 2, 3]) == [1, 2, 3]
False
```

One should just use a copy of the referent instead when making comparisons.

class multiprocessing.managers.BaseProxy

Proxy objects are instances of subclasses of *BaseProxy*.

```python
_callmethod(methodname[, args[, kwds]])
```
Call and return the result of a method of the proxy’s referent.

If `proxy` is a proxy whose referent is `obj` then the expression

```python
proxy._callmethod(methodname, args, kwds)
```
will evaluate the expression

```python
getattr(obj, methodname)(*args, **kwds)
```
in the manager’s process.
The returned value will be a copy of the result of the call or a proxy to a new shared object – see documentation for the `method_to_typeid` argument of `BaseManager.register()`.

If an exception is raised by the call, then it is re-raised by `_callmethod()`. If some other exception is raised in the manager's process then this is converted into a `RemoteError` exception and is raised by `_callmethod()`.

Note in particular that an exception will be raised if `methodname` has not been exposed.

An example of the usage of `_callmethod()`:

```python
>>> l = manager.list(range(10))
>>> l._callmethod('__len__')
10
>>> l._callmethod('__getslice__', (2, 7))  # e.g. [2, 3, 4, 5, 6]
>>> l._callmethod('__getitem__', (20,))  # e.g. Traceback (most recent call last):
...                IndexError: list index out of range
```

`__getvalue__`

Return a copy of the referent.

If the referent is unpicklable then this will raise an exception.

`__repr__`

Return a representation of the proxy object.

`__str__`
Return the representation of the referent.

17.2.2.8.1. Cleanup

A proxy object uses a weakref callback so that when it gets garbage collected it deregisters itself from the manager which owns its referent.

A shared object gets deleted from the manager process when there are no longer any proxies referring to it.

17.2.2.9. Process Pools

One can create a pool of processes which will carry out tasks submitted to it with the Pool class.

```python
class multiprocessing.pool.Pool([processes[, initializer[, initargs[, maxtasksperchild]]]])
```

A process pool object which controls a pool of worker processes to which jobs can be submitted. It supports asynchronous results with timeouts and callbacks and has a parallel map implementation.

- `processes` is the number of worker processes to use. If `processes` is None then the number returned by `cpu_count()` is used. If `initializer` is not None then each worker process will call `initializer(*initargs)` when it starts.

Note that the methods of the pool object should only be called by the process which created the pool.

*New in version 3.2:* `maxtasksperchild` is the number of tasks a worker process can complete before it will exit and be replaced with a fresh worker process, to enable unused resources to be
freed. The default `maxtasksperchild` is None, which means worker processes will live as long as the pool.

**Note:** Worker processes within a **Pool** typically live for the complete duration of the Pool’s work queue. A frequent pattern found in other systems (such as Apache, mod_wsgi, etc) to free resources held by workers is to allow a worker within a pool to complete only a set amount of work before being exiting, being cleaned up and a new process spawned to replace the old one. The `maxtasksperchild` argument to the **Pool** exposes this ability to the end user.

```python
apply(func[, args[, kwds]])
```

Call `func` with arguments `args` and keyword arguments `kwds`. It blocks until the result is ready. Given this blocks, `apply_async()` is better suited for performing work in parallel. Additionally, `func` is only executed in one of the workers of the pool.

```python
apply_async(func[, args[, kwds[, callback[, error_callback]]]])
```

A variant of the `apply()` method which returns a result object.

If `callback` is specified then it should be a callable which accepts a single argument. When the result becomes ready `callback` is applied to it, that is unless the call failed, in which case the `error_callback` is applied instead.

If `error_callback` is specified then it should be a callable which accepts a single argument. If the target function fails, then the `error_callback` is called with the exception instance.

Callbacks should complete immediately since otherwise the
thread which handles the results will get blocked.

**map**(*func, iterable[, chunksize]*)
A parallel equivalent of the map() built-in function (it supports only one iterable argument though). It blocks until the result is ready.

This method chops the iterable into a number of chunks which it submits to the process pool as separate tasks. The (approximate) size of these chunks can be specified by setting chunksize to a positive integer.

**map_async**(*func, iterable[, chunksize[, callback[, error_callback]]]*)
A variant of the map() method which returns a result object.

If callback is specified then it should be a callable which accepts a single argument. When the result becomes ready callback is applied to it, that is unless the call failed, in which case the error_callback is applied instead.

If error_callback is specified then it should be a callable which accepts a single argument. If the target function fails, then the error_callback is called with the exception instance.

Callbacks should complete immediately since otherwise the thread which handles the results will get blocked.

**imap**(*func, iterable[, chunksize]*)
A lazier version of map().

The chunksize argument is the same as the one used by the map() method. For very long iterables using a large value for
chunksize can make the job complete much faster than using the default value of 1.

Also if chunksize is 1 then the next() method of the iterator returned by the imap() method has an optional timeout parameter: next(timeout) will raise multiprocessing.TimeoutError if the result cannot be returned within timeout seconds.

imap_unordered(func, iterable[, chunksize])

The same as imap() except that the ordering of the results from the returned iterator should be considered arbitrary. (Only when there is only one worker process is the order guaranteed to be “correct”).

starmap(func, iterable[, chunksize])

Like map() except that the elements of the iterable are expected to be iterables that are unpacked as arguments.

Hence an iterable of [(1,2), (3, 4)] results in [func(1,2), func(3,4)].

New in version 3.3.

starmap_async(func, iterable[, chunksize[, callback[, error_back]]]])

A combination of starmap() and map_async() that iterates over iterable of iterables and calls func with the iterables unpacked. Returns a result object.

New in version 3.3.
close()
Prevents any more tasks from being submitted to the pool. Once all the tasks have been completed the worker processes will exit.

terminate()
Stops the worker processes immediately without completing outstanding work. When the pool object is garbage collected `terminate()` will be called immediately.

join()
Wait for the worker processes to exit. One must call close() or terminate() before using join().

New in version 3.3: Pool objects now support the context manager protocol – see Context Manager Types. __enter__() returns the pool object, and __exit__() calls terminate().

class multiprocessing.pool.AsyncResult
The class of the result returned by Pool.apply_async() and Pool.map_async().

get([timeout])
Return the result when it arrives. If timeout is not None and the result does not arrive within timeout seconds then multiprocessing.TimeoutError is raised. If the remote call raised an exception then that exception will be reraised by get().

wait([timeout])
Wait until the result is available or until timeout seconds pass.
**ready()**
Return whether the call has completed.

**successful()**
Return whether the call completed without raising an exception. Will raise `AssertionError` if the result is not ready.

The following example demonstrates the use of a pool:

```python
from multiprocessing import Pool

def f(x):
    return x*x

if __name__ == '__main__':
    with Pool(processes=4) as pool:
        result = pool.apply_async(f, (10,))  # evaluate "f(10)" asynchronously
        print(result.get(timeout=1))  # prints "100" unless your computer is *very* slow

    print(pool.map(f, range(10)))  # prints 
[0, 1, 4, ..., 81]

    it = pool.imap(f, range(10))
    print(next(it))  # prints
    print(next(it))  # prints
    print(it.next(timeout=1))  # raises

    import time
    result = pool.apply_async(time.sleep, (10,))
    print(result.get(timeout=1))  # raises
```

### 17.2.2.10. Listeners and Clients

Usually message passing between processes is done using queues or by using `Connection` objects returned by `Pipe()`.
However, the `multiprocessing.connection` module allows some extra flexibility. It basically gives a high level message oriented API for dealing with sockets or Windows named pipes. It also has support for *digest authentication* using the `hmac` module, and for polling multiple connections at the same time.

`multiprocessing.connection.deliver_challenge(connection, authkey)`

Send a randomly generated message to the other end of the connection and wait for a reply.

If the reply matches the digest of the message using `authkey` as the key then a welcome message is sent to the other end of the connection. Otherwise `AuthenticationError` is raised.

`multiprocessing.connection.answer_challenge(connect, authkey)`

Receive a message, calculate the digest of the message using `authkey` as the key, and then send the digest back.

If a welcome message is not received, then `AuthenticationError` is raised.

`multiprocessing.connection.Client(address[, family[, authenticate[, authkey]]])`  

Attempt to set up a connection to the listener which is using address `address`, returning a `Connection`.

The type of the connection is determined by `family` argument, but this can generally be omitted since it can usually be inferred from the format of `address`. (See *Address Formats*)

If `authenticate` is True or `authkey` is a byte string then digest
authentication is used. The key used for authentication will be either authkey or current_process().authkey if authkey is None. If authentication fails then AuthenticationError is raised. See Authentication keys.

```python
class multiprocessing.connection.Listener([address[, family[, backlog[, authenticate[, authkey]]]])
```

A wrapper for a bound socket or Windows named pipe which is ‘listening’ for connections.

- **address**: is the address to be used by the bound socket or named pipe of the listener object.

  **Note**: If an address of ‘0.0.0.0’ is used, the address will not be a connectable end point on Windows. If you require a connectable end-point, you should use ‘127.0.0.1’.

- **family**: is the type of socket (or named pipe) to use. This can be one of the strings 'AF_INET' (for a TCP socket), 'AF_UNIX' (for a Unix domain socket) or 'AF_PIPE' (for a Windows named pipe). Of these only the first is guaranteed to be available. If family is None then the family is inferred from the format of address. If address is also None then a default is chosen. This default is the family which is assumed to be the fastest available. See Address Formats. Note that if family is 'AF_UNIX' and address is None then the socket will be created in a private temporary directory created using tempfile.mkstemp().

If the listener object uses a socket then backlog (1 by default) is passed to the listen() method of the socket once it has been bound.
If `authenticate` is True (False by default) or `authkey` is not `None` then digest authentication is used.

If `authkey` is a byte string then it will be used as the authentication key; otherwise it must be `None`.

If `authkey` is `None` and `authenticate` is True then `current_process().authkey` is used as the authentication key. If `authkey` is `None` and `authenticate` is `False` then no authentication is done. If authentication fails then `AuthenticationError` is raised. See `Authentication keys`.

**accept()**

Accept a connection on the bound socket or named pipe of the listener object and return a `Connection` object. If authentication is attempted and fails, then `AuthenticationError` is raised.

**close()**

Close the bound socket or named pipe of the listener object. This is called automatically when the listener is garbage collected. However it is advisable to call it explicitly.

Listener objects have the following read-only properties:

**address**

The address which is being used by the Listener object.

**last_accepted**

The address from which the last accepted connection came. If this is unavailable then it is `None`.

*New in version 3.3:* Listener objects now support the context
manager protocol – see Context Manager Types. __enter__() returns the listener object, and __exit__() calls close().

multiprocessing.connection.wait(object_list, timeout=None)
Wait till an object in object_list is ready. Returns the list of those objects in object_list which are ready. If timeout is a float then the call blocks for at most that many seconds. If timeout is None then it will block for an unlimited period. A negative timeout is equivalent to a zero timeout.

For both Unix and Windows, an object can appear in object_list if it is

- a readable Connection object;
- a connected and readable socket.socket object; or
- the sentinel attribute of a Process object.

A connection or socket object is ready when there is data available to be read from it, or the other end has been closed.

Unix: wait(object_list, timeout) almost equivalent select.select(object_list, [], [], timeout). The difference is that, if select.select() is interrupted by a signal, it can raise OSError with an error number of EINTR, whereas wait() will not.

Windows: An item in object_list must either be an integer handle which is waitable (according to the definition used by the documentation of the Win32 function WaitForMultipleObjects()) or it can be an object with a fileno() method which returns a socket handle or pipe handle. (Note that pipe handles and socket handles are not waitable handles.)
New in version 3.3.

Examples

The following server code creates a listener which uses `'secret password'` as an authentication key. It then waits for a connection and sends some data to the client:

```python
from multiprocessing.connection import Listener
from array import array

address = ('localhost', 6000)  # family is deduced

with Listener(address, authkey=b'secret password') as listener:
    with listener.accept() as conn:
        print('connection accepted from', listener.last_accepted)

        conn.send([2.25, None, 'junk', float])
        conn.send_bytes(b'hello')
        conn.send_bytes(array('i', [42, 1729]))
```

The following code connects to the server and receives some data from the server:

```python
from multiprocessing.connection import Client
from array import array

address = ('localhost', 6000)

with Client(address, authkey=b'secret password') as conn:
    print(conn.recv())  # => [2.25, None, 'junk', float]
    print(conn.recv_bytes())  # => 'hello'
```
arr = array('i', [0, 0, 0, 0, 0])
print(conn.recv_bytes_into(arr))  # => 8
print(arr)  # => array('i',

The following code uses \texttt{wait()} to wait for messages from multiple processes at once:

```python
import time, random
from multiprocessing import Process, Pipe, current_process
from multiprocessing.connection import wait

def foo(w):
    for i in range(10):
        w.send((i, current_process().name))
    w.close()

if __name__ == '__main__':
    readers = []

    for i in range(4):
        r, w = Pipe(duplex=False)
        readers.append(r)
        p = Process(target=foo, args=(w,))
        p.start()
        # We close the writable end of the pipe now
        # \texttt{p} is the only process which owns a handle
        # ensures that when \texttt{p} closes its handle for
        # \texttt{wait()} will promptly report the readable end
        w.close()

while readers:
    for r in wait(readers):
        try:
            msg = r.recv()
        except EOFError:
```
17.2.2.10.1. Address Formats

- An 'AF_INET' address is a tuple of the form \((\text{hostname}, \text{port})\) where \(\text{hostname}\) is a string and \(\text{port}\) is an integer.

- An 'AF_UNIX' address is a string representing a filename on the filesystem.

- An 'AF_PIPE' address is a string of the form \(r'\backslash.\backslash\text{PipeName}'\). To use \(\text{Client()}\) to connect to a named pipe on a remote computer called \(\text{ServerName}\) one should use an address of the form \(r'\backslash\backslash\text{ServerName}\backslash\text{pipe}\backslash\text{PipeName}'\) instead.

Note that any string beginning with two backslashes is assumed by default to be an 'AF_PIPE' address rather than an 'AF_UNIX' address.

17.2.2.11. Authentication keys

When one uses \(\text{Connection.recv}\), the data received is automatically unpickled. Unfortunately unpickling data from an untrusted source is a security risk. Therefore \(\text{Listener}\) and \(\text{Client()}\) use the \(\text{hmac}\) module to provide digest authentication.

An authentication key is a byte string which can be thought of as a password: once a connection is established both ends will demand proof that the other knows the authentication key. (Demonstrating that
both ends are using the same key does not involve sending the key over the connection.)

If authentication is requested but no authentication key is specified then the return value of `current_process().authkey` is used (see `Process`). This value will automatically inherited by any `Process` object that the current process creates. This means that (by default) all processes of a multi-process program will share a single authentication key which can be used when setting up connections between themselves.

Suitable authentication keys can also be generated by using `os.urandom()`.

17.2.2.12. Logging

Some support for logging is available. Note, however, that the `logging` package does not use process shared locks so it is possible (depending on the handler type) for messages from different processes to get mixed up.

`multiprocessing.get_logger()`

Returns the logger used by `multiprocessing`. If necessary, a new one will be created.

When first created the logger has level `logging.NOTSET` and no default handler. Messages sent to this logger will not by default propagate to the root logger.

Note that on Windows child processes will only inherit the level of the parent process's logger – any other customization of the logger will not be inherited.
multiprocessing.\texttt{log\_to\_stderr()}  

This function performs a call to \texttt{get\_logger()} but in addition to returning the logger created by \texttt{get\_logger}, it adds a handler which sends output to \texttt{sys.stderr} using format ‘\texttt{[%(levelname)s/%(processName)s] %(message)s}’.

Below is an example session with logging turned on:

```python
>>> import multiprocessing, logging
>>> logger = multiprocessing.log_to_stderr()
>>> logger.setLevel(logging.INFO)
>>> logger.warning('doomed')
[WARNING/MainProcess] doomed
>>> m = multiprocessing.Manager()
[INFO/SyncManager-....] child process calling self.run()
[INFO/SyncManager-....] created temp directory /.../pymp-
[INFO/SyncManager-....] manager serving at '/.../listener-
>>> del m
[INFO/MainProcess] sending shutdown message to manager
[INFO/SyncManager-....] manager exiting with exitcode
```

In addition to having these two logging functions, the multiprocessing also exposes two additional logging level attributes. These are \texttt{SUBWARNING} and \texttt{SUBDEBUG}. The table below illustrates where theses fit in the normal level hierarchy.

<table>
<thead>
<tr>
<th>Level</th>
<th>Numeric value</th>
</tr>
</thead>
<tbody>
<tr>
<td>SUBWARNING</td>
<td>25</td>
</tr>
<tr>
<td>SUBDEBUG</td>
<td>5</td>
</tr>
</tbody>
</table>

For a full table of logging levels, see the \texttt{logging} module.

These additional logging levels are used primarily for certain debug
messages within the multiprocessing module. Below is the same example as above, except with SUBDEBUG enabled:

```python
>>> import multiprocessing, logging
>>> logger = multiprocessing.log_to_stderr()
>>> logger.setLevel(multiprocessing.SUBDEBUG)
>>> logger.warning('doomed')
[WARNING/MainProcess] doomed
>>> m = multiprocessing.Manager()
[INFO/SyncManager-....] child process calling self.run()
[INFO/SyncManager-....] created temp directory /.../pymp
[INFO/SyncManager-....] manager serving at '/.../pymp-djGBXN/listener-...'
>>> del m
[SUBDEBUG/MainProcess] finalizer calling ...
[INFO/MainProcess] sending shutdown message to manager
[DEBUG/SyncManager-....] manager received shutdown message
[SUBDEBUG/SyncManager-....] calling <Finalize object, callback=unlink, ...
[SUBDEBUG/SyncManager-....] finalizer calling <built-in function unlink> ...
[SUBDEBUG/SyncManager-....] calling <Finalize object, dead>
[SUBDEBUG/SyncManager-....] finalizer calling <function rmtree at 0x5aa730> ...
[INFO/SyncManager-....] manager exiting with exitcode 0
```

17.2.2.13. The `multiprocessing.dummy` module

`multiprocessing.dummy` replicates the API of `multiprocessing` but is no more than a wrapper around the `threading` module.
17.2.3. Programming guidelines

There are certain guidelines and idioms which should be adhered to when using `multiprocessing`.

17.2.3.1. All platforms

Avoid shared state

As far as possible one should try to avoid shifting large amounts of data between processes.

It is probably best to stick to using queues or pipes for communication between processes rather than using the lower level synchronization primitives.

Picklability

Ensure that the arguments to the methods of proxies are picklable.

Thread safety of proxies

Do not use a proxy object from more than one thread unless you protect it with a lock.

(There is never a problem with different processes using the same proxy.)

Joining zombie processes

On Unix when a process finishes but has not been joined it becomes a zombie. There should never be very many because each time a new process starts (or `active_children()` is
called) all completed processes which have not yet been joined will be joined. Also calling a finished process’s `Process.is_alive` will join the process. Even so it is probably good practice to explicitly join all the processes that you start.

Better to inherit than pickle/unpickle

On Windows many types from `multiprocessing` need to be picklable so that child processes can use them. However, one should generally avoid sending shared objects to other processes using pipes or queues. Instead you should arrange the program so that a process which needs access to a shared resource created elsewhere can inherit it from an ancestor process.

Avoid terminating processes

Using the `Process.terminate` method to stop a process is liable to cause any shared resources (such as locks, semaphores, pipes and queues) currently being used by the process to become broken or unavailable to other processes.

Therefore it is probably best to only consider using `Process.terminate` on processes which never use any shared resources.

Joining processes that use queues

Bear in mind that a process that has put items in a queue will wait before terminating until all the buffered items are fed by the “feeder” thread to the underlying pipe. (The child process can call the `Queue.cancel_join_thread` method of the queue to avoid this behaviour.)

This means that whenever you use a queue you need to make sure that all items which have been put on the queue will
eventually be removed before the process is joined. Otherwise you cannot be sure that processes which have put items on the queue will terminate. Remember also that non-daemonic processes will be automatically be joined.

An example which will deadlock is the following:

```python
from multiprocessing import Process, Queue

def f(q):
    q.put('X' * 1000000)

if __name__ == '__main__':
    queue = Queue()
    p = Process(target=f, args=(queue,))
    p.start()
    p.join()  # this deadlocks
    obj = queue.get()
```

A fix here would be to swap the last two lines round (or simply remove the `p.join()` line).

Explicitly pass resources to child processes

On Unix a child process can make use of a shared resource created in a parent process using a global resource. However, it is better to pass the object as an argument to the constructor for the child process.

Apart from making the code (potentially) compatible with Windows this also ensures that as long as the child process is still alive the object will not be garbage collected in the parent process. This might be important if some resource is freed when the object is garbage collected in the parent process.
So for instance

```python
from multiprocessing import Process, Lock

def f():
    ... do something using "lock" ... 

if __name__ == '__main__':
    lock = Lock()
    for i in range(10):
        Process(target=f).start()
```

should be rewritten as

```python
from multiprocessing import Process, Lock

def f(l):
    ... do something using "l" ... 

if __name__ == '__main__':
    lock = Lock()
    for i in range(10):
        Process(target=f, args=(lock,)).start() 
```

Beware of replacing `sys.stdin` with a “file like object”

```python
multiprocessing originally unconditionally called:

os.close(sys.stdin.fileno())
```

in the `multiprocessing.Process._bootstrap()` method — this resulted in issues with processes-in-processes. This has been changed to:

```python
sys.stdin.close()
```
Which solves the fundamental issue of processes colliding with each other resulting in a bad file descriptor error, but introduces a potential danger to applications which replace `sys.stdin()` with a “file-like object” with output buffering. This danger is that if multiple processes call `close()` on this file-like object, it could result in the same data being flushed to the object multiple times, resulting in corruption.

If you write a file-like object and implement your own caching, you can make it fork-safe by storing the pid whenever you append to the cache, and discarding the cache when the pid changes. For example:

```python
@property
def cache(self):
    pid = os.getpid()
    if pid != self._pid:
        self._pid = pid
        self._cache = []
    return self._cache
```

For more information, see issue 5155, issue 5313 and issue 5331

### 17.2.3.2. Windows

Since Windows lacks `os.fork()` it has a few extra restrictions:

More picklability

Ensure that all arguments to `Process.__init__()` are picklable. This means, in particular, that bound or unbound
methods cannot be used directly as the `target` argument on Windows — just define a function and use that instead.

Also, if you subclass `Process` then make sure that instances will be picklable when the `Process.start` method is called.

Global variables

Bear in mind that if code run in a child process tries to access a global variable, then the value it sees (if any) may not be the same as the value in the parent process at the time that `Process.start` was called.

However, global variables which are just module level constants cause no problems.

Safe importing of main module

Make sure that the main module can be safely imported by a new Python interpreter without causing unintended side effects (such a starting a new process).

For example, under Windows running the following module would fail with a `RuntimeError`:

```python
from multiprocessing import Process

def foo():
    print('hello')

p = Process(target=foo)
p.start()
```

Instead one should protect the “entry point” of the program by
using `if __name__ == '__main__':` as follows:

```python
from multiprocessing import Process, freeze_support

def foo():
    print('hello')

if __name__ == '__main__':
    freeze_support()
    p = Process(target=foo)
    p.start()
```

(The `freeze_support()` line can be omitted if the program will be run normally instead of frozen.)

This allows the newly spawned Python interpreter to safely import the module and then run the module’s `foo()` function.

Similar restrictions apply if a pool or manager is created in the main module.
17.2.4. Examples

Demonstration of how to create and use customized managers and proxies:

```python
# This module shows how to use arbitrary callables with `BaseManager`.
#
# Copyright (c) 2006-2008, R Oudkerk
# All rights reserved.
#
from multiprocessing import freeze_support
from multiprocessing.managers import BaseManager, BaseProxy

##
class Foo:
    def f(self):
        print('you called Foo.f()')
    def g(self):
        print('you called Foo.g()')
    def _h(self):
        print('you called Foo._h()')

# A simple generator function
def baz():
    for i in range(10):
        yield i*i

# Proxy type for generator objects
class GeneratorProxy(BaseProxy):
    _exposed_ = ('next', '__next__')
```
```python
def __iter__(self):
    return self
def __next__(self):
    return self._callmethod('next')
def __next__(self):
    return self._callmethod('__next__')

# Function to return the operator module
def get_operator_module():
    return operator

###
class MyManager(BaseManager):
    pass

# register the Foo class; make `f()` and `g()` accessible
MyManager.register('Foo1', Foo)

# register the Foo class; make `g()` and `_h()` accessible
MyManager.register('Foo2', Foo, exposed=('g', '_h'))

# register the generator function baz; use `GeneratorProxy` to make proxies
MyManager.register('baz', baz, proxytype=GeneratorProxy)

# register get_operator_module(); make public functions accessible
MyManager.register('operator', get_operator_module)

###

def test():
    manager = MyManager()
    manager.start()

    print('-' * 20)

    f1 = manager.Foo1()
```
f1.f()
f1.g()

```python
assert not hasattr(f1, '_h')
assert sorted(f1._exposed_) == sorted(['f', 'g'])
```

print('-' * 20)

f2 = manager.Foo2()
f2.g()
f2._h()

```python
assert not hasattr(f2, 'f')
assert sorted(f2._exposed_) == sorted(['g', '_h'])
```

print('-' * 20)

it = manager.baz()
for i in it:
    print('<%d>' % i, end='
')
print()

print('-' * 20)

op = manager.operator()
print('op.add(23, 45) =', op.add(23, 45))
print('op.pow(2, 94) =', op.pow(2, 94))
print('op.getslice(range(10), 2, 6) =', op.getslice(range(10), 2, 6))
print('op.repeat(range(5), 3) =', op.repeat(list))
print('op._exposed_ =', op._exposed_)

##

```python
if __name__ == '__main__':
    freeze_support()

An example showing how to use queues to feed tasks to a collection of worker processes and collect the results:

```python
import time
import random
from multiprocessing import Process, Queue, current_process

# Function run by worker processes

def worker(input, output):
    for func, args in iter(input.get, 'STOP'):
        result = calculate(func, args)
        output.put(result)
```

# Simple example which uses a pool of workers to carry out some tasks.

# Notice that the results will probably not come out of the output queue in the same order as the corresponding tasks were put on the input queue. If it is important to get the results back in the original order then consider using `Pool.map()` or `Pool.imap()` (which will save on the amount of code needed anyway).

    cond = multiprocessing.Condition()
    elapsed = 0
    iterations = 1

    while elapsed < delta:
        iterations *= 2
```python
p = multiprocessing.Process(target=pipe_func, args=(d, cond, i
cond.acquire()
p.start()
cond.wait()
cond.release()

result = None
t = _timer()

while result != 'STOP':
    result = c.recv()

elapsed = _timer() - t
p.join()

print(iterations, 'objects passed through connection')
print('average number/sec:', iterations/elapsed)

### TEST_SEQSPEED

def test_seqspeed(seq):
    elapsed = 0
    iterations = 1

    while elapsed < delta:
        iterations *= 2

    t = _timer()

    for i in range(iterations):
        a = seq[5]

    elapsed = _timer() - t
```
print(iterations, 'iterations in', elapsed, 'sec')
print('average number/sec:', iterations/elapsed)

#### TEST_LOCK

def test_lockspeed(l):
    elapsed = 0
    iterations = 1
    while elapsed < delta:
        iterations *= 2
        t = _timer()
        for i in range(iterations):
            l.acquire()
            l.release()
            elapsed = _timer() - t
    print(iterations, 'iterations in', elapsed, 'sec')
    print('average number/sec:', iterations/elapsed)

#### TEST_CONDITION

def conditionspeed_func(c, N):
    c.acquire()
    c.notify()
    for i in range(N):
        c.wait()
        c.notify()
    c.release()
```python
def test_conditionspeed(Process, c):
    elapsed = 0
    iterations = 1

    while elapsed < delta:
        iterations *= 2

        c.acquire()
        p = Process(target=conditionspeed_func, args=)
        p.start()

        c.wait()

        t = _timer()

        for i in range(iterations):
            c.notify()
            c.wait()

        elapsed = _timer() - t

        c.release()
        p.join()

    print(iterations * 2, 'waits in', elapsed, 'seconds')
    print('average number/sec:', iterations * 2 / elapsed)

17.3. The concurrent package

Currently, there is only one module in this package:

- `concurrent.futures` – Launching parallel tasks
17.4. `concurrent.futures` — Launching parallel tasks

*New in version 3.2.*

**Source code:** `Lib/concurrent/futures/thread.py` and `Lib/concurrent/futures/process.py`

The `concurrent.futures` module provides a high-level interface for asynchronously executing callables.

The asynchronous execution can be performed with threads, using `ThreadPoolExecutor`, or separate processes, using `ProcessPoolExecutor`. Both implement the same interface, which is defined by the abstract `Executor` class.
17.4.1. Executor Objects

class concurrent.futures.Executor

An abstract class that provides methods to execute calls asynchronously. It should not be used directly, but through its concrete subclasses.

submit(fn, *args, **kwargs)

Schedules the callable, \( fn \), to be executed as \( \text{fn}(*\text{args} **\text{kwargs}) \) and returns a Future object representing the execution of the callable.

```python
with ThreadPoolExecutor(max_workers=1) as executor:
    future = executor.submit(pow, 323, 1235)
    print(future.result())
```

map(func, *iterables, timeout=None)

Equivalent to map(func, *iterables) except func is executed asynchronously and several calls to func may be made concurrently. The returned iterator raises a TimeoutError if \( \text{__next__}() \) is called and the result isn't available after timeout seconds from the original call to Executor.map(). timeout can be an int or a float. If timeout is not specified or None, there is no limit to the wait time. If a call raises an exception, then that exception will be raised when its value is retrieved from the iterator.

shutdown(wait=True)

Signal the executor that it should free any resources that it is using when the currently pending futures are done
executing. Calls to `Executor.submit()` and `Executor.map()` made after shutdown will raise `RuntimeError`.

If `wait` is True then this method will not return until all the pending futures are done executing and the resources associated with the executor have been freed. If `wait` is False then this method will return immediately and the resources associated with the executor will be freed when all pending futures are done executing. Regardless of the value of `wait`, the entire Python program will not exit until all pending futures are done executing.

You can avoid having to call this method explicitly if you use the `with` statement, which will shutdown the `Executor` (waiting as if `Executor.shutdown()` were called with `wait` set to True):

```python
import shutil
with ThreadPoolExecutor(max_workers=4) as e:
    e.submit(shutil.copy, 'src1.txt', 'dest1.txt')
    e.submit(shutil.copy, 'src2.txt', 'dest2.txt')
    e.submit(shutil.copy, 'src3.txt', 'dest3.txt')
    e.submit(shutil.copy, 'src3.txt', 'dest4.txt')
```
17.4.2. ThreadPoolExecutor

ThreadPoolExecutor is a Executor subclass that uses a pool of threads to execute calls asynchronously.

Deadlocks can occur when the callable associated with a Future waits on the results of another Future. For example:

```python
import time
def wait_on_b():
    time.sleep(5)
    print(b.result())  # b will never complete because it is waiting on a.
    return 5
def wait_on_a():
    time.sleep(5)
    print(a.result())  # a will never complete because it is waiting on b.
    return 6

executor = ThreadPoolExecutor(max_workers=2)
a = executor.submit(wait_on_b)
b = executor.submit(wait_on_a)
```

And:

```python
def wait_on_future():
    f = executor.submit(pow, 5, 2)
    # This will never complete because there is only one worker thread and it is executing this function.
    print(f.result())

executor = ThreadPoolExecutor(max_workers=1)
executor.submit(wait_on_future)
```
class concurrent.futures.ThreadingPoolExecutor(max_workers)
    An Executor subclass that uses a pool of at most max_workers threads to execute calls asynchronously.

17.4.2.1. ThreadPoolExecutor Example

```python
import concurrent.futures
import urllib.request

URLS = ['http://www.foxnews.com/',
        'http://www.cnn.com/',
        'http://europe.wsj.com/',
        'http://www.bbc.co.uk/',
        'http://some-made-up-domain.com/']

# Retrieve a single page and report the url and content
def load_url(url, timeout):
    conn = urllib.request.urlopen(url, timeout=timeout)
    return conn.readall()

# We can use a with statement to ensure threads are cleansed
with concurrent.futures.ThreadPoolExecutor(max_workers=5):
    # Start the load operations and mark each future
    future_to_url = {executor.submit(load_url, url, timeout=5): url
                     for url in URLS}
    for future in concurrent.futures.as_completed(future_to_url):
        url = future_to_url[future]
        try:
            data = future.result()
        except Exception as exc:
            print('%r generated an exception: %s' % (url, exc))
        else:
            print('%r page is %d bytes' % (url, len(data)))
```
17.4.3. ProcessPoolExecutor

The ProcessPoolExecutor class is an Executor subclass that uses a pool of processes to execute calls asynchronously. ProcessPoolExecutor uses the multiprocessing module, which allows it to side-step the Global Interpreter Lock but also means that only picklable objects can be executed and returned.

Calling Executor or Future methods from a callable submitted to a ProcessPoolExecutor will result in deadlock.

class concurrent.futures.ProcessPoolExecutor(max_workers=\n
An Executor subclass that executes calls asynchronously using a pool of at most max_workers processes. If max_workers is None or not given, it will default to the number of processors on the machine.

Changed in version 3.3: When one of the worker processes terminates abruptly, a BrokenProcessPool error is now raised. Previously, behaviour was undefined but operations on the executor or its futures would often freeze or deadlock.

17.4.3.1. ProcessPoolExecutor Example

```python
import concurrent.futures
import math

PRIMES = [
    112272535095293,
    112582705942171,
    112272535095293,
]```
def is_prime(n):
    if n % 2 == 0:
        return False

    sqrt_n = int(math.floor(math.sqrt(n)))
    for i in range(3, sqrt_n + 1, 2):
        if n % i == 0:
            return False
    return True

def main():
    with concurrent.futures.ProcessPoolExecutor() as executor:
        for number, prime in zip(PRIMES, executor.map(is_prime, PRIMES)):
            print('{} is prime: {}' % (number, prime))

if __name__ == '__main__':
    main()
17.4.4. Future Objects

The `Future` class encapsulates the asynchronous execution of a callable. `Future` instances are created by `Executor.submit()`.

```python
class concurrent.futures.Future
    Encapsulates the asynchronous execution of a callable. Future instances are created by Executor.submit() and should not be created directly except for testing.

    cancel()
        Attempt to cancel the call. If the call is currently being executed and cannot be cancelled then the method will return False, otherwise the call will be cancelled and the method will return True.

    cancelled()
        Return True if the call was successfully cancelled.

    running()
        Return True if the call is currently being executed and cannot be cancelled.

    done()
        Return True if the call was successfully cancelled or finished running.

    result(timeout=None)
        Return the value returned by the call. If the call hasn’t yet completed then this method will wait up to timeout seconds. If the call hasn’t completed in timeout seconds,
then a `TimeoutError` will be raised. `timeout` can be an int or float. If `timeout` is not specified or `None`, there is no limit to the wait time.

If the future is cancelled before completing then `CancelledError` will be raised.

If the call raised, this method will raise the same exception.

**exception** *(timeout=\text{None})*

Return the exception raised by the call. If the call hasn’t yet completed then this method will wait up to `timeout` seconds. If the call hasn’t completed in `timeout` seconds, then a `TimeoutError` will be raised. `timeout` can be an int or float. If `timeout` is not specified or `None`, there is no limit to the wait time.

If the future is cancelled before completing then `CancelledError` will be raised.

If the call completed without raising, `None` is returned.

**add\_done\_callback** *(fn)*

Attaches the callable `fn` to the future. `fn` will be called, with the future as its only argument, when the future is cancelled or finishes running.

Added callables are called in the order that they were added and are always called in a thread belonging to the process that added them. If the callable raises a `Exception` subclass, it will be logged and ignored. If the callable raises a `BaseException` subclass, the behavior is undefined.
If the future has already completed or been cancelled, \( fn \) will be called immediately.

The following \texttt{Future} methods are meant for use in unit tests and \texttt{Executor} implementations.

\texttt{set\_running\_or\_notify\_cancel()}

This method should only be called by \texttt{Executor} implementations before executing the work associated with the \texttt{Future} and by unit tests.

If the method returns \texttt{False} then the \texttt{Future} was cancelled, i.e. \texttt{Future.cancel()} was called and returned \texttt{True}. Any threads waiting on the \texttt{Future} completing (i.e. through \texttt{as\_completed()} or \texttt{wait()}) will be woken up.

If the method returns \texttt{True} then the \texttt{Future} was not cancelled and has been put in the running state, i.e. calls to \texttt{Future.running()} will return \texttt{True}.

This method can only be called once and cannot be called after \texttt{Future.set\_result()} or \texttt{Future.set\_exception()} have been called.

\texttt{set\_result(result)}

Sets the result of the work associated with the \texttt{Future} to \texttt{result}.

This method should only be used by \texttt{Executor} implementations and unit tests.

\texttt{set\_exception(exception)}
Sets the result of the work associated with the `Future` to the `Exception` exception.

This method should only be used by `Executor` implementations and unit tests.
17.4.5. Module Functions

concurrent.futures.wait(fs, timeout=None, return_when=ALL_COMPLETED)

Wait for the Future instances (possibly created by different Executor instances) given by fs to complete. Returns a named 2-tuple of sets. The first set, named done, contains the futures that completed (finished or were cancelled) before the wait completed. The second set, named not_done, contains uncompleted futures.

timeout can be used to control the maximum number of seconds to wait before returning. timeout can be an int or float. If timeout is not specified or None, there is no limit to the wait time.

return_when indicates when this function should return. It must be one of the following constants:

<table>
<thead>
<tr>
<th>Constant</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>FIRST_COMPLETED</td>
<td>The function will return when any future finishes or is cancelled.</td>
</tr>
<tr>
<td>FIRST_EXCEPTION</td>
<td>The function will return when any future finishes by raising an exception. If no future raises an exception then it is equivalent to ALL_COMPLETED.</td>
</tr>
<tr>
<td>ALL_COMPLETED</td>
<td>The function will return when all futures finish or are cancelled.</td>
</tr>
</tbody>
</table>

concurrent.futures.as_completed(fs, timeout=None)

Returns an iterator over the Future instances (possibly created by different Executor instances) given by fs that yields futures as
they complete (finished or were cancelled). Any futures that completed before `as_completed()` is called will be yielded first. The returned iterator raises a `TimeoutError` if `__next__()` is called and the result isn’t available after `timeout` seconds from the original call to `as_completed()`. `timeout` can be an int or float. If `timeout` is not specified or None, there is no limit to the wait time.

See also:

**PEP 3148 – futures - execute computations asynchronously**

The proposal which described this feature for inclusion in the Python standard library.
17.4.6. Exception classes

`exception concurrent.futures.BrokenProcessPool`

Derived from `RuntimeError`, this exception class is raised when one of the workers of a `ProcessPoolExecutor` has terminated in a non-clean fashion (for example, if it was killed from the outside).

*New in version 3.3.*
17.5. subprocess — Subprocess management

The subprocess module allows you to spawn new processes, connect to their input/output/error pipes, and obtain their return codes. This module intends to replace several other, older modules and functions, such as:

```
os.system
os.spawn*
```

Information about how the subprocess module can be used to replace these modules and functions can be found in the following sections.

See also: PEP 324 – PEP proposing the subprocess module
17.5.1. Using the subprocess Module

The recommended approach to invoking subprocesses is to use the following convenience functions for all use cases they can handle. For more advanced use cases, the underlying Popen interface can be used directly.

```
subprocess.call(args, *, stdin=None, stdout=None, stderr=None, shell=False, timeout=None)
```

Run the command described by `args`. Wait for command to complete, then return the `returncode` attribute.

The arguments shown above are merely the most common ones, described below in `Frequently Used Arguments` (hence the use of keyword-only notation in the abbreviated signature). The full function signature is largely the same as that of the Popen constructor - this function passes all supplied arguments other than `timeout` directly through to that interface.

The `timeout` argument is passed to `Popen.wait()`. If the timeout expires, the child process will be killed and then waited for again. The `TimeoutExpired` exception will be re-raised after the child process has terminated.

Examples:

```
>>> subprocess.call(['ls', '-l'])
0

>>> subprocess.call('exit 1', shell=True)
1
```
Warning: Invoking the system shell with `shell=True` can be a security hazard if combined with untrusted input. See the warning under *Frequently Used Arguments* for details.

Note: Do not use `stdout=PIPE` or `stderr=PIPE` with this function. As the pipes are not being read in the current process, the child process may block if it generates enough output to a pipe to fill up the OS pipe buffer.

*Changed in version 3.3:* `timeout` was added.

```python
subprocess.check_call(args, *, stdin=None, stdout=None, stderr=None, shell=False, timeout=None)
```

Run command with arguments. Wait for command to complete. If the return code was zero then return, otherwise raise `CalledProcessError`. The `CalledProcessError` object will have the return code in the `returncode` attribute.

The arguments shown above are merely the most common ones, described below in *Frequently Used Arguments* (hence the use of keyword-only notation in the abbreviated signature). The full function signature is largely the same as that of the `Popen` constructor - this function passes all supplied arguments other than `timeout` directly through to that interface.

The `timeout` argument is passed to `Popen.wait()`. If the timeout expires, the child process will be killed and then waited for again. The `TimeoutExpired` exception will be re-raised after the child process has terminated.

Examples:

```python
>>> subprocess.check_call(['ls', '-l'])
```
>>> subprocess.check_call("exit 1", shell=True)
Traceback (most recent call last):
...
subprocess.CalledProcessError: Command 'exit 1' r

Warning: Invoking the system shell with shell=True can be a security hazard if combined with untrusted input. See the warning under Frequently Used Arguments for details.

Note: Do not use stdout=PIPE or stderr=PIPE with this function. As the pipes are not being read in the current process, the child process may block if it generates enough output to a pipe to fill up the OS pipe buffer.

Changed in version 3.3: timeout was added.

subprocess.check_output(args, *, stdin=None, stderr=None, shell=False, universal_newlines=False, timeout=None)
Run command with arguments and return its output.

If the return code was non-zero it raises a CalledProcessError. The CalledProcessError object will have the return code in the returncode attribute and any output in the output attribute.

The arguments shown above are merely the most common ones, described below in Frequently Used Arguments (hence the use of keyword-only notation in the abbreviated signature). The full function signature is largely the same as that of the Popen constructor - this functions passes all supplied arguments other
than *timeout* directly through to that interface. In addition, *stdout* is not permitted as an argument, as it is used internally to collect the output from the subprocess.

The *timeout* argument is passed to *Popen.wait()* If the timeout expires, the child process will be killed and then waited for again. The *TimeoutExpired* exception will be re-raised after the child process has terminated.

Examples:

```python
>>> subprocess.check_output(['echo', 'Hello World'])
'Hello World!
'
>>> subprocess.check_output(['echo', 'Hello World'])
>>> subprocess.check_output(['exit 1', shell=True])
Traceback (most recent call last):
...
subprocess.CalledProcessError: Command 'exit 1' r
```

By default, this function will return the data as encoded bytes. The actual encoding of the output data may depend on the command being invoked, so the decoding to text will often need to be handled at the application level.

This behaviour may be overridden by setting *universal_newlines* to True as described below in *Frequently Used Arguments*.

To also capture standard error in the result, use *stderr=subprocess.STDOUT*:

```python
>>> subprocess.check_output(  
```
New in version 3.1.

**Warning:** Invoking the system shell with `shell=True` can be a security hazard if combined with untrusted input. See the warning under *Frequently Used Arguments* for details.

**Note:** Do not use `stderr=PIPE` with this function. As the pipe is not being read in the current process, the child process may block if it generates enough output to the pipe to fill up the OS pipe buffer.

*Changed in version 3.3: timeout was added.*

**subprocess.DEVNULL**

Special value that can be used as the `stdin`, `stdout` or `stderr` argument to `Popen` and indicates that the special file `os.devnull` will be used.

*New in version 3.3.*

**subprocess.PIPE**

Special value that can be used as the `stdin`, `stdout` or `stderr` argument to `Popen` and indicates that a pipe to the standard stream should be opened.

**subprocess.STDOUT**

Special value that can be used as the `stderr` argument to `Popen` and indicates that standard error should go into the same handle
as standard output.

*exception* subprocess. **SubprocessError**
Base class for all other exceptions from this module.

*New in version 3.3.*

*exception* subprocess. **TimeoutExpired**
Subclass of **SubprocessError**, raised when a timeout expires while waiting for a child process.

**cmd**
Command that was used to spawn the child process.

**timeout**
Timeout in seconds.

**output**
Output of the child process if this exception is raised by `check_output()` . Otherwise, None.

*New in version 3.3.*

*exception* subprocess. **CalledProcessError**
Subclass of **SubprocessError**, raised when a process run by `check_call()` or `check_output()` returns a non-zero exit status.

**returncode**
Exit status of the child process.

**cmd**
Command that was used to spawn the child process.
output

Output of the child process if this exception is raised by check_output(). Otherwise, None.

17.5.1.1. Frequently Used Arguments

To support a wide variety of use cases, the Popen constructor (and the convenience functions) accept a large number of optional arguments. For most typical use cases, many of these arguments can be safely left at their default values. The arguments that are most commonly needed are:

*args* is required for all calls and should be a string, or a sequence of program arguments. Providing a sequence of arguments is generally preferred, as it allows the module to take care of any required escaping and quoting of arguments (e.g. to permit spaces in file names). If passing a single string, either *shell* must be *True* (see below) or else the string must simply name the program to be executed without specifying any arguments.

*stdin*, *stdout* and *stderr* specify the executed program's standard input, standard output and standard error file handles, respectively. Valid values are PIPE, DEVNULL, an existing file descriptor (a positive integer), an existing file object, and None. PIPE indicates that a new pipe to the child should be created. DEVNULL indicates that the special file os.devnull will be used. With the default settings of None, no redirection will occur; the child’s file handles will be inherited from the parent. Additionally, *stderr* can be STDOUT, which indicates that the stderr data from the child process should be captured into the same file handle as for *stdout*. 
If `universal_newlines` is False the file objects `stdin`, `stdout` and `stderr` will be opened as binary streams, and no line ending conversion is done.

If `universal_newlines` is True, these file objects will be opened as text streams in `universal newlines` mode using the encoding returned by `locale.getpreferredencoding(False)`. For `stdin`, line ending characters `\n` in the input will be converted to the default line separator `os.linesep`. For `stdout` and `stderr`, all line endings in the output will be converted to `\n`. For more information see the documentation of the `io.TextIOWrapper` class when the `newline` argument to its constructor is None.

**Note:** The newlines attribute of the file objects `Popen.stdin`, `Popen.stdout` and `Popen.stderr` are not updated by the `Popen.communicate()` method.

If `shell` is True, the specified command will be executed through the shell. This can be useful if you are using Python primarily for the enhanced control flow it offers over most system shells and still want convenient access to other shell features such as shell pipes, filename wildcards, environment variable expansion, and expansion of `~` to a user's home directory. However, note that Python itself offers implementations of many shell-like features (in particular, `glob`, `fnmatch`, `os.walk()`, `os.path.expandvars()`, `os.path.expanduser()`, and `shutil`).

*Changed in version 3.3:* When `universal_newlines` is True, the class uses the encoding `locale.getpreferredencoding(False)` instead of
locale.getpreferredencoding(). See the io.TextIOWrapper class for more information on this change.

**Warning:** Executing shell commands that incorporate unsanitized input from an untrusted source makes a program vulnerable to shell injection, a serious security flaw which can result in arbitrary command execution. For this reason, the use of shell=True is strongly discouraged in cases where the command string is constructed from external input:

```
>>> from subprocess import call
>>> filename = input("What file would you like to display?
non_existent; rm -rf / #
>>> call("cat " + filename, shell=True) # Uh-oh
```

shell=False disables all shell based features, but does not suffer from this vulnerability; see the Note in the Popen constructor documentation for helpful hints in getting shell=False to work.

When using shell=True, shlex.quote() can be used to properly escape whitespace and shell metacharacters in strings that are going to be used to construct shell commands.

These options, along with all of the other options, are described in more detail in the Popen constructor documentation.

### 17.5.1.2. Popen Constructor

The underlying process creation and management in this module is
handled by the `Popen` class. It offers a lot of flexibility so that developers are able to handle the less common cases not covered by the convenience functions.

```python
class subprocess.Popen(args, bufsize=-1, executable=None, stdin=None, stdout=None, stderr=None, preexec_fn=None, close_fds=True, shell=False, cwd=None, env=None, universal_newlines=False, startupinfo=None, creationflags=0, restore_signals=True, start_new_session=False, pass_fds=())
```

Execute a child program in a new process. On Unix, the class uses `os.execvp()`-like behavior to execute the child program. On Windows, the class uses the Windows `CreateProcess()` function. The arguments to `Popen` are as follows.

`args` should be a sequence of program arguments or else a single string. By default, the program to execute is the first item in `args` if `args` is a sequence. If `args` is a string, the interpretation is platform-dependent and described below. See the `shell` and `executable` arguments for additional differences from the default behavior. Unless otherwise stated, it is recommended to pass `args` as a sequence.

On Unix, if `args` is a string, the string is interpreted as the name or path of the program to execute. However, this can only be done if not passing arguments to the program.

**Note:** `shlex.split()` can be useful when determining the correct tokenization for `args`, especially in complex cases:

```python
>>> import shlex, subprocess
>>> command_line = input()
/bin/vikings -input eggs.txt -output "spam spam."
>>> args = shlex.split(command_line)
```
>>> print(args)
['/bin/vikings', '-input', 'eggs.txt', '-output' 

Note in particular that options (such as `-input`) and arguments (such as `eggs.txt`) that are separated by whitespace in the shell go in separate list elements, while arguments that need quoting or backslash escaping when used in the shell (such as filenames containing spaces or the `echo` command shown above) are single list elements.

On Windows, if `args` is a sequence, it will be converted to a string in a manner described in *Converting an argument sequence to a string on Windows*. This is because the underlying `CreateProcess()` operates on strings.

The `shell` argument (which defaults to `False`) specifies whether to use the shell as the program to execute. If `shell` is `True`, it is recommended to pass `args` as a string rather than as a sequence.

On Unix with `shell=True`, the shell defaults to `/bin/sh`. If `args` is a string, the string specifies the command to execute through the shell. This means that the string must be formatted exactly as it would be when typed at the shell prompt. This includes, for example, quoting or backslash escaping filenames with spaces in them. If `args` is a sequence, the first item specifies the command string, and any additional items will be treated as additional arguments to the shell itself. That is to say, `Popen` does the equivalent of:

```
Popen(['/bin/sh', '-c', args[0], args[1], ...])
```

On Windows with `shell=True`, the `COMSPEC` environment
variable specifies the default shell. The only time you need to specify \texttt{shell=True} on Windows is when the command you wish to execute is built into the shell (e.g. \texttt{dir} or \texttt{copy}). You do not need \texttt{shell=True} to run a batch file or console-based executable.

\textbf{Warning:} Passing \texttt{shell=True} can be a security hazard if combined with untrusted input. See the warning under \textit{Frequently Used Arguments} for details.

\textit{bufsize} will be supplied as the corresponding argument to the \texttt{io.open()} function when creating the stdin/stdout/stderr pipe file objects: 0 means unbuffered (read and write are one system call and can return short), 1 means line buffered, any other positive value means use a buffer of approximately that size. A negative \textit{bufsize} (the default) means the system default of \texttt{io.DEFAULT_BUFFER_SIZE} will be used.

\textit{Changed in version 3.2.4, 3.3.1}

\textit{bufsize} now defaults to -1 to enable buffering by default to match the behavior that most code expects. In 3.2.0 through 3.2.3 and 3.3.0 it incorrectly defaulted to 0 which was unbuffered and allowed short reads. This was unintentional and did not match the behavior of Python 2 as most code expected.

The \textit{executable} argument specifies a replacement program to execute. It is very seldom needed. When \texttt{shell=False}, \textit{executable} replaces the program to execute specified by \textit{args}. However, the original \textit{args} is still passed to the program. Most programs treat the program specified by \textit{args} as the command name, which can then be different from the program actually executed. On Unix, the \textit{args} name becomes the display name for
the executable in utilities such as `ps`. If `shell=True`, on Unix the `executable` argument specifies a replacement shell for the default `/bin/sh`.

`stdin`, `stdout` and `stderr` specify the executed program’s standard input, standard output and standard error file handles, respectively. Valid values are `PIPE`, `DEVNULL`, an existing file descriptor (a positive integer), an existing `file object`, and `None`. `PIPE` indicates that a new pipe to the child should be created. `DEVNULL` indicates that the special file `os.devnull` will be used. With the default settings of `None`, no redirection will occur; the child’s file handles will be inherited from the parent. Additionally, `stderr` can be `STDOUT`, which indicates that the stderr data from the applications should be captured into the same file handle as for stdout.

If `preexec_fn` is set to a callable object, this object will be called in the child process just before the child is executed. (Unix only)

**Warning:** The `preexec_fn` parameter is not safe to use in the presence of threads in your application. The child process could deadlock before exec is called. If you must use it, keep it trivial! Minimize the number of libraries you call into.

**Note:** If you need to modify the environment for the child use the `env` parameter rather than doing it in a `preexec_fn`. The `start_new_session` parameter can take the place of a previously common use of `preexec_fn` to call `os.setsid()` in the child.

If `close_fds` is true, all file descriptors except 0, 1 and 2 will be closed before the child process is executed. (Unix only). The default varies by platform: Always true on Unix. On Windows it is true when `stdin/stdout/stderr` are `None`, false otherwise. On
Windows, if close_fds is true then no handles will be inherited by the child process. Note that on Windows, you cannot set close_fds to true and also redirect the standard handles by setting stdin, stdout or stderr.

**Changed in version 3.2:** The default for close_fds was changed from **False** to what is described above.

pass_fds is an optional sequence of file descriptors to keep open between the parent and child. Providing any pass_fds forces close_fds to be **True**. (Unix only)

**New in version 3.2:** The pass_fds parameter was added.

If cwd is not None, the function changes the working directory to cwd before executing the child. In particular, the function looks for executable (or for the first item in args) relative to cwd if the executable path is a relative path.

If restore_signals is True (the default) all signals that Python has set to SIG_IGN are restored to SIG_DFL in the child process before the exec. Currently this includes the SIGPIPE, SIGXFZ and SIGXFSZ signals. (Unix only)

**Changed in version 3.2:** restore_signals was added.

If start_new_session is True the setsid() system call will be made in the child process prior to the execution of the subprocess. (Unix only)

**Changed in version 3.2:** start_new_session was added.

If env is not None, it must be a mapping that defines the environment variables for the new process; these are used instead
of the default behavior of inheriting the current process' environment.

**Note:** If specified, `env` must provide any variables required for the program to execute. On Windows, in order to run a side-by-side assembly the specified `env` must include a valid SystemRoot.

If `universal_newlines` is True, the file objects `stdin`, `stdout` and `stderr` are opened as text streams in universal newlines mode, as described above in *Frequently Used Arguments*, otherwise they are opened as binary streams.

If given, `startupinfo` will be a STARTUPINFO object, which is passed to the underlying `CreateProcess` function. `creationflags`, if given, can be CREATE_NEW_CONSOLE or CREATE_NEW_PROCESS_GROUP. (Windows only)

Popen objects are supported as context managers via the `with` statement: on exit, standard file descriptors are closed, and the process is waited for.

```python
with Popen(['ifconfig'], stdout=PIPE) as proc:
    log.write(proc.stdout.read())
```

*Changed in version 3.2:* Added context manager support.

### 17.5.1.3. Exceptions

Exceptions raised in the child process, before the new program has started to execute, will be re-raised in the parent. Additionally, the exception object will have one extra attribute called
child_traceback, which is a string containing traceback information from the child's point of view.

The most common exception raised is OSError. This occurs, for example, when trying to execute a non-existent file. Applications should prepare for OSError exceptions.

A ValueError will be raised if Popen is called with invalid arguments.

check_call() and check_output() will raise CalledProcessError if the called process returns a non-zero return code.

All of the functions and methods that accept a timeout parameter, such as call() and Popen.communicate() will raise TimeoutExpired if the timeout expires before the process exits.

Exceptions defined in this module all inherit from SubprocessError.

New in version 3.3: The SubprocessError base class was added.

17.5.1.4. Security

Unlike some other popen functions, this implementation will never call a system shell implicitly. This means that all characters, including shell metacharacters, can safely be passed to child processes. Obviously, if the shell is invoked explicitly, then it is the application’s responsibility to ensure that all whitespace and metacharacters are quoted appropriately.
17.5.2. Popen Objects

Instances of the Popen class have the following methods:

Popen.poll()
    Check if child process has terminated. Set and return returncode attribute.

Popen.wait(timeout=None)
    Wait for child process to terminate. Set and return returncode attribute.

    If the process does not terminate after timeout seconds, raise a TimeoutExpired exception. It is safe to catch this exception and retry the wait.

    Warning: This will deadlock when using stdout=PIPE and/or stderr=PIPE and the child process generates enough output to a pipe such that it blocks waiting for the OS pipe buffer to accept more data. Use communicate() to avoid that.

    Changed in version 3.3: timeout was added.

Popen.communicate(input=None, timeout=None)
    Interact with process: Send data to stdin. Read data from stdout and stderr, until end-of-file is reached. Wait for process to terminate. The optional input argument should be data to be sent to the child process, or None, if no data should be sent to the child. The type of input must be bytes or, if universal_newlines was True, a string.
communicate() returns a tuple (stdoutdata, stderrdata).

Note that if you want to send data to the process’s stdin, you need to create the Popen object with stdin=PIPE. Similarly, to get anything other than None in the result tuple, you need to give stdout=PIPE and/or stderr=PIPE too.

If the process does not terminate after timeout seconds, a TimeoutExpired exception will be raised. Catching this exception and retrying communication will not lose any output.

The child process is not killed if the timeout expires, so in order to cleanup properly a well-behaved application should kill the child process and finish communication:

```python
proc = subprocess.Popen(...)  
try:                        
    outs, errs = proc.communicate(timeout=15)  
except TimeoutExpired:      
    proc.kill()  
    outs, errs = proc.communicate()
```

**Note:** The data read is buffered in memory, so do not use this method if the data size is large or unlimited.

*Changed in version 3.3:* timeout was added.

Popen.send_signal(signal)

Sends the signal signal to the child.

**Note:** On Windows, SIGTERM is an alias for terminate(). CTRL_C_EVENT and CTRL_BREAK_EVENT can be sent to processes started with a creationflags parameter which includes
Popen.*terminate()

Stop the child. On Posix OSs the method sends SIGTERM to the child. On Windows the Win32 API function TerminateProcess() is called to stop the child.

Popen.*kill()

Kills the child. On Posix OSs the function sends SIGKILL to the child. On Windows kill() is an alias for terminate().

The following attributes are also available:

**Warning:** Use communicate() rather than .stdin.write, .stdout.read or .stderr.read to avoid deadlocks due to any of the other OS pipe buffers filling up and blocking the child process.

Popen.*stdin

If the stdin argument was PIPE, this attribute is a file object that provides input to the child process. Otherwise, it is None.

Popen.*stdout

If the stdout argument was PIPE, this attribute is a file object that provides output from the child process. Otherwise, it is None.

Popen.*stderr

If the stderr argument was PIPE, this attribute is a file object that provides error output from the child process. Otherwise, it is None.

Popen.*pid

The process ID of the child process.
Note that if you set the *shell* argument to `True`, this is the process ID of the spawned shell.

**Popen.** `returncode`

The child return code, set by `poll()` and `wait()` (and indirectly by `communicate()`). A `None` value indicates that the process hasn’t terminated yet.

A negative value `-N` indicates that the child was terminated by signal `N` (Unix only).
17.5.3. Windows Popen Helpers

The `STARTUPINFO` class and following constants are only available on Windows.

class subprocess.STARTUPINFO

Partial support of the Windows `STARTUPINFO` structure is used for `Popen` creation.

dwFlags

A bit field that determines whether certain `STARTUPINFO` attributes are used when the process creates a window.

```python
si = subprocess.STARTUPINFO()
si.dwFlags = subprocess.STARTF_USESTDHANDLES |
```

hStdInput

If `dwFlags` specifies `STARTF_USESTDHANDLES`, this attribute is the standard input handle for the process. If `STARTF_USESTDHANDLES` is not specified, the default for standard input is the keyboard buffer.

hStdOutput

If `dwFlags` specifies `STARTF_USESTDHANDLES`, this attribute is the standard output handle for the process. Otherwise, this attribute is ignored and the default for standard output is the console window's buffer.

hStdError

If `dwFlags` specifies `STARTF_USESTDHANDLES`, this attribute is the standard error handle for the process. Otherwise, this
attribute is ignored and the default for standard error is the console window's buffer.

**wShowWindow**

If `dwFlags` specifies `STARTF_USESHOWWINDOW`, this attribute can be any of the values that can be specified in the `nCmdShow` parameter for the `ShowWindow` function, except for `SW_SHOWDEFAULT`. Otherwise, this attribute is ignored.

`SW_HIDE` is provided for this attribute. It is used when `Popen` is called with `shell=True`.

### 17.5.3.1. Constants

The `subprocess` module exposes the following constants.

*subprocess.* **STD_INPUT_HANDLE**

The standard input device. Initially, this is the console input buffer, `CONIN$`.

*subprocess.* **STD_OUTPUT_HANDLE**

The standard output device. Initially, this is the active console screen buffer, `CONOUT$`.

*subprocess.* **STD_ERROR_HANDLE**

The standard error device. Initially, this is the active console screen buffer, `CONOUT$`.

*subprocess.* **SW_HIDE**

Hides the window. Another window will be activated.

*subprocess.* **STARTF_USESTDHANDLES**
Specifies that the `STARTUPINFO.hStdInput`, `STARTUPINFO.hStdOutput`, and `STARTUPINFO.hStdError` attributes contain additional information.

**subprocess.** `STARTF_USESHOWWINDOW`

This subroutine specifies that the `STARTUPINFO.wShowWindow` attribute contains additional information.

**subprocess.** `CREATE_NEW_CONSOLE`

The new process has a new console, instead of inheriting its parent’s console (the default).

This flag is always set when `Popen` is created with `shell=True`.

**subprocess.** `CREATE_NEW_PROCESS_GROUP`

A `Popen` creationflags parameter to specify that a new process group will be created. This flag is necessary for using `os.kill()` on the subprocess.

This flag is ignored if `CREATE_NEW_CONSOLE` is specified.
17.5.4. Replacing Older Functions with the subprocess Module

In this section, “a becomes b” means that b can be used as a replacement for a.

**Note:** All “a” functions in this section fail (more or less) silently if the executed program cannot be found; the “b” replacements raise OSError instead.

In addition, the replacements using check_output() will fail with a CalledProcessError if the requested operation produces a non-zero return code. The output is still available as the output attribute of the raised exception.

In the following examples, we assume that the relevant functions have already been imported from the subprocess module.

### 17.5.4.1. Replacing /bin/sh shell backquote

```
output=`mycmd myarg`
# becomes
output = check_output(["mycmd", "myarg"])
```

### 17.5.4.2. Replacing shell pipeline

```
output=`dmesg | grep hda`
# becomes
p1 = Popen(["dmesg"], stdout=PIPE)
p2 = Popen(["grep", "hda"], stdin=p1.stdout, stdout=```
p1.stdout.close()  # Allow p1 to receive a SIGPIPE if p2 exits.
output = p2.communicate()[0]

The p1.stdout.close() call after starting the p2 is important in order for p1 to receive a SIGPIPE if p2 exits before p1.

Alternatively, for trusted input, the shell's own pipeline support may still be used directly:

```
output=`dmesg | grep hda`
# becomes
output=check_output("dmesg | grep hda", shell=True)
```

17.5.4.3. Replacing `os.system()`

```
sts = os.system("mycmd" + " myarg")
# becomes
sts = call("mycmd" + " myarg", shell=True)
```

Notes:

- Calling the program through the shell is usually not required.

A more realistic example would look like this:

```
try:
    retcode = call("mycmd" + " myarg", shell=True)
    if retcode < 0:
        print("Child was terminated by signal", -retcode)
    else:
        print("Child returned", retcode, file=sys.stderr)
except OSError as e:
    print("Execution failed:", e, file=sys.stderr)
```
17.5.4.4. Replacing the `os.spawn` family

**P_NOWAIT example:**

```python
pid = os.spawnlp(os.P_NOWAIT, "/bin/mycmd", "mycmd",
==>
pid = Popen(['/bin/mycmd', "myarg"]).pid
```

**P_WAIT example:**

```python
retcode = os.spawnlp(os.P_WAIT, "/bin/mycmd", "mycmd",
==>
retcode = call(['/bin/mycmd', "myarg"])
```

**Vector example:**

```python
os.spawnvp(os.P_NOWAIT, path, args)
==>
Popen([path] + args[1:])
```

**Environment example:**

```python
os.spawnlpe(os.P_NOWAIT, "/bin/mycmd", "mycmd", "myarg",
==>
Popen(['/bin/mycmd', "myarg"], env={"PATH": "/usr/bin"})
```

17.5.4.5. Replacing `os.popen()`, `os.popen2()`, `os.popen3()`

```python
(child_stdin, child_stdout) = os.popen2(cmd, mode, bufsize)
==>
```
Return code handling translates as follows:

```python
pipe = os.popen(cmd, 'w')
...
rc = pipe.close()
if rc is not None and rc >> 8:
    print("There were some errors")
=>
process = Popen(cmd, 'w', stdin=PIPE)
...
process.stdin.close()
if process.wait() != 0:
    print("There were some errors")
```
17.5.4.6. Replacing functions from the popen2 module

**Note:** If the cmd argument to popen2 functions is a string, the command is executed through /bin/sh. If it is a list, the command is directly executed.

```python
(child_stdout, child_stdin) = popen2.popen2("somestring")
p = Popen(['somestring'], shell=True, bufsize=bufsize,
           stdin=PIPE, stdout=PIPE, close_fds=True)
(child_stdout, child_stdin) = (p.stdout, p.stdin)
```

```python
(child_stdout, child_stdin) = popen2.popen2(['mycmd'])
p = Popen(['mycmd', 'myarg'], bufsize=bufsize,
           stdin=PIPE, stdout=PIPE, close_fds=True)
(child_stdout, child_stdin) = (p.stdout, p.stdin)
```

popen2.Popen3 and popen2.Popen4 basically work as subprocess.Popen, except that:

- **Popen** raises an exception if the execution fails.
- the **capturestderr** argument is replaced with the **stderr** argument.
- **stdin=PIPE** and **stdout=PIPE** must be specified.
- popen2 closes all file descriptors by default, but you have to specify **close_fds=True** with **Popen** to guarantee this behavior on all platforms or past Python versions.
17.5.5. Legacy Shell Invocation Functions

This module also provides the following legacy functions from the 2.x commands module. These operations implicitly invoke the system shell and none of the guarantees described above regarding security and exception handling consistency are valid for these functions.

subprocess.\texttt{getstatusoutput}(cmd)

Return (status, output) of executing \texttt{cmd} in a shell.

Execute the string \texttt{cmd} in a shell with \texttt{os.popen()} and return a 2-tuple (status, output). \texttt{cmd} is actually run as \{ \texttt{cmd} ; \} 2>&1, so that the returned output will contain output or error messages. A trailing newline is stripped from the output. The exit status for the command can be interpreted according to the rules for the C function \texttt{wait()}. Example:

```python
>>> subprocess.getstatusoutput('ls /bin/ls')
(0, '/bin/ls')
>>> subprocess.getstatusoutput('cat /bin/junk')
(256, 'cat: /bin/junk: No such file or directory')
>>> subprocess.getstatusoutput('/bin/junk')
(256, 'sh: /bin/junk: not found')
```

Availability: UNIX.

subprocess.\texttt{getoutput}(cmd)

Return output (stdout and stderr) of executing \texttt{cmd} in a shell.

Like \texttt{getstatusoutput()}, except the exit status is ignored and the return value is a string containing the command's output. Example:
Availability: UNIX.
17.5.6. Notes

17.5.6.1. Converting an argument sequence to a string on Windows

On Windows, an *args sequence is converted to a string that can be parsed using the following rules (which correspond to the rules used by the MS C runtime):

1. Arguments are delimited by white space, which is either a space or a tab.
2. A string surrounded by double quotation marks is interpreted as a single argument, regardless of white space contained within. A quoted string can be embedded in an argument.
3. A double quotation mark preceded by a backslash is interpreted as a literal double quotation mark.
4. Backslashes are interpreted literally, unless they immediately precede a double quotation mark.
5. If backslashes immediately precede a double quotation mark, every pair of backslashes is interpreted as a literal backslash. If the number of backslashes is odd, the last backslash escapes the next double quotation mark as described in rule 3.

Last updated on Nov 11, 2013. Found a bug?

Created using Sphinx 1.0.7.
The *sched* module defines a class which implements a general purpose event scheduler:

```python
class sched.scheduler(timefunc=time.monotonic, delayfunc=time.sleep)
```

The *scheduler* class defines a generic interface to scheduling events. It needs two functions to actually deal with the “outside world” — *timefunc* should be callable without arguments, and return a number (the “time”, in any units whatsoever). If time.monotonic is not available, the *timefunc* default is time.time instead. The *delayfunc* function should be callable with one argument, compatible with the output of *timefunc*, and should delay that many time units. *delayfunc* will also be called with the argument 0 after each event is run to allow other threads an opportunity to run in multi-threaded applications.

*Changed in version 3.3*: *timefunc* and *delayfunc* parameters are optional.

*Changed in version 3.3*: *scheduler* class can be safely used in multi-threaded environments.

Example:

```python
>>> import sched, time
>>> s = sched.scheduler(time.time, time.sleep)
>>> def print_time(a='default'):
```
>>> def print_some_times():
    print(time.time())
    s.enter(10, 1, print_time)
    s.enter(5, 2, print_time, argument=("positional",))
    s.enter(5, 1, print_time, kwargs={"a": "keyword"})
    s.run()
    print(time.time())

>>> print_some_times()
930343690.257
930343695.274 positional
930343695.275 keyword
930343700.273 default
930343700.276
17.6.1. Scheduler Objects

`scheduler` instances have the following methods and attributes:

```python
scheduler.enterabs(time, priority, action, argument=(), kwargs={})
```

Schedule a new event. The `time` argument should be a numeric type compatible with the return value of the `timefunc` function passed to the constructor. Events scheduled for the same `time` will be executed in the order of their `priority`.

Executing the event means executing `action(*argument, **kwargs)`. `argument` is a sequence holding the positional arguments for `action`. `kwargs` is a dictionary holding the keyword arguments for `action`.

Return value is an event which may be used for later cancellation of the event (see `cancel()`).

*Changed in version 3.3:* `argument` parameter is optional.

*New in version 3.3:* `kwargs` parameter was added.

```python
scheduler.enter(delay, priority, action, argument=(), kwargs={})
```

Schedule an event for `delay` more time units. Other than the relative time, the other arguments, the effect and the return value are the same as those for `enterabs()`.

*Changed in version 3.3:* `argument` parameter is optional.

*New in version 3.3:* `kwargs` parameter was added.

```python
scheduler.cancel(event)
```
Remove the event from the queue. If event is not an event currently in the queue, this method will raise a `ValueError`.

`scheduler.empty()`
Return true if the event queue is empty.

`scheduler.run(blocking=True)`
Run all scheduled events. This method will wait (using the `delayfunc()` function passed to the constructor) for the next event, then execute it and so on until there are no more scheduled events.

If `blocking` is False executes the scheduled events due to expire soonest (if any) and then return the deadline of the next scheduled call in the scheduler (if any).

Either `action` or `delayfunc` can raise an exception. In either case, the scheduler will maintain a consistent state and propagate the exception. If an exception is raised by `action`, the event will not be attempted in future calls to `run()`.

If a sequence of events takes longer to run than the time available before the next event, the scheduler will simply fall behind. No events will be dropped; the calling code is responsible for canceling events which are no longer pertinent.

*New in version 3.3: `blocking` parameter was added.*

`scheduler.queue`
Read-only attribute returning a list of upcoming events in the order they will be run. Each event is shown as a `named tuple` with the following fields: time, priority, action, argument, kwargs.
17.7. queue — A synchronized queue class

Source code: Lib/queue.py

The `queue` module implements multi-producer, multi-consumer queues. It is especially useful in threaded programming when information must be exchanged safely between multiple threads. The `Queue` class in this module implements all the required locking semantics. It depends on the availability of thread support in Python; see the `threading` module.

The module implements three types of queue, which differ only in the order in which the entries are retrieved. In a FIFO queue, the first tasks added are the first retrieved. In a LIFO queue, the most recently added entry is the first retrieved (operating like a stack). With a priority queue, the entries are kept sorted (using the `heapq` module) and the lowest valued entry is retrieved first.

The `queue` module defines the following classes and exceptions:

```python
class queue.Queue(maxsize=0)
    Constructor for a FIFO queue. `maxsize` is an integer that sets the upperbound limit on the number of items that can be placed in the queue. Insertion will block once this size has been reached, until queue items are consumed. If `maxsize` is less than or equal to zero, the queue size is infinite.

class queue.LifoQueue(maxsize=0)
    Constructor for a LIFO queue. `maxsize` is an integer that sets the
```
upperbound limit on the number of items that can be placed in the queue. Insertion will block once this size has been reached, until queue items are consumed. If \textit{maxsize} is less than or equal to zero, the queue size is infinite.

\texttt{class queue.PriorityQueue(maxsize=0)}

Constructor for a priority queue. \textit{maxsize} is an integer that sets the upperbound limit on the number of items that can be placed in the queue. Insertion will block once this size has been reached, until queue items are consumed. If \textit{maxsize} is less than or equal to zero, the queue size is infinite.

The lowest valued entries are retrieved first (the lowest valued entry is the one returned by \texttt{sorted(list(entries))[0]}). A typical pattern for entries is a tuple in the form: \texttt{(priority_number, data)}.

\texttt{exception queue.Empty}

Exception raised when non-blocking \texttt{get()} (or \texttt{get_nowait()}) is called on a \texttt{Queue} object which is empty.

\texttt{exception queue.Full}

Exception raised when non-blocking \texttt{put()} (or \texttt{put_nowait()}) is called on a \texttt{Queue} object which is full.
17.7.1. Queue Objects

Queue objects (Queue, LifoQueue, or PriorityQueue) provide the public methods described below.

Queue.qsize()
Return the approximate size of the queue. Note, qsize() > 0 doesn’t guarantee that a subsequent get() will not block, nor will qsize() < maxsize guarantee that put() will not block.

Queue.empty()
Return True if the queue is empty, False otherwise. If empty() returns True it doesn’t guarantee that a subsequent call to put() will not block. Similarly, if empty() returns False it doesn’t guarantee that a subsequent call to get() will not block.

Queue.full()
Return True if the queue is full, False otherwise. If full() returns True it doesn’t guarantee that a subsequent call to get() will not block. Similarly, if full() returns False it doesn’t guarantee that a subsequent call to put() will not block.

Queue.put(item, block=True, timeout=None)
Put item into the queue. If optional args block is true and timeout is None (the default), block if necessary until a free slot is available. If timeout is a positive number, it blocks at most timeout seconds and raises the Full exception if no free slot was available within that time. Otherwise (block is false), put an item on the queue if a free slot is immediately available, else raise the Full exception (timeout is ignored in that case).
Queue. **put_nowait**(item)
Equivalent to **put**(item, False).

Queue. **get**(block=True, timeout=None)
Remove and return an item from the queue. If optional args **block** is true and **timeout** is None (the default), block if necessary until an item is available. If **timeout** is a positive number, it blocks at most **timeout** seconds and raises the **Empty** exception if no item was available within that time. Otherwise (**block** is false), return an item if one is immediately available, else raise the **Empty** exception (**timeout** is ignored in that case).

Queue. **get_nowait**()
Equivalent to **get**(False).

Two methods are offered to support tracking whether enqueued tasks have been fully processed by daemon consumer threads.

Queue. **task_done**()
Indicate that a formerly enqueued task is complete. Used by queue consumer threads. For each **get()** used to fetch a task, a subsequent call to **task_done()** tells the queue that the processing on the task is complete.

If a **join()** is currently blocking, it will resume when all items have been processed (meaning that a **task_done()** call was received for every item that had been **put()** into the queue).

Raises a **ValueError** if called more times than there were items placed in the queue.

Queue. **join**()
Blocks until all items in the queue have been gotten and processed.

The count of unfinished tasks goes up whenever an item is added to the queue. The count goes down whenever a consumer thread calls `task_done()` to indicate that the item was retrieved and all work on it is complete. When the count of unfinished tasks drops to zero, `join()` unblocks.

Example of how to wait for enqueued tasks to be completed:

```python
def worker():
    while True:
        item = q.get()
        do_work(item)
        q.task_done()

q = Queue()
for i in range(num_worker_threads):
    t = Thread(target=worker)
    t.daemon = True
    t.start()

for item in source():
    q.put(item)
q.join()       # block until all tasks are done
```

See also:

**Class `multiprocessing.Queue`**

A queue class for use in a multi-processing (rather than multi-threading) context.

`collections.deque` is an alternative implementation of
unbounded queues with fast atomic `append()` and `popleft()` operations that do not require locking.
17.8. **select** — Waiting for I/O completion

This module provides access to the `select()` and `poll()` functions available in most operating systems, `devpoll()` available on Solaris and derivatives, `epoll()` available on Linux 2.5+ and `kqueue()` available on most BSD. Note that on Windows, it only works for sockets; on other operating systems, it also works for other file types (in particular, on Unix, it works on pipes). It cannot be used on regular files to determine whether a file has grown since it was last read.

The module defines the following:

**exception select.error**

A deprecated alias of `OSError`.

*Changed in version 3.3:* Following PEP 3151, this class was made an alias of `OSError`.

**select.devpoll()**

(Only supported on Solaris and derivatives.) Returns a `/dev/poll` polling object; see section `/dev/poll Polling Objects` below for the methods supported by devpoll objects.

`devpoll()` objects are linked to the number of file descriptors allowed at the time of instantiation. If your program reduces this value, `devpoll()` will fail. If your program increases this value, `devpoll()` may return an incomplete list of active file descriptors.

*New in version 3.3.*
select.epoll(sizehint=-1, flags=0)
(Only supported on Linux 2.5.44 and newer.) Return an edge polling object, which can be used as Edge or Level Triggered interface for I/O events. sizehint is deprecated and completely ignored. flags can be set to EPOLL_CLOEXEC, which causes the epoll descriptor to be closed automatically when os.execve() is called. See section Edge and Level Trigger Polling (epoll) Objects below for the methods supported by epolling objects.

Changed in version 3.3: Added the flags parameter.

select.poll()
(Not supported by all operating systems.) Returns a polling object, which supports registering and unregistering file descriptors, and then polling them for I/O events; see section Polling Objects below for the methods supported by polling objects.

select.kqueue()
(Only supported on BSD.) Returns a kernel queue object; see section Kqueue Objects below for the methods supported by kqueue objects.

select.kevent(ident, filter=KQ_FILTER_READ, flags=KQ_EV_ADD, fflags=0, data=0, udata=0)
(Only supported on BSD.) Returns a kernel event object; see section Kevent Objects below for the methods supported by kevent objects.

select.select(rlist, wlist, xlist[, timeout])
This is a straightforward interface to the Unix select() system call. The first three arguments are sequences of 'waitable objects': either integers representing file descriptors or objects with a
parameterless method named `fileno()` returning such an integer:

- `rlist`: wait until ready for reading
- `wlist`: wait until ready for writing
- `xlist`: wait for an “exceptional condition” (see the manual page for what your system considers such a condition)

Empty sequences are allowed, but acceptance of three empty sequences is platform-dependent. (It is known to work on Unix but not on Windows.) The optional `timeout` argument specifies a time-out as a floating point number in seconds. When the `timeout` argument is omitted the function blocks until at least one file descriptor is ready. A time-out value of zero specifies a poll and never blocks.

The return value is a triple of lists of objects that are ready: subsets of the first three arguments. When the time-out is reached without a file descriptor becoming ready, three empty lists are returned.

Among the acceptable object types in the sequences are Python file objects (e.g. `sys.stdin`, or objects returned by `open()` or `os.popen()`), socket objects returned by `socket.socket()`. You may also define a wrapper class yourself, as long as it has an appropriate `fileno()` method (that really returns a file descriptor, not just a random integer).

**Note:** File objects on Windows are not acceptable, but sockets are. On Windows, the underlying `select()` function is provided by the WinSock library, and does not handle file descriptors that don’t originate from WinSock.

`select.PIPE_BUF`
The minimum number of bytes which can be written without blocking to a pipe when the pipe has been reported as ready for writing by `select()`, `poll()` or another interface in this module. This doesn’t apply to other kind of file-like objects such as sockets.

This value is guaranteed by POSIX to be at least 512. Availability: Unix.

*New in version 3.2.*
17.8.1. /dev/poll Polling Objects

http://developers.sun.com/solaris/articles/using_devpoll.html
http://developers.sun.com/solaris/articles/polling_efficient.html

Solaris and derivatives have /dev/poll. While select() is O(highest file descriptor) and poll() is O(number of file descriptors), /dev/poll is O(active file descriptors).

/dev/poll behaviour is very close to the standard poll() object.

devpoll. register(fd[, eventmask])

Register a file descriptor with the polling object. Future calls to the poll() method will then check whether the file descriptor has any pending I/O events. fd can be either an integer, or an object with a fileno() method that returns an integer. File objects implement fileno(), so they can also be used as the argument.

eventmask is an optional bitmask describing the type of events you want to check for. The constants are the same that with poll() object. The default value is a combination of the constants POLLIN, POLLPRI, and POLLOUT.

Warning: Registering a file descriptor that’s already registered is not an error, but the result is undefined. The appropriate action is to unregister or modify it first. This is an important difference compared with poll().

devpoll. modify(fd[, eventmask])

This method does an unregister() followed by a register(). It is (a bit) more efficient that doing the same explicitly.
devpoll.\texttt{unregister}(fd)

Remove a file descriptor being tracked by a polling object. Just like the \texttt{register()} method, \textit{fd} can be an integer or an object with a \texttt{fileno()} method that returns an integer.

Attempting to remove a file descriptor that was never registered is safely ignored.

devpoll.\texttt{poll}([\textit{timeout}])

Polls the set of registered file descriptors, and returns a possibly-empty list containing \((\text{fd}, \text{event})\) 2-tuples for the descriptors that have events or errors to report. \textit{fd} is the file descriptor, and \textit{event} is a bitmask with bits set for the reported events for that descriptor — POLLIN for waiting input, POLLOUT to indicate that the descriptor can be written to, and so forth. An empty list indicates that the call timed out and no file descriptors had any events to report. If \textit{timeout} is given, it specifies the length of time in milliseconds which the system will wait for events before returning. If \textit{timeout} is omitted, -1, or \texttt{None}, the call will block until there is an event for this poll object.
17.8.2. Edge and Level Trigger Polling (epoll) Objects

http://linux.die.net/man/4/epoll

eventmask

<table>
<thead>
<tr>
<th>Constant</th>
<th>Meaning</th>
</tr>
</thead>
<tbody>
<tr>
<td>EPOLLIN</td>

<td>EPPOLMSG</td>
<td>Ignored.</td>
</tr>
</tbody>
</table>

epoll.close()

Close the control file descriptor of the epoll object.

epoll.filenos()
Return the file descriptor number of the control fd.

epoll. **fromfd**(*fd*)
    Create an epoll object from a given file descriptor.

epoll. **register**(*fd*, *eventmask*)
    Register a fd descriptor with the epoll object.

epoll. **modify**(*fd*, *eventmask*)
    Modify a register file descriptor.

epoll. **unregister**(*fd*)
    Remove a registered file descriptor from the epoll object.

epoll. **poll**(*timeout*= -1, *maxevents*= -1)
    Wait for events. timeout in seconds (float)
17.8.3. Polling Objects

The `poll()` system call, supported on most Unix systems, provides better scalability for network servers that service many, many clients at the same time. `poll()` scales better because the system call only requires listing the file descriptors of interest, while `select()` builds a bitmap, turns on bits for the fds of interest, and then afterward the whole bitmap has to be linearly scanned again. `select()` is \(O(\text{highest file descriptor})\), while `poll()` is \(O(\text{number of file descriptors})\).

`poll()`

```c
register(fd[, eventmask])
```

Register a file descriptor with the polling object. Future calls to the `poll()` method will then check whether the file descriptor has any pending I/O events. `fd` can be either an integer, or an object with a `fileno()` method that returns an integer. File objects implement `fileno()`, so they can also be used as the argument.

`eventmask` is an optional bitmask describing the type of events you want to check for, and can be a combination of the constants `POLLIN`, `POLLPRI`, and `POLLOUT`, described in the table below. If not specified, the default value used will check for all 3 types of events.

<table>
<thead>
<tr>
<th>Constant</th>
<th>Meaning</th>
</tr>
</thead>
<tbody>
<tr>
<td>POLLIN</td>
<td>There is data to read</td>
</tr>
<tr>
<td>POLLPRI</td>
<td>There is urgent data to read</td>
</tr>
<tr>
<td>POLLOUT</td>
<td>Ready for output: writing will not block</td>
</tr>
<tr>
<td>POLLERR</td>
<td>Error condition of some sort</td>
</tr>
</tbody>
</table>

<table>
<thead>
<tr>
<th>POLLHUP</th>
<th>Hung up</th>
</tr>
</thead>
<tbody>
<tr>
<td>POLLNVAL</td>
<td>Invalid request: descriptor not open</td>
</tr>
</tbody>
</table>

Registering a file descriptor that’s already registered is not an error, and has the same effect as registering the descriptor exactly once.

**poll. `modify(fd, eventmask)`**

Modifies an already registered fd. This has the same effect as `register(fd, eventmask)`. Attempting to modify a file descriptor that was never registered causes an `IOError` exception with errno ENOENT to be raised.

**poll. `unregister(fd)`**

Remove a file descriptor being tracked by a polling object. Just like the `register()` method, `fd` can be an integer or an object with a `fileno()` method that returns an integer.

Attempting to remove a file descriptor that was never registered causes a `KeyError` exception to be raised.

**poll. `poll([timeout])`**

Polls the set of registered file descriptors, and returns a possibly-empty list containing `(fd, event)` 2-tuples for the descriptors that have events or errors to report. `fd` is the file descriptor, and `event` is a bitmask with bits set for the reported events for that descriptor — POLLIN for waiting input, POLLOUT to indicate that the descriptor can be written to, and so forth. An empty list indicates that the call timed out and no file descriptors had any events to report. If `timeout` is given, it specifies the length of time in milliseconds which the system will wait for events before returning. If `timeout` is omitted, negative, or `None`, the call will block until there is an event for this poll object.
17.8.4. Kqueue Objects

kqueue. close()
   Close the control file descriptor of the kqueue object.

kqueue. fileno()
   Return the file descriptor number of the control fd.

kqueue. fromfd(fd)
   Create a kqueue object from a given file descriptor.

kqueue. control(changelist, max_events[, timeout=None]) → eventlist
   Low level interface to kevent
     - changelist must be an iterable of kevent object or None
     - max_events must be 0 or a positive integer
     - timeout in seconds (floats possible)
17.8.5. Kevent Objects

**kevent.** `ident`  
Value used to identify the event. The interpretation depends on the filter but it's usually the file descriptor. In the constructor `ident` can either be an int or an object with a `fileno()` method. `kevent` stores the integer internally.

**kevent.** `filter`  
Name of the kernel filter.

<table>

</tbody>
</table>

`kevent.data`
Filter specific data.

kevent.udata
User defined value.
17.9. **dummy_threading** — Drop-in replacement for the **threading** module

**Source code:** Lib/dummy_threading.py

This module provides a duplicate interface to the **threading** module. It is meant to be imported when the **_thread** module is not provided on a platform.

Suggested usage is:

```python
try:
    import threading
except ImportError:
    import dummy_threading as threading
```

Be careful to not use this module where deadlock might occur from a thread being created that blocks waiting for another thread to be created. This often occurs with blocking I/O.
17.10. _thread — Low-level threading API

This module provides low-level primitives for working with multiple threads (also called light-weight processes or tasks) — multiple threads of control sharing their global data space. For synchronization, simple locks (also called mutexes or binary semaphores) are provided. The threading module provides an easier to use and higher-level threading API built on top of this module.

The module is optional. It is supported on Windows, Linux, SGI IRIX, Solaris 2.x, as well as on systems that have a POSIX thread (a.k.a. “pthread”) implementation. For systems lacking the _thread module, the _dummy_thread module is available. It duplicates this module's interface and can be used as a drop-in replacement.

It defines the following constants and functions:

```python
exception _thread.error
    Raised on thread-specific errors.

    Changed in version 3.3: This is now a synonym of the built-in RuntimeError.

_thread.LockType
    This is the type of lock objects.

_thread.start_new_thread(function, args[, kwargs])
    Start a new thread and return its identifier. The thread executes the function function with the argument list args (which must be a
```
tuple). The optional *kwargs argument specifies a dictionary of keyword arguments. When the function returns, the thread silently exits. When the function terminates with an unhandled exception, a stack trace is printed and then the thread exits (but other threads continue to run).

**_thread.interrupt_main()**

Raise a `KeyboardInterrupt` exception in the main thread. A subthread can use this function to interrupt the main thread.

**_thread.exit()**

Raise the `SystemExit` exception. When not caught, this will cause the thread to exit silently.

**_thread.allocate_lock()**

Return a new lock object. Methods of locks are described below. The lock is initially unlocked.

**_thread.get_ident()**

Return the ‘thread identifier’ of the current thread. This is a nonzero integer. Its value has no direct meaning; it is intended as a magic cookie to be used e.g. to index a dictionary of thread-specific data. Thread identifiers may be recycled when a thread exits and another thread is created.

**_thread.stack_size([size])**

Return the thread stack size used when creating new threads. The optional *size argument specifies the stack size to be used for subsequently created threads, and must be 0 (use platform or configured default) or a positive integer value of at least 32,768 (32 KiB). If changing the thread stack size is unsupported, a `RuntimeError` is raised. If the specified stack size is invalid, a
**ValueError** is raised and the stack size is unmodified. 32 KiB is currently the minimum supported stack size value to guarantee sufficient stack space for the interpreter itself. Note that some platforms may have particular restrictions on values for the stack size, such as requiring a minimum stack size > 32 KiB or requiring allocation in multiples of the system memory page size - platform documentation should be referred to for more information (4 KiB pages are common; using multiples of 4096 for the stack size is the suggested approach in the absence of more specific information). Availability: Windows, systems with POSIX threads.

**_thread.TIMEOUT_MAX**

The maximum value allowed for the *timeout* parameter of Lock.acquire(). Specifying a timeout greater than this value will raise an **OverflowError**.

*New in version 3.2.*

Lock objects have the following methods:

**lock.acquire(**waitflag=1, timeout=-1)**

Without any optional argument, this method acquires the lock unconditionally, if necessary waiting until it is released by another thread (only one thread at a time can acquire a lock — that’s their reason for existence).

If the integer *waitflag* argument is present, the action depends on its value: if it is zero, the lock is only acquired if it can be acquired immediately without waiting, while if it is nonzero, the lock is acquired unconditionally as above.

If the floating-point *timeout* argument is present and positive, it specifies the maximum wait time in seconds before returning. A
negative `timeout` argument specifies an unbounded wait. You cannot specify a `timeout` if `waitflag` is zero.

The return value is `True` if the lock is acquired successfully, `False` if not.

*Changed in version 3.2:* The `timeout` parameter is new.

*Changed in version 3.2:* Lock acquires can now be interrupted by signals on POSIX.

`lock.release()`
Releases the lock. The lock must have been acquired earlier, but not necessarily by the same thread.

`lock.locked()`
Return the status of the lock: `True` if it has been acquired by some thread, `False` if not.

In addition to these methods, lock objects can also be used via the `with` statement, e.g.:

```python
import _thread
a_lock = _thread.allocate_lock()

with a_lock:
    print("a_lock is locked while this executes")
```

**Caveats:**

- Threads interact strangely with interrupts: the `KeyboardInterrupt` exception will be received by an arbitrary thread. (When the `signal` module is available, interrupts always
go to the main thread.)

- Calling `sys.exit()` or raising the `SystemExit` exception is equivalent to calling `_thread.exit()`.
- Not all built-in functions that may block waiting for I/O allow other threads to run. (The most popular ones (`time.sleep()`, `io.FileIO.read()`, `select.select()`) work as expected.)
- It is not possible to interrupt the `acquire()` method on a lock — the `KeyboardInterrupt` exception will happen after the lock has been acquired.
- When the main thread exits, it is system defined whether the other threads survive. On most systems, they are killed without executing `try ... finally` clauses or executing object destructors.
- When the main thread exits, it does not do any of its usual cleanup (except that `try ... finally` clauses are honored), and the standard I/O files are not flushed.
17.11. _dummy_thread — Drop-in replacement for the _thread module

Source code: Lib/_dummy_thread.py

This module provides a duplicate interface to the _thread module. It is meant to be imported when the _thread module is not provided on a platform.

Suggested usage is:

```
try:
    import _thread
except ImportError:
    import _dummy_thread as _thread
```

Be careful to not use this module where deadlock might occur from a thread being created that blocks waiting for another thread to be created. This often occurs with blocking I/O.
18. Interprocess Communication and Networking

The modules described in this chapter provide mechanisms for different processes to communicate.

Some modules only work for two processes that are on the same machine, e.g. signal and mmap. Other modules support networking protocols that two or more processes can used to communicate across machines.

The list of modules described in this chapter is:

- **18.1. socket** — Low-level networking interface
  - 18.1.1. Socket families
  - 18.1.2. Module contents
  - 18.1.3. Socket Objects
  - 18.1.4. Notes on socket timeouts
    - 18.1.4.1. Timeouts and the connect method
    - 18.1.4.2. Timeouts and the accept method
  - 18.1.5. Example
- **18.2. ssl** — TLS/SSL wrapper for socket objects
  - 18.2.1. Functions, Constants, and Exceptions
    - 18.2.1.1. Socket creation
    - 18.2.1.2. Random generation
    - 18.2.1.3. Certificate handling
    - 18.2.1.4. Constants
  - 18.2.2. SSL Sockets
  - 18.2.3. SSL Contexts
  - 18.2.4. Certificates
    - 18.2.4.1. Certificate chains
    - 18.2.4.2. CA certificates
18.2.4.3. Combined key and certificate
18.2.4.4. Self-signed certificates

18.2.5. Examples
- 18.2.5.1. Testing for SSL support
- 18.2.5.2. Client-side operation
- 18.2.5.3. Server-side operation
- 18.2.6. Notes on non-blocking sockets
- 18.2.7. Security considerations
  - 18.2.7.1. Verifying certificates
  - 18.2.7.2. Protocol versions
  - 18.2.7.3. Cipher selection

18.3. asyncore — Asynchronous socket handler
- 18.3.1. asyncore Example basic HTTP client
- 18.3.2. asyncore Example basic echo server

18.4. asynchat — Asynchronous socket command/response handler
- 18.4.1. asynchat - Auxiliary Classes
- 18.4.2. asynchat Example

18.5. signal — Set handlers for asynchronous events
- 18.5.1. General rules
  - 18.5.1.1. Execution of Python signal handlers
  - 18.5.1.2. Signals and threads
- 18.5.2. Module contents
- 18.5.3. Example

18.6. mmap — Memory-mapped file support
18.1. `socket` — Low-level networking interface

This module provides access to the BSD `socket` interface. It is available on all modern Unix systems, Windows, MacOS, OS/2, and probably additional platforms.

**Note:** Some behavior may be platform dependent, since calls are made to the operating system socket APIs.

The Python interface is a straightforward transliteration of the Unix system call and library interface for sockets to Python’s object-oriented style: the `socket()` function returns a `socket object` whose methods implement the various socket system calls. Parameter types are somewhat higher-level than in the C interface: as with `read()` and `write()` operations on Python files, buffer allocation on receive operations is automatic, and buffer length is implicit on send operations.

**See also:**

- **Module** `socketserver`
  Classes that simplify writing network servers.
- **Module** `ssl`
  A TLS/SSL wrapper for socket objects.
18.1.1. Socket families

Depending on the system and the build options, various socket families are supported by this module.

The address format required by a particular socket object is automatically selected based on the address family specified when the socket object was created. Socket addresses are represented as follows:

- The address of an **AF_UNIX** socket bound to a file system node is represented as a string, using the file system encoding and the "surrogateescape" error handler (see [PEP 383](https://www.python.org/dev/peps/pep-0383/)). An address in Linux's abstract namespace is returned as a **bytes** object with an initial null byte; note that sockets in this namespace can communicate with normal file system sockets, so programs intended to run on Linux may need to deal with both types of address. A string or **bytes** object can be used for either type of address when passing it as an argument.

  Changed in version 3.3: Previously, **AF_UNIX** socket paths were assumed to use UTF-8 encoding.

- A pair (host, port) is used for the **AF_INET** address family, where **host** is a string representing either a hostname in Internet domain notation like 'daring.cwi.nl' or an IPv4 address like '100.50.200.5', and **port** is an integer.

- For **AF_INET6** address family, a four-tuple (host, port, flowinfo, scopeid) is used, where **flowinfo** and **scopeid** represent the sin6_flowinfo and sin6_scope_id members.
in struct sockaddr_in6 in C. For socket module methods, flowinfo and scopeid can be omitted just for backward compatibility. Note, however, omission of scopeid can cause problems in manipulating scoped IPv6 addresses.

- AF_NETLINK sockets are represented as pairs (pid, groups).

- Linux-only support for TIPC is available using the AF_TIPC address family. TIPC is an open, non-IP based networked protocol designed for use in clustered computer environments. Addresses are represented by a tuple, and the fields depend on the address type. The general tuple form is \((addr \_type, v1, v2, v3 [, scope])\), where:
  
  - \(addr \_type\) is one of TIPC_ADDR_NAMESEQ, TIPC_ADDR_NAME, or TIPC_ADDR_ID.
  
  - \(scope\) is one of TIPC_ZONE_SCOPE, TIPC_CLUSTER_SCOPE, and TIPC_NODE_SCOPE.

  - If \(addr \_type\) is TIPC_ADDR_NAME, then \(v1\) is the server type, \(v2\) is the port identifier, and \(v3\) should be 0.

  If \(addr \_type\) is TIPC_ADDR_NAMESEQ, then \(v1\) is the server type, \(v2\) is the lower port number, and \(v3\) is the upper port number.

  If \(addr \_type\) is TIPC_ADDR_ID, then \(v1\) is the node, \(v2\) is the reference, and \(v3\) should be set to 0.

  If \(addr \_type\) is TIPC_ADDR_ID, then \(v1\) is the node, \(v2\) is the reference, and \(v3\) should be set to 0.
A tuple (interface,) is used for the AF_CAN address family, where interface is a string representing a network interface name like 'can0'. The network interface name ' ' can be used to receive packets from all network interfaces of this family.

A string or a tuple (id, unit) is used for the SYSPROTO_CONTROL protocol of the PF_SYSTEM family. The string is the name of a kernel control using a dynamically-assigned ID. The tuple can be used if ID and unit number of the kernel control are known or if a registered ID is used.

*New in version 3.3.*

Certain other address families (AF_BLUETOOTH, AF_PACKET) support specific representations.

For IPv4 addresses, two special forms are accepted instead of a host address: the empty string represents INADDR_ANY, and the string '<broadcast>' represents INADDR_BROADCAST. This behavior is not compatible with IPv6, therefore, you may want to avoid these if you intend to support IPv6 with your Python programs.

If you use a hostname in the host portion of IPv4/v6 socket address, the program may show a nondeterministic behavior, as Python uses the first address returned from the DNS resolution. The socket address will be resolved differently into an actual IPv4/v6 address, depending on the results from DNS resolution and/or the host configuration. For deterministic behavior use a numeric address in host portion.

All errors raise exceptions. The normal exceptions for invalid argument types and out-of-memory conditions can be raised; starting from Python 3.3, errors related to socket or address semantics raise
OSError or one of its subclasses (they used to raise `socket.error`).

Non-blocking mode is supported through `setblocking()`. A generalization of this based on timeouts is supported through `settimeout()`.
18.1.2. Module contents

The module `socket` exports the following constants and functions:

```
exception socket.error
    A deprecated alias of OSError.

    Changed in version 3.3: Following PEP 3151, this class was made an alias of OSError.
```

```
exception socket.herror
    A subclass of OSError, this exception is raised for address-related errors, i.e. for functions that use h_errno in the POSIX C API, including gethostbyname_ex() and gethostbyaddr(). The accompanying value is a pair (h_errno, string) representing an error returned by a library call. h_errno is a numeric value, while string represents the description of h_errno, as returned by the hstrerror() C function.

    Changed in version 3.3: This class was made a subclass of OSError.
```

```
exception socket.gaierror
    A subclass of OSError, this exception is raised for address-related errors by getaddrinfo() and getnameinfo(). The accompanying value is a pair (error, string) representing an error returned by a library call. string represents the description of error, as returned by the gai_strerror() C function. The numeric error value will match one of the EAI_* constants defined in this module.
```
Changed in version 3.3: This class was made a subclass of OSError.

exception socket.timeout
A subclass of OSError, this exception is raised when a timeout occurs on a socket which has had timeouts enabled via a prior call to settimeout() (or implicitly through setdefaulttimeout()). The accompanying value is a string whose value is currently always “timed out”.

Changed in version 3.3: This class was made a subclass of OSError.

socket.AF_UNIX
socket.AF_INET
socket.AF_INET6
These constants represent the address (and protocol) families, used for the first argument to socket(). If the AF_UNIX constant is not defined then this protocol is unsupported. More constants may be available depending on the system.

socket.SOCK_STREAM
socket.SOCK_DGRAM
socket.SOCK_RAW
socket.SOCK_RDM
socket.SOCK_SEQPACKET
These constants represent the socket types, used for the second argument to socket(). More constants may be available depending on the system. (Only SOCK_STREAM and SOCK_DGRAM appear to be generally useful.)

socket.SOCK_CLOEXEC
socket.SOCK_NONBLOCK
These two constants, if defined, can be combined with the socket types and allow you to set some flags atomically (thus avoiding possible race conditions and the need for separate calls).

See also: Secure File Descriptor Handling for a more thorough explanation.

Availability: Linux >= 2.6.27.

New in version 3.2.

SO_*
socket.SOMAXCONN
MSG_*
SOL_*
SCM_*
IPPROTO_*
IPPORT_*
INADDR_*
IP_*
IPV6_*
EAI_*
AI_*
NI_*
TCP_*

Many constants of these forms, documented in the Unix documentation on sockets and/or the IP protocol, are also defined in the socket module. They are generally used in arguments to the setsockopt() and getsockopt() methods of socket objects. In most cases, only those symbols that are defined in the Unix header files are defined; for a few symbols, default values are provided.
socket.AF_CAN
socket.PF_CAN
SOL_CAN_*
CAN_*
Many constants of these forms, documented in the Linux documentation, are also defined in the socket module.

Availability: Linux >= 2.6.25.

New in version 3.3.

socket.AF_RDS
socket.PF_RDS
socket.SOL_RDS
RDS_*
Many constants of these forms, documented in the Linux documentation, are also defined in the socket module.

Availability: Linux >= 2.6.30.

New in version 3.3.

SIO_*
RCVALL_*
Constants for Windows’ WSAIoctl(). The constants are used as arguments to the ioctl() method of socket objects.

TIPC_*
TIPC related constants, matching the ones exported by the C socket API. See the TIPC documentation for more information.

socket.has_ipv6
This constant contains a boolean value which indicates if IPv6 is supported on this platform.
socket.create_connection(address[, timeout[, source_address]])

Connect to a TCP service listening on the Internet address (a 2-tuple (host, port)), and return the socket object. This is a higher-level function than socket.connect(): if host is a non-numeric hostname, it will try to resolve it for both AF_INET and AF_INET6, and then try to connect to all possible addresses in turn until a connection succeeds. This makes it easy to write clients that are compatible to both IPv4 and IPv6.

Passing the optional timeout parameter will set the timeout on the socket instance before attempting to connect. If no timeout is supplied, the global default timeout setting returned by getdefaulttimeout() is used.

If supplied, source_address must be a 2-tuple (host, port) for the socket to bind to as its source address before connecting. If host or port are "" or 0 respectively the OS default behavior will be used.

Changed in version 3.2: source_address was added.

Changed in version 3.2: support for the with statement was added.

socket.getaddrinfo(host, port, family=0, type=0, proto=0, flags=0)

Translate the host/port argument into a sequence of 5-tuples that contain all the necessary arguments for creating a socket connected to that service. host is a domain name, a string representation of an IPv4/v6 address or None. port is a string service name such as 'http', a numeric port number or None.
By passing None as the value of \textit{host} and \textit{port}, you can pass NULL to the underlying C API.

The \textit{family}, \textit{type} and \textit{proto} arguments can be optionally specified in order to narrow the list of addresses returned. Passing zero as a value for each of these arguments selects the full range of results. The \textit{flags} argument can be one or several of the \texttt{AI\_*} constants, and will influence how results are computed and returned. For example, \texttt{AI\_NUMERICHOST} will disable domain name resolution and will raise an error if \textit{host} is a domain name.

The function returns a list of 5-tuples with the following structure:

\[(\texttt{family, type, proto, canonname, sockaddr})\]

In these tuples, \texttt{family}, \texttt{type}, \texttt{proto} are all integers and are meant to be passed to the \texttt{socket()} function. \texttt{canonname} will be a string representing the canonical name of the \textit{host} if \texttt{AI\_CANONNAME} is part of the \textit{flags} argument; else \texttt{canonname} will be empty. \texttt{sockaddr} is a tuple describing a socket address, whose format depends on the returned \texttt{family} (a (\texttt{address, port}) 2-tuple for \texttt{AF\_INET}, a (\texttt{address, port, flow info, scope id}) 4-tuple for \texttt{AF\_INET6}), and is meant to be passed to the \texttt{socket.connect()} method.

The following example fetches address information for a hypothetical TCP connection to \texttt{www.python.org} on port 80 (results may differ on your system if IPv6 isn't enabled):

\begin{verbatim}
>>> socket.getaddrinfo("www.python.org", 80, proto)
[(2, 1, 6, '', ('82.94.164.162', 80)),
 (10, 1, 6, '', ('2001:888:2000:d::a2', 80, 0, 0))]
\end{verbatim}
Changed in version 3.2: parameters can now be passed as single keyword arguments.

socket.\texttt{getfqdn([name])}

Return a fully qualified domain name for \texttt{name}. If \texttt{name} is omitted or empty, it is interpreted as the local host. To find the fully qualified name, the hostname returned by \texttt{gethostbyaddr()} is checked, followed by aliases for the host, if available. The first name which includes a period is selected. In case no fully qualified domain name is available, the hostname as returned by \texttt{gethostname()} is returned.

socket.\texttt{gethostbyname(hostname)}

Translate a host name to IPv4 address format. The IPv4 address is returned as a string, such as '100.50.200.5'. If the host name is an IPv4 address itself it is returned unchanged. See \texttt{gethostbyname\_ex()} for a more complete interface. \texttt{gethostbyname()} does not support IPv6 name resolution, and \texttt{getaddrinfo()} should be used instead for IPv4/v6 dual stack support.

socket.\texttt{gethostbyname\_ex(hostname)}

Translate a host name to IPv4 address format, extended interface. Return a triple (hostname, aliaslist, ipaddrlist) where \texttt{hostname} is the primary host name responding to the given \texttt{ip\_address}, \texttt{aliaslist} is a (possibly empty) list of alternative host names for the same address, and \texttt{ipaddrlist} is a list of IPv4 addresses for the same interface on the same host (often but not always a single address). \texttt{gethostbyname\_ex()} does not support IPv6 name resolution, and \texttt{getaddrinfo()} should be used instead for IPv4/v6 dual stack support.
socket.gethostname()

Return a string containing the hostname of the machine where the Python interpreter is currently executing.

If you want to know the current machine's IP address, you may want to use gethostbyname(gethostname()). This operation assumes that there is a valid address-to-host mapping for the host, and the assumption does not always hold.

Note: gethostname() doesn't always return the fully qualified domain name; use getfqdn() (see above).

socket.gethostbyaddr(ip_address)

Return a triple (hostname, aliaslist, ipaddrlist) where hostname is the primary host name responding to the given ip_address, aliaslist is a (possibly empty) list of alternative host names for the same address, and ipaddrlist is a list of IPv4/IPv6 addresses for the same interface on the same host (most likely containing only a single address). To find the fully qualified domain name, use the function getfqdn(). gethostbyaddr() supports both IPv4 and IPv6.

socket.getnameinfo(sockaddr, flags)

Translate a socket address sockaddr into a 2-tuple (host, port). Depending on the settings of flags, the result can contain a fully-qualified domain name or numeric address representation in host. Similarly, port can contain a string port name or a numeric port number.

socket.getprotobynumber(protocolname)

Translate an Internet protocol name (for example, 'icmp') to a constant suitable for passing as the (optional) third argument to the
socket() function. This is usually only needed for sockets opened in “raw” mode (SOCK_RAW); for the normal socket modes, the correct protocol is chosen automatically if the protocol is omitted or zero.

socket.getservbyname(servicename[, protocolname])
Translate an Internet service name and protocol name to a port number for that service. The optional protocol name, if given, should be 'tcp' or 'udp', otherwise any protocol will match.

socket.getservbyport(port[, protocolname])
Translate an Internet port number and protocol name to a service name for that service. The optional protocol name, if given, should be 'tcp' or 'udp', otherwise any protocol will match.

socket.socket([family[, type[, proto]]])
Create a new socket using the given address family, socket type and protocol number. The address family should be AF_INET (the default), AF_INET6, AF_UNIX, AF_CAN or AF_RDS. The socket type should be SOCK_STREAM (the default), SOCK_DGRAM, SOCK_RAW or perhaps one of the other SOCK_ constants. The protocol number is usually zero and may be omitted in that case or CAN_RAW in case the address family is AF_CAN.

Changed in version 3.3: The AF_CAN family was added. The AF_RDS family was added.

socket.socketpair([family[, type[, proto]]])
Build a pair of connected socket objects using the given address family, socket type, and protocol number. Address family, socket type, and protocol number are as for the socket() function
above. The default family is **AF_UNIX** if defined on the platform; otherwise, the default is **AF_INET**. Availability: Unix.

*Changed in version 3.2:* The returned socket objects now support the whole socket API, rather than a subset.

**socket.fromfd(fd, family, type[, proto])**

Duplicate the file descriptor `fd` (an integer as returned by a file object’s `fileno()` method) and build a socket object from the result. Address family, socket type and protocol number are as for the `socket()` function above. The file descriptor should refer to a socket, but this is not checked — subsequent operations on the object may fail if the file descriptor is invalid. This function is rarely needed, but can be used to get or set socket options on a socket passed to a program as standard input or output (such as a server started by the Unix inet daemon). The socket is assumed to be in blocking mode.

**socket.ntohl(x)**

Convert 32-bit positive integers from network to host byte order. On machines where the host byte order is the same as network byte order, this is a no-op; otherwise, it performs a 4-byte swap operation.

**socket.ntohs(x)**

Convert 16-bit positive integers from network to host byte order. On machines where the host byte order is the same as network byte order, this is a no-op; otherwise, it performs a 2-byte swap operation.

**socket.htonl(x)**

Convert 32-bit positive integers from host to network byte order. On
machines where the host byte order is the same as network byte order, this is a no-op; otherwise, it performs a 4-byte swap operation.

socket.\texttt{htons}(x)

Convert 16-bit positive integers from host to network byte order. On machines where the host byte order is the same as network byte order, this is a no-op; otherwise, it performs a 2-byte swap operation.

socket.\texttt{inet\_atons}(ip\_string)

Convert an IPv4 address from dotted-quad string format (for example, ‘123.45.67.89’) to 32-bit packed binary format, as a bytes object four characters in length. This is useful when conversing with a program that uses the standard C library and needs objects of type \texttt{struct in\_addr}, which is the C type for the 32-bit packed binary this function returns.

\texttt{inet\_atons()} also accepts strings with less than three dots; see the Unix manual page \texttt{inet(3)} for details.

If the IPv4 address string passed to this function is invalid, \texttt{OSError} will be raised. Note that exactly what is valid depends on the underlying C implementation of \texttt{inet\_atons()}.

\texttt{inet\_atons()} does not support IPv6, and \texttt{inet\_pton()} should be used instead for IPv4/v6 dual stack support.

socket.\texttt{inet\_ntoa}(packed\_ip)

Convert a 32-bit packed IPv4 address (a bytes object four characters in length) to its standard dotted-quad string representation (for example, ‘123.45.67.89’). This is useful when conversing with a program that uses the standard C library and
needs objects of type struct in_addr, which is the C type for the 32-bit packed binary data this function takes as an argument.

If the byte sequence passed to this function is not exactly 4 bytes in length, OSError will be raised. inet_ntoa() does not support IPv6, and inet_ntop() should be used instead for IPv4/v6 dual stack support.

socket.inet_pton(address_family, ip_string)
Convert an IP address from its family-specific string format to a packed, binary format. inet_pton() is useful when a library or network protocol calls for an object of type struct in_addr (similar to inet_aton()) or struct in6_addr.

Supported values for address_family are currently AF_INET and AF_INET6. If the IP address string ip_string is invalid, OSError will be raised. Note that exactly what is valid depends on both the value of address_family and the underlying implementation of inet_pton().

Availability: Unix (maybe not all platforms).

socket.inet_ntop(address_family, packed_ip)
Convert a packed IP address (a bytes object of some number of characters) to its standard, family-specific string representation (for example, '7.10.0.5' or '5aef:2b::8'). inet_ntop() is useful when a library or network protocol returns an object of type struct in_addr (similar to inet_ntoa()) or struct in6_addr.

Supported values for address_family are currently AF_INET and AF_INET6. If the string packed_ip is not the correct length for the
specified address family, `ValueError` will be raised. A `OSError` is raised for errors from the call to `inet_ntop()`.

Availability: Unix (maybe not all platforms).

socket.**CMSG_LEN**(length)

Return the total length, without trailing padding, of an ancillary data item with associated data of the given `length`. This value can often be used as the buffer size for `recvmsg()` to receive a single item of ancillary data, but **RFC 3542** requires portable applications to use `CMSG_SPACE()` and thus include space for padding, even when the item will be the last in the buffer. Raises **OverflowError** if `length` is outside the permissible range of values.

Availability: most Unix platforms, possibly others.

*New in version 3.3.*

socket.**CMSG_SPACE**(length)

Return the buffer size needed for `recvmsg()` to receive an ancillary data item with associated data of the given `length`, along with any trailing padding. The buffer space needed to receive multiple items is the sum of the `CMSG_SPACE()` values for their associated data lengths. Raises **OverflowError** if `length` is outside the permissible range of values.

Note that some systems might support ancillary data without providing this function. Also note that setting the buffer size using the results of this function may not precisely limit the amount of ancillary data that can be received, since additional data may be able to fit into the padding area.
Availability: most Unix platforms, possibly others.

New in version 3.3.

socket.getdefaulttimeout()  
Return the default timeout in seconds (float) for new socket objects. A value of None indicates that new socket objects have no timeout. When the socket module is first imported, the default is None.

socket.setdefaulttimeout(timeout)  
Set the default timeout in seconds (float) for new socket objects. When the socket module is first imported, the default is None. See settimeout() for possible values and their respective meanings.

socket.sethostname(name)  
Set the machine’s hostname to name. This will raise a OSError if you don’t have enough rights.

Availability: Unix.

New in version 3.3.

socket.if_nameindex()  
Return a list of network interface information (index int, name string) tuples. OSError if the system call fails.

Availability: Unix.

New in version 3.3.

socket.if_nametoindex(if_name)  
Return a network interface index number corresponding to an
interface name. **OSError** if no interface with the given name exists.

Availability: Unix.

*New in version 3.3.*

**socket**. `if_indextoname(if_index)`

Return a network interface name corresponding to a interface index number. **OSError** if no interface with the given index exists.

Availability: Unix.

*New in version 3.3.*

**socket**. `fromshare(data)`

Instantiate a socket from data obtained from `share()`. The socket is assumed to be in blocking mode.

Availability: Windows.

*New in version 3.3.*

**socket**. `SocketType`

This is a Python type object that represents the socket object type. It is the same as `type(socket(...))`. 
18.1.3. Socket Objects

Socket objects have the following methods. Except for `makefile()` these correspond to Unix system calls applicable to sockets.

**socket.**`accept()`

Accept a connection. The socket must be bound to an address and listening for connections. The return value is a pair `(conn, address)` where `conn` is a new socket object usable to send and receive data on the connection, and `address` is the address bound to the socket on the other end of the connection.

**socket.**`bind(address)`

Bind the socket to `address`. The socket must not already be bound. (The format of `address` depends on the address family — see above.)

**socket.**`close()`

Close the socket. All future operations on the socket object will fail. The remote end will receive no more data (after queued data is flushed). Sockets are automatically closed when they are garbage-collected.

**Note:** `close()` releases the resource associated with a connection but does not necessarily close the connection immediately. If you want to close the connection in a timely fashion, call `shutdown()` before `close()`.

**socket.**`connect(address)`

Connect to a remote socket at `address`. (The format of `address` depends on the address family — see above.)
socket.**connect_ex**(address)
Like `connect(address)`, but return an error indicator instead of raising an exception for errors returned by the C-level `connect()` call (other problems, such as “host not found,” can still raise exceptions). The error indicator is 0 if the operation succeeded, otherwise the value of the `errno` variable. This is useful to support, for example, asynchronous connects.

socket.**detach**()
Put the socket object into closed state without actually closing the underlying file descriptor. The file descriptor is returned, and can be reused for other purposes.

*New in version 3.2.*

socket.**fileno**()
Return the socket's file descriptor (a small integer). This is useful with `select.select()`.

Under Windows the small integer returned by this method cannot be used where a file descriptor can be used (such as `os.fdopen()`). Unix does not have this limitation.

socket.**getpeername**()
Return the remote address to which the socket is connected. This is useful to find out the port number of a remote IPv4/v6 socket, for instance. (The format of the address returned depends on the address family — see above.) On some systems this function is not supported.

socket.**getsockname**()
Return the socket's own address. This is useful to find out the port
number of an IPv4/v6 socket, for instance. (The format of the address returned depends on the address family — see above.)

socket.getsockopt(level, optname[, buflen])
Return the value of the given socket option (see the Unix man page getsockopt(2)). The needed symbolic constants (SO_* etc.) are defined in this module. If buflen is absent, an integer option is assumed and its integer value is returned by the function. If buflen is present, it specifies the maximum length of the buffer used to receive the option in, and this buffer is returned as a bytes object. It is up to the caller to decode the contents of the buffer (see the optional built-in module struct for a way to decode C structures encoded as byte strings).

socket.gettimeout()
Return the timeout in seconds (float) associated with socket operations, or None if no timeout is set. This reflects the last call to setblocking() or settimeout().

socket.ioctl(control, option)

| Platform: | Windows |

The ioctl() method is a limited interface to the WSAioctl system interface. Please refer to the Win32 documentation for more information.

On other platforms, the generic fcntl.fcntl() and fcntl.ioctl() functions may be used; they accept a socket object as their first argument.

socket.listen(backlog)
Listen for connections made to the socket. The backlog argument
specifies the maximum number of queued connections and should be at least 0; the maximum value is system-dependent (usually 5), the minimum value is forced to 0.

socket.makefile(mode='r', buffering=None, *, encoding=None, errors=None, newline=None)

Return a file object associated with the socket. The exact returned type depends on the arguments given to makefile(). These arguments are interpreted the same way as by the built-in open() function.

Closing the file object won’t close the socket unless there are no remaining references to the socket. The socket must be in blocking mode; it can have a timeout, but the file object’s internal buffer may end up in an inconsistent state if a timeout occurs.

**Note:** On Windows, the file-like object created by makefile() cannot be used where a file object with a file descriptor is expected, such as the stream arguments of subprocess.Popen().

socket.recv(bufsize[, flags])

Receive data from the socket. The return value is a bytes object representing the data received. The maximum amount of data to be received at once is specified by bufsize. See the Unix manual page recv(2) for the meaning of the optional argument flags; it defaults to zero.

**Note:** For best match with hardware and network realities, the value of bufsize should be a relatively small power of 2, for example, 4096.
socket.recvfrom(bufsize[, flags])

Receive data from the socket. The return value is a pair (bytes, address) where bytes is a bytes object representing the data received and address is the address of the socket sending the data. See the Unix manual page recv(2) for the meaning of the optional argument flags; it defaults to zero. (The format of address depends on the address family — see above.)

socket.recvmsg(bufsize[, ancbufsize[, flags]])

Receive normal data (up to bufsize bytes) and ancillary data from the socket. The ancbufsize argument sets the size in bytes of the internal buffer used to receive the ancillary data; it defaults to 0, meaning that no ancillary data will be received. Appropriate buffer sizes for ancillary data can be calculated using CMSG_SPACE() or CMSG_LEN(), and items which do not fit into the buffer might be truncated or discarded. The flags argument defaults to 0 and has the same meaning as for recv().

The return value is a 4-tuple: (data, ancdata, msg_flags, address). The data item is a bytes object holding the non-ancillary data received. The ancdata item is a list of zero or more tuples (cmsg_level, cmsg_type, cmsg_data) representing the ancillary data (control messages) received: cmsg_level and cmsg_type are integers specifying the protocol level and protocol-specific type respectively, and cmsg_data is a bytes object holding the associated data. The msg_flags item is the bitwise OR of various flags indicating conditions on the received message; see your system documentation for details. If the receiving socket is unconnected, address is the address of the sending socket, if available; otherwise, its value is unspecified.
On some systems, `sendmsg()` and `recvmsg()` can be used to pass file descriptors between processes over an AF_UNIX socket. When this facility is used (it is often restricted to SOCK_STREAM sockets), `recvmsg()` will return, in its ancillary data, items of the form `(socket.SOL_SOCKET, socket.SCM_RIGHTS, fds)`, where `fds` is a bytes object representing the new file descriptors as a binary array of the native C int type. If `recvmsg()` raises an exception after the system call returns, it will first attempt to close any file descriptors received via this mechanism.

Some systems do not indicate the truncated length of ancillary data items which have been only partially received. If an item appears to extend beyond the end of the buffer, `recvmsg()` will issue a RuntimeWarning, and will return the part of it which is inside the buffer provided it has not been truncated before the start of its associated data.

On systems which support the SCM_RIGHTS mechanism, the following function will receive up to `maxfds` file descriptors, returning the message data and a list containing the descriptors (while ignoring unexpected conditions such as unrelated control messages being received). See also `sendmsg()`.

```python
import socket, array

def recv_fds(sock, msglen, maxfds):
    fds = array.array("i")  # Array of ints
    msg, ancdata, flags, addr = sock.recvmsg(msglen)
    for cmsg_level, cmsg_type, cmsg_data in ancdata:
        if (cmsg_level == socket.SOL_SOCKET and cmsg_type == socket.SCM_RIGHTS):
            # Append data, ignoring any truncated
            fds.fromstring(cmsg_data[:len(cmsg_data)])
    return msg, list(fds)
```
Availability: most Unix platforms, possibly others.

New in version 3.3.

socket.recvmsg_into(buffers[, ancbufsize[, flags]])

Receive normal data and ancillary data from the socket, behaving as recvmsg() would, but scatter the non-ancillary data into a series of buffers instead of returning a new bytes object. The buffers argument must be an iterable of objects that export writable buffers (e.g. bytearray objects); these will be filled with successive chunks of the non-ancillary data until it has all been written or there are no more buffers. The operating system may set a limit (sysconf() value SC_I0V_MAX) on the number of buffers that can be used. The ancbufsize and flags arguments have the same meaning as for recvmsg().

The return value is a 4-tuple: (nbytes, ancdata, msg_flags, address), where nbytes is the total number of bytes of non-ancillary data written into the buffers, and ancdata, msg_flags and address are the same as for recvmsg().

Example:

```python
>>> import socket
>>> s1, s2 = socket.socketpair()
>>> b1 = bytearray(b'----')
>>> b2 = bytearray(b'0123456789')
>>> b3 = bytearray(b'-------------')
>>> s1.send(b'Mary had a little lamb')
22
>>> s2.recvmsg_into([[b1, memoryview(b2)[2:9]], b3])
(22, [], 0, None)
```
Availability: most Unix platforms, possibly others.

New in version 3.3.

socket.recfrom_into(buffer[, nbytes[, flags]])
Receive data from the socket, writing it into buffer instead of creating a new bytestring. The return value is a pair (nbytes, address) where nbytes is the number of bytes received and address is the address of the socket sending the data. See the Unix manual page recv(2) for the meaning of the optional argument flags; it defaults to zero. (The format of address depends on the address family — see above.)

socket.recv_into(buffer[, nbytes[, flags]])
Receive up to nbytes bytes from the socket, storing the data into a buffer rather than creating a new bytestring. If nbytes is not specified (or 0), receive up to the size available in the given buffer. Returns the number of bytes received. See the Unix manual page recv(2) for the meaning of the optional argument flags; it defaults to zero.

socket.send(bytes[, flags])
Send data to the socket. The socket must be connected to a remote socket. The optional flags argument has the same meaning as for recv() above. Returns the number of bytes sent. Applications are responsible for checking that all data has been sent; if only some of the data was transmitted, the application needs to attempt delivery of the remaining data. For further
information on this topic, consult the *Socket Programming HOWTO*.

```python
socket.sendall(bytes[, flags])
```
Send data to the socket. The socket must be connected to a remote socket. The optional `flags` argument has the same meaning as for `recv()` above. Unlike `send()`, this method continues to send data from `bytes` until either all data has been sent or an error occurs. None is returned on success. On error, an exception is raised, and there is no way to determine how much data, if any, was successfully sent.

```python
socket.sendto(bytes, address)
socket.sendto(bytes, flags, address)
```
Send data to the socket. The socket should not be connected to a remote socket, since the destination socket is specified by `address`. The optional `flags` argument has the same meaning as for `recv()` above. Return the number of bytes sent. (The format of `address` depends on the address family — see above.)

```python
socket.sendmsg(buffers[, ancdata[, flags[, address]]]])
```
Send normal and ancillary data to the socket, gathering the non-ancillary data from a series of buffers and concatenating it into a single message. The `buffers` argument specifies the non-ancillary data as an iterable of buffer-compatible objects (e.g. `bytes` objects); the operating system may set a limit (`sysconf()` value `SC_IOV_MAX`) on the number of buffers that can be used. The `ancdata` argument specifies the ancillary data (control messages) as an iterable of zero or more tuples `(cmsg_level, cmsg_type, cmsg_data)`, where `cmsg_level` and `cmsg_type` are integers specifying the protocol level and protocol-specific type.
respectively, and \textit{cmsg\_data} is a buffer-compatible object holding
the associated data. Note that some systems (in particular, systems without \texttt{CMSG\_SPACE()}) might support sending only one
control message per call. The \textit{flags} argument defaults to 0 and has
the same meaning as for \texttt{send()}. If \textit{address} is supplied and not
\texttt{None}, it sets a destination address for the message. The return
value is the number of bytes of non-ancillary data sent.

The following function sends the list of file descriptors \textit{fds} over an
\texttt{AF\_UNIX} socket, on systems which support the \texttt{SCM\_RIGHTS}
mechanism. See also \texttt{recvmsg()}.  

\begin{verbatim}
import socket, array

def send_fds(sock, msg, fds):
    return sock.sendmsg([msg], [(socket.SOL_SOCKET, socket

Availability: most Unix platforms, possibly others.

\textit{New in version 3.3.}

\texttt{socket.setblocking(flag)}

Set blocking or non-blocking mode of the socket: if \textit{flag} is false, the
socket is set to non-blocking, else to blocking mode.

This method is a shorthand for certain \texttt{settimeout()} calls:

- \texttt{sock.setblocking(True)} is equivalent to
  \texttt{sock.settimeout(None)}
- \texttt{sock.setblocking(False)} is equivalent to
  \texttt{sock.settimeout(0.0)}

\texttt{socket.settimeout(value)}
Set a timeout on blocking socket operations. The value argument can be a nonnegative floating point number expressing seconds, or None. If a non-zero value is given, subsequent socket operations will raise a timeout exception if the timeout period value has elapsed before the operation has completed. If zero is given, the socket is put in non-blocking mode. If None is given, the socket is put in blocking mode.

For further information, please consult the notes on socket timeouts.

socket.setsockopt(level, optname, value)

Set the value of the given socket option (see the Unix manual page setsockopt(2)). The needed symbolic constants are defined in the socket module (SO_* etc.). The value can be an integer or a bytes object representing a buffer. In the latter case it is up to the caller to ensure that the bytestring contains the proper bits (see the optional built-in module struct for a way to encode C structures as bytestrings).

socket.shutdown(how)

Shut down one or both halves of the connection. If how is SHUT_RD, further receives are disallowed. If how is SHUT_WR, further sends are disallowed. If how is SHUT_RDWR, further sends and receives are disallowed.

socket.share(process_id)

platform: Windows

Duplacet a socket and prepare it for sharing with a target process. The target process must be provided with process_id. The resulting bytes object can then be passed to the target
process using some form of interprocess communication and the socket can be recreated there using `fromshare()`. Once this method has been called, it is safe to close the socket since the operating system has already duplicated it for the target process.

*New in version 3.3.*

Note that there are no methods `read()` or `write()`; use `recv()` and `send()` without `flags` argument instead.

Socket objects also have these (read-only) attributes that correspond to the values given to the `socket` constructor.

- `socket.family`
  - The socket family.

- `socket.type`
  - The socket type.

- `socket.proto`
  - The socket protocol.
18.1.4. Notes on socket timeouts

A socket object can be in one of three modes: blocking, non-blocking, or timeout. Sockets are by default always created in blocking mode, but this can be changed by calling `setdefaulttimeout()`.

- In **blocking mode**, operations block until complete or the system returns an error (such as connection timed out).
- In **non-blocking mode**, operations fail (with an error that is unfortunately system-dependent) if they cannot be completed immediately: functions from the `select` can be used to know when and whether a socket is available for reading or writing.
- In **timeout mode**, operations fail if they cannot be completed within the timeout specified for the socket (they raise a `timeout` exception) or if the system returns an error.

**Note:** At the operating system level, sockets in **timeout mode** are internally set in non-blocking mode. Also, the blocking and timeout modes are shared between file descriptors and socket objects that refer to the same network endpoint. This implementation detail can have visible consequences if e.g. you decide to use the `fileno()` of a socket.

18.1.4.1. Timeouts and the `connect` method

The `connect()` operation is also subject to the timeout setting, and in general it is recommended to call `settimeout()` before calling `connect()` or pass a timeout parameter to `create_connection()`. However, the system network stack may also return a connection timeout error of its own regardless of any Python socket timeout setting.
18.1.4.2. Timeouts and the accept method

If `getdefaulttimeout()` is not `None`, sockets returned by the `accept()` method inherit that timeout. Otherwise, the behaviour depends on settings of the listening socket:

- if the listening socket is in **blocking mode** or in **timeout mode**, the socket returned by `accept()` is in **blocking mode**;
- if the listening socket is in **non-blocking mode**, whether the socket returned by `accept()` is in blocking or non-blocking mode is operating system-dependent. If you want to ensure cross-platform behaviour, it is recommended you manually override this setting.
18.1.5. Example

Here are four minimal example programs using the TCP/IP protocol: a server that echoes all data that it receives back (servicing only one client), and a client using it. Note that a server must perform the sequence `socket()`, `bind()`, `listen()`, `accept()` (possibly repeating the `accept()` to service more than one client), while a client only needs the sequence `socket()`, `connect()`. Also note that the server does not `sendall()`/`recv()` on the socket it is listening on but on the new socket returned by `accept()`.

The first two examples support IPv4 only.

```python
# Echo server program
import socket

HOST = ''  # Symbolic name meaning all available interfaces
PORT = 50007  # Arbitrary non-privileged port
s = socket.socket(socket.AF_INET, socket.SOCK_STREAM)
s.bind((HOST, PORT))
s.listen(1)
conn, addr = s.accept()
print('Connected by', addr)
while True:
    data = conn.recv(1024)
    if not data: break
    conn.sendall(data)
conn.close()

# Echo client program
import socket

HOST = 'daring.cwi.nl'  # The remote host
```
PORT = 50007  # The same port as used by
s = socket.socket(socket.AF_INET, socket.SOCK_STREAM)
s.connect((HOST, PORT))
s.sendall(b'Hello, world')
data = s.recv(1024)
s.close()
print('Received', repr(data))

The next two examples are identical to the above two, but support both IPv4 and IPv6. The server side will listen to the first address family available (it should listen to both instead). On most of IPv6-ready systems, IPv6 will take precedence and the server may not accept IPv4 traffic. The client side will try to connect to the all addresses returned as a result of the name resolution, and sends traffic to the first one connected successfully.

# Echo server program
import socket
import sys

HOST = None  # Symbolic name meaning all available interfaces
PORT = 50007  # Arbitrary non-privileged port
s = None
for res in socket.getaddrinfo(HOST, PORT, socket.AF_UNSPEC, socket.SOCK_STREAM, 0, socket.AI_PASSIVE):
    af, socktype, proto, canonname, sa = res
    try:
        s = socket.socket(af, socktype, proto)
    except OSError as msg:
        s = None
        continue
    try:
        s.bind(sa)
        s.listen(1)
    except OSError as msg:
```python
s.close()
s = None
continue
break
if s is None:
    print('could not open socket')
    sys.exit(1)
conn, addr = s.accept()
print('Connected by', addr)
while True:
    data = conn.recv(1024)
    if not data: break
    conn.send(data)
conn.close()
```

---

```python
# Echo client program
import socket
import sys

HOST = 'daring.cwi.nl'  # The remote host
PORT = 50007            # The same port as used by
s = None
for res in socket.getaddrinfo(HOST, PORT, socket.AF_
af, socktype, proto, canonname, sa = res
try:
    s = socket.socket(af, socktype, proto)
except OSError as msg:
    s = None
    continue
try:
    s.connect(sa)
except OSError as msg:
    s.close()
s = None
    continue
break
```
The next example shows how to write a very simple network sniffer with raw sockets on Windows. The example requires administrator privileges to modify the interface:

```python
import socket

# the public network interface
HOST = socket.gethostbyname(socket.gethostname())

# create a raw socket and bind it to the public interface
s = socket.socket(socket.AF_INET, socket.SOCK_RAW, socket.IPPROTO_IP)
s.bind((HOST, 0))

# Include IP headers
s.setsockopt(socket.IPPROTO_IP, socket.IP_HDRINCL, 1)

# receive all packages
s.ioctl(socket.SIO_RCVALL, socket.RCVALL_ON)

# receive a package
print(s.recvfrom(65565))

# disabled promiscuous mode
s.ioctl(socket.SIO_RCVALL, socket.RCVALL_OFF)
```

The last example shows how to use the socket interface to communicate to a CAN network. This example might require special
import socket
import struct

can_frame_fmt = '=IB3x8s'
can_frame_size = struct.calcsize(can_frame_fmt)

def build_can_frame(can_id, data):
    can_dlc = len(data)
    data = data.ljust(8, b'\x00')
    return struct.pack(can_frame_fmt, can_id, can_dlc, data)

def dissect_can_frame(frame):
    can_id, can_dlc, data = struct.unpack(can_frame_fmt)
    return (can_id, can_dlc, data[:can_dlc])

# create a raw socket and bind it to the 'vcan0' interface
s = socket.socket(socket.AF_CAN, socket.SOCK_RAW, socket.CAN_RAW)
s.bind(('vcan0',))

while True:
    cf, addr = s.recvfrom(can_frame_size)

    print('Received: can_id=%x, can_dlc=%x, data=%s'

    try:
        s.send(cf)
    except OSError:
        print('Error sending CAN frame')

    try:
        s.send(build_can_frame(0x01, b'\x01\x02\x03'))
```python
except OSError:
    print('Error sending CAN frame')
```

Running an example several times with too small delay between executions, could lead to this error:

```
OSError: [Errno 98] Address already in use
```

This is because the previous execution has left the socket in a TIME_WAIT state, and can't be immediately reused.

There is a `socket` flag to set, in order to prevent this, `socket.SO_REUSEADDR`:

```python
s = socket.socket(socket.AF_INET, socket.SOCK_STREAM)
```

```python
s.setsockopt(socket.SOL_SOCKET, socket.SO_REUSEADDR)
```

```python
s.bind((HOST, PORT))
```

the SO_REUSEADDR flag tells the kernel to reuse a local socket in TIME_WAIT state, without waiting for its natural timeout to expire.

**See also:** For an introduction to socket programming (in C), see the following papers:

- *An Introductory 4.3BSD Interprocess Communication Tutorial*, by Stuart Sechrest
- *An Advanced 4.3BSD Interprocess Communication Tutorial*, by Samuel J. Leffler et al,

both in the UNIX Programmer’s Manual, Supplementary Documents 1 (sections PS1:7 and PS1:8). The platform-specific reference material for the various socket-related system calls are also a valuable source of information on the details of socket semantics.
For Unix, refer to the manual pages; for Windows, see the WinSock (or Winsock 2) specification. For IPv6-ready APIs, readers may want to refer to RFC 3493 titled Basic Socket Interface Extensions for IPv6.
18.2. **ssl** — TLS/SSL wrapper for socket objects

**Source code:** Lib/ssl.py

This module provides access to Transport Layer Security (often known as “Secure Sockets Layer”) encryption and peer authentication facilities for network sockets, both client-side and server-side. This module uses the OpenSSL library. It is available on all modern Unix systems, Windows, Mac OS X, and probably additional platforms, as long as OpenSSL is installed on that platform.

**Note:** Some behavior may be platform dependent, since calls are made to the operating system socket APIs. The installed version of OpenSSL may also cause variations in behavior.

This section documents the objects and functions in the `ssl` module; for more general information about TLS, SSL, and certificates, the reader is referred to the documents in the “See Also” section at the bottom.

This module provides a class, `ssl.SSLSocket`, which is derived from the `socket.socket` type, and provides a socket-like wrapper that also encrypts and decrypts the data going over the socket with SSL. It supports additional methods such as `getpeercert()`, which retrieves the certificate of the other side of the connection, and `cipher()`, which retrieves the cipher being used for the secure connection.
For more sophisticated applications, the `ssl.SSLContext` class helps manage settings and certificates, which can then be inherited by SSL sockets created through the `SSLContext.wrap_socket()` method.
18.2.1. Functions, Constants, and Exceptions

*exception* `ssl.SSLError`

Raised to signal an error from the underlying SSL implementation (currently provided by the OpenSSL library). This signifies some problem in the higher-level encryption and authentication layer that’s superimposed on the underlying network connection. This error is a subtype of `OSError`. The error code and message of `SSLError` instances are provided by the OpenSSL library.

*Changed in version 3.3:* `SSLError` used to be a subtype of `socket.error`.

*library*

A string mnemonic designating the OpenSSL submodule in which the error occurred, such as `SSL`, `PEM` or `X509`. The range of possible values depends on the OpenSSL version.

*New in version 3.3.*

*reason*

A string mnemonic designating the reason this error occurred, for example `CERTIFICATE_VERIFY_FAILED`. The range of possible values depends on the OpenSSL version.

*New in version 3.3.*

*exception* `ssl.SSLZeroReturnError`

A subclass of `SSLError` raised when trying to read or write and the SSL connection has been closed cleanly. Note that this doesn’t
mean that the underlying transport (read TCP) has been closed.

*New in version 3.3.*

**exception ssl.** **SSLWantReadError**
A subclass of **SSLError** raised by a *non-blocking SSL socket* when trying to read or write data, but more data needs to be received on the underlying TCP transport before the request can be fulfilled.

*New in version 3.3.*

**exception ssl.** **SSLWantWriteError**
A subclass of **SSLError** raised by a *non-blocking SSL socket* when trying to read or write data, but more data needs to be sent on the underlying TCP transport before the request can be fulfilled.

*New in version 3.3.*

**exception ssl.** **SSLSyscallError**
A subclass of **SSLError** raised when a system error was encountered while trying to fulfill an operation on a SSL socket. Unfortunately, there is no easy way to inspect the original errno number.

*New in version 3.3.*

**exception ssl.** **SSLEOFError**
A subclass of **SSLError** raised when the SSL connection has been terminated abruptly. Generally, you shouldn’t try to reuse the underlying transport when this error is encountered.

*New in version 3.3.*
exception ssl.CertificateError

Raised to signal an error with a certificate (such as mismatching hostname). Certificate errors detected by OpenSSL, though, raise an SSLError.

18.2.1.1. Socket creation

The following function allows for standalone socket creation. Starting from Python 3.2, it can be more flexible to use SSLContext.wrap_socket() instead.

```
ssl.wrap_socket(sock, keyfile=None, certfile=None, server_side=False, cert_reqs=CERT_NONE, ssl_version={see docs}, ca_certs=None, do_handshake_on_connect=True, suppress_ragged_eofs=True, ciphers=None)
```

Takes an instance sock of socket.socket, and returns an instance of ssl.SSLSocket, a subtype of socket.socket, which wraps the underlying socket in an SSL context. For client-side sockets, the context construction is lazy; if the underlying socket isn’t connected yet, the context construction will be performed after connect() is called on the socket. For server-side sockets, if the socket has no remote peer, it is assumed to be a listening socket, and the server-side SSL wrapping is automatically performed on client connections accepted via the accept() method. wrap_socket() may raise SSLError.

The keyfile and certfile parameters specify optional files which contain a certificate to be used to identify the local side of the connection. See the discussion of Certificates for more information on how the certificate is stored in the certfile.

The parameter server_side is a boolean which identifies
whether server-side or client-side behavior is desired from this socket.

The parameter `cert_reqs` specifies whether a certificate is required from the other side of the connection, and whether it will be validated if provided. It must be one of the three values `CERT_NONE` (certificates ignored), `CERT_OPTIONAL` (not required, but validated if provided), or `CERT_REQUIRED` (required and validated). If the value of this parameter is not `CERT_NONE`, then the `ca_certs` parameter must point to a file of CA certificates.

The `ca_certs` file contains a set of concatenated “certification authority” certificates, which are used to validate certificates passed from the other end of the connection. See the discussion of `Certificates` for more information about how to arrange the certificates in this file.

The parameter `ssl_version` specifies which version of the SSL protocol to use. Typically, the server chooses a particular protocol version, and the client must adapt to the server’s choice. Most of the versions are not interoperable with the other versions. If not specified, the default is `PROTOCOL_SSLv23`; it provides the most compatibility with other versions.

Here’s a table showing which versions in a client (down the side) can connect to which versions in a server (along the top):

<table>
<thead>
<tr>
<th>client / server</th>
<th>SSLv2</th>
<th>SSLv3</th>
<th>SSLv23</th>
<th>TLSv1</th>
</tr>
</thead>
<tbody>
<tr>
<td>SSLv2</td>
<td>yes</td>
<td>no</td>
<td>yes</td>
<td>no</td>
</tr>
<tr>
<td>SSLv3</td>
<td>no</td>
<td>yes</td>
<td>yes</td>
<td>no</td>
</tr>
<tr>
<td>SSLv23</td>
<td>yes</td>
<td>no</td>
<td>yes</td>
<td>no</td>
</tr>
<tr>
<td>$TLSv1$</td>
<td>no</td>
<td>no</td>
<td>yes</td>
<td>yes</td>
</tr>
</tbody>
</table>

**Note:** Which connections succeed will vary depending on the version of OpenSSL. For instance, in some older versions of OpenSSL (such as 0.9.7l on OS X 10.4), an SSLv2 client could not connect to an SSLv23 server. Another example: beginning with OpenSSL 1.0.0, an SSLv23 client will not actually attempt SSLv2 connections unless you explicitly enable SSLv2 ciphers; for example, you might specify "ALL" or "SSLv2" as the `ciphers` parameter to enable them.

The `ciphers` parameter sets the available ciphers for this SSL object. It should be a string in the OpenSSL cipher list format.

The parameter `do_handshake_on_connect` specifies whether to do the SSL handshake automatically after doing a `socket.connect()`, or whether the application program will call it explicitly, by invoking the `SSLSocket.do_handshake()` method. Calling `SSLSocket.do_handshake()` explicitly gives the program control over the blocking behavior of the socket I/O involved in the handshake.

The parameter `suppress_ragged_eofs` specifies how the `SSLSocket.recv()` method should signal unexpected EOF from the other end of the connection. If specified as `True` (the default), it returns a normal EOF (an empty bytes object) in response to unexpected EOF errors raised from the underlying socket; if `False`, it will raise the exceptions back to the caller.

*Changed in version 3.2:* New optional argument `ciphers`.

### 18.2.1.2. Random generation

ssl.\texttt{\texttt{RAND\_bytes}(num)}

Returns \textit{num} cryptographically strong pseudo-random bytes. Raises an \texttt{SSLError} if the PRNG has not been seeded with enough data or if the operation is not supported by the current RAND method. \texttt{RAND\_status()} can be used to check the status of the PRNG and \texttt{RAND\_add()} can be used to seed the PRNG.

Read the Wikipedia article, Cryptographically secure pseudorandom number generator (CSPRNG), to get the requirements of a cryptographically generator.

\emph{New in version 3.3.}

ssl.\texttt{\texttt{RAND\_pseudo\_bytes}(num)}

Returns (bytes, is\_cryptographic): bytes are \textit{num} pseudo-random bytes, is\_cryptographic is True if the bytes generated are cryptographically strong. Raises an \texttt{SSLError} if the operation is not supported by the current RAND method.

Generated pseudo-random byte sequences will be unique if they are of sufficient length, but are not necessarily unpredictable. They can be used for non-cryptographic purposes and for certain purposes in cryptographic protocols, but usually not for key generation etc.

\emph{New in version 3.3.}

ssl.\texttt{\texttt{RAND\_status}()}

Returns True if the SSL pseudo-random number generator has been seeded with ‘enough’ randomness, and False otherwise. You can use \texttt{ssl.RAND\_egd()} and \texttt{ssl.RAND\_add()} to increase the randomness of the pseudo-random number generator.
ssl.\texttt{RAND\_egd}(\textit{path})

If you are running an entropy-gathering daemon (EGD) somewhere, and \textit{path} is the pathname of a socket connection open to it, this will read 256 bytes of randomness from the socket, and add it to the SSL pseudo-random number generator to increase the security of generated secret keys. This is typically only necessary on systems without better sources of randomness.

See \url{http://egd.sourceforge.net/} or \url{http://prngd.sourceforge.net/} for sources of entropy-gathering daemons.

ssl.\texttt{RAND\_add}(\textit{bytes, entropy})

Mixes the given \textit{bytes} into the SSL pseudo-random number generator. The parameter \textit{entropy} (a float) is a lower bound on the entropy contained in string (so you can always use 0.0). See RFC 1750 for more information on sources of entropy.

### 18.2.1.3. Certificate handling

ssl.\texttt{match\_hostname}(\textit{cert, hostname})

Verify that \textit{cert} (in decoded format as returned by \texttt{SSLSocket.getpeercert()}) matches the given \textit{hostname}. The rules applied are those for checking the identity of HTTPS servers as outlined in RFC 2818 and RFC 6125, except that IP addresses are not currently supported. In addition to HTTPS, this function should be suitable for checking the identity of servers in various SSL-based protocols such as FTPS, IMAPS, POOPS and others.

\texttt{CertificateError} is raised on failure. On success, the function returns nothing:

```python
>>> cert = {'subject': (((('commonName', 'example.'}
```python
>>> ssl.match_hostname(cert, "example.com")
>>> ssl.match_hostname(cert, "example.org")
Traceback (most recent call last):
  File "<stdin>", line 1, in <module>
  File "/home/py3k/Lib/ssl.py", line 130, in match_hostname
ssl.CertificateError: hostname 'example.org' doesn't match 'example.com'

New in version 3.2.

Changed in version 3.3.3: The function now follows RFC 6125, section 6.4.3 and does neither match multiple wildcards (e.g. *.com or *a*.example.org) nor a wildcard inside an internationalized domain names (IDN) fragment. IDN A-labels such as www*.xn--pthon-kva.org are still supported, but x*.python.org no longer matches xn--tda.python.org.

ssl.cert_time_to_seconds(timestring)
Returns a floating-point value containing a normal seconds-after-the-epoch time value, given the time-string representing the “notBefore” or “notAfter” date from a certificate.

Here's an example:

```python
>>> import ssl
>>> ssl.cert_time_to_seconds("May 00:00:00 2007 GMT")
1178694000.0
>>> import time
>>> time.ctime(ssl.cert_time_to_seconds("May 00:00:00 2007 GMT"))
'Wed May 9 00:00:00 2007'

```

ssl.get_server_certificate(addr, ssl_version=PROTOCOL_SSLv3, ca_certs=None)
Given the address `addr` of an SSL-protected server, as a
(hostname, port-number) pair, fetches the server’s certificate, and returns it as a PEM-encoded string. If ssl_version is specified, uses that version of the SSL protocol to attempt to connect to the server. If ca_certs is specified, it should be a file containing a list of root certificates, the same format as used for the same parameter in wrap_socket(). The call will attempt to validate the server certificate against that set of root certificates, and will fail if the validation attempt fails.

*Changed in version 3.3:* This function is now IPv6-compatible.

**ssl.DER_cert_to_PEM_cert(DER_cert_bytes)**
Given a certificate as a DER-encoded blob of bytes, returns a PEM-encoded string version of the same certificate.

**ssl.PEM_cert_to_DER_cert(PEM_cert_string)**
Given a certificate as an ASCII PEM string, returns a DER-encoded sequence of bytes for that same certificate.

### 18.2.1.4. Constants

**ssl.CERT_NONE**
Possible value for SSLContext.verify_mode, or the cert_reqs parameter to wrap_socket(). In this mode (the default), no certificates will be required from the other side of the socket connection. If a certificate is received from the other end, no attempt to validate it is made.

See the discussion of *Security considerations* below.

**ssl.CERT_OPTIONAL**
Possible value for SSLContext.verify_mode, or the
cert_reqs parameter to wrap_socket(). In this mode no certificates will be required from the other side of the socket connection; but if they are provided, validation will be attempted and an SSLError will be raised on failure.

Use of this setting requires a valid set of CA certificates to be passed, either to SSLContext.load_verify_locations() or as a value of the ca_certs parameter to wrap_socket().

ssl. CERT_REQUIRED
Possible value for SSLContext.verify_mode, or the cert_reqs parameter to wrap_socket(). In this mode, certificates are required from the other side of the socket connection; an SSLError will be raised if no certificate is provided, or if its validation fails.

Use of this setting requires a valid set of CA certificates to be passed, either to SSLContext.load_verify_locations() or as a value of the ca_certs parameter to wrap_socket().

ssl. PROTOCOL_SSLv2
Selects SSL version 2 as the channel encryption protocol.

This protocol is not available if OpenSSL is compiled with OPENSSL_NO_SSL2 flag.

**Warning:** SSL version 2 is insecure. Its use is highly discouraged.

ssl. PROTOCOL_SSLv23
Selects SSL version 2 or 3 as the channel encryption protocol. This is a setting to use with servers for maximum compatibility with the
other end of an SSL connection, but it may cause the specific ciphers chosen for the encryption to be of fairly low quality.

**ssl.PROTOCOL_SSLv3**

Selects SSL version 3 as the channel encryption protocol. For clients, this is the maximally compatible SSL variant.

**ssl.PROTOCOL_TLSv1**

Selects TLS version 1 as the channel encryption protocol. This is the most modern version, and probably the best choice for maximum protection, if both sides can speak it.

**ssl.OP_ALL**

Enables workarounds for various bugs present in other SSL implementations. This option is set by default. It does not necessarily set the same flags as OpenSSL's `SSL_OP_ALL` constant.

*New in version 3.2.*

**ssl.OP_NO_SSLv2**

Prevents an SSLv2 connection. This option is only applicable in conjunction with `PROTOCOL_SSLv23`. It prevents the peers from choosing SSLv2 as the protocol version.

*New in version 3.2.*

**ssl.OP_NO_SSLv3**

Prevents an SSLv3 connection. This option is only applicable in conjunction with `PROTOCOL_SSLv23`. It prevents the peers from choosing SSLv3 as the protocol version.

*New in version 3.2.*
**ssl.OP_NO_TLSv1**
Prevents a TLSv1 connection. This option is only applicable in conjunction with `PROTOCOL_SSLv23`. It prevents the peers from choosing TLSv1 as the protocol version.

*New in version 3.2.*

**ssl.OP_CIPHER_SERVER_PREFERENCE**
Use the server's cipher ordering preference, rather than the client's. This option has no effect on client sockets and SSLv2 server sockets.

*New in version 3.3.*

**ssl.OP_SINGLE_DH_USE**
Prevents re-use of the same DH key for distinct SSL sessions. This improves forward secrecy but requires more computational resources. This option only applies to server sockets.

*New in version 3.3.*

**ssl.OP_SINGLE_ECDH_USE**
Prevents re-use of the same ECDH key for distinct SSL sessions. This improves forward secrecy but requires more computational resources. This option only applies to server sockets.

*New in version 3.3.*

**ssl.OP_NO_COMPRESSION**
Disable compression on the SSL channel. This is useful if the application protocol supports its own compression scheme.

This option is only available with OpenSSL 1.0.0 and later.
New in version 3.3.

ssl. **HAS_ECDH**
Whether the OpenSSL library has built-in support for Elliptic Curve-based Diffie-Hellman key exchange. This should be true unless the feature was explicitly disabled by the distributor.

New in version 3.3.

ssl. **HAS_SNI**
Whether the OpenSSL library has built-in support for the Server Name Indication extension to the SSLv3 and TLSv1 protocols (as defined in RFC 4366). When true, you can use the `server_hostname` argument to `SSLContext.wrap_socket()`.

New in version 3.2.

ssl. **HAS_NPN**
Whether the OpenSSL library has built-in support for Next Protocol Negotiation as described in the NPN draft specification. When true, you can use the `SSLContext.set_npn_protocols()` method to advertise which protocols you want to support.

New in version 3.3.

ssl. **CHANNEL_BINDING_TYPES**
List of supported TLS channel binding types. Strings in this list can be used as arguments to `SSLSocket.get_channel_binding()`.

New in version 3.3.

ssl. **OPENSSL_VERSION**
The version string of the OpenSSL library loaded by the interpreter:
>>> ssl.OPENSSL_VERSION
'OpenSSL 0.9.8k 25 Mar 2009'

*New in version 3.2.*

**ssl. OPENSSL_VERSION_INFO**

A tuple of five integers representing version information about the OpenSSL library:

```python
>>> ssl.OPENSSL_VERSION_INFO
(0, 9, 8, 11, 15)

*New in version 3.2.*

**ssl. OPENSSL_VERSION_NUMBER**

The raw version number of the OpenSSL library, as a single integer:

```python
>>> ssl.OPENSSL_VERSION_NUMBER
9470143
>>> hex(ssl.OPENSSL_VERSION_NUMBER)
'0x9080bf'
```

*New in version 3.2.*
18.2.2. SSL Sockets

SSL sockets provide the following methods of *Socket Objects*:

- `accept()`
- `bind()`
- `close()`
- `connect()`
- `detach()`
- `fileno()`
- `getpeername()`, `getsockname()`
- `getsockopt()`, `setsockopt()`
- `gettimeout()`, `settimeout()`, `setblocking()`
- `listen()`
- `makefile()`
- `recv()`, `recv_into()` (but passing a non-zero flags argument is not allowed)
- `send()`, `sendall()` (with the same limitation)
- `shutdown()`

However, since the SSL (and TLS) protocol has its own framing atop of TCP, the SSL sockets abstraction can, in certain respects, diverge from the specification of normal, OS-level sockets. See especially the *notes on non-blocking sockets*.

SSL sockets also have the following additional methods and attributes:

**SSLSocket**. **do_handshake()**

Perform the SSL setup handshake.

**SSLSocket**. **getpeercert**(binary_form=False).

If there is no certificate for the peer on the other end of the
connection, returns None.

If the binary_form parameter is False, and a certificate was received from the peer, this method returns a dict instance. If the certificate was not validated, the dict is empty. If the certificate was validated, it returns a dict with several keys, amongst them subject (the principal for which the certificate was issued) and issuer (the principal issuing the certificate). If a certificate contains an instance of the Subject Alternative Name extension (see RFC 3280), there will also be a subjectAltName key in the dictionary.

The subject and issuer fields are tuples containing the sequence of relative distinguished names (RDNs) given in the certificate's data structure for the respective fields, and each RDN is a sequence of name-value pairs. Here is a real-world example:

```python
{'issuer': (((('countryName', 'IL'),),)
(('organizationName', 'StartCom Ltd.'
('organizationalUnitName',
 'Secure Digital Certificate Signing
('commonName',
 'StartCom Class 2 Primary Intermedi
',

'notAfter': 'Nov 22 08:15:19 2013 GMT',
'notBefore': 'Nov 21 03:09:52 2011 GMT',
'serialNumber': '95F0',
'subject': (((('description', '571208-SLe257oHY9f
('countryName', 'US'),),)
(('stateOrProvinceName', 'California
('localityName', 'San Francisco'),)
(('organizationName', 'Electronic Fr
('commonName', '*.eff.org'),),)
(('emailAddress', 'hostmaster@eff.or
'subjectAltName': (('DNS', '*.eff.org'), ('DNS',
```
'version': 3}

Note: To validate a certificate for a particular service, you can use the `match_hostname()` function.

If the `binary_form` parameter is `True`, and a certificate was provided, this method returns the DER-encoded form of the entire certificate as a sequence of bytes, or `None` if the peer did not provide a certificate. Whether the peer provides a certificate depends on the SSL socket's role:

- for a client SSL socket, the server will always provide a certificate, regardless of whether validation was required;
- for a server SSL socket, the client will only provide a certificate when requested by the server; therefore `getpeercert()` will return `None` if you used `CERT_NONE` (rather than `CERT_OPTIONAL` or `CERT_REQUIRED`).

*Changed in version 3.2:* The returned dictionary includes additional items such as `issuer` and `notBefore`.

`SSLSocket.cipher()`

Returns a three-value tuple containing the name of the cipher being used, the version of the SSL protocol that defines its use, and the number of secret bits being used. If no connection has been established, returns `None`.

`SSLSocket.compression()`

Return the compression algorithm being used as a string, or `None` if the connection isn’t compressed.

If the higher-level protocol supports its own compression mechanism, you can use `OP_NO_COMPRESSION` to disable SSL-
level compression.

New in version 3.3.

SSLSocket.get_channel_binding(cb_type="tls-unique")
Get channel binding data for current connection, as a bytes object. Returns None if not connected or the handshake has not been completed.

The cb_type parameter allow selection of the desired channel binding type. Valid channel binding types are listed in the CHANNEL_BINDING_TYPES list. Currently only the ‘tls-unique’ channel binding, defined by RFC 5929, is supported. ValueError will be raised if an unsupported channel binding type is requested.

New in version 3.3.

SSLSocket.selected_npn_protocol()
Returns the protocol that was selected during the TLS/SSL handshake. If SSLContext.set_npn_protocols() was not called, or if the other party does not support NPN, or if the handshake has not yet happened, this will return None.

New in version 3.3.

SSLSocket.unwrap()
Performs the SSL shutdown handshake, which removes the TLS layer from the underlying socket, and returns the underlying socket object. This can be used to go from encrypted operation over a connection to unencrypted. The returned socket should always be used for further communication with the other side of the connection, rather than the original socket.
SSLSSocket. **context**

The **SSLContext** object this SSL socket is tied to. If the SSL socket was created using the top-level `wrap_socket()` function (rather than `SSLContext.wrap_socket()`), this is a custom context object created for this SSL socket.

*New in version 3.2.*
18.2.3. SSL Contexts

*New in version 3.2.*

An SSL context holds various data longer-lived than single SSL connections, such as SSL configuration options, certificate(s) and private key(s). It also manages a cache of SSL sessions for server-side sockets, in order to speed up repeated connections from the same clients.

```python
class ssl.SSLContext(protocol)
    Create a new SSL context. You must pass protocol which must be one of the PROTOCOL_* constants defined in this module. PROTOCOL_SSLv23 is recommended for maximum interoperability.
```

`SSLContext` objects have the following methods and attributes:

```python
SSLContext.load_cert_chain(certfile, keyfile=None, password=None)
    Load a private key and the corresponding certificate. The certfile string must be the path to a single file in PEM format containing the certificate as well as any number of CA certificates needed to establish the certificate’s authenticity. The keyfile string, if present, must point to a file containing the private key in. Otherwise the private key will be taken from certfile as well. See the discussion of Certificates for more information on how the certificate is stored in the certfile.

    The password argument may be a function to call to get the password for decrypting the private key. It will only be called if the private key is encrypted and a password is necessary. It will be called with no arguments, and it should return a string, bytes, or...
bytearray. If the return value is a string it will be encoded as UTF-8 before using it to decrypt the key. Alternatively a string, bytes, or bytearray value may be supplied directly as the `password` argument. It will be ignored if the private key is not encrypted and no password is needed.

If the `password` argument is not specified and a password is required, OpenSSL's built-in password prompting mechanism will be used to interactively prompt the user for a password.

An `SSLError` is raised if the private key doesn't match with the certificate.

*Changed in version 3.3:* New optional argument `password`.

`SSLContext.load_verify_locations(cafile=None, capath=None)`

Load a set of “certification authority” (CA) certificates used to validate other peers' certificates when `verify_mode` is other than `CERT_NONE`. At least one of `cafile` or `capath` must be specified.

The `cafile` string, if present, is the path to a file of concatenated CA certificates in PEM format. See the discussion of `Certificates` for more information about how to arrange the certificates in this file.

The `capath` string, if present, is the path to a directory containing several CA certificates in PEM format, following an OpenSSL specific layout.

`SSLContext.set_default_verify_paths()`

Load a set of default “certification authority” (CA) certificates from a filesystem path defined when building the OpenSSL library. Unfortunately, there's no easy way to know whether this method
succeeds: no error is returned if no certificates are to be found. When the OpenSSL library is provided as part of the operating system, though, it is likely to be configured properly.

SSLContext.set_ciphers(ciphers)
Set the available ciphers for sockets created with this context. It should be a string in the OpenSSL cipher list format. If no cipher can be selected (because compile-time options or other configuration forbids use of all the specified ciphers), an SSLError will be raised.

Note: when connected, the SSLSocket.cipher() method of SSL sockets will give the currently selected cipher.

SSLContext.set_npn_protocols(protocols)
Specify which protocols the socket should advertise during the SSL/TLS handshake. It should be a list of strings, like ['http/1.1', 'spdy/2'], ordered by preference. The selection of a protocol will happen during the handshake, and will play out according to the NPN draft specification. After a successful handshake, the SSLSocket.selected_npn_protocol() method will return the agreed-upon protocol.

This method will raise NotImplemented if HAS_NPN is False.

New in version 3.3.

SSLContext.load_dh_params(dhfile)
Load the key generation parameters for Diffie-Helman (DH) key exchange. Using DH key exchange improves forward secrecy at the expense of computational resources (both on the server and on
the client). The `dhfile` parameter should be the path to a file containing DH parameters in PEM format.

This setting doesn't apply to client sockets. You can also use the `OP_SINGLE_DH_USE` option to further improve security.

*New in version 3.3.*

**SSLContext.set_ecdh_curve(curve_name)**

Set the curve name for Elliptic Curve-based Diffie-Hellman (ECDH) key exchange. ECDH is significantly faster than regular DH while arguably as secure. The `curve_name` parameter should be a string describing a well-known elliptic curve, for example `prime256v1` for a widely supported curve.

This setting doesn't apply to client sockets. You can also use the `OP_SINGLE_ECDH_USE` option to further improve security.

This method is not available if `HAS_ECDH` is False.

*New in version 3.3.*

**See also:** SSL/TLS & Perfect Forward Secrecy Vincent Bernat.

**SSLContext.wrap_socket(sock, server_side=False, do_handshake_on_connect=True, suppress_ragged_eofs=True, server_hostname=None)**

Wrap an existing Python socket `sock` and return an `SSLSocket` object. The SSL socket is tied to the context, its settings and certificates. The parameters `server_side`, `do_handshake_on_connect` and `suppress_ragged_eofs` have the same meaning as in the top-level `wrap_socket()` function.
On client connections, the optional parameter `server_hostname` specifies the hostname of the service which we are connecting to. This allows a single server to host multiple SSL-based services with distinct certificates, quite similarly to HTTP virtual hosts. Specifying `server_hostname` will raise a `ValueError` if the OpenSSL library doesn’t have support for it (that is, if `HAS_SNI` is `False`). Specifying `server_hostname` will also raise a `ValueError` if `server_side` is true.

**SSLContext.**`session_stats()`

Get statistics about the SSL sessions created or managed by this context. A dictionary is returned which maps the names of each piece of information to their numeric values. For example, here is the total number of hits and misses in the session cache since the context was created:

```python
>>> stats = context.session_stats()
>>> stats['hits'], stats['misses']
(0, 0)
```

**SSLContext.**`options`

An integer representing the set of SSL options enabled on this context. The default value is `OP_ALL`, but you can specify other options such as `OP_NO_SSLv2` by ORing them together.

**Note:** With versions of OpenSSL older than 0.9.8m, it is only possible to set options, not to clear them. Attempting to clear an option (by resetting the corresponding bits) will raise a `ValueError`.

**SSLContext.**`protocol`

The protocol version chosen when constructing the context. This
attribute is read-only.

**SSLContext.verify_mode**

Whether to try to verify other peers’ certificates and how to behave if verification fails. This attribute must be one of `CERT_NONE`, `CERT_OPTIONAL` or `CERT_REQUIRED`. 
18.2.4. Certificates

Certificates in general are part of a public-key / private-key system. In this system, each principal, (which may be a machine, or a person, or an organization) is assigned a unique two-part encryption key. One part of the key is public, and is called the public key; the other part is kept secret, and is called the private key. The two parts are related, in that if you encrypt a message with one of the parts, you can decrypt it with the other part, and only with the other part.

A certificate contains information about two principals. It contains the name of a subject, and the subject’s public key. It also contains a statement by a second principal, the issuer, that the subject is who he claims to be, and that this is indeed the subject’s public key. The issuer’s statement is signed with the issuer’s private key, which only the issuer knows. However, anyone can verify the issuer’s statement by finding the issuer’s public key, decrypting the statement with it, and comparing it to the other information in the certificate. The certificate also contains information about the time period over which it is valid. This is expressed as two fields, called “notBefore” and “notAfter”.

In the Python use of certificates, a client or server can use a certificate to prove who they are. The other side of a network connection can also be required to produce a certificate, and that certificate can be validated to the satisfaction of the client or server that requires such validation. The connection attempt can be set to raise an exception if the validation fails. Validation is done automatically, by the underlying OpenSSL framework; the application need not concern itself with its mechanics. But the application does usually need to provide sets of certificates to allow this process to take place.

Python uses files to contain certificates. They should be formatted as
“PEM” (see RFC 1422), which is a base-64 encoded form wrapped with a header line and a footer line:

```
-----BEGIN CERTIFICATE-----
... (certificate in base64 PEM encoding) ...
-----END CERTIFICATE-----
```

### 18.2.4.1. Certificate chains

The Python files which contain certificates can contain a sequence of certificates, sometimes called a certificate chain. This chain should start with the specific certificate for the principal who “is” the client or server, and then the certificate for the issuer of that certificate, and then the certificate for the issuer of that certificate, and so on up the chain till you get to a certificate which is self-signed, that is, a certificate which has the same subject and issuer, sometimes called a root certificate. The certificates should just be concatenated together in the certificate file. For example, suppose we had a three certificate chain, from our server certificate to the certificate of the certification authority that signed our server certificate, to the root certificate of the agency which issued the certification authority’s certificate:

```
-----BEGIN CERTIFICATE-----
... (certificate for your server)...
-----END CERTIFICATE-----
-----BEGIN CERTIFICATE-----
... (the certificate for the CA)...
-----END CERTIFICATE-----
-----BEGIN CERTIFICATE-----
... (the root certificate for the CA's issuer)...
-----END CERTIFICATE-----
```

### 18.2.4.2. CA certificates
If you are going to require validation of the other side of the connection's certificate, you need to provide a “CA certs” file, filled with the certificate chains for each issuer you are willing to trust. Again, this file just contains these chains concatenated together. For validation, Python will use the first chain it finds in the file which matches. Some “standard” root certificates are available from various certification authorities: CACert.org, Thawte, Verisign, Positive SSL (used by python.org), Equifax and GeoTrust.

In general, if you are using SSL3 or TLS1, you don’t need to put the full chain in your “CA certs” file; you only need the root certificates, and the remote peer is supposed to furnish the other certificates necessary to chain from its certificate to a root certificate. See RFC 4158 for more discussion of the way in which certification chains can be built.

18.2.4.3. Combined key and certificate

Often the private key is stored in the same file as the certificate; in this case, only the certfile parameter to SSLContext.load_cert_chain() and wrap_socket() needs to be passed. If the private key is stored with the certificate, it should come before the first certificate in the certificate chain:

```
-----BEGIN RSA PRIVATE KEY-----
... (private key in base64 encoding) ...
-----END RSA PRIVATE KEY-----
-----BEGIN CERTIFICATE-----
... (certificate in base64 PEM encoding) ...
-----END CERTIFICATE-----
```

18.2.4.4. Self-signed certificates
If you are going to create a server that provides SSL-encrypted connection services, you will need to acquire a certificate for that service. There are many ways of acquiring appropriate certificates, such as buying one from a certification authority. Another common practice is to generate a self-signed certificate. The simplest way to do this is with the OpenSSL package, using something like the following:

```
% openssl req -new -x509 -days 365 -nodes -out cert.pem
Generating a 1024 bit RSA private key
........+++++
.............................+++++
writing new private key to 'cert.pem'
-----
You are about to be asked to enter information that into your certificate request.
What you are about to enter is what is called a Dist
There are quite a few fields but you can leave some For some fields there will be a default value,
If you enter '.', the field will be left blank.
-----
Country Name (2 letter code) [AU]:US
State or Province Name (full name) [Some-State]:MySt
Locality Name (eg, city) []:Some City
Organization Name (eg, company) [Internet Widgits Pt
Organizational Unit Name (eg, section) []:My Group
Common Name (eg, YOUR name) []:myserver.mygroup.myorganization
Email Address []:ops@myserver.mygroup.myorganization
```

The disadvantage of a self-signed certificate is that it is its own root certificate, and no one else will have it in their cache of known (and trusted) root certificates.
18.2.5. Examples

18.2.5.1. Testing for SSL support

To test for the presence of SSL support in a Python installation, user code should use the following idiom:

```python
try:
    import ssl
except ImportError:
    pass
else:
    ... # do something that requires SSL support
```

18.2.5.2. Client-side operation

This example connects to an SSL server and prints the server's certificate:

```python
import socket, ssl, pprint

s = socket.socket(socket.AF_INET, socket.SOCK_STREAM)
# require a certificate from the server
ssl_sock = ssl.wrap_socket(s,
    ca_certs="/etc/ca_certs_file",
    cert_reqs=ssl.CERT_REQUIRED)
ssl_sock.connect(('www.verisign.com', 443))

pprint.pprint(ssl_sock.getpeercert())
# note that closing the SSLSocket will also close the underlying socket
ssl_sock.close()
```

As of January 6, 2012, the certificate printed by this program looks like
This other example first creates an SSL context, instructs it to verify certificates sent by peers, and feeds it a set of recognized certificate
authorities (CA):

```python
>>> context = ssl.SSLContext(ssl.PROTOCOL_SSLv23)
>>> context.verify_mode = ssl.CERT_REQUIRED
>>> context.load_verify_locations("/etc/ssl/certs/ca-bundle.crt")
```

(it is assumed your operating system places a bundle of all CA certificates in `/etc/ssl/certs/ca-bundle.crt`; if not, you'll get an error and have to adjust the location)

When you use the context to connect to a server, `CERT_REQUIRED` validates the server certificate: it ensures that the server certificate was signed with one of the CA certificates, and checks the signature for correctness:

```python
>>> conn = context.wrap_socket(socket.socket(socket.
...                               socket.AF_INET,
...                               socket.SOCK_STREAM))
>>> conn.connect(("linuxfr.org", 443))
```

You should then fetch the certificate and check its fields for conformity:

```python
>>> cert = conn.getpeercert()
>>> ssl.match_hostname(cert, "linuxfr.org")
```

Visual inspection shows that the certificate does identify the desired service (that is, the HTTPS host `linuxfr.org`):

```python
>>> pprint.pprint(cert)
{'issuer': (((('organizationName', 'CAcert Inc.'),),
             (('organizationalUnitName', 'http://www.CAcert.org'),),
             (('commonName', 'CAcert Class 3 Root'),)),
 'notAfter': 'Jun  7 21:02:24 2013 GMT',
 'notBefore': 'Jun  8 21:02:24 2011 GMT',
 'serialNumber': 'D3E9',
```
Now that you are assured of its authenticity, you can proceed to talk with the server:

```python
>>> conn.sendall(b"HEAD / HTTP/1.0\r\nHost: linuxfr.org")
>>> pprint.pprint(conn.recv(1024).split(b'\r\n'))
[b'HTTP/1.1 302 Found',
 b'Date: Sun, 16 May 2010 13:43:28 GMT',
 b'Server: Apache/2.2',
 b'Location: https://linuxfr.org/pub/',
 b'Vary: Accept-Encoding',
 b'Connection: close',
 b'Content-Type: text/html; charset=iso-8859-1',
 b'','
 b'']
```

See the discussion of Security considerations below.

18.2.5.3. Server-side operation
For server operation, typically you’ll need to have a server certificate, and private key, each in a file. You’ll first create a context holding the key and the certificate, so that clients can check your authenticity. Then you’ll open a socket, bind it to a port, call listen() on it, and start waiting for clients to connect:

```python
import socket, ssl

context = ssl.SSLContext(ssl.PROTOCOL_TLSv1)
context.load_cert_chain(certfile="mycertfile", keyfile="mykeyfile"

bindsocket = socket.socket()
bindsocket.bind(('myaddr.mydomain.com', 10023))
bindsocket.listen(5)
```

When a client connects, you’ll call accept() on the socket to get the new socket from the other end, and use the context’s `SSLContext.wrap_socket()` method to create a server-side SSL socket for the connection:

```python
while True:
    newsocket, fromaddr = bindsocket.accept()
    connstream = context.wrap_socket(newsocket, server_side=True,
    try:
        deal_with_client(connstream)
    finally:
        connstream.shutdown(socket.SHUT_RDWR)
        connstream.close()
```

Then you’ll read data from the `connstream` and do something with it till you are finished with the client (or the client is finished with you):

```python
def deal_with_client(connstream):
```
data = connstream.recv(1024)
# empty data means the client is finished with us
while data:
    if not do_something(connstream, data):
        # we'll assume do_something returns False
        # when we're finished with client
        break
    data = connstream.recv(1024)
# finished with client

And go back to listening for new client connections (of course, a real server would probably handle each client connection in a separate thread, or put the sockets in non-blocking mode and use an event loop).
18.2.6. Notes on non-blocking sockets

When working with non-blocking sockets, there are several things you need to be aware of:

- Calling `select()` tells you that the OS-level socket can be read from (or written to), but it does not imply that there is sufficient data at the upper SSL layer. For example, only part of an SSL frame might have arrived. Therefore, you must be ready to handle `SSLSocket.recv()` and `SSLSocket.send()` failures, and retry after another call to `select()`.

  (of course, similar provisions apply when using other primitives such as `poll()`)

- The SSL handshake itself will be non-blocking: the `SSLSocket.do_handshake()` method has to be retried until it returns successfully. Here is a synopsis using `select()` to wait for the socket's readiness:

```
while True:
    try:
        sock.do_handshake()
        break
    except ssl.SSLWantReadError:
        select.select([sock], [], [])
    except ssl.SSLWantWriteError:
        select.select([], [sock], [])
```
18.2.7. Security considerations

18.2.7.1. Verifying certificates

CERT_NONE is the default. Since it does not authenticate the other peer, it can be insecure, especially in client mode where most of time you would like to ensure the authenticity of the server you’re talking to. Therefore, when in client mode, it is highly recommended to use CERT_REQUIRED. However, it is in itself not sufficient; you also have to check that the server certificate, which can be obtained by calling SSLSocket.getpeercert(), matches the desired service. For many protocols and applications, the service can be identified by the hostname; in this case, the match_hostname() function can be used.

In server mode, if you want to authenticate your clients using the SSL layer (rather than using a higher-level authentication mechanism), you’ll also have to specify CERT_REQUIRED and similarly check the client certificate.

**Note:** In client mode, CERT_OPTIONAL and CERT_REQUIRED are equivalent unless anonymous ciphers are enabled (they are disabled by default).

18.2.7.2. Protocol versions

SSL version 2 is considered insecure and is therefore dangerous to use. If you want maximum compatibility between clients and servers, it is recommended to use PROTOCOL_SSLv23 as the protocol version and then disable SSLv2 explicitly using the SSLContext.options
The SSL context created above will allow SSLv3 and TLSv1 connections, but not SSLv2.

### 18.2.7.3. Cipher selection

If you have advanced security requirements, fine-tuning of the ciphers enabled when negotiating a SSL session is possible through the `SSLContext.set_ciphers()` method. Starting from Python 3.2.3, the ssl module disables certain weak ciphers by default, but you may want to further restrict the cipher choice. For example:

```python
context = ssl.SSLContext(ssl.PROTOCOL_TLSv1)
context.set_ciphers('HIGH:!aNULL:!eNULL')
```

The `!aNULL:!eNULL` part of the cipher spec is necessary to disable ciphers which don't provide both encryption and authentication. Be sure to read OpenSSL's documentation about the cipher list format. If you want to check which ciphers are enabled by a given cipher list, use the `openssl ciphers` command on your system.

18.3. **asyncore** — Asynchronous socket handler

**Source code:** Lib/asyncore.py

This module provides the basic infrastructure for writing asynchronous socket service clients and servers.

There are only two ways to have a program on a single processor do “more than one thing at a time.” Multi-threaded programming is the simplest and most popular way to do it, but there is another very different technique, that lets you have nearly all the advantages of multi-threading, without actually using multiple threads. It’s really only practical if your program is largely I/O bound. If your program is processor bound, then pre-emptive scheduled threads are probably what you really need. Network servers are rarely processor bound, however.

If your operating system supports the `select()` system call in its I/O library (and nearly all do), then you can use it to juggle multiple communication channels at once; doing other work while your I/O is taking place in the “background.” Although this strategy can seem strange and complex, especially at first, it is in many ways easier to understand and control than multi-threaded programming. The **asyncore** module solves many of the difficult problems for you, making the task of building sophisticated high-performance network servers and clients a snap. For “conversational” applications and protocols the companion **asynchat** module is invaluable.

The basic idea behind both modules is to create one or more network
channels, instances of class `asyncore.dispatcher` and `asynchat.async_chat`. Creating the channels adds them to a global map, used by the `loop()` function if you do not provide it with your own `map`.

Once the initial channel(s) is(are) created, calling the `loop()` function activates channel service, which continues until the last channel (including any that have been added to the map during asynchronous service) is closed.

```
asyncore.loop([timeout[, use_poll[, map[, count]]]])
```

Enter a polling loop that terminates after count passes or all open channels have been closed. All arguments are optional. The `count` parameter defaults to None, resulting in the loop terminating only when all channels have been closed. The `timeout` argument sets the timeout parameter for the appropriate `select()` or `poll()` call, measured in seconds; the default is 30 seconds. The `use_poll` parameter, if true, indicates that `poll()` should be used in preference to `select()` (the default is False).

The `map` parameter is a dictionary whose items are the channels to watch. As channels are closed they are deleted from their map. If `map` is omitted, a global map is used. Channels (instances of `asyncore.dispatcher`, `asynchat.async_chat` and subclasses thereof) can freely be mixed in the map.

```
class asyncore.dispatcher
```

The `dispatcher` class is a thin wrapper around a low-level socket object. To make it more useful, it has a few methods for event-handling which are called from the asynchronous loop. Otherwise, it can be treated as a normal non-blocking socket object.
The firing of low-level events at certain times or in certain connection states tells the asynchronous loop that certain higher-level events have taken place. For example, if we have asked for a socket to connect to another host, we know that the connection has been made when the socket becomes writable for the first time (at this point you know that you may write to it with the expectation of success). The implied higher-level events are:

<table>
<thead>
<tr>
<th>Event</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>handle_connect()</td>
<td>Implied by the first read or write event</td>
</tr>
<tr>
<td>handle_close()</td>
<td>Implied by a read event with no data available</td>
</tr>
<tr>
<td>handle_accepted()</td>
<td>Implied by a read event on a listening socket</td>
</tr>
</tbody>
</table>

During asynchronous processing, each mapped channel's `readable()` and `writable()` methods are used to determine whether the channel's socket should be added to the list of channels `select()`ed or `poll()`ed for read and write events.

Thus, the set of channel events is larger than the basic socket events. The full set of methods that can be overridden in your subclass follows:

**handle_read()**

Called when the asynchronous loop detects that a `read()` call on the channel’s socket will succeed.

**handle_write()**

Called when the asynchronous loop detects that a writable socket can be written. Often this method will implement the necessary buffering for performance. For example:
def handle_write(self):
    sent = self.send(self.buffer)
    self.buffer = self.buffer[:sent:]

handle_expt()
Called when there is out of band (OOB) data for a socket connection. This will almost never happen, as OOB is tenuously supported and rarely used.

handle_connect()
Called when the active opener’s socket actually makes a connection. Might send a “welcome” banner, or initiate a protocol negotiation with the remote endpoint, for example.

handle_close()
Called when the socket is closed.

handle_error()
Called when an exception is raised and not otherwise handled. The default version prints a condensed traceback.

handle_accept()
Called on listening channels (passive openers) when a connection can be established with a new remote endpoint that has issued a connect() call for the local endpoint. Deprecated in version 3.2; use handle_accepted() instead.

handle_accepted(sock, addr)
Called on listening channels (passive openers) when a connection has been established with a new remote endpoint
that has issued a `connect()` call for the local endpoint. `sock` is a *new* socket object usable to send and receive data on the connection, and `addr` is the address bound to the socket on the other end of the connection.

*New in version 3.2.*

**readable()**

Called each time around the asynchronous loop to determine whether a channel’s socket should be added to the list on which read events can occur. The default method simply returns `True`, indicating that by default, all channels will be interested in read events.

**writable()**

Called each time around the asynchronous loop to determine whether a channel’s socket should be added to the list on which write events can occur. The default method simply returns `True`, indicating that by default, all channels will be interested in write events.

In addition, each channel delegates or extends many of the socket methods. Most of these are nearly identical to their socket partners.

**create_socket** *(family=socket.AF_INET, type=socket.SOCK_STREAM)*

This is identical to the creation of a normal socket, and will use the same options for creation. Refer to the `socket` documentation for information on creating sockets.

*Changed in version 3.3: family and type arguments can be omitted.*
**connect**(*address*)

As with the normal socket object, *address* is a tuple with the first element the host to connect to, and the second the port number.

**send**(*data*)

Send *data* to the remote end-point of the socket.

**recv**(*buffer_size*)

Read at most *buffer_size* bytes from the socket's remote end-point. An empty string implies that the channel has been closed from the other end.

**listen**(*backlog*)

Listen for connections made to the socket. The *backlog* argument specifies the maximum number of queued connections and should be at least 1; the maximum value is system-dependent (usually 5).

**bind**(*address*)

Bind the socket to *address*. The socket must not already be bound. (The format of *address* depends on the address family — refer to the socket documentation for more information.) To mark the socket as re-usable (setting the SO_REUSEADDR option), call the dispatcher object's set_reuse_addr() method.

**accept**()

Accept a connection. The socket must be bound to an address and listening for connections. The return value can be either None or a pair (conn, address) where conn is a new socket object usable to send and receive data on the
connection, and *address* is the address bound to the socket on the other end of the connection. When None is returned it means the connection didn’t take place, in which case the server should just ignore this event and keep listening for further incoming connections.

**close()**

Close the socket. All future operations on the socket object will fail. The remote end-point will receive no more data (after queued data is flushed). Sockets are automatically closed when they are garbage-collected.

*class asyncore.* **dispatcher_with_send**

A *dispatcher* subclass which adds simple buffered output capability, useful for simple clients. For more sophisticated usage use *asynchat.async_chat*.

*class asyncore.* **file_dispatcher**

A file_dispatcher takes a file descriptor or *file object* along with an optional map argument and wraps it for use with the *poll()* or *loop()* functions. If provided a file object or anything with a *fileno()* method, that method will be called and passed to the *file_wrapper* constructor. Availability: UNIX.

*class asyncore.* **file_wrapper**

A file_wrapper takes an integer file descriptor and calls *os.dup()* to duplicate the handle so that the original handle may be closed independently of the file_wrapper. This class implements sufficient methods to emulate a socket for use by the *file_dispatcher* class. Availability: UNIX.
Here is a very basic HTTP client that uses the `dispatcher` class to implement its socket handling:

```python
import asyncore

class HTTPClient(asyncore.dispatcher):
    def __init__(self, host, path):
        asyncore.dispatcher.__init__(self)
        self.create_socket()
        self.connect((host, 80))
        self.buffer = bytes('GET %s HTTP/1.0\r\nHost: %s' % (path, host), 'ascii')

    def handle_connect(self):
        pass

    def handle_close(self):
        self.close()

    def handle_read(self):
        print(self.recv(8192))

    def writable(self):
        return (len(self.buffer) > 0)

    def handle_write(self):
        sent = self.send(self.buffer)
        self.buffer = self.buffer[sent:]

client = HTTPClient('www.python.org', '/')
```

asyncore.loop()
18.3.2. asyncore Example basic echo server

Here is a basic echo server that uses the `dispatcher` class to accept connections and dispatches the incoming connections to a handler:

```python
import asyncore

class EchoHandler(asyncore.dispatcher_with_send):
    def handle_read(self):
        data = self.recv(8192)
        if data:
            self.send(data)

class EchoServer(asyncore.dispatcher):
    def __init__(self, host, port):
        asyncore.dispatcher.__init__(self)
        self.create_socket()
        self.set_reuse_addr()
        self.bind((host, port))
        self.listen(5)

    def handle_accepted(self, sock, addr):
        print('Incoming connection from %s' % repr(addr))
        handler = EchoHandler(sock)

server = EchoServer('localhost', 8080)
asyncore.loop()
```
18.4. **asynchat** — Asynchronous socket command/response handler

**Source code:** Lib/asynchat.py

This module builds on the **asyncore** infrastructure, simplifying asynchronous clients and servers and making it easier to handle protocols whose elements are terminated by arbitrary strings, or are of variable length. **asynchat** defines the abstract class **async_chat** that you subclass, providing implementations of the `collect_incoming_data()` and `found_terminator()` methods. It uses the same asynchronous loop as **asyncore**, and the two types of channel, **asyncore.dispatcher** and **asynchat.async_chat**, can freely be mixed in the channel map. Typically an **asyncore.dispatcher** server channel generates new **asynchat.async_chat** channel objects as it receives incoming connection requests.

**class** **asynchat.async_chat**

This class is an abstract subclass of **asyncore.dispatcher**. To make practical use of the code you must subclass **async_chat**, providing meaningful `collect_incoming_data()` and `found_terminator()` methods. The **asyncore.dispatcher** methods can be used, although not all make sense in a message/response context.

Like **asyncore.dispatcher**, **async_chat** defines a set of events that are generated by an analysis of socket conditions after a `select()` call. Once the polling loop has been started the
async_chat object’s methods are called by the event-processing framework with no action on the part of the programmer.

Two class attributes can be modified, to improve performance, or possibly even to conserve memory.

**ac_in_buffer_size**
The asynchronous input buffer size (default 4096).

**ac_out_buffer_size**
The asynchronous output buffer size (default 4096).

Unlike asyncore.dispatcher, async_chat allows you to define a first-in-first-out queue (fifo) of producers. A producer need have only one method, more(), which should return data to be transmitted on the channel. The producer indicates exhaustion (i.e. that it contains no more data) by having its more() method return the empty string. At this point the async_chat object removes the producer from the fifo and starts using the next producer, if any. When the producer fifo is empty the handle_write() method does nothing. You use the channel object's set_terminator() method to describe how to recognize the end of, or an important breakpoint in, an incoming transmission from the remote endpoint.

To build a functioning async_chat subclass your input methods collect_incoming_data() and found_terminator() must handle the data that the channel receives asynchronously. The methods are described below.

**async_chat.close_when_done()**
Pushes a None on to the producer fifo. When this producer is popped off the fifo it causes the channel to be closed.
async_chat.**collect_incoming_data**(data)

Called with *data* holding an arbitrary amount of received data. The default method, which must be overridden, raises a `NotImplementedError` exception.

async_chat.**discard_buffers**()

In emergencies this method will discard any data held in the input and/or output buffers and the producer fifo.

async_chat.**found_terminator**()

Called when the incoming data stream matches the termination condition set by `set_terminator()`. The default method, which must be overridden, raises a `NotImplementedError` exception. The buffered input data should be available via an instance attribute.

async_chat.**get_terminator**()

Returns the current terminator for the channel.

async_chat.**push**(data)

Pushes data on to the channel's fifo to ensure its transmission. This is all you need to do to have the channel write the data out to the network, although it is possible to use your own producers in more complex schemes to implement encryption and chunking, for example.

async_chat.**push_with_producer**(producer)

Takes a producer object and adds it to the producer fifo associated with the channel. When all currently-pushed producers have been exhausted the channel will consume this producer’s data by calling its `more()` method and send the data to the remote endpoint.
async_chat.set_terminator(term)

Sets the terminating condition to be recognized on the channel. `term` may be any of three types of value, corresponding to three different ways to handle incoming protocol data.

<table>
<thead>
<tr>
<th>term</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>string</td>
<td>Will call <code>found_terminator()</code> when the string is found in the input stream</td>
</tr>
<tr>
<td>integer</td>
<td>Will call <code>found_terminator()</code> when the indicated number of characters have been received</td>
</tr>
<tr>
<td>None</td>
<td>The channel continues to collect data forever</td>
</tr>
</tbody>
</table>

Note that any data following the terminator will be available for reading by the channel after `found_terminator()` is called.
18.4.1. asynchat - Auxiliary Classes

class asynchat.fifo(list=None)

A fifo holding data which has been pushed by the application but not yet popped for writing to the channel. A fifo is a list used to hold data and/or producers until they are required. If the list argument is provided then it should contain producers or data items to be written to the channel.

is_empty()

Returns True if and only if the fifo is empty.

first()

Returns the least-recently push()ed item from the fifo.

push(data)

Adds the given data (which may be a string or a producer object) to the producer fifo.

pop()

If the fifo is not empty, returns True, first(), deleting the popped item. Returns False, None for an empty fifo.
18.4.2. asynchat Example

The following partial example shows how HTTP requests can be read with `async_chat`. A web server might create an `http_request_handler` object for each incoming client connection. Notice that initially the channel terminator is set to match the blank line at the end of the HTTP headers, and a flag indicates that the headers are being read.

Once the headers have been read, if the request is of type POST (indicating that further data are present in the input stream) then the `Content-Length:` header is used to set a numeric terminator to read the right amount of data from the channel.

The `handle_request()` method is called once all relevant input has been marshalled, after setting the channel terminator to None to ensure that any extraneous data sent by the web client are ignored.

```python
import asynchat
class http_request_handler(asynchat.async_chat):
    def __init__(self, sock, addr, sessions, log):
        asynchat.async_chat.__init__(self, sock=sock
        self.addr = addr
        self.sessions = sessions
        self.ibuffer = []
        self.obuffer = b""
        self.set_terminator(b"\r\n\r\n")
        self.reading_headers = True
        self.handling = False
        self.cgi_data = None
        self.log = log
```
def collect_incoming_data(self, data):
    """Buffer the data""
    self.ibuffer.append(data)

def found_terminator(self):
    if self.reading_headers:
        self.reading_headers = False
        self.parse_headers("".join(self.ibuffer)
        self.ibuffer = []
    if self.op.upper() == b"POST":
        clen = self.headers.getheader("content-length")
        self.set_terminator(int(clen))
    else:
        self.handling = True
        self.set_terminator(None)
        self.handle_request()
    elif not self.handling:
        self.set_terminator(None)  # browsers sometimes over-send
        self.cgi_data = parse(self.headers, b"
        self.handling = True
        self.ibuffer = []
        self.handle_request()
18.5. **signal** — Set handlers for asynchronous events

This module provides mechanisms to use signal handlers in Python.
18.5.1. General rules

The `signal.signal()` function allows to define custom handlers to be executed when a signal is received. A small number of default handlers are installed: SIGPIPE is ignored (so write errors on pipes and sockets can be reported as ordinary Python exceptions) and SIGINT is translated into a `KeyboardInterrupt` exception.

A handler for a particular signal, once set, remains installed until it is explicitly reset (Python emulates the BSD style interface regardless of the underlying implementation), with the exception of the handler for SIGCHLD, which follows the underlying implementation.

There is no way to “block” signals temporarily from critical sections (since this is not supported by all Unix flavors).

18.5.1.1. Execution of Python signal handlers

A Python signal handler does not get executed inside the low-level (C) signal handler. Instead, the low-level signal handler sets a flag which tells the *virtual machine* to execute the corresponding Python signal handler at a later point (for example at the next *bytecode* instruction). This has consequences:

- It makes little sense to catch synchronous errors like SIGFPE or SIGSEGV that are caused by an invalid operation in C code. Python will return from the signal handler to the C code, which is likely to raise the same signal again, causing Python to apparently hang. From Python 3.3 onwards, you can use the `faulthandler` module to report on synchronous errors.
- A long-running calculation implemented purely in C (such as regular expression matching on a large body of text) may run
uninterrupted for an arbitrary amount of time, regardless of any signals received. The Python signal handlers will be called when the calculation finishes.

18.5.1.2. Signals and threads

Python signal handlers are always executed in the main Python thread, even if the signal was received in another thread. This means that signals can’t be used as a means of inter-thread communication. You can use the synchronization primitives from the threading module instead.

Besides, only the main thread is allowed to set a new signal handler.
18.5.2. Module contents

The variables defined in the `signal` module are:

**signal.SIG_DFL**

This is one of two standard signal handling options; it will simply perform the default function for the signal. For example, on most systems the default action for SIGQUIT is to dump core and exit, while the default action for SIGCHLD is to simply ignore it.

**signal.SIG_IGN**

This is another standard signal handler, which will simply ignore the given signal.

**SIG***

All the signal numbers are defined symbolically. For example, the hangup signal is defined as `signal.SIGHUP`; the variable names are identical to the names used in C programs, as found in `<signal.h>`. The Unix man page for ‘signal()’ lists the existing signals (on some systems this is `signal(2)`, on others the list is in `signal(7)`). Note that not all systems define the same set of signal names; only those names defined by the system are defined by this module.

**signal.CTRL_C_EVENT**

The signal corresponding to the CTRL+C keystroke event. This signal can only be used with `os.kill()`.

Availability: Windows.

*New in version 3.2.*
**signal.** **CTRL_BREAK_EVENT**

The signal corresponding to the CTRL+BREAK keystroke event. This signal can only be used with `os.kill()`.

Availability: Windows.

*New in version 3.2.*

**signal.** **NSIG**

One more than the number of the highest signal number.

**signal.** **ITIMER_REAL**

Decrements interval timer in real time, and delivers SIGALRM upon expiration.

**signal.** **ITIMER_VIRTUAL**

Decrements interval timer only when the process is executing, and delivers SIGVTALRM upon expiration.

**signal.** **ITIMER_PROF**

Decrements interval timer both when the process executes and when the system is executing on behalf of the process. Coupled with ITIMER_VIRTUAL, this timer is usually used to profile the time spent by the application in user and kernel space. SIGPROF is delivered upon expiration.

**signal.** **SIG_BLOCK**

A possible value for the *how* parameter to `pthread_sigmask()` indicating that signals are to be blocked.

*New in version 3.3.*

**signal.** **SIG_UNBLOCK**
A possible value for the how parameter to `pthread_sigmask()` indicating that signals are to be unblocked.

*New in version 3.3.*

**signal.SIG_SETMASK**

A possible value for the how parameter to `pthread_sigmask()` indicating that the signal mask is to be replaced.

*New in version 3.3.*

The `signal` module defines one exception:

**exception signal. ItimerError**

Raised to signal an error from the underlying `setitimer()` or `getitimer()` implementation. Expect this error if an invalid interval timer or a negative time is passed to `setitimer()`. This error is a subtype of `OSError`.

*New in version 3.3:* This error used to be a subtype of `IOError`, which is now an alias of `OSError`.

The `signal` module defines the following functions:

**signal.alarm(time)**

If `time` is non-zero, this function requests that a SIGALRM signal be sent to the process in `time` seconds. Any previously scheduled alarm is canceled (only one alarm can be scheduled at any time). The returned value is then the number of seconds before any previously set alarm was to have been delivered. If `time` is zero, no alarm is scheduled, and any scheduled alarm is canceled. If the return value is zero, no alarm is currently scheduled. (See the Unix man page `alarm(2).`) Availability: Unix.
signal.getsignal(signalnum)

Return the current signal handler for the signal `signalnum`. The returned value may be a callable Python object, or one of the special values `signal.SIG_IGN`, `signal.SIG_DFL` or `None`. Here, `signal.SIG_IGN` means that the signal was previously ignored, `signal.SIG_DFL` means that the default way of handling the signal was previously in use, and `None` means that the previous signal handler was not installed from Python.

signal.pause()

Cause the process to sleep until a signal is received; the appropriate handler will then be called. Returns nothing. Not on Windows. (See the Unix man page `signal(2)`.)

See also `sigwait()`, `sigwaitinfo()`, `sigtimedwait()` and `sigpending()`.

signal.pthread_kill(thread_id, signum)

Send the signal `signum` to the thread `thread_id`, another thread in the same process as the caller. The target thread can be executing any code (Python or not). However, if the target thread is executing the Python interpreter, the Python signal handlers will be `executed by the main thread`. Therefore, the only point of sending a signal to a particular Python thread would be to force a running system call to fail with `InterruptedError`.

Use `threading.get_ident()` or the `ident` attribute of `threading.Thread` objects to get a suitable value for `thread_id`.

If `signum` is 0, then no signal is sent, but error checking is still performed; this can be used to check if the target thread is still running.
Availability: Unix (see the man page `pthread_kill(3)` for further information).

See also `os.kill()`.

*New in version 3.3.*

**signal.**`pthread_sigmask`(how, mask)

Fetch and/or change the signal mask of the calling thread. The signal mask is the set of signals whose delivery is currently blocked for the caller. Return the old signal mask as a set of signals.

The behavior of the call is dependent on the value of how, as follows.

- **SIG_BLOCK**: The set of blocked signals is the union of the current set and the `mask` argument.
- **SIG_UNBLOCK**: The signals in `mask` are removed from the current set of blocked signals. It is permissible to attempt to unblock a signal which is not blocked.
- **SIG_SETMASK**: The set of blocked signals is set to the `mask` argument.

`mask` is a set of signal numbers (e.g. `{signal.SIGINT, signal.SIGTERM}`). Use `range(1, signal.NSIG)` for a full mask including all signals.

For example, `signal.pthread_sigmask(signal.SIG_BLOCK, [])` reads the signal mask of the calling thread.

Availability: Unix. See the man page `sigprocmask(3)` and `pthread_sigmask(3)` for further information.
See also `pause()`, `sigpending()` and `sigwait()`.

*New in version 3.3.*

**signal.setitimer**(which, seconds[, interval])

Sets given interval timer (one of `signal.ITIMER_REAL`, `signal.ITIMER_VIRTUAL` or `signal.ITIMER_PROF`) specified by `which` to fire after `seconds` (float is accepted, different from `alarm()`)) and after that every `interval` seconds. The interval timer specified by `which` can be cleared by setting `seconds` to zero.

When an interval timer fires, a signal is sent to the process. The signal sent is dependent on the timer being used; `signal.ITIMER_REAL` will deliver `SIGALRM`, `signal.ITIMER_VIRTUAL` sends `SIGVTALRM`, and `signal.ITIMER_PROF` will deliver `SIGPROF`.

The old values are returned as a tuple: (delay, interval).

Attempting to pass an invalid interval timer will cause an `ItimerError`. Availability: Unix.

**signal.getitimer**(which)

Returns current value of a given interval timer specified by `which`. Availability: Unix.

**signal.set_wakeup_fd**(fd)

Set the wakeup file descriptor to `fd`. When a signal is received, the signal number is written as a single byte into the fd. This can be used by a library to wakeup a poll or select call, allowing the signal to be fully processed.

The old wakeup fd is returned. `fd` must be non-blocking. It is up to
the library to remove any bytes before calling poll or select again.

Use for example `struct.unpack('%uB' % len(data), data)` to decode the signal numbers list.

When threads are enabled, this function can only be called from the main thread; attempting to call it from other threads will cause a `ValueError` exception to be raised.

**signal.** `siginterrupt(signalnum, flag)`

Change system call restart behaviour: if `flag` is `False`, system calls will be restarted when interrupted by signal `signalnum`, otherwise system calls will be interrupted. Returns nothing. Availability: Unix (see the man page `siginterrupt(3)` for further information).

Note that installing a signal handler with `signal()` will reset the restart behaviour to interruptible by implicitly calling `siginterrupt()` with a true `flag` value for the given signal.

**signal.** `signal(signalnum, handler)`

Set the handler for signal `signalnum` to the function `handler`. `handler` can be a callable Python object taking two arguments (see below), or one of the special values `signal.SIG_IGN` or `signal.SIG_DFL`. The previous signal handler will be returned (see the description of `getsignal()` above). (See the Unix man page `signal(2)`.)

When threads are enabled, this function can only be called from the main thread; attempting to call it from other threads will cause a `ValueError` exception to be raised.

The `handler` is called with two arguments: the signal number and
the current stack frame (None or a frame object; for a description of frame objects, see the `description in the type hierarchy` or see the attribute descriptions in the `inspect` module).

On Windows, `signal()` can only be called with SIGABRT, SIGFPE, SIGILL, SIGINT, SIGSEGV, or SIGTERM. A `ValueError` will be raised in any other case.

**signal. sigpending()**

Examine the set of signals that are pending for delivery to the calling thread (i.e., the signals which have been raised while blocked). Return the set of the pending signals.

Availability: Unix (see the man page `sigpending(2)` for further information).

See also `pause()`, `pthread_sigmask()` and `sigwait()`.

*New in version 3.3.*

**signal. sigwait(sigset)**

Suspend execution of the calling thread until the delivery of one of the signals specified in the signal set `sigset`. The function accepts the signal (removes it from the pending list of signals), and returns the signal number.

Availability: Unix (see the man page `sigwait(3)` for further information).

See also `pause()`, `pthread_sigmask()`, `sigpending()`, `sigwaitinfo()` and `sigtimedwait()`.

*New in version 3.3.*
signal. **sigwaitinfo**(sigset)

Suspend execution of the calling thread until the delivery of one of the signals specified in the signal set `sigset`. The function accepts the signal and removes it from the pending list of signals. If one of the signals in `sigset` is already pending for the calling thread, the function will return immediately with information about that signal. The signal handler is not called for the delivered signal. The function raises an **InterruptedError** if it is interrupted by a signal that is not in `sigset`.

The return value is an object representing the data contained in the `siginfo_t` structure, namely: `si_signo`, `si_code`, `si_errno`, `si_pid`, `si_uid`, `si_status`, `si_band`.

Availability: Unix (see the man page `sigwaitinfo(2)` for further information).

See also **pause()**, **sigwait()** and **sigtimedwait()**.

*New in version 3.3.*

signal. **sigtimedwait**(sigset, timeout)

Like `sigwaitinfo()`, but takes an additional `timeout` argument specifying a timeout. If `timeout` is specified as 0, a poll is performed. Returns **None** if a timeout occurs.

Availability: Unix (see the man page `sigtimedwait(2)` for further information).

See also **pause()**, **sigwait()** and **sigwaitinfo()**.

*New in version 3.3.*
18.5.3. Example

Here is a minimal example program. It uses the `alarm()` function to limit the time spent waiting to open a file; this is useful if the file is for a serial device that may not be turned on, which would normally cause the `os.open()` to hang indefinitely. The solution is to set a 5-second alarm before opening the file; if the operation takes too long, the alarm signal will be sent, and the handler raises an exception.

```python
import signal, os

def handler(signum, frame):
    print('Signal handler called with signal', signum)
    raise OSError("Couldn't open device!")

# Set the signal handler and a 5-second alarm
signal.signal(signal.SIGALRM, handler)
signal.alarm(5)

# This open() may hang indefinitely
fd = os.open('/dev/ttyS0', os.O_RDWR)

signal.alarm(0) # Disable the alarm
```
18.6. `mmap` — Memory-mapped file support

Memory-mapped file objects behave like both `bytearray` and like `file objects`. You can use `mmap` objects in most places where `bytearray` are expected; for example, you can use the `re` module to search through a memory-mapped file. You can also change a single byte by doing `obj[index] = 97`, or change a subsequence by assigning to a slice: `obj[i1:i2] = b'...'`. You can also read and write data starting at the current file position, and `seek()` through the file to different positions.

A memory-mapped file is created by the `mmap` constructor, which is different on Unix and on Windows. In either case you must provide a file descriptor for a file opened for update. If you wish to map an existing Python file object, use its `fileno()` method to obtain the correct value for the `fileno` parameter. Otherwise, you can open the file using the `os.open()` function, which returns a file descriptor directly (the file still needs to be closed when done).

**Note:** If you want to create a memory-mapping for a writable, buffered file, you should `flush()` the file first. This is necessary to ensure that local modifications to the buffers are actually available to the mapping.

For both the Unix and Windows versions of the constructor, `access` may be specified as an optional keyword parameter. `access` accepts one of three values: `ACCESS_READ`, `ACCESS_WRITE`, or `ACCESS_COPY` to specify read-only, write-through or copy-on-write
memory respectively. access can be used on both Unix and Windows. If access is not specified, Windows mmap returns a write-through mapping. The initial memory values for all three access types are taken from the specified file. Assignment to an ACCESS_READ memory map raises a TypeError exception. Assignment to an ACCESS_WRITE memory map affects both memory and the underlying file. Assignment to an ACCESS_COPY memory map affects memory but does not update the underlying file.

To map anonymous memory, -1 should be passed as the fileno along with the length.

class mmap.mmap(fileno, length, tagname=None,
access=ACCESS_DEFAULT[, offset])

(Windows version) Maps length bytes from the file specified by the file handle fileno, and creates a mmap object. If length is larger than the current size of the file, the file is extended to contain length bytes. If length is 0, the maximum length of the map is the current size of the file, except that if the file is empty Windows raises an exception (you cannot create an empty mapping on Windows).

tagname, if specified and not None, is a string giving a tag name for the mapping. Windows allows you to have many different mappings against the same file. If you specify the name of an existing tag, that tag is opened, otherwise a new tag of this name is created. If this parameter is omitted or None, the mapping is created without a name. Avoiding the use of the tag parameter will assist in keeping your code portable between Unix and Windows.

offset may be specified as a non-negative integer offset. mmap references will be relative to the offset from the beginning of the
file. offset defaults to 0. offset must be a multiple of the ALLOCATIONGRANULARITY.

class mmap { mmap(fileno, length, flags=MAP_SHARED,
prot=PROT_WRITE|PROT_READ, access=ACCESS_DEFAULT[, offset])
}

(Unix version) Maps length bytes from the file specified by the file descriptor fileno, and returns a mmap object. If length is 0, the maximum length of the map will be the current size of the file when mmap is called.

flags specifies the nature of the mapping. MAP_PRIVATE creates a private copy-on-write mapping, so changes to the contents of the mmap object will be private to this process, and MAP_SHARED creates a mapping that’s shared with all other processes mapping the same areas of the file. The default value is MAP_SHARED.

prot, if specified, gives the desired memory protection; the two most useful values are PROT_READ and PROT_WRITE, to specify that the pages may be read or written. prot defaults to PROT_READ | PROT_WRITE.

access may be specified in lieu of flags and prot as an optional keyword parameter. It is an error to specify both flags, prot and access. See the description of access above for information on how to use this parameter.

offset may be specified as a non-negative integer offset. mmap references will be relative to the offset from the beginning of the file. offset defaults to 0. offset must be a multiple of the PAGESIZE or ALLOCATIONGRANULARITY.
To ensure validity of the created memory mapping the file specified by the descriptor \textit{fileno} is internally automatically synchronized with physical backing store on Mac OS X and OpenVMS.

This example shows a simple way of using \texttt{mmap}:

```python
import mmap

# write a simple example file
with open("hello.txt", "wb") as f:
    f.write(b"Hello Python!
"
)

with open("hello.txt", "r+b") as f:
    # memory-map the file, size 0 means whole file
    mm = mmap.mmap(f.fileno(), 0)
    # read content via standard file methods
    print(mm.readline())  # prints b"Hello Python"
    # read content via slice notation
    print(mm[:5])  # prints b"Hello"
    # update content using slice notation;
    # note that new content must have same size
    mm[6:] = b" world!\n"
    # ... and read again using standard file methods
    mm.seek(0)
    print(mm.readline())  # prints b"Hello world"
# close the map
mm.close()
```

\texttt{mmap} can also be used as a context manager in a \texttt{with} statement:

```python
import mmap

with mmap.mmap(-1, 13) as mm:
    mm.write("Hello world!")
```
New in version 3.2: Context manager support.

The next example demonstrates how to create an anonymous map and exchange data between the parent and child processes:

```python
import mmap
import os

mm = mmap.mmap(-1, 13)
mm.write(b"Hello world!")

pid = os.fork()

if pid == 0:  # In a child process
    mm.seek(0)
    print(mm.readline())
    mm.close()
```

Memory-mapped file objects support the following methods:

- `mmap.close()`
  Closes the mmap. Subsequent calls to other methods of the object will result in a ValueError exception being raised. This will not close the open file.

- `mmap.closed`  
  True if the file is closed.

  New in version 3.2.

- `mmap.find(sub[, start[, end]])`
  Returns the lowest index in the object where the subsequence `sub` is found, such that `sub` is contained in the range `[start, end]`. Optional arguments `start` and `end` are interpreted as in
slice notation. Returns -1 on failure.

\texttt{mmap. flush([[offset[, size]])}

Flushes changes made to the in-memory copy of a file back to disk. Without use of this call there is no guarantee that changes are written back before the object is destroyed. If \texttt{offset} and \texttt{size} are specified, only changes to the given range of bytes will be flushed to disk; otherwise, the whole extent of the mapping is flushed.

\textbf{(Windows version)} A nonzero value returned indicates success; zero indicates failure.

\textbf{(Unix version)} A zero value is returned to indicate success. An exception is raised when the call failed.

\texttt{mmap. move(dest, src, count)}

Copy the \texttt{count} bytes starting at offset \texttt{src} to the destination index \texttt{dest}. If the \texttt{mmap} was created with ACCESS_READ, then calls to move will raise a \texttt{TypeError} exception.

\texttt{mmap. read([n])}

Return a \texttt{bytes} containing up to \texttt{n} bytes starting from the current file position. If the argument is omitted, \texttt{None} or negative, return all bytes from the current file position to the end of the mapping. The file position is updated to point after the bytes that were returned.

\textit{Changed in version 3.3:} Argument can be omitted or \texttt{None}.

\texttt{mmap. read_byte()}

Returns a byte at the current file position as an integer, and
advances the file position by 1.

mmap.readline()
Returns a single line, starting at the current file position and up to the next newline.

mmap.resize(newsize)
Resizes the map and the underlying file, if any. If the mmap was created with ACCESS_READ or ACCESS_COPY, resizing the map will raise a TypeError exception.

mmap.rfind(sub[, start[, end]])
Returns the highest index in the object where the subsequence sub is found, such that sub is contained in the range [start, end]. Optional arguments start and end are interpreted as in slice notation. Returns -1 on failure.

mmap.seek(pos[, whence])
Set the file's current position. whence argument is optional and defaults to os.SEEK_SET or 0 (absolute file positioning); other values are os.SEEK_CUR or 1 (seek relative to the current position) and os.SEEK_END or 2 (seek relative to the file's end).

mmap.size()
Return the length of the file, which can be larger than the size of the memory-mapped area.

mmap.tell()
Returns the current position of the file pointer.

mmap.write(bytes)
Write the bytes in \textit{bytes} into memory at the current position of the file pointer; the file position is updated to point after the bytes that were written. If the mmap was created with ACCESS_READ, then writing to it will raise a \texttt{TypeError} exception.

\texttt{mmap.write_byte}(\textit{byte})

Write the integer \textit{byte} into memory at the current position of the file pointer; the file position is advanced by \texttt{1}. If the mmap was created with ACCESS_READ, then writing to it will raise a \texttt{TypeError} exception.
19. Internet Data Handling

This chapter describes modules which support handling data formats commonly used on the Internet.

- **19.1. email** — An email and MIME handling package
  - 19.1.1. email.message: Representing an email message
  - 19.1.2. email.parser: Parsing email messages
    - 19.1.2.1. FeedParser API
    - 19.1.2.2. Parser class API
    - 19.1.2.3. Additional notes
  - 19.1.3. email.generator: Generating MIME documents
  - 19.1.4. email.policy: Policy Objects
  - 19.1.5. email.headerregistry: Custom Header Objects
  - 19.1.6. email.mime: Creating email and MIME objects from scratch
  - 19.1.7. email.header: Internationalized headers
  - 19.1.8. email.charset: Representing character sets
  - 19.1.9. email.encoders: Encoders
  - 19.1.10. email.errors: Exception and Defect classes
  - 19.1.11. email.utils: Miscellaneous utilities
  - 19.1.12. email.iterators: Iterators
  - 19.1.13. email: Examples
  - 19.1.15. Differences from mimelib

- **19.2. json** — JSON encoder and decoder
  - 19.2.1. Basic Usage
  - 19.2.2. Encoders and Decoders
  - 19.2.3. Standard Compliance
    - 19.2.3.1. Character Encodings
    - 19.2.3.2. Top-level Non-Object, Non-Array Values
19.2.3.3. Infinite and NaN Number Values
19.2.3.4. Repeated Names Within an Object

- 19.3. mailcap — Mailcap file handling
- 19.4. mailbox — Manipulate mailboxes in various formats
  - 19.4.1. Mailbox objects
    - 19.4.1.1. Maildir
    - 19.4.1.2. mbox
    - 19.4.1.3. MH
    - 19.4.1.4. Babyl
    - 19.4.1.5. MMDF
  - 19.4.2. Message objects
    - 19.4.2.1. MaildirMessage
    - 19.4.2.2. mboxMessage
    - 19.4.2.3. MHMessage
    - 19.4.2.4. BabylMessage
    - 19.4.2.5. MMDFMessage
  - 19.4.3. Exceptions
  - 19.4.4. Examples
- 19.5. mimetypes — Map filenames to MIME types
  - 19.5.1. MimeType Objects
- 19.6. base64 — RFC 3548: Base16, Base32, Base64 Data Encodings
- 19.7. binhex — Encode and decode binhex4 files
  - 19.7.1. Notes
- 19.8. binascii — Convert between binary and ASCII
- 19.9. quopri — Encode and decode MIME quoted-printable data
- 19.10. uu — Encode and decode uuencode files
19.1. email — An email and MIME handling package

The email package is a library for managing email messages, including MIME and other RFC 2822-based message documents. It is specifically not designed to do any sending of email messages to SMTP (RFC 2821), NNTP, or other servers; those are functions of modules such as smtplib and nntplib. The email package attempts to be as RFC-compliant as possible, supporting in addition to RFC 2822, such MIME-related RFCs as RFC 2045, RFC 2046, RFC 2047, and RFC 2231.

The primary distinguishing feature of the email package is that it splits the parsing and generating of email messages from the internal object model representation of email. Applications using the email package deal primarily with objects; you can add sub-objects to messages, remove sub-objects from messages, completely re-arrange the contents, etc. There is a separate parser and a separate generator which handles the transformation from flat text to the object model, and then back to flat text again. There are also handy subclasses for some common MIME object types, and a few miscellaneous utilities that help with such common tasks as extracting and parsing message field values, creating RFC-compliant dates, etc.

The following sections describe the functionality of the email package. The ordering follows a progression that should be common in applications: an email message is read as flat text from a file or other source, the text is parsed to produce the object structure of the email message, this structure is manipulated, and finally, the object tree is rendered back into flat text.
It is perfectly feasible to create the object structure out of whole cloth — i.e. completely from scratch. From there, a similar progression can be taken as above.

Also included are detailed specifications of all the classes and modules that the email package provides, the exception classes you might encounter while using the email package, some auxiliary utilities, and a few examples. For users of the older mimelib package, or previous versions of the email package, a section on differences and porting is provided.

Contents of the email package documentation:

- 19.1.1. email.message: Representing an email message
- 19.1.2. email.parser: Parsing email messages
  - 19.1.2.1. FeedParser API
  - 19.1.2.2. Parser class API
  - 19.1.2.3. Additional notes
- 19.1.3. email.generator: Generating MIME documents
- 19.1.4. email.policy: Policy Objects
- 19.1.5. email.headerregistry: Custom Header Objects
- 19.1.6. email.mime: Creating email and MIME objects from scratch
- 19.1.7. email.header: Internationalized headers
- 19.1.8. email.charset: Representing character sets
- 19.1.9. email.encoders: Encoders
- 19.1.10. email.errors: Exception and Defect classes
- 19.1.11. email.utils: Miscellaneous utilities
- 19.1.12. email.iterators: Iterators
- 19.1.13. email: Examples

19.1.14. Package History

This table describes the release history of the email package, corresponding to the version of Python that the package was released with. For purposes of this document, when you see a note about change or added versions, these refer to the Python version the change was made in, not the email package version. This table also describes the Python compatibility of each version of the package.

</table>

Here are the major differences between email version 5.1 and version 5.0:

- It is once again possible to parse messages containing non-ASCII bytes, and to reproduce such messages if the data containing the non-ASCII bytes is not modified.
- New functions `message_from_bytes()` and `message_from_binary_file()`, and new classes `BytesFeedParser` and `BytesParser` allow binary message data to be parsed into model objects.
- Given bytes input to the model, `get_payload()` will by default
decode a message body that has a `Content-Transfer-Encoding` of 8bit using the charset specified in the MIME headers and return the resulting string.

- Given bytes input to the model, `Generator` will convert message bodies that have a `Content-Transfer-Encoding` of 8bit to instead have a 7bit Content-Transfer-Encoding.
- New class `BytesGenerator` produces bytes as output, preserving any unchanged non-ASCII data that was present in the input used to build the model, including message bodies with a `Content-Transfer-Encoding` of 8bit.

Here are the major differences between `email` version 5.0 and version 4:

- All operations are on unicode strings. Text inputs must be strings, text outputs are strings. Outputs are limited to the ASCII character set and so can be encoded to ASCII for transmission. Inputs are also limited to ASCII; this is an acknowledged limitation of email 5.0 and means it can only be used to parse email that is 7bit clean.

Here are the major differences between `email` version 4 and version 3:

- All modules have been renamed according to PEP 8 standards. For example, the version 3 module `email.Message` was renamed to `email.message` in version 4.

- A new subpackage `email.mime` was added and all the version 3 `email.MIME*` modules were renamed and situated into the `email.mime` subpackage. For example, the version 3 module `email.MIMEText` was renamed to `email.mime.text`.

  Note that the version 3 names will continue to work until Python
2.6.

- The `email.mime.application` module was added, which contains the `MIMEApplication` class.

- Methods that were deprecated in version 3 have been removed. These include `Generator.__call__()`, `Message.get_type()`, `Message.get_main_type()`, `Message.get_subtype()`.

- Fixes have been added for RFC 2231 support which can change some of the return types for `Message.get_param` and friends. Under some circumstances, values which used to return a 3-tuple now return simple strings (specifically, if all extended parameter segments were unencoded, there is no language and charset designation expected, so the return type is now a simple string). Also, %-decoding used to be done for both encoded and unencoded segments; this decoding is now done only for encoded segments.

Here are the major differences between `email` version 3 and version 2:

- The `FeedParser` class was introduced, and the `Parser` class was implemented in terms of the `FeedParser`. All parsing therefore is non-strict, and parsing will make a best effort never to raise an exception. Problems found while parsing messages are stored in the message’s `defect` attribute.

- All aspects of the API which raised `DeprecationWarnings` in version 2 have been removed. These include the `_encoder` argument to the `MIMEText` constructor, the `Message.add_payload()` method, the `Utils.dump_address_pair()` function, and the functions
Utils.decode() and Utils.encode().

- New DeprecationWarnings have been added to: Generator.__call__(), Message.get_type(), Message.get_main_type(), Message.get_subtype(), and the strict argument to the Parser class. These are expected to be removed in future versions.
- Support for Pythons earlier than 2.3 has been removed.

Here are the differences between email version 2 and version 1:

- The email.Header and email.Charset modules have been added.
- The pickle format for Message instances has changed. Since this was never (and still isn't) formally defined, this isn't considered a backward incompatibility. However if your application pickles and unpickles Message instances, be aware that in email version 2, Message instances now have private variables _charset and _default_type.
- Several methods in the Message class have been deprecated, or their signatures changed. Also, many new methods have been added. See the documentation for the Message class for details. The changes should be completely backward compatible.
- The object structure has changed in the face of message/rfc822 content types. In email version 1, such a type would be represented by a scalar payload, i.e. the container message's is_multipart() returned false, get_payload() was not a list object, but a single Message instance.

This structure was inconsistent with the rest of the package, so the object representation for message/rfc822 content types was
changed. In email version 2, the container does return True from is_multipart(), and get_payload() returns a list containing a single Message item.

Note that this is one place that backward compatibility could not be completely maintained. However, if you’re already testing the return type of get_payload(), you should be fine. You just need to make sure your code doesn’t do a set_payload() with a Message instance on a container with a content type of message/rfc822.

- The Parser constructor’s strict argument was added, and its parse() and parsestr() methods grew a headersonly argument. The strict flag was also added to functions email.message_from_file() and email.message_from_string().

- Generator.__call__() is deprecated; use Generator.flatten instead. The Generator class has also grown the clone() method.

- The DecodedGenerator class in the email.generator module was added.

- The intermediate base classes MIMENonMultipart and MIMEMultipart have been added, and interposed in the class hierarchy for most of the other MIME-related derived classes.

- The _encoder argument to the MIMEText constructor has been deprecated. Encoding now happens implicitly based on the _charset argument.
• The following functions in the email.Utils module have been deprecated: dump_address_pairs(), decode(), and encode(). The following functions have been added to the module: make_msgid(), decode_rfc2231(), encode_rfc2231(), and decode_params().

• The non-public function email.Iterators._structure() was added.
19.1.15. Differences from mimelib

The email package was originally prototyped as a separate library called mimelib. Changes have been made so that method names are more consistent, and some methods or modules have either been added or removed. The semantics of some of the methods have also changed. For the most part, any functionality available in mimelib is still available in the email package, albeit often in a different way. Backward compatibility between the mimelib package and the email package was not a priority.

Here is a brief description of the differences between the mimelib and the email packages, along with hints on how to port your applications.

Of course, the most visible difference between the two packages is that the package name has been changed to email. In addition, the top-level package has the following differences:

- messageFromString() has been renamed to message_from_string().
- messageFromFile() has been renamed to message_from_file().

The Message class has the following differences:

- The method asString() was renamed to as_string().
- The method ismultipart() was renamed to is_multipart().
- The get_payload() method has grown a decode optional argument.
- The method getall() was renamed to get_all().
- The method `addheader()` was renamed to `add_header()`.
- The method `gettype()` was renamed to `get_type()`.
- The method `getmaintype()` was renamed to `get_main_type()`.
- The method `getsubtype()` was renamed to `get_subtype()`.
- The method `getparams()` was renamed to `get_params()`. Also, whereas `getparams()` returned a list of strings, `get_params()` returns a list of 2-tuples, effectively the key/value pairs of the parameters, split on the '=' sign.
- The method `getparam()` was renamed to `get_param()`.
- The method `getcharsets()` was renamed to `get_charsets()`.
- The method `getfilename()` was renamed to `get_filename()`.
- The method `getboundary()` was renamed to `get_boundary()`.
- The method `setboundary()` was renamed to `set_boundary()`.
- The method `getdecodedpayload()` was removed. To get similar functionality, pass the value 1 to the `decode` flag of the `get_payload()` method.
- The method `getpayloadastext()` was removed. Similar functionality is supported by the `DecodedGenerator` class in the `email.generator` module.
- The method `getbodyastext()` was removed. You can get similar functionality by creating an iterator with `typed_subpart_iterator()` in the `email.iterators` module.

The `Parser` class has no differences in its public interface. It does have some additional smarts to recognize `message/delivery-status` type messages, which it represents as a `Message` instance containing
separate Message subparts for each header block in the delivery status notification [1].

The Generator class has no differences in its public interface. There is a new class in the email.generator module though, called DecodedGenerator which provides most of the functionality previously available in the Message.getpayloadastext() method.

The following modules and classes have been changed:

- The MIMEBase class constructor arguments _major and _minor have changed to _maintype and _subtype respectively.
- The Image class/module has been renamed to MIMEImage. The _minor argument has been renamed to _subtype.
- The Text class/module has been renamed to MIMEText. The _minor argument has been renamed to _subtype.
- The MessageRFC822 class/module has been renamed to MIMEMessage. Note that an earlier version of mimelib called this class/module RFC822, but that clashed with the Python standard library module rfc822 on some case-insensitive file systems.

    Also, the MIMEMessage class now represents any kind of MIME message with main type message. It takes an optional argument _subtype which is used to set the MIME subtype. _subtype defaults to rfc822.

mimelib provided some utility functions in its address and date modules. All of these functions have been moved to the
email.utils module.

The MsgReader class/module has been removed. Its functionality is most closely supported in the body_line_iterator() function in the email.iterators module.

Footnotes

[1] Delivery Status Notifications (DSN) are defined in RFC 1894.
19.1.1. email.message: Representing an email message

The central class in the email package is the Message class, imported from the email.message module. It is the base class for the email object model. Message provides the core functionality for setting and querying header fields, and for accessing message bodies.

Conceptually, a Message object consists of headers and payloads. Headers are RFC 2822 style field names and values where the field name and value are separated by a colon. The colon is not part of either the field name or the field value.

Headers are stored and returned in case-preserving form but are matched case-insensitively. There may also be a single envelope header, also known as the Unix-From header or the From_ header. The payload is either a string in the case of simple message objects or a list of Message objects for MIME container documents (e.g. multipart/* and message/rfc822).

Message objects provide a mapping style interface for accessing the message headers, and an explicit interface for accessing both the headers and the payload. It provides convenience methods for generating a flat text representation of the message object tree, for accessing commonly used header parameters, and for recursively walking over the object tree.

Here are the methods of the Message class:

```python
class email.message.Message(policy=compat32)
```
The policy argument determines the policy that will be used to update the message model. The default value, compat32 maintains backward compatibility with the Python 3.2 version of the email package. For more information see the policy documentation.

*Changed in version 3.3:* The policy keyword argument was added.

**as_string**(unixfrom=False, maxheaderlen=0)

Return the entire message flattened as a string. When optional unixfrom is True, the envelope header is included in the returned string. unixfrom defaults to False. Flattening the message may trigger changes to the Message if defaults need to be filled in to complete the transformation to a string (for example, MIME boundaries may be generated or modified).

Note that this method is provided as a convenience and may not always format the message the way you want. For example, by default it does not do the mangling of lines that begin with From that is required by the unix mbox format. For more flexibility, instantiate a Generator instance and use its flatten() method directly. For example:

```python
from io import StringIO
from email.generator import Generator
fp = StringIO()
g = Generator(fp, mangle_from_=True, maxheaderlen=0)
g.flatten(msg)
text = fp.getvalue()
```

```
__str__()
```

Equivalent to as_string(unixfrom=True).
is_multipart()

Return True if the message’s payload is a list of sub-Message objects, otherwise return False. When is_multipart() returns False, the payload should be a string object.

set_unixfrom(unixfrom)

Set the message’s envelope header to unixfrom, which should be a string.

get_unixfrom()

Return the message’s envelope header. Defaults to None if the envelope header was never set.

attach(payload)

Add the given payload to the current payload, which must be None or a list of Message objects before the call. After the call, the payload will always be a list of Message objects. If you want to set the payload to a scalar object (e.g. a string), use set_payload() instead.

get_payload(i=None, decode=False)

Return the current payload, which will be a list of Message objects when is_multipart() is True, or a string when is_multipart() is False. If the payload is a list and you mutate the list object, you modify the message's payload in place.

With optional argument i, get_payload() will return the i-th element of the payload, counting from zero, if is_multipart() is True. An IndexError will be raised if i is less than 0 or greater than or equal to the number of items in the payload. If the payload is a string (i.e. is_multipart() is
False) and $i$ is given, a `TypeError` is raised.

Optional `decode` is a flag indicating whether the payload should be decoded or not, according to the `Content-Transfer-Encoding` header. When `True` and the message is not a multipart, the payload will be decoded if this header's value is `quoted-printable` or `base64`. If some other encoding is used, or `Content-Transfer-Encoding` header is missing, the payload is returned as-is (undecoded). In all cases the returned value is binary data. If the message is a multipart and the `decode` flag is `True`, then None is returned. If the payload is base64 and it was not perfectly formed (missing padding, characters outside the base64 alphabet), then an appropriate defect will be added to the message's defect property (`InvalidBase64PaddingDefect` or `InvalidBase64CharactersDefect`, respectively).

When `decode` is `False` (the default) the body is returned as a string without decoding the `Content-Transfer-Encoding`. However, for a `Content-Transfer-Encoding` of 8bit, an attempt is made to decode the original bytes using the charset specified by the `Content-Type` header, using the `replace` error handler. If no charset is specified, or if the charset given is not recognized by the email package, the body is decoded using the default ASCII charset.

**set_payload**(payload, charset=None)

Set the entire message object's payload to `payload`. It is the client's responsibility to ensure the payload invariants. Optional `charset` sets the message's default character set; see `set_charset()` for details.
**set_charset**(*charset*)

Set the character set of the payload to *charset*, which can either be a `Charset` instance (see `email.charset`), a string naming a character set, or `None`. If it is a string, it will be converted to a `Charset` instance. If *charset* is `None`, the charset parameter will be removed from the *Content-Type* header (the message will not be otherwise modified). Anything else will generate a `TypeError`.

If there is no existing *MIME-Version* header one will be added. If there is no existing *Content-Type* header, one will be added with a value of *text/plain*. Whether the *Content-Type* header already exists or not, its charset parameter will be set to *charset.output_charset*. If *charset.input_charset* and *charset.output_charset* differ, the payload will be re-encoded to the *output_charset*. If there is no existing *Content-Transfer-Encoding* header, then the payload will be transfer-encoded, if needed, using the specified `Charset`, and a header with the appropriate value will be added. If a *Content-Transfer-Encoding* header already exists, the payload is assumed to already be correctly encoded using that *Content-Transfer-Encoding* and is not modified.

**get_charset()**

Return the `Charset` instance associated with the message's payload.

The following methods implement a mapping-like interface for accessing the message's RFC 2822 headers. Note that there are some semantic differences between these methods and a normal mapping (i.e. dictionary) interface. For example, in a dictionary there are no duplicate keys, but here there may be duplicate
message headers. Also, in dictionaries there is no guaranteed order to the keys returned by \texttt{keys()}, but in a \texttt{Message} object, headers are always returned in the order they appeared in the original message, or were added to the message later. Any header deleted and then re-added are always appended to the end of the header list.

These semantic differences are intentional and are biased toward maximal convenience.

Note that in all cases, any envelope header present in the message is not included in the mapping interface.

In a model generated from bytes, any header values that (in contravention of the RFCs) contain non-ASCII bytes will, when retrieved through this interface, be represented as \texttt{Header} objects with a charset of \textit{unknown-8bit}.

\texttt{\_len\_}()

Return the total number of headers, including duplicates.

\texttt{\_contains\_}(\textit{name})

Return true if the message object has a field named \textit{name}. Matching is done case-insensitively and \textit{name} should not include the trailing colon. Used for the \texttt{in} operator, e.g.:

\begin{verbatim}
if 'message-id' in myMessage:
    print('Message-ID:', myMessage['message-id'])
\end{verbatim}

\texttt{\_getitem\_}(\textit{name})

Return the value of the named header field. \textit{name} should not include the colon field separator. If the header is missing, None
is returned; a :class:`KeyError` is never raised.

Note that if the named field appears more than once in the message’s headers, exactly which of those field values will be returned is undefined. Use the :meth:`get_all()` method to get the values of all the extant named headers.

.. _setitem:

__setitem__(\textit{name}, \textit{val})

Add a header to the message with field name \textit{name} and value \textit{val}. The field is appended to the end of the message’s existing fields.

Note that this does *not* overwrite or delete any existing header with the same name. If you want to ensure that the new header is the only one present in the message with field name \textit{name}, delete the field first, e.g.:

```python
del msg['subject']
msg['subject'] = 'Python roolz!'
```

.. _delitem:

__delitem__(\textit{name})

Delete all occurrences of the field with name \textit{name} from the message’s headers. No exception is raised if the named field isn’t present in the headers.

.. _keys:

keys()

Return a list of all the message’s header field names.

.. _values:

values()

Return a list of all the message’s field values.

.. _items:

items()

Return a list of 2-tuples containing all the message’s field
headers and values.

**get**(name, failobj=None)

Return the value of the named header field. This is identical to `__getitem__()`, except that optional `failobj` is returned if the named header is missing (defaults to None).

Here are some additional useful methods:

**get_all**(name, failobj=None)

Return a list of all the values for the field named `name`. If there are no such named headers in the message, `failobj` is returned (defaults to None).

**add_header**(name, value, **params)

Extended header setting. This method is similar to `__setitem__()`, except that additional header parameters can be provided as keyword arguments. `name` is the header field to add and `value` is the primary value for the header.

For each item in the keyword argument dictionary `params`, the key is taken as the parameter name, with underscores converted to dashes (since dashes are illegal in Python identifiers). Normally, the parameter will be added as `key="value"` unless the value is None, in which case only the key will be added. If the value contains non-ASCII characters, it can be specified as a three tuple in the format `(CHARSET, LANGUAGE, VALUE)`, where `CHARSET` is a string naming the charset to be used to encode the value, `LANGUAGE` can usually be set to None or the empty string (see RFC 2231 for other possibilities), and `VALUE` is the string value containing non-ASCII code points. If a three tuple is not passed and the
value contains non-ASCII characters, it is automatically encoded in RFC 2231 format using a CHARSET of utf-8 and a LANGUAGE of None.

Here's an example:

```python
def add_header(msg, name, value):
    msg.add_header(name, value)
```  

This will add a header that looks like

```
Content-Disposition: attachment; filename="bud.gif"
```  

An example with non-ASCII characters:

```python
def add_header(msg, name, value):
    msg.add_header(name, value)
```  

Which produces

```
Content-Disposition: attachment; filename*="Fußballer.ppt"
```  

**replace_header(name, value)**

Replace a header. Replace the first header found in the message that matches name, retaining header order and field name case. If no matching header was found, a KeyError is raised.

**get_content_type()**

Return the message's content type. The returned string is coerced to lower case of the form maintype/subtype. If there was no Content-Type header in the message the default type
as given by get_default_type() will be returned. Since according to RFC 2045, messages always have a default type, get_content_type() will always return a value.

RFC 2045 defines a message’s default type to be text/plain unless it appears inside a multipart/digest container, in which case it would be message/rfc822. If the Content-Type header has an invalid type specification, RFC 2045 mandates that the default type be text/plain.

get_content_maintype()

Return the message’s main content type. This is the maintype part of the string returned by get_content_type().

get_content_subtype()

Return the message’s sub-content type. This is the subtype part of the string returned by get_content_type().

get_default_type()

Return the default content type. Most messages have a default content type of text/plain, except for messages that are subparts of multipart/digest containers. Such subparts have a default content type of message/rfc822.

set_default_type(ctype)

Set the default content type. ctype should either be text/plain or message/rfc822, although this is not enforced. The default content type is not stored in the Content-Type header.

get_params(failobj=None, header='content-type', unquote=True)

Return the message’s Content-Type parameters, as a list. The
elements of the returned list are 2-tuples of key/value pairs, as split on the '==' sign. The left hand side of the '==' is the key, while the right hand side is the value. If there is no '==' sign in the parameter the value is the empty string, otherwise the value is as described in get_param() and is unquoted if optional unquote is True (the default).

Optional failobj is the object to return if there is no Content-Type header. Optional header is the header to search instead of Content-Type.

get_param(param, failobj=None, header='content-type', unquote=True)

Return the value of the Content-Type header's parameter param as a string. If the message has no Content-Type header or if there is no such parameter, then failobj is returned (defaults to None).

Optional header if given, specifies the message header to use instead of Content-Type.

Parameter keys are always compared case insensitively. The return value can either be a string, or a 3-tuple if the parameter was RFC 2231 encoded. When it's a 3-tuple, the elements of the value are of the form (CHARSET, LANGUAGE, VALUE). Note that both CHARSET and LANGUAGE can be None, in which case you should consider VALUE to be encoded in the us-ascii charset. You can usually ignore LANGUAGE.

If your application doesn’t care whether the parameter was encoded as in RFC 2231, you can collapse the parameter value by calling email.utils-collapse_rfc2231_value(),
passing in the return value from \texttt{get\_param()}. This will return a suitably decoded Unicode string when the value is a tuple, or the original string unquoted if it isn't. For example:

```python
rawparam = msg.get_param('foo')
param = email.utils.collapse_rfc2231_value(rawparam)
```

In any case, the parameter value (either the returned string, or the \texttt{VALUE} item in the 3-tuple) is always unquoted, unless \texttt{unquote} is set to \texttt{False}.

\textbf{set\_param}(\texttt{param}, \texttt{value}, \texttt{header='Content-Type'}, \texttt{requote=True}, \texttt{charset=None}, \texttt{language=''}

Set a parameter in the \texttt{Content-Type} header. If the parameter already exists in the header, its value will be replaced with \texttt{value}. If the \texttt{Content-Type} header as not yet been defined for this message, it will be set to \texttt{text/plain} and the new parameter value will be appended as per \textbf{RFC 2045}.

Optional \texttt{header} specifies an alternative header to \texttt{Content-Type}, and all parameters will be quoted as necessary unless optional \texttt{requote} is \texttt{False} (the default is \texttt{True}).

If optional \texttt{charset} is specified, the parameter will be encoded according to \textbf{RFC 2231}. Optional \texttt{language} specifies the RFC 2231 language, defaulting to the empty string. Both \texttt{charset} and \texttt{language} should be strings.

\textbf{del\_param}(\texttt{param}, \texttt{header='content-type'}, \texttt{requote=True})

Remove the given parameter completely from the \texttt{Content-Type} header. The header will be re-written in place without the parameter or its value. All values will be quoted as necessary
unless `requote` is False (the default is True). Optional `header` specifies an alternative to `Content-Type`.

**set_type**(type, header='Content-Type', requote=True)

Set the main type and subtype for the `Content-Type` header. `type` must be a string in the form `maintype/subtype`, otherwise a `ValueError` is raised.

This method replaces the `Content-Type` header, keeping all the parameters in place. If `requote` is False, this leaves the existing header’s quoting as is, otherwise the parameters will be quoted (the default).

An alternative header can be specified in the `header` argument. When the `Content-Type` header is set a `MIME-Version` header is also added.

**get_filename**(failobj=None)

Return the value of the `filename` parameter of the `Content-Disposition` header of the message. If the header does not have a `filename` parameter, this method falls back to looking for the `name` parameter on the `Content-Type` header. If neither is found, or the header is missing, then `failobj` is returned. The returned string will always be unquoted as per `email.utils.unquote()`.

**get_boundary**(failobj=None)

Return the value of the `boundary` parameter of the `Content-Type` header of the message, or `failobj` if either the header is missing, or has no `boundary` parameter. The returned string will always be unquoted as per `email.utils.unquote()`.
**set_boundary**(boundary)

Set the boundary parameter of the Content-Type header to *boundary*. `set_boundary()` will always quote *boundary* if necessary. A `HeaderParseError` is raised if the message object has no Content-Type header.

Note that using this method is subtly different than deleting the old Content-Type header and adding a new one with the new boundary via `add_header()`, because `set_boundary()` preserves the order of the Content-Type header in the list of headers. However, it does *not* preserve any continuation lines which may have been present in the original Content-Type header.

**get_content_charset**(failobj=None)

Return the charset parameter of the Content-Type header, coerced to lower case. If there is no Content-Type header, or if that header has no charset parameter, *failobj* is returned.

Note that this method differs from `get_charset()` which returns the Charset instance for the default encoding of the message body.

**get_charsets**(failobj=None)

Return a list containing the character set names in the message. If the message is a *multipart*, then the list will contain one element for each subpart in the payload, otherwise, it will be a list of length 1.

Each item in the list will be a string which is the value of the charset parameter in the Content-Type header for the represented subpart. However, if the subpart has no Content-
Type header, no charset parameter, or is not of the text main MIME type, then that item in the returned list will be failobj.

walk()
The walk() method is an all-purpose generator which can be used to iterate over all the parts and subparts of a message object tree, in depth-first traversal order. You will typically use walk() as the iterator in a for loop; each iteration returns the next subpart.

Here's an example that prints the MIME type of every part of a multipart message structure:

```python
>>> for part in msg.walk():
...     print(part.get_content_type())
multipart/report
text/plain
message/delivery-status
text/plain
text/plain
message/rfc822
text/plain
```

Message objects can also optionally contain two instance attributes, which can be used when generating the plain text of a MIME message.

preamble
The format of a MIME document allows for some text between the blank line following the headers, and the first multipart boundary string. Normally, this text is never visible in a MIME-aware mail reader because it falls outside the standard MIME armor. However, when viewing the raw text of the message, or
when viewing the message in a non-MIME aware reader, this text can become visible.

The *preamble* attribute contains this leading extra-armor text for MIME documents. When the *Parser* discovers some text after the headers but before the first boundary string, it assigns this text to the message’s *preamble* attribute. When the *Generator* is writing out the plain text representation of a MIME message, and it finds the message has a *preamble* attribute, it will write this text in the area between the headers and the first boundary. See `email.parser` and `email.generator` for details.

Note that if the message object has no preamble, the *preamble* attribute will be `None`.

**epilogue**

The *epilogue* attribute acts the same way as the *preamble* attribute, except that it contains text that appears between the last boundary and the end of the message.

You do not need to set the epilogue to the empty string in order for the *Generator* to print a newline at the end of the file.

**defects**

The *defects* attribute contains a list of all the problems found when parsing this message. See `email.errors` for a detailed description of the possible parsing defects.

Created using Sphinx 1.0.7.
19.1.2. **email.parser**: Parsing email messages

Message object structures can be created in one of two ways: they can be created from whole cloth by instantiating `Message` objects and stringing them together via `attach()` and `set_payload()` calls, or they can be created by parsing a flat text representation of the email message.

The `email` package provides a standard parser that understands most email document structures, including MIME documents. You can pass the parser a string or a file object, and the parser will return to you the root `Message` instance of the object structure. For simple, non-MIME messages the payload of this root object will likely be a string containing the text of the message. For MIME messages, the root object will return True from its `is_multipart()` method, and the subparts can be accessed via the `get_payload()` and `walk()` methods.

There are actually two parser interfaces available for use, the classic `Parser` API and the incremental `FeedParser` API. The classic `Parser` API is fine if you have the entire text of the message in memory as a string, or if the entire message lives in a file on the file system. `FeedParser` is more appropriate for when you're reading the message from a stream which might block waiting for more input (e.g. reading an email message from a socket). The `FeedParser` can consume and parse the message incrementally, and only returns the root object when you close the parser [1].

Note that the parser can be extended in limited ways, and of course
you can implement your own parser completely from scratch. There is no magical connection between the email package's bundled parser and the Message class, so your custom parser can create message object trees any way it finds necessary.
19.1.2.1. FeedParser API

The **FeedParser**, imported from the `email.feedparser` module, provides an API that is conducive to incremental parsing of email messages, such as would be necessary when reading the text of an email message from a source that can block (e.g. a socket). The **FeedParser** can of course be used to parse an email message fully contained in a string or a file, but the classic **Parser** API may be more convenient for such use cases. The semantics and results of the two parser APIs are identical.

The **FeedParser**'s API is simple; you create an instance, feed it a bunch of text until there's no more to feed it, then close the parser to retrieve the root message object. The **FeedParser** is extremely accurate when parsing standards-compliant messages, and it does a very good job of parsing non-compliant messages, providing information about how a message was deemed broken. It will populate a message object's *defects* attribute with a list of any problems it found in a message. See the `email.errors` module for the list of defects that it can find.

Here is the API for the **FeedParser**:

```python
class email.parser.FeedParser(_factory=email.message.Message, *, policy=policy.default)
```

Create a **FeedParser** instance. Optional `_factory` is a no-argument callable that will be called whenever a new message object is needed. It defaults to the `email.message.Message` class.
The `policy` keyword specifies a `policy` object that controls a number of aspects of the parser’s operation. The default policy maintains backward compatibility.

*Changed in version 3.3: Added the `policy` keyword.*

**feed**(data)

Feed the `FeedParser` some more data. `data` should be a string containing one or more lines. The lines can be partial and the `FeedParser` will stitch such partial lines together properly. The lines in the string can have any of the common three line endings, carriage return, newline, or carriage return and newline (they can even be mixed).

**close()**

Closing a `FeedParser` completes the parsing of all previously fed data, and returns the root message object. It is undefined what happens if you feed more data to a closed `FeedParser`.

**class**

```python
email.parser.BytesFeedParser(_factory=email.message.Message)
```

Works exactly like `FeedParser` except that the input to the `feed()` method must be bytes and not string.

*New in version 3.2.*
19.1.2.2. Parser class API

The Parser class, imported from the email.parser module, provides an API that can be used to parse a message when the complete contents of the message are available in a string or file. The email.parser module also provides header-only parsers, called HeaderParser and BytesHeaderParser, which can be used if you're only interested in the headers of the message. HeaderParser and BytesHeaderParser can be much faster in these situations, since they do not attempt to parse the message body, instead setting the payload to the raw body as a string. They have the same API as the Parser and BytesParser classes.

New in version 3.3: The BytesHeaderParser class.

class email.parser.Parser(_class=email.message.Message, *, policy=policy.default)

The constructor for the Parser class takes an optional argument _class. This must be a callable factory (such as a function or a class), and it is used whenever a sub-message object needs to be created. It defaults to Message (see email.message). The factory will be called without arguments.

The policy keyword specifies a policy object that controls a number of aspects of the parser's operation. The default policy maintains backward compatibility.

Changed in version 3.3: Removed the strict argument that was deprecated in 2.4. Added the policy keyword.

The other public Parser methods are:
**parse**(fp, headersonly=False)

Read all the data from the file-like object fp, parse the resulting text, and return the root message object. fp must support both the `readline()` and the `read()` methods on file-like objects.

The text contained in fp must be formatted as a block of RFC 2822 style headers and header continuation lines, optionally preceded by an envelope header. The header block is terminated either by the end of the data or by a blank line. Following the header block is the body of the message (which may contain MIME-encoded subparts).

Optional headersonly is a flag specifying whether to stop parsing after reading the headers or not. The default is False, meaning it parses the entire contents of the file.

**parsestr**(text, headersonly=False)

Similar to the `parse()` method, except it takes a string object instead of a file-like object. Calling this method on a string is exactly equivalent to wrapping text in a `StringIO` instance first and calling `parse()`.

Optional headersonly is as with the `parse()` method.

class email.parser.BytesParser(_class=email.message.Message, *, policy=policy.default)

This class is exactly parallel to Parser, but handles bytes input. The _class and strict arguments are interpreted in the same way as for the Parser constructor.

The policy keyword specifies a policy object that controls a number of aspects of the parser’s operation. The default policy
maintains backward compatibility.

*Changed in version 3.3:* Removed the *strict* argument. Added the *policy* keyword.

**parse**(*fp, headeronly=\texttt{False})*

Read all the data from the binary file-like object *fp*, parse the resulting bytes, and return the message object. *fp* must support both the `readline()` and the `read()` methods on file-like objects.

The bytes contained in *fp* must be formatted as a block of RFC 2822 style headers and header continuation lines, optionally preceded by a envelope header. The header block is terminated either by the end of the data or by a blank line. Following the header block is the body of the message (which may contain MIME-encoded subparts, including subparts with a *Content-Transfer-Encoding* of \texttt{8bit}.

Optional *headersonly* is a flag specifying whether to stop parsing after reading the headers or not. The default is \texttt{False}, meaning it parses the entire contents of the file.

**parsebytes**(*bytes, headeronly=\texttt{False})*

Similar to the `parse()` method, except it takes a byte string object instead of a file-like object. Calling this method on a byte string is exactly equivalent to wrapping *text* in a BytesIO instance first and calling `parse()`.

Optional *headersonly* is as with the `parse()` method.

*New in version 3.2.*
Since creating a message object structure from a string or a file object is such a common task, four functions are provided as a convenience. They are available in the top-level `email` package namespace.

email.**message_from_string**(*s*,
  _class_=email.message.Message, *, _policy_=policy.default)
  
  Return a message object structure from a string. This is exactly equivalent to `Parser().parsestr(s)`.
  _class_ and _policy_ are interpreted as with the `Parser` class constructor.

  *Changed in version 3.3:* Removed the strict argument. Added the policy keyword.

email.**message_from_bytes**(*s*,
  _class_=email.message.Message, *, _policy_=policy.default)
  
  Return a message object structure from a byte string. This is exactly equivalent to `BytesParser().parsebytes(s)`.
  Optional _class_ and strict are interpreted as with the `Parser` class constructor.

  *New in version 3.2.*

  *Changed in version 3.3:* Removed the strict argument. Added the policy keyword.

email.**message_from_file**(*fp*,
  _class_=email.message.Message, *, _policy_=policy.default)
  
  Return a message object structure tree from an open file object.
  This is exactly equivalent to `Parser().parse(fp)`.
  _class_ and _policy_ are interpreted as with the `Parser` class constructor.

  *Changed in version Removed:* the strict argument. Added the policy keyword.
email.message_from_binary_file(fp, _class=email.message.Message, *, policy=policy.default)

Return a message object structure tree from an open binary file. This is exactly equivalent to BytesParser().parse(fp). _class and policy are interpreted as with the Parser class constructor.

New in version 3.2.

Changed in version 3.3: Removed the strict argument. Added the policy keyword.

Here's an example of how you might use this at an interactive Python prompt:

```python
>>> import email
>>> msg = email.message_from_string(myString)
```
19.1.2.3. Additional notes

Here are some notes on the parsing semantics:

- Most non-
  multipart type messages are parsed as a single message object with a string payload. These objects will return False for is_multipart(). Their get_payload() method will return a string object.
- All multipart type messages will be parsed as a container message object with a list of sub-message objects for their payload. The outer container message will return True for is_multipart() and their get_payload() method will return the list of Message subparts.
- Most messages with a content type of message/* (e.g. message/delivery-status and message/rfc822) will also be parsed as container object containing a list payload of length 1. Their is_multipart() method will return True. The single element in the list payload will be a sub-message object.
- Some non-standards compliant messages may not be internally consistent about their multipart-edness. Such messages may have a Content-Type header of type multipart, but their is_multipart() method may return False. If such messages were parsed with the FeedParser, they will have an instance of the MultipartInvariantViolationDefect class in their defects attribute list. See email.errors for details.

Footnotes

[1] As of email package version 3.0, introduced in Python 2.4, the classic Parser was re-implemented in terms of the FeedParser, so the semantics and results are identical between the two parsers.
19.1.3. **email.generator**: Generating MIME documents

One of the most common tasks is to generate the flat text of the email message represented by a message object structure. You will need to do this if you want to send your message via the `smtplib` module or the `nntplib` module, or print the message on the console. Taking a message object structure and producing a flat text document is the job of the `Generator` class.

Again, as with the `email.parser` module, you aren't limited to the functionality of the bundled generator; you could write one from scratch yourself. However the bundled generator knows how to generate most email in a standards-compliant way, should handle MIME and non-MIME email messages just fine, and is designed so that the transformation from flat text, to a message structure via the `Parser` class, and back to flat text, is idempotent (the input is identical to the output) [1]. On the other hand, using the Generator on a `Message` constructed by program may result in changes to the `Message` object as defaults are filled in.

`bytes` output can be generated using the `BytesGenerator` class. If the message object structure contains non-ASCII bytes, this generator's `flatten()` method will emit the original bytes. Parsing a binary message and then flattening it with `BytesGenerator` should be idempotent for standards compliant messages.

Here are the public methods of the `Generator` class, imported from the `email.generator` module:
class email.generator.**Generator**(outfp, mangle_from_=True, maxheaderlen=78, *, policy=None)

The constructor for the **Generator** class takes a *file-like object* called *outfp* for an argument. *outfp* must support the *write()* method and be usable as the output file for the *print()* function.

Optional *mangle_from_* is a flag that, when True, puts a > character in front of any line in the body that starts exactly as *From*, i.e. *From* followed by a space at the beginning of the line. This is the only guaranteed portable way to avoid having such lines be mistaken for a Unix mailbox format envelope header separator (see [WHY THE CONTENT-LENGTH FORMAT IS BAD](#) for details). *mangle_from_* defaults to True, but you might want to set this to False if you are not writing Unix mailbox format files.

Optional *maxheaderlen* specifies the longest length for a non-continued header. When a header line is longer than *maxheaderlen* (in characters, with tabs expanded to 8 spaces), the header will be split as defined in the **Header** class. Set to zero to disable header wrapping. The default is 78, as recommended (but not required) by [RFC 2822](#).

The *policy* keyword specifies a *policy* object that controls a number of aspects of the generator’s operation. If no *policy* is specified, then the *policy* attached to the message object passed to **flatten** is used.

*Changed in version 3.3:* Added the *policy* keyword.

The other public **Generator** methods are:

**flatten**(msg, unixfrom=False, linesep=None)
Print the textual representation of the message object structure rooted at `msg` to the output file specified when the `Generator` instance was created. Subparts are visited depth-first and the resulting text will be properly MIME encoded.

Optional `unixfrom` is a flag that forces the printing of the envelope header delimiter before the first RFC 2822 header of the root message object. If the root object has no envelope header, a standard one is crafted. By default, this is set to `False` to inhibit the printing of the envelope delimiter.

Note that for subparts, no envelope header is ever printed.

Optional `linesep` specifies the line separator character used to terminate lines in the output. If specified it overrides the value specified by the `msg`'s or `Generator`'s policy.

Because strings cannot represent non-ASCII bytes, if the policy that applies when `flatten` is run has `cte_type` set to 8bit, `Generator` will operate as if it were set to 7bit. This means that messages parsed with a Bytes parser that have a `Content-Transfer-Encoding` of 8bit will be converted to a use a 7bit Content-Transfer-Encoding. Non-ASCII bytes in the headers will be RFC 2047 encoded with a charset of `unknown-8bit`.

*Changed in version 3.2:* Added support for re-encoding 8bit message bodies, and the `linesep` argument.

**clone(fp)**

Return an independent clone of this `Generator` instance with the exact same options.

**write(s)**
Write the string \( s \) to the underlying file object, i.e. \( \textit{outfp} \) passed to \texttt{Generator}'s constructor. This provides just enough file-like API for \texttt{Generator} instances to be used in the \texttt{print()} function.

As a convenience, see the \texttt{Message} methods \texttt{as\_string()} and \texttt{str(aMessage)}, a.k.a. \texttt{\_\_str\_()} , which simplify the generation of a formatted string representation of a message object. For more detail, see \texttt{email.message}.

\texttt{class email.generator.Byte\_Generator(outfp, mangle\_from\_=True, maxheaderlen=78, *, policy=policy.default)}

The constructor for the \texttt{BytesGenerator} class takes a binary \textit{file-like object} called \texttt{outfp} for an argument. \texttt{outfp} must support a \texttt{write()} method that accepts binary data.

Optional \texttt{mangle\_from\_} is a flag that, when True, puts a > character in front of any line in the body that starts exactly as \texttt{From}, i.e. \texttt{From} followed by a space at the beginning of the line. This is the only guaranteed portable way to avoid having such lines be mistaken for a Unix mailbox format envelope header separator (see \texttt{WHY THE CONTENT-LENGTH FORMAT IS BAD} for details). \texttt{mangle\_from\_} defaults to True, but you might want to set this to False if you are not writing Unix mailbox format files.

Optional \texttt{maxheaderlen} specifies the longest length for a non-continued header. When a header line is longer than \texttt{maxheaderlen} (in characters, with tabs expanded to 8 spaces), the header will be split as defined in the \texttt{Header} class. Set to zero to disable header wrapping. The default is 78, as recommended (but not required) by \texttt{RFC 2822}. 
The *policy* keyword specifies a *policy* object that controls a number of aspects of the generator's operation. The default policy maintains backward compatibility.

*Changed in version 3.3:* Added the *policy* keyword.

The other public *BytesGenerator* methods are:

**`flatten(msg, unixfrom=False, linesep=None)`**

Print the textual representation of the message object structure rooted at *msg* to the output file specified when the *BytesGenerator* instance was created. Subparts are visited depth-first and the resulting text will be properly MIME encoded. If the *policy* option *cte_type* is *8bit* (the default), then any bytes with the high bit set in the original parsed message that have not been modified will be copied faithfully to the output. If *cte_type* is *7bit*, the bytes will be converted as needed using an ASCII-compatible Content-Transfer-Encoding. In particular, RFC-invalid non-ASCII bytes in headers will be encoded using the MIME unknown-8bit character set, thus rendering them RFC-compliant.

Messages parsed with a Bytes parser that have a *Content-Transfer-Encoding* of 8bit will be reconstructed as 8bit if they have not been modified.

Optional *unixfrom* is a flag that forces the printing of the envelope header delimiter before the first *RFC 2822* header of the root message object. If the root object has no envelope header, a standard one is crafted. By default, this is set to False to inhibit the printing of the envelope delimiter.

Note that for subparts, no envelope header is ever printed.
Optional linesep specifies the line separator character used to terminate lines in the output. If specified it overrides the value specified by the Generator's policy.

clone(fp)
Return an independent clone of this BytesGenerator instance with the exact same options.

write(s)
Write the string s to the underlying file object. s is encoded using the ASCII codec and written to the write method of the outfp outfp passed to the BytesGenerator's constructor. This provides just enough file-like API for BytesGenerator instances to be used in the print() function.

New in version 3.2.

The email.generator module also provides a derived class, called DecodedGenerator which is like the Generator base class, except that non-text parts are substituted with a format string representing the part.

class email.generator.DecodedGenerator(outfp, mangle_from_=True, maxheaderlen=78, fmt=None)
This class, derived from Generator walks through all the subparts of a message. If the subpart is of main type text, then it prints the decoded payload of the subpart. Optional mangle_from_ and maxheaderlen are as with the Generator base class.

If the subpart is not of main type text, optional fmt is a format string that is used instead of the message payload. fmt is expanded with
the following keywords, \%(keyword)s format:

- **type** – Full MIME type of the non-text part
- **maintype** – Main MIME type of the non-text part
- **subtype** – Sub-MIME type of the non-text part
- **filename** – Filename of the non-text part
- **description** – Description associated with the non-text part
- **encoding** – Content transfer encoding of the non-text part

The default value for *fmt* is None, meaning

```
[Non-text (%(type)s) part of message omitted, fil
```

**Footnotes**

This statement assumes that you use the appropriate setting for the *unixfrom* argument, and that you set maxheaderlen=0
(which will preserve whatever the input line lengths were). It is also not strictly true, since in many cases runs of whitespace in headers are collapsed into single blanks. The latter is a bug that will eventually be fixed.
19.1. **email** — An email and MIME handling package
19.1.4. **email.policy**: Policy Objects

*New in version 3.3.*

The *email* package's prime focus is the handling of email messages as described by the various email and MIME RFCs. However, the general format of email messages (a block of header fields each consisting of a name followed by a colon followed by a value, the whole block followed by a blank line and an arbitrary ‘body’), is a format that has found utility outside of the realm of email. Some of these uses conform fairly closely to the main RFCs, some do not. And even when working with email, there are times when it is desirable to break strict compliance with the RFCs.

Policy objects give the email package the flexibility to handle all these disparate use cases.

A **Policy** object encapsulates a set of attributes and methods that control the behavior of various components of the email package during use. **Policy** instances can be passed to various classes and methods in the email package to alter the default behavior. The settable values and their defaults are described below.

There is a default policy used by all classes in the email package. This policy is named **Compat32**, with a corresponding pre-defined instance named compat32. It provides for complete backward compatibility (in some cases, including bug compatibility) with the pre-Python3.3 version of the email package.

The first part of this documentation covers the features of **Policy**, an
abstract base class that defines the features that are common to all policy objects, including compat32. This includes certain hook methods that are called internally by the email package, which a custom policy could override to obtain different behavior.

When a Message object is created, it acquires a policy. By default this will be compat32, but a different policy can be specified. If the Message is created by a parser, a policy passed to the parser will be the policy used by the Message it creates. If the Message is created by the program, then the policy can be specified when it is created. When a Message is passed to a generator, the generator uses the policy from the Message by default, but you can also pass a specific policy to the generator that will override the one stored on the Message object.

Policy instances are immutable, but they can be cloned, accepting the same keyword arguments as the class constructor and returning a new Policy instance that is a copy of the original but with the specified attributes values changed.

As an example, the following code could be used to read an email message from a file on disk and pass it to the system sendmail program on a Unix system:

```python
>>> from email import message_from_binary_file
>>> from email.generator import BytesGenerator
>>> from email import policy
>>> from subprocess import Popen, PIPE
>>> with open('mymsg.txt', 'rb') as f:
...     msg = message_from_binary_file(f, policy=p)
>>> p = Popen(['sendmail', msg['To'].addresses[0]],
>>> g = BytesGenerator(p.stdin, policy=msg.policy.clone)
>>> g.flatten(msg)
```
Here we are telling *BytesGenerator* to use the RFC correct line separator characters when creating the binary string to feed into *sendmail*'s *stdin*, where the default policy would use \n line separators.

Policy objects can also be combined using the addition operator, producing a policy object whose settings are a combination of the non-default values of the summed objects:

```python
>>> compat_SMTP = policy.compat32.clone(linesep='\r

>>> compat_strict = policy.compat32.clone(raise_on_defect=

>>> compat_strict_SMTP = compat_SMTP + compat_strict
```

This operation is not commutative; that is, the order in which the objects are added matters. To illustrate:

```python
>>> policy100 = policy.compat32.clone(max_line_length=100)
>>> policy80 = policy.compat32.clone(max_line_length=80)
>>> apolicy = policy100 + policy80
>>> apolicy.max_line_length 100
```

```python
>>> apolicy = policy80 + policy100
>>> apolicy.max_line_length 80
```

```python
class email.policy.*Policy(**kw)
```

This is the *abstract base class* for all policy classes. It provides default implementations for a couple of trivial methods, as well as the implementation of the immutability property, the *clone()*
method, and the constructor semantics.

The constructor of a policy class can be passed various keyword arguments. The arguments that may be specified are any non-method properties on this class, plus any additional non-method properties on the concrete class. A value specified in the constructor will override the default value for the corresponding attribute.

This class defines the following properties, and thus values for the following may be passed in the constructor of any policy class:

**max_line_length**

The maximum length of any line in the serialized output, not counting the end of line character(s). Default is 78, per RFC 5322. A value of 0 or None indicates that no line wrapping should be done at all.

**linesep**

The string to be used to terminate lines in serialized output. The default is \n because that’s the internal end-of-line discipline used by Python, though \r\n is required by the RFCs.

**cte_type**

Controls the type of Content Transfer Encodings that may be or are required to be used. The possible values are:

<table>
<thead>
<tr>
<th>7bit</th>
<th>all data must be “7 bit clean” (ASCII-only). This means that where necessary data will be encoded using either quoted-printable or base64 encoding.</th>
</tr>
</thead>
<tbody>
<tr>
<td>8bit</td>
<td>data is not constrained to be 7 bit clean. Data in headers is still required to be ASCII-only and so will be encoded (see ‘binary_fold’ below for an</td>
</tr>
</tbody>
</table>
exception), but body parts may use the 8bit CTE.

A `cte_type` value of 8bit only works with BytesGenerator, not Generator, because strings cannot contain binary data. If a Generator is operating under a policy that specifies `cte_type=8bit`, it will act as if `cte_type` is 7bit.

**raise_on_defect**

If `True`, any defects encountered will be raised as errors. If `False` (the default), defects will be passed to the `register_defect()` method.

The following `Policy` method is intended to be called by code using the email library to create policy instances with custom settings:

**clone(**kw**)**

Return a new `Policy` instance whose attributes have the same values as the current instance, except where those attributes are given new values by the keyword arguments.

The remaining `Policy` methods are called by the email package code, and are not intended to be called by an application using the email package. A custom policy must implement all of these methods.

**handle_defect**(obj, defect)**

Handle a `defect` found on `obj`. When the email package calls this method, `defect` will always be a subclass of Defect.

The default implementation checks the `raise_on_defect` flag. If it is `True`, `defect` is raised as an exception. If it is `False`
(the default), obj and defect are passed to register_defect().

**register_defect(obj, defect)**

Register a defect on obj. In the email package, defect will always be a subclass of Defect.

The default implementation calls the append method of the defects attribute of obj. When the email package calls handle_defect, obj will normally have a defects attribute that has an append method. Custom object types used with the email package (for example, custom Message objects) should also provide such an attribute, otherwise defects in parsed messages will raise unexpected errors.

**header_max_count(name)**

Return the maximum allowed number of headers named name.

Called when a header is added to a Message object. If the returned value is not 0 or None, and there are already a number of headers with the name name equal to the value returned, a ValueError is raised.

Because the default behavior of Message.__setitem__ is to append the value to the list of headers, it is easy to create duplicate headers without realizing it. This method allows certain headers to be limited in the number of instances of that header that may be added to a Message programmatically. (The limit is not observed by the parser, which will faithfully produce as many headers as exist in the message being parsed.)
The default implementation returns None for all header names.

**header_source_parse**(*sourcelines*)

The email package calls this method with a list of strings, each string ending with the line separation characters found in the source being parsed. The first line includes the field header name and separator. All whitespace in the source is preserved. The method should return the *(name, value)* tuple that is to be stored in the Message to represent the parsed header.

If an implementation wishes to retain compatibility with the existing email package policies, *name* should be the case preserved name (all characters up to the ‘:’ separator), while *value* should be the unfolded value (all line separator characters removed, but whitespace kept intact), stripped of leading whitespace.

*sourcelines* may contain surrogateescaped binary data.

There is no default implementation

**header_store_parse**(*name, value*)

The email package calls this method with the name and value provided by the application program when the application program is modifying a Message programmatically (as opposed to a Message created by a parser). The method should return the *(name, value)* tuple that is to be stored in the Message to represent the header.

If an implementation wishes to retain compatibility with the existing email package policies, the *name* and *value* should be strings or string subclasses that do not change the content of the passed in arguments.
There is no default implementation

**header_fetch_parse**(*name*, *value*)

The email package calls this method with the *name* and *value* currently stored in the Message when that header is requested by the application program, and whatever the method returns is what is passed back to the application as the value of the header being retrieved. Note that there may be more than one header with the same name stored in the Message; the method is passed the specific name and value of the header destined to be returned to the application.

*value* may contain surrogateescaped binary data. There should be no surrogateescaped binary data in the value returned by the method.

There is no default implementation

**fold**(*name*, *value*)

The email package calls this method with the *name* and *value* currently stored in the Message for a given header. The method should return a string that represents that header "folded" correctly (according to the policy settings) by composing the *name* with the *value* and inserting *linesep* characters at the appropriate places. See RFC 5322 for a discussion of the rules for folding email headers.

*value* may contain surrogateescaped binary data. There should be no surrogateescaped binary data in the string returned by the method.

**fold_binary**(*name*, *value*)
The same as `fold()`, except that the returned value should be a bytes object rather than a string.

`value` may contain surrogateescaped binary data. These could be converted back into binary data in the returned bytes object.

class email.policyCompat32(**kw)

This concrete `Policy` is the backward compatibility policy. It replicates the behavior of the email package in Python 3.2. The `policy` module also defines an instance of this class, `compat32`, that is used as the default policy. Thus the default behavior of the email package is to maintain compatibility with Python 3.2.

The class provides the following concrete implementations of the abstract methods of `Policy`:

`header_source_parse(sourcelines)`
The name is parsed as everything up to the ‘:’ and returned unmodified. The value is determined by stripping leading whitespace off the remainder of the first line, joining all subsequent lines together, and stripping any trailing carriage return or linefeed characters.

`header_store_parse(name, value)`
The name and value are returned unmodified.

`header_fetch_parse(name, value)`
If the value contains binary data, it is converted into a `Header` object using the `unknown-8bit` charset. Otherwise it is returned unmodified.

`fold(name, value)`
Headers are folded using the Header folding algorithm, which preserves existing line breaks in the value, and wraps each resulting line to the max_line_length. Non-ASCII binary data are CTE encoded using the unknown-8bit charset.

__fold_binary__(name, value)

Headers are folded using the Header folding algorithm, which preserves existing line breaks in the value, and wraps each resulting line to the max_line_length. If cte_type is 7bit, non-ascii binary data is CTE encoded using the unknown-8bit charset. Otherwise the original source header is used, with its existing line breaks and any (RFC invalid) binary data it may contain.

**Note:** The documentation below describes new policies that are included in the standard library on a provisional basis. Backwards incompatible changes (up to and including removal of the feature) may occur if deemed necessary by the core developers.

```ruby
class email.policy. EmailPolicy(**kw)
    This concrete Policy provides behavior that is intended to be fully compliant with the current email RFCs. These include (but are not limited to) RFC 5322, RFC 2047, and the current MIME RFCs.

    This policy adds new header parsing and folding algorithms. Instead of simple strings, headers are custom objects with custom attributes depending on the type of the field. The parsing and folding algorithm fully implement RFC 2047 and RFC 5322.

    In addition to the settable attributes listed above that apply to all policies, this policy adds the following additional attributes:
```
refold_source

If the value for a header in the `Message` object originated from a parser (as opposed to being set by a program), this attribute indicates whether or not a generator should refold that value when transforming the message back into stream form. The possible values are:

<table>
<thead>
<tr>
<th>none</th>
<th>all source values use original folding</th>
</tr>
</thead>
<tbody>
<tr>
<td>long</td>
<td>source values that have any line that is longer than <code>max_line_length</code> will be refolded</td>
</tr>
<tr>
<td>all</td>
<td>all values are refolded.</td>
</tr>
</tbody>
</table>

The default is `long`.

header_factory

A callable that takes two arguments, `name` and `value`, where `name` is a header field name and `value` is an unfolded header field value, and returns a string subclass that represents that header. A default `header_factory` (see `headerregistry`) is provided that understands some of the RFC 5322 header field types. (Currently address fields and date fields have special treatment, while all other fields are treated as unstructured. This list will be completed before the extension is marked stable.)

The class provides the following concrete implementations of the abstract methods of `Policy`:

header_max_count `name`

Returns the value of the `max_count` attribute of the specialized class used to represent the header with the given name.
header_source_parse(sourcelines)
The implementation of this method is the same as that for the Compat32 policy.

header_store_parse(name, value)
The name is returned unchanged. If the input value has a name attribute and it matches name ignoring case, the value is returned unchanged. Otherwise the name and value are passed to header_factory, and the resulting custom header object is returned as the value. In this case a ValueError is raised if the input value contains CR or LF characters.

header_fetch_parse(name, value)
If the value has a name attribute, it is returned to unmodified. Otherwise the name, and the value with any CR or LF characters removed, are passed to the header_factory, and the resulting custom header object is returned. Any surrogateescaped bytes get turned into the unicode unknown-character glyph.

fold(name, value)
Header folding is controlled by the refold_source policy setting. A value is considered to be a 'source value' if and only if it does not have a name attribute (having a name attribute means it is a header object of some sort). If a source value needs to be refolded according to the policy, it is converted into a custom header object by passing the name and the value with any CR and LF characters removed to the header_factory. Folding of a custom header object is done by calling its fold method with the current policy.
Source values are split into lines using `splitlines()`. If the value is not to be refolded, the lines are rejoined using the `linesep` from the policy and returned. The exception is lines containing non-ascii binary data. In that case the value is refolded regardless of the `refold_source` setting, which causes the binary data to be CTE encoded using the `unknown-8bit` charset.

**fold_binary** *(name, value)*

The same as `fold()` if `cte_type` is 7bit, except that the returned value is bytes.

If `cte_type` is 8bit, non-ASCII binary data is converted back into bytes. Headers with binary data are not refolded, regardless of the `refold_header` setting, since there is no way to know whether the binary data consists of single byte characters or multibyte characters.

The following instances of `EmailPolicy` provide defaults suitable for specific application domains. Note that in the future the behavior of these instances (in particular the HTTP instance) may be adjusted to conform even more closely to the RFCs relevant to their domains.

**email.policy.default**

An instance of `EmailPolicy` with all defaults unchanged. This policy uses the standard Python `\n` line endings rather than the RFC-correct `\r\n`.

**email.policy.SMTP**

Suitable for serializing messages in conformance with the email RFCs. Like `default`, but with `linesep` set to `\r\n`, which is RFC compliant.
email.policy.HTTP

Suitable for serializing headers with for use in HTTP traffic. Like SMTP except that max_line_length is set to None (unlimited).

email.policy.strict

Convenience instance. The same as default except that raise_on_defect is set to True. This allows any policy to be made strict by writing:

```python
somepolicy + policy.strict
```

With all of these EmailPolicies, the effective API of the email package is changed from the Python 3.2 API in the following ways:

- Setting a header on a Message results in that header being parsed and a custom header object created.
- Fetching a header value from a Message results in that header being parsed and a custom header object created and returned.
- Any custom header object, or any header that is refolded due to the policy settings, is folded using an algorithm that fully implements the RFC folding algorithms, including knowing where encoded words are required and allowed.

From the application view, this means that any header obtained through the Message is a custom header object with custom attributes, whose string value is the fully decoded unicode value of the header. Likewise, a header may be assigned a new value, or a new header created, using a unicode string, and the policy will take care of converting the unicode string into the correct RFC encoded form.

The custom header objects and their attributes are described in headerregistry.
19.1.5. 

email.headerregistry: Custom Header Objects

**Note:** The headerregistry module has been included in the standard library on a *provisional basis*. Backwards incompatible changes (up to and including removal of the module) may occur if deemed necessary by the core developers.

*New in version 3.3:* as a *provisional module*.

Headers are represented by customized subclasses of `str`. The particular class used to represent a given header is determined by the `header_factory` of the `policy` in effect when the headers are created. This section documents the particular `header_factory` implemented by the email package for handling RFC 5322 compliant email messages, which not only provides customized header objects for various header types, but also provides an extension mechanism for applications to add their own custom header types.

When using any of the policy objects derived from `EmailPolicy`, all headers are produced by `HeaderRegistry` and have `BaseHeader` as their last base class. Each header class has an additional base class that is determined by the type of the header. For example, many headers have the class `UnstructuredHeader` as their other base class. The specialized second class for a header is determined by the name of the header, using a lookup table stored in the `HeaderRegistry`. All of this is managed transparently for the typical application program, but interfaces are provided for modifying the
default behavior for use by more complex applications.

The sections below first document the header base classes and their attributes, followed by the API for modifying the behavior of HeaderRegistry, and finally the support classes used to represent the data parsed from structured headers.

class email.headerregistry.BaseHeader(name, value)
    name and value are passed to BaseHeader from the header_factory call. The string value of any header object is the value fully decoded to unicode.

This base class defines the following read-only properties:

name
    The name of the header (the portion of the field before the ‘:’). This is exactly the value passed in the header_factory call for name; that is, case is preserved.

defects
    A tuple of HeaderDefect instances reporting any RFC compliance problems found during parsing. The email package tries to be complete about detecting compliance issues. See the errors module for a discussion of the types of defects that may be reported.

max_count
    The maximum number of headers of this type that can have the same name. A value of None means unlimited. The BaseHeader value for this attribute is None; it is expected that specialized header classes will override this value as needed.

BaseHeader also provides the following method, which is called
by the email library code and should not in general be called by application programs:

**fold**(*, policy*)

Return a string containing *linesep* characters as required to correctly fold the header according to *policy*. A *cte_type* of 8bit will be treated as if it were 7bit, since strings may not contain binary data.

**BaseHeader** by itself cannot be used to create a header object. It defines a protocol that each specialized header cooperates with in order to produce the header object. Specifically, **BaseHeader** requires that the specialized class provide a **classmethod()** named parse. This method is called as follows:

```python
def parse(string, kwds):
    kwds = {}  # dictionary containing one pre-initialized key, defects.
    defects = []  # is an empty list. The parse method should append any detected defects to this list. On return, the kwds dictionary must contain values for at least the keys decoded and defects.
    decoded = ...  # should be the string value for the header (that is, the header value fully decoded to unicode). The parse method should assume that string may contain transport encoded parts, but should correctly handle all valid unicode characters as well so that it can parse un-encoded header values.

    BaseHeader's **__new__** then creates the header instance, and calls its init method. The specialized class only needs to provide an init method if it wishes to set additional attributes beyond those provided by **BaseHeader** itself. Such an init method should look like this:
```python
def init(self, *args, **kw):
    self._myattr = kw.pop('myattr')
super().init(*args, **kw)
```

That is, anything extra that the specialized class puts in to the `kwds` dictionary should be removed and handled, and the remaining contents of `kw` (and `args`) passed to the `BaseHeader.init` method.

class email.headerregistry.UnstructuredHeader

An “unstructured” header is the default type of header in RFC 5322. Any header that does not have a specified syntax is treated as unstructured. The classic example of an unstructured header is the `Subject` header.

In RFC 5322, an unstructured header is a run of arbitrary text in the ASCII character set. RFC 2047, however, has an RFC 5322 compatible mechanism for encoding non-ASCII text as ASCII characters within a header value. When a `value` containing encoded words is passed to the constructor, the `UnstructuredHeader` parser converts such encoded words back in to the original unicode, following the RFC 2047 rules for unstructured text. The parser uses heuristics to attempt to decode certain non-compliant encoded words. Defects are registered in such cases, as well as defects for issues such as invalid characters within the encoded words or the non-encoded text.

This header type provides no additional attributes.

class email.headerregistry.DateHeader

RFC 5322 specifies a very specific format for dates within email headers. The `DateHeader` parser recognizes that date format, as
well as recognizing a number of variant forms that are sometimes found “in the wild”.

This header type provides the following additional attributes:

**datetime**

If the header value can be recognized as a valid date of one form or another, this attribute will contain a `datetime` instance representing that date. If the timezone of the input date is specified as `-0000` (indicating it is in UTC but contains no information about the source timezone), then `datetime` will be a naive `datetime`. If a specific timezone offset is found (including `+0000`), then `datetime` will contain an aware `datetime` that uses `datetime.timezone` to record the timezone offset.

The decoded value of the header is determined by formatting the `datetime` according to the RFC 5322 rules; that is, it is set to:

```python
email.utils.format_datetime(self.datetime)
```

When creating a `DateHeader`, `value` may be `datetime` instance. This means, for example, that the following code is valid and does what one would expect:

```python
msg['Date'] = datetime(2011, 7, 15, 21)
```

Because this is a naive `datetime` it will be interpreted as a UTC timestamp, and the resulting value will have a timezone of `-0000`. Much more useful is to use the `localtime()` function from the `utils` module:
msg[\'Date\'] = utils.localtime()

This example sets the date header to the current time and date using the current timezone offset.

class email.headerregistry.AddressHeader

Address headers are one of the most complex structured header types. The AddressHeader class provides a generic interface to any address header.

This header type provides the following additional attributes:

**groups**

A tuple of Group objects encoding the addresses and groups found in the header value. Addresses that are not part of a group are represented in this list as single-address Groups whose display_name is None.

**addresses**

A tuple of Address objects encoding all of the individual addresses from the header value. If the header value contains any groups, the individual addresses from the group are included in the list at the point where the group occurs in the value (that is, the list of addresses is “flattened” into a one dimensional list).

The decoded value of the header will have all encoded words decoded to unicode. idna encoded domain names are also decoded to unicode. The decoded value is set by joining the str value of the elements of the groups attribute with ",".

A list of Address and Group objects in any combination may be
used to set the value of an address header. `Group` objects whose `display_name` is None will be interpreted as single addresses, which allows an address list to be copied with groups intact by using the list obtained `groups` attribute of the source header.

class email.headerregistry. `SingleAddressHeader`
A subclass of `AddressHeader` that adds one additional attribute:

`address`
The single address encoded by the header value. If the header value actually contains more than one address (which would be a violation of the RFC under the default `policy`), accessing this attribute will result in a `ValueError`.

Many of the above classes also have a `Unique` variant (for example, `UniqueUnstructuredHeader`). The only difference is that in the `Unique` variant, `max_count` is set to 1.

class email.headerregistry. `MIMEVersionHeader`
There is really only one valid value for the `MIME-Version` header, and that is 1.0. For future proofing, this header class supports other valid version numbers. If a version number has a valid value per RFC 2045, then the header object will have non-None values for the following attributes:

`version`
The version number as a string, with any whitespace and/or comments removed.

`major`
The major version number as an integer

`minor`
The minor version number as an integer

```python
class email.headerregistry.ParameterizedMIMEHeader
```

MOME headers all start with the prefix ‘Content-‘. Each specific header has a certain value, described under the class for that header. Some can also take a list of supplemental parameters, which have a common format. This class serves as a base for all the MIME headers that take parameters.

```python
params
```

A dictionary mapping parameter names to parameter values.

```python
class email.headerregistry.ContentTypeHeader
```

A `ParameterizedMIMEHeader` class that handles the `Content-Type` header.

```python
content_type
```

The content type string, in the form `maintype/subtype`.

```python
maintype
```

```python
subtype
```

```python
class email.headerregistry.ContentDispositionHeader
```

A `ParameterizedMIMEHeader` class that handles the `Content-Disposition` header.

```python
content-disposition
```

`inline` and `attachment` are the only valid values in common use.

```python
class email.headerregistry.ContentTransferEncoding
```

Handles the `Content-Transfer-Encoding` header.
**cte**

Valid values are 7bit, 8bit, base64, and quoted-printable. See RFC 2045 for more information.

class email.headerregistry.HeaderRegistry(base_class=BaseHeader, default_class=UnstructuredHeader, use_default_map=True)

This is the factory used by EmailPolicy by default. `HeaderRegistry` builds the class used to create a header instance dynamically, using `base_class` and a specialized class retrieved from a registry that it holds. When a given header name does not appear in the registry, the class specified by `default_class` is used as the specialized class. When `use_default_map` is True (the default), the standard mapping of header names to classes is copied into the registry during initialization. `base_class` is always the last class in the generated class's `__bases__` list.

The default mappings are:

<table>
<thead>
<tr>
<th>Field</th>
<th>Class</th>
</tr>
</thead>
<tbody>
<tr>
<td>subject:</td>
<td>UniqueUnstructuredHeader</td>
</tr>
<tr>
<td>date:</td>
<td>UniqueDateHeader</td>
</tr>
<tr>
<td>resent-date:</td>
<td>DateHeader</td>
</tr>
<tr>
<td>orig-date:</td>
<td>UniqueDateHeader</td>
</tr>
<tr>
<td>sender:</td>
<td>UniqueSingleAddressHeader</td>
</tr>
<tr>
<td>resent-sender:</td>
<td>SingleAddressHeader</td>
</tr>
<tr>
<td>to:</td>
<td>UniqueAddressHeader</td>
</tr>
<tr>
<td>resent-to:</td>
<td>AddressHeader</td>
</tr>
<tr>
<td>cc:</td>
<td>UniqueAddressHeader</td>
</tr>
<tr>
<td>resent-cc:</td>
<td>AddressHeader</td>
</tr>
</tbody>
</table>
The following classes are the classes used to represent data parsed from structured headers and can, in general, be used by an application program to construct structured values to assign to specific headers.

```python
class email.headerregistry.Address(display_name='', username='', domain='', addr_spec=None)
```

The class used to represent an email address. The general form of an address is:
where each part must conform to specific syntax rules spelled out in **RFC 5322**.

As a convenience `addr_spec` can be specified instead of `username` and `domain`, in which case `username` and `domain` will be parsed from the `addr_spec`. An `addr_spec` must be a properly RFC quoted string; if it is not `Address` will raise an error. Unicode characters are allowed and will be properly encoded when serialized. However, per the RFCs, unicode is not allowed in the username portion of the address.

**display_name**  
The display name portion of the address, if any, with all quoting removed. If the address does not have a display name, this attribute will be an empty string.

**username**  
The `username` portion of the address, with all quoting removed.

**domain**  
The `domain` portion of the address.

**addr_spec**  
The `username@domain` portion of the address, correctly quoted for use as a bare address (the second form shown above). This attribute is not mutable.
__str__()

The str value of the object is the address quoted according to RFC 5322 rules, but with no Content Transfer Encoding of any non-ASCII characters.

To support SMTP (RFC 5321), Address handles one special case: if username and domain are both the empty string (or None), then the string value of the Address is <>.

class email.headerregistry.Group(display_name=None, addresses=None)

The class used to represent an address group. The general form of an address group is:

```plaintext
display_name: [address-list];
```

As a convenience for processing lists of addresses that consist of a mixture of groups and single addresses, a Group may also be used to represent single addresses that are not part of a group by setting display_name to None and providing a list of the single address as addresses.

display_name

The display_name of the group. If it is None and there is exactly one Address in addresses, then the Group represents a single address that is not in a group.

addresses

A possibly empty tuple of Address objects representing the addresses in the group.

__str__()
The `str` value of a `Group` is formatted according to [RFC 5322](https://tools.ietf.org/html/rfc5322), but with no Content Transfer Encoding of any non-ASCII characters. If `display_name` is none and there is a single `Address` in the `addresses` list, the `str` value will be the same as the `str` of that single `Address`. 
19.1.6. **email.mime**: Creating email and MIME objects from scratch

Ordinarily, you get a message object structure by passing a file or some text to a parser, which parses the text and returns the root message object. However, you can also build a complete message structure from scratch, or even individual `Message` objects by hand. In fact, you can also take an existing structure and add new `Message` objects, move them around, etc. This makes a very convenient interface for slicing-and-dicing MIME messages.

You can create a new object structure by creating `Message` instances, adding attachments and all the appropriate headers manually. For MIME messages though, the `email` package provides some convenient subclasses to make things easier.

Here are the classes:

```python
class email.mime.base.MIMEBase(_maintype, _subtype, **_params)
```

Module: `email.mime.base`

This is the base class for all the MIME-specific subclasses of `Message`. Ordinarily, you won’t create instances specifically of `MIMEBase`, although you could. `MIMEBase` is provided primarily as a convenient base class for more specific MIME-aware subclasses.

`_maintype` is the `Content-Type` major type (e.g. `text` or `image`), and `_subtype` is the `Content-Type` minor type (e.g. `plain` or `gif`).
_params is a parameter key/value dictionary and is passed directly to Message.add_header.

The MIMEBase class always adds a Content-Type header (based on _maintype, _subtype, and _params), and a MIME-Version header (always set to 1.0).

class email.mime.nonmultipart.MIMENonMultipart
Module: email.mime.nonmultipart

A subclass of MIMEBase, this is an intermediate base class for MIME messages that are not multipart. The primary purpose of this class is to prevent the use of the attach() method, which only makes sense for multipart messages. If attach() is called, a MultipartConversionError exception is raised.

class email.mime.multipart.MIMEMultipart(_subtype='mixed', boundary=None, _subparts=None, **_params)
Module: email.mime.multipart

A subclass of MIMEBase, this is an intermediate base class for MIME messages that are multipart. Optional _subtype defaults to mixed, but can be used to specify the subtype of the message. A Content-Type header of multipart/_subtype will be added to the message object. A MIME-Version header will also be added.

Optional boundary is the multipart boundary string. When None (the default), the boundary is calculated when needed (for example, when the message is serialized).

_subparts is a sequence of initial subparts for the payload. It must be possible to convert this sequence to a list. You can always
attach new subparts to the message by using the `Message.attach` method.

Additional parameters for the `Content-Type` header are taken from the keyword arguments, or passed into the `_params` argument, which is a keyword dictionary.

```python
class email.mime.application.MIMEApplication(_data, _subtype='octet-stream', _encoder=email.encoders.encode_base64, **_params)
Module: email.mime.application
```

A subclass of `MIMENonMultipart`, the `MIMEApplication` class is used to represent MIME message objects of major type `application`. `_data` is a string containing the raw byte data. Optional `_subtype` specifies the MIME subtype and defaults to `octet-stream`.

Optional `_encoder` is a callable (i.e. function) which will perform the actual encoding of the data for transport. This callable takes one argument, which is the `MIMEApplication` instance. It should use `get_payload()` and `set_payload()` to change the payload to encoded form. It should also add any `Content-Transfer-Encoding` or other headers to the message object as necessary. The default encoding is base64. See the `email.encoders` module for a list of the built-in encoders.

`_params` are passed straight through to the base class constructor.

```python
class email.mime.audio.MIMEAudio(_audiodata, _subtype=None, _encoder=email.encoders.encode_base64, **_params)
Module: email.mime.audio
```
A subclass of `MIMENonMultipart`, the `MIMEAudio` class is used to create MIME message objects of major type `audio`. `_audiodata` is a string containing the raw audio data. If this data can be decoded by the standard Python module `sndhdr`, then the subtype will be automatically included in the `Content-Type` header. Otherwise you can explicitly specify the audio subtype via the `_subtype` argument. If the minor type could not be guessed and `_subtype` was not given, then `TypeError` is raised.

Optional `_encoder` is a callable (i.e. function) which will perform the actual encoding of the audio data for transport. This callable takes one argument, which is the `MIMEAudio` instance. It should use `get_payload()` and `set_payload()` to change the payload to encoded form. It should also add any `Content-Transfer-Encoding` or other headers to the message object as necessary. The default encoding is base64. See the `email.encoders` module for a list of the built-in encoders.

 `_params` are passed straight through to the base class constructor.

```python
class email.mime.image.MIMEImage(_imagedata, 
    _subtype=\None,  \encoder=email.encoders.encode_base64, 
    **\params)
```

Module: email.mime.image

A subclass of `MIMENonMultipart`, the `MIMEImage` class is used to create MIME message objects of major type `image`. `_imagedata` is a string containing the raw image data. If this data can be decoded by the standard Python module `imghdr`, then the subtype will be automatically included in the `Content-Type` header. Otherwise you can explicitly specify the image subtype via the `_subtype` argument. If the minor type could not be guessed and
_subtype was not given, then **TypeError** is raised.

Optional `_encoder` is a callable (i.e. function) which will perform the actual encoding of the image data for transport. This callable takes one argument, which is the **MIMEImage** instance. It should use `get_payload()` and `set_payload()` to change the payload to encoded form. It should also add any `Content-Transfer-Encoding` or other headers to the message object as necessary. The default encoding is base64. See the `email.encoders` module for a list of the built-in encoders.

`_params` are passed straight through to the **MIMEBase** constructor.

```python
class email.mime.message.MIMEMessage(_msg, _subtype='rfc822')
    Module: email.mime.message

A subclass of **MIMENonMultipart**, the **MIMEMessage** class is used to create MIME objects of main type **message**. `_msg` is used as the payload, and must be an instance of class **Message** (or a subclass thereof), otherwise a **TypeError** is raised.

Optional `_subtype` sets the subtype of the message; it defaults to **rfc822**.
```

```python
class email.mime.text.MIMEText(_text, _subtype='plain', _charset=None)
    Module: email.mime.text

A subclass of **MIMENonMultipart**, the **MIMEText** class is used to create MIME objects of major type **text**. `_text` is the string for the payload. `_subtype` is the minor type and defaults to **plain**. `_charset` is the character set of the text and is passed as an argument to the
**MIMENonMultipart** constructor; it defaults to **us-ascii** if the string contains only **ascii** codepoints, and **utf-8** otherwise.

Unless the _charset argument is explicitly set to None, the MIMEText object created will have both a **Content-Type** header with a _charset parameter, and a **Content-Transfer-Encoding** header. This means that a subsequent **set_payload** call will not result in an encoded payload, even if a charset is passed in the **set_payload** command. You can “reset” this behavior by deleting the **Content-Transfer-Encoding** header, after which a **set_payload** call will automatically encode the new payload (and add a new **Content-Transfer-Encoding** header).
19.1.7. email.header:
Internationalized headers
RFC 2822 is the base standard that describes the format of email
messages. It derives from the older RFC 822 standard which came
into widespread use at a time when most email was composed of
ASCII characters only. RFC 2822 is a specification written assuming
email contains only 7-bit ASCII characters.
Of course, as email has been deployed worldwide, it has become
internationalized, such that language specific character sets can now
be used in email messages. The base standard still requires email
messages to be transferred using only 7-bit ASCII characters, so a
slew of RFCs have been written describing how to encode email
containing non-ASCII characters into RFC 2822-compliant format.
These RFCs include RFC 2045, RFC 2046, RFC 2047, and RFC
2231. The email package supports these standards in its
email.header and email.charset modules.
If you want to include non-ASCII characters in your email headers, say
in the Subject or To fields, you should use the Header class and
assign the field in the Message object to an instance of Header
instead of using a string for the header value. Import the Header class
from the email.header module. For example:
>>>
>>>
>>>
>>>
>>>
>>>

from email.message import Message
from email.header import Header
msg = Message()
h = Header('p\xf6stal', 'iso-8859-1')
msg['Subject'] = h
msg.as_string()


Notice here how we wanted the Subject field to contain a non-ASCII character? We did this by creating a Header instance and passing in the character set that the byte string was encoded in. When the subsequent Message instance was flattened, the Subject field was properly RFC 2047 encoded. MIME-aware mail readers would show this header using the embedded ISO-8859-1 character.

Here is the Header class description:

```python
class email.header.Header(s=None, charset=None, maxlinelen=None, header_name=None, continuation_ws=' ', errors='strict')
```

Create a MIME-compliant header that can contain strings in different character sets.

Optional s is the initial header value. If None (the default), the initial header value is not set. You can later append to the header with `append()` method calls. s may be an instance of bytes or str, but see the `append()` documentation for semantics.

Optional charset serves two purposes: it has the same meaning as the charset argument to the `append()` method. It also sets the default character set for all subsequent `append()` calls that omit the charset argument. If charset is not provided in the constructor (the default), the us-ascii character set is used both as s's initial charset and as the default for subsequent `append()` calls.

The maximum line length can be specified explicitly via maxlinelen. For splitting the first line to a shorter value (to account for the field header which isn't included in s, e.g. Subject) pass in the name of the field in header_name. The default maxlinelen is 76, and the
default value for header_name is None, meaning it is not taken into account for the first line of a long, split header.

Optional continuation_ws must be RFC 2822-compliant folding whitespace, and is usually either a space or a hard tab character. This character will be prepended to continuation lines. continuation_ws defaults to a single space character.

Optional errors is passed straight through to the append() method.

**append** (s, charset=None, errors='strict')

Append the string s to the MIME header.

Optional charset, if given, should be a Charset instance (see email.charset) or the name of a character set, which will be converted to a Charset instance. A value of None (the default) means that the charset given in the constructor is used.

s may be an instance of bytes or str. If it is an instance of bytes, then charset is the encoding of that byte string, and a UnicodeError will be raised if the string cannot be decoded with that character set.

If s is an instance of str, then charset is a hint specifying the character set of the characters in the string.

In either case, when producing an RFC 2822-compliant header using RFC 2047 rules, the string will be encoded using the output codec of the charset. If the string cannot be encoded using the output codec, a UnicodeError will be raised.

Optional errors is passed as the errors argument to the decode
call if s is a byte string.

**encode**(splitchars=';', \t', maxlinelen=None, linesep='\n')

Encode a message header into an RFC-compliant format, possibly wrapping long lines and encapsulating non-ASCII parts in base64 or quoted-printable encodings.

Optional `splitchars` is a string containing characters which should be given extra weight by the splitting algorithm during normal header wrapping. This is in very rough support of RFC 2822's 'higher level syntactic breaks': split points preceded by a splitchar are preferred during line splitting, with the characters preferred in the order in which they appear in the string. Space and tab may be included in the string to indicate whether preference should be given to one over the other as a split point when other split chars do not appear in the line being split. Splitchars does not affect RFC 2047 encoded lines.

`maxlinelen`, if given, overrides the instance's value for the maximum line length.

`linesep` specifies the characters used to separate the lines of the folded header. It defaults to the most useful value for Python application code (\n), but \r\n can be specified in order to produce headers with RFC-compliant line separators.

*Changed in version 3.2: Added the linesep argument.*

The **Header** class also provides a number of methods to support standard operators and built-in functions.

**str**()

Returns an approximation of the **Header** as a string, using an
unlimited line length. All pieces are converted to unicode using the specified encoding and joined together appropriately. Any pieces with a charset of 'unknown-8bit' are decoded as ASCII using the 'replace' error handler.

*Changed in version 3.2:* Added handling for the 'unknown-8bit' charset.

```python
__eq__(other)
```
This method allows you to compare two `Header` instances for equality.

```python
__ne__(other)
```
This method allows you to compare two `Header` instances for inequality.

The `email.header` module also provides the following convenient functions.

```python
e-mail.header.decode_header(header)
```
Decode a message header value without converting the character set. The header value is in `header`.

This function returns a list of `(decoded_string, charset)` pairs containing each of the decoded parts of the header. `charset` is None for non-encoded parts of the header, otherwise a lower case string containing the name of the character set specified in the encoded string.

Here's an example:

```python
>>> from email.header import decode_header
>>> decode_header('=?iso-8859-1?q?p=F6stal?=
')
```
email.header.make_header(decoded_seq, maxlinelen=None, header_name=None, continuation_ws=' ')  
Create a Header instance from a sequence of pairs as returned by decode_header().

decode_header() takes a header value string and returns a sequence of pairs of the format (decoded_string, charset) where charset is the name of the character set.

This function takes one of those sequence of pairs and returns a Header instance. Optional maxlinelen, header_name, and continuation_ws are as in the Header constructor.
19.1.8. **email.charset**: Representing character sets

This module provides a class `Charset` for representing character sets and character set conversions in email messages, as well as a character set registry and several convenience methods for manipulating this registry. Instances of `Charset` are used in several other modules within the `email` package.

Import this class from the `email.charset` module.

```python
class email.charset.Charset(input_charset=DEFAULT_CHARSET)

    Map character sets to their email properties.

    This class provides information about the requirements imposed on email for a specific character set. It also provides convenience routines for converting between character sets, given the availability of the applicable codecs. Given a character set, it will do its best to provide information on how to use that character set in an email message in an RFC-compliant way.

    Certain character sets must be encoded with quoted-printable or base64 when used in email headers or bodies. Certain character sets must be converted outright, and are not allowed in email.

    Optional `input_charset` is as described below; it is always coerced to lower case. After being alias normalized it is also used as a lookup into the registry of character sets to find out the header encoding, body encoding, and output conversion codec to be used for the character set. For example, if `input_charset` is iso-8859-
1, then headers and bodies will be encoded using quoted-printable and no output conversion codec is necessary. If input_charset is euc-jp, then headers will be encoded with base64, bodies will not be encoded, but output text will be converted from the euc-jp character set to the iso-2022-jp character set.

Charset instances have the following data attributes:

**input_charset**
The initial character set specified. Common aliases are converted to their *official* email names (e.g. latin_1 is converted to iso-8859-1). Defaults to 7-bit us-ascii.

**header_encoding**
If the character set must be encoded before it can be used in an email header, this attribute will be set to Charset.QP (for quoted-printable), Charset.BASE64 (for base64 encoding), or Charset.SHORTEST for the shortest of QP or BASE64 encoding. Otherwise, it will be None.

**body_encoding**
Same as header_encoding, but describes the encoding for the mail message's body, which indeed may be different than the header encoding. Charset.SHORTEST is not allowed for body_encoding.

**output_charset**
Some character sets must be converted before they can be used in email headers or bodies. If the input_charset is one of them, this attribute will contain the name of the character set output will be converted to. Otherwise, it will be None.
**input_codec**

The name of the Python codec used to convert the `input_charset` to Unicode. If no conversion codec is necessary, this attribute will be None.

**output_codec**

The name of the Python codec used to convert Unicode to the `output_charset`. If no conversion codec is necessary, this attribute will have the same value as the `input_codec`.

*Charset* instances also have the following methods:

**get_body_encoding()**

Return the content transfer encoding used for body encoding.

This is either the string `quoted-printable` or `base64` depending on the encoding used, or it is a function, in which case you should call the function with a single argument, the Message object being encoded. The function should then set the `Content-Transfer-Encoding` header itself to whatever is appropriate.

Returns the string `quoted-printable` if `body_encoding` is `QP`, returns the string `base64` if `body_encoding` is `BASE64`, and returns the string `7bit` otherwise.

**get_output_charset()**

Return the output character set.

This is the `output_charset` attribute if that is not None, otherwise it is `input_charset`.

**header_encode**(string)
Header-encode the string `string`.

The type of encoding (base64 or quoted-printable) will be based on the `header_encoding` attribute.

**header_encode_lines**(`string`, `maxlengths`)

Header-encode a `string` by converting it first to bytes.

This is similar to `header_encode()` except that the string is fit into maximum line lengths as given by the argument `maxlengths`, which must be an iterator: each element returned from this iterator will provide the next maximum line length.

**body_encode**(`string`)

Body-encode the string `string`.

The type of encoding (base64 or quoted-printable) will be based on the `body_encoding` attribute.

The `Charset` class also provides a number of methods to support standard operations and built-in functions.

__**str**__()  
Returns `input_charset` as a string coerced to lower case. __**repr**__() is an alias for __**str**__().

__**eq**__(other)

This method allows you to compare two `Charset` instances for equality.

__**ne**__(other)

This method allows you to compare two `Charset` instances for inequality.
The `email.charset` module also provides the following functions for adding new entries to the global character set, alias, and codec registries:

```python
email.charset.add_charset(charset, header_enc=None, body_enc=None, output_charset=None)
```

Add character properties to the global registry.

`charset` is the input character set, and must be the canonical name of a character set.

Optional `header_enc` and `body_enc` is either `Charset.QP` for quoted-printable, `Charset.BASE64` for base64 encoding, `Charset.SHORTEST` for the shortest of quoted-printable or base64 encoding, or None for no encoding. `SHORTEST` is only valid for `header_enc`. The default is None for no encoding.

Optional `output_charset` is the character set that the output should be in. Conversions will proceed from input charset, to Unicode, to the output charset when the method `Charset.convert()` is called. The default is to output in the same character set as the input.

Both `input_charset` and `output_charset` must have Unicode codec entries in the module’s character set-to-codec mapping; use `add_codec()` to add codecs the module does not know about. See the `codecs` module’s documentation for more information.

The global character set registry is kept in the module global dictionary `CHARSETS`.

```python
email.charset.add_alias(alias, canonical)
```

Add a character set alias. `alias` is the alias name, e.g. `latin-1`. 
canonical is the character set’s canonical name, e.g. iso-8859-1.

The global charset alias registry is kept in the module global dictionary ALIASES.

email.charset.add_codec(charset, codecname)

Add a codec that map characters in the given character set to and from Unicode.

charset is the canonical name of a character set. codecname is the name of a Python codec, as appropriate for the second argument to the str’s encode() method
19.1. **email** — An email and MIME handling package
19.1.9. **email.encoders:** Encoders

When creating `Message` objects from scratch, you often need to encode the payloads for transport through compliant mail servers. This is especially true for `image/*` and `text/*` type messages containing binary data.

The `email` package provides some convenient encodings in its `encoders` module. These encoders are actually used by the `MIMEAudio` and `MIMEImage` class constructors to provide default encodings. All encoder functions take exactly one argument, the message object to encode. They usually extract the payload, encode it, and reset the payload to this newly encoded value. They should also set the `Content-Transfer-Encoding` header as appropriate.

Note that these functions are not meaningful for a multipart message. They must be applied to individual subparts instead, and will raise a `TypeError` if passed a message whose type is multipart.

Here are the encoding functions provided:

**email.encoders.** `encode_quopri(msg)`

Encodes the payload into quoted-printable form and sets the `Content-Transfer-Encoding` header to `quoted-printable` [1]. This is a good encoding to use when most of your payload is normal printable data, but contains a few unprintable characters.

**email.encoders.** `encode_base64(msg)`

Encodes the payload into base64 form and sets the `Content-Transfer-Encoding` header to `base64`. This encoding is useful for binary data that cannot be reasonably represented in ASCII.
**Transfer-Encoding** header to base64. This is a good encoding to use when most of your payload is unprintable data since it is a more compact form than quoted-printable. The drawback of base64 encoding is that it renders the text non-human readable.

email.encoders.**encode_7or8bit**(msg)

This doesn’t actually modify the message’s payload, but it does set the **Content-Transfer-Encoding** header to either 7bit or 8bit as appropriate, based on the payload data.

email.encoders.**encode_noop**(msg)

This does nothing; it doesn’t even set the **Content-Transfer-Encoding** header.

**Footnotes**

[1] Note that encoding with **encode_quopri()** also encodes all tabs and space characters in the data.
19. Internet Data Handling  19.1. **email** — An email and MIME handling package

```python
# Placeholder for code
```
19.1.10. **email.errors:**
Exception and Defect classes

The following exception classes are defined in the `email.errors` module:

*exception* `email.errors.MessageError`

This is the base class for all exceptions that the `email` package can raise. It is derived from the standard `Exception` class and defines no additional methods.

*exception* `email.errors.MessageParseError`

This is the base class for exceptions raised by the `Parser` class. It is derived from `MessageError`.

*exception* `email.errors.HeaderParseError`

Raised under some error conditions when parsing the RFC 2822 headers of a message, this class is derived from `MessageParseError`. It can be raised from the `Parser.parse` or `Parser.parsestr` methods.

Situations where it can be raised include finding an envelope header after the first RFC 2822 header of the message, finding a continuation line before the first RFC 2822 header is found, or finding a line in the headers which is neither a header or a continuation line.

*exception* `email.errors.BoundaryError`

Raised under some error conditions when parsing the RFC 2822 headers of a message, this class is derived from...
**MessageParseError.** It can be raised from the `Parser.parse` or `Parser.parsestr` methods.

Situations where it can be raised include not being able to find the starting or terminating boundary in a `multipart/*` message when strict parsing is used.

**exception** `email.errors.MultipartConversionError`

Raised when a payload is added to a `Message` object using `add_payload()`, but the payload is already a scalar and the message's `Content-Type` main type is not either `multipart` or missing. `MultipartConversionError` multiply inherits from `MessageError` and the built-in `TypeError`.

Since `Message.add_payload()` is deprecated, this exception is rarely raised in practice. However the exception may also be raised if the `attach()` method is called on an instance of a class derived from `MIMENonMultipart` (e.g. `MIMEImage`).

Here's the list of the defects that the `FeedParser` can find while parsing messages. Note that the defects are added to the message where the problem was found, so for example, if a message nested inside a `multipart/alternative` had a malformed header, that nested message object would have a defect, but the containing messages would not.

All defect classes are subclassed from `email.errors.MessageDefect`, but this class is *not* an exception!

- **NoBoundaryInMultipartDefect** – A message claimed to be a multipart, but had no `boundary` parameter.
- **StartBoundaryNotFoundDefect** – The start boundary
claimed in the *Content-Type* header was never found.

- **CloseBoundaryNotFoundDefect** – A start boundary was found, but no corresponding close boundary was ever found.

  *New in version 3.3.*

- **FirstHeaderLineIsContinuationDefect** – The message had a continuation line as its first header line.

- **MisplacedEnvelopeHeaderDefect** - A “Unix From” header was found in the middle of a header block.

- **MissingHeaderBodySeparatorDefect** - A line was found while parsing headers that had no leading white space but contained no ‘:’. Parsing continues assuming that the line represents the first line of the body.

  *New in version 3.3.*

- **MalformedHeaderDefect** – A header was found that was missing a colon, or was otherwise malformed.

  *Deprecated since version 3.3:* This defect has not been used for several Python versions.

- **MultipartInvariantViolationDefect** – A message claimed to be a *multipart*, but no subparts were found. Note that when a message has this defect, its *is_multipart()* method may return false even though its content type claims to be *multipart*.

- **InvalidBase64PaddingDefect** – When decoding a block of
base64 encoded bytes, the padding was not correct. Enough padding is added to perform the decode, but the resulting decoded bytes may be invalid.

- **InvalidBase64CharactersDefect** – When decoding a block of base64 encoded bytes, characters outside the base64 alphabet were encountered. The characters are ignored, but the resulting decoded bytes may be invalid.
19.1. `email` — An email and MIME handling package
19.1.11. **email.utils:**

Miscellaneous utilities

There are several useful utilities provided in the `email.utils` module:

- **email.utils.quote(str)**
  
  Return a new string with backslashes in *str* replaced by two backslashes, and double quotes replaced by backslash-double quote.

- **email.utils.unquote(str)**
  
  Return a new string which is an *unquoted* version of *str*. If *str* ends and begins with double quotes, they are stripped off. Likewise if *str* ends and begins with angle brackets, they are stripped off.

- **email.utils.parseaddr(address)**
  
  Parse address – which should be the value of some address-containing field such as *To* or *Cc* – into its constituent *realname* and *email address* parts. Returns a tuple of that information, unless the parse fails, in which case a 2-tuple of ('', '') is returned.

- **email.utils.formataddr(pair, charset='utf-8')**
  
  The inverse of `parseaddr()`, this takes a 2-tuple of the form *(realname, email_address)* and returns the string value suitable for a *To* or *Cc* header. If the first element of *pair* is false, then the second element is returned unmodified.

  Optional *charset* is the character set that will be used in the **RFC 2047** encoding of the *realname* if the *realname* contains non-
ASCII characters. Can be an instance of \texttt{str} or a \texttt{Charset}. Defaults to \texttt{utf-8}.

\textit{Changed in version 3.3: Added the charset option.}

estutils.\texttt{getaddresses(fieldvalues)}

This method returns a list of 2-tuples of the form returned by \texttt{parseaddr()}. \texttt{fieldvalues} is a sequence of header field values as might be returned by \texttt{Message.get_all}. Here's a simple example that gets all the recipients of a message:

\begin{verbatim}
from email.utils import getaddresses
tos = msg.get_all('to', [])
ccs = msg.get_all('cc', [])
resent_tos = msg.get_all('resent-to', [])
resent_ccs = msg.get_all('resent-cc', [])
all_recipients = getaddresses(tos + ccs + resent_tos + resent_ccs)
\end{verbatim}

\textit{email.utils.parsedate(date)}

Attempts to parse a date according to the rules in \texttt{RFC 2822}. However, some mailers don't follow that format as specified, so \texttt{parsedate()} tries to guess correctly in such cases. \texttt{date} is a string containing an \texttt{RFC 2822} date, such as "Mon, 20 Nov 1995 19:12:08 -0500". If it succeeds in parsing the date, \texttt{parsedate()} returns a 9-tuple that can be passed directly to \texttt{time.mktime()}; otherwise None will be returned. Note that indexes 6, 7, and 8 of the result tuple are not usable.

\textit{email.utils.parsedate_tz(date)}

Performs the same function as \texttt{parsedate()}, but returns either None or a 10-tuple; the first 9 elements make up a tuple that can
be passed directly to `time.mktime()`, and the tenth is the offset of the date's timezone from UTC (which is the official term for Greenwich Mean Time) [1]. If the input string has no timezone, the last element of the tuple returned is None. Note that indexes 6, 7, and 8 of the result tuple are not usable.

```
be passed directly to `time.mktime()`, and the tenth is the offset of the date's timezone from UTC (which is the official term for Greenwich Mean Time) [1]. If the input string has no timezone, the last element of the tuple returned is None. Note that indexes 6, 7, and 8 of the result tuple are not usable.

email.utils.parsedate_to_datetime(date)
The inverse of `format_datetime()`. Performs the same function as `parsedate()`, but on success returns a `datetime`. If the input date has a timezone of `-0000`, the `datetime` will be a naive `datetime`, and if the date is conforming to the RFCs it will represent a time in UTC but with no indication of the actual source timezone of the message the date comes from. If the input date has any other valid timezone offset, the `datetime` will be an aware `datetime` with the corresponding a `timezone tzinfo`.

New in version 3.3.

email.utils.mktime_tz(tuple)
Turn a 10-tuple as returned by `parsedate_tz()` into a UTC timestamp. If the timezone item in the tuple is None, assume local time. Minor deficiency: `mktime_tz()` interprets the first 8 elements of `tuple` as a local time and then compensates for the timezone difference. This may yield a slight error around changes in daylight savings time, though not worth worrying about for common use.

email.utils.formatdate(timeval=None, localtime=False, usegmt=False)
Returns a date string as per RFC 2822, e.g.:

```
Fri, 09 Nov 2001 01:08:47 -0000
```
Optional \textit{timeval} if given is a floating point time value as accepted by \texttt{time.gmtime()} and \texttt{time.localtime()}, otherwise the current time is used.

Optional \textit{localtime} is a flag that when \texttt{True}, interprets \texttt{timeval}, and returns a date relative to the local timezone instead of UTC, properly taking daylight savings time into account. The default is \texttt{False} meaning UTC is used.

Optional \textit{usegmt} is a flag that when \texttt{True}, outputs a date string with the timezone as an ascii string \texttt{GMT}, rather than a numeric \texttt{-0000}. This is needed for some protocols (such as HTTP). This only applies when \texttt{localtime} is \texttt{False}. The default is \texttt{False}.

\texttt{email.utils.format_datetime(dt, usegmt=False)}

Like \texttt{formatdate}, but the input is a \texttt{datetime} instance. If it is a naive \texttt{datetime}, it is assumed to be “UTC with no information about the source timezone”, and the conventional \texttt{-0000} is used for the timezone. If it is an aware \texttt{datetime}, then the numeric timezone offset is used. If it is an aware timezone with offset zero, then \textit{usegmt} may be set to \texttt{True}, in which case the string \texttt{GMT} is used instead of the numeric timezone offset. This provides a way to generate standards conformant HTTP date headers.

\textit{New in version 3.3.}

\texttt{email.utils.localtime(dt=None)}

Return local time as an aware \texttt{datetime} object. If called without arguments, return current time. Otherwise \texttt{dt} argument should be a \texttt{datetime} instance, and it is converted to the local time zone according to the system time zone database. If \texttt{dt} is naive (that is, \texttt{dt.tzinfo} is \texttt{None}), it is assumed to be in local time. In this
case, a positive or zero value for isdst causes localtime to presume initially that summer time (for example, Daylight Saving Time) is or is not (respectively) in effect for the specified time. A negative value for isdst causes the localtime to attempt to divine whether summer time is in effect for the specified time.

*New in version 3.3.*

**email.utils.make_msgid(idstring=None, domain=None)**

Returns a string suitable for an RFC 2822-compliant Message-ID header. Optional idstring if given, is a string used to strengthen the uniqueness of the message id. Optional domain if given provides the portion of the msgid after the '@'. The default is the local hostname. It is not normally necessary to override this default, but may be useful certain cases, such as a constructing distributed system that uses a consistent domain name across multiple hosts.

*Changed in version 3.2:* Added the domain keyword.

**email.utils.decode_rfc2231(s)**

Decode the string s according to RFC 2231.

**email.utils.encode_rfc2231(s, charset=None, language=None)**

Encode the string s according to RFC 2231. Optional charset and language, if given is the character set name and language name to use. If neither is given, s is returned as-is. If charset is given but language is not, the string is encoded using the empty string for language.

**email.utils.collapse_rfc2231_value(value, errors='replace', fallback_charset='us-ascii')**

When a header parameter is encoded in RFC 2231 format,
Message.get_param may return a 3-tuple containing the character set, language, and value. 
collapse_rfc2231_value() turns this into a unicode string. Optional errors is passed to the errors argument of str's encode() method; it defaults to 'replace'. Optional fallback_charset specifies the character set to use if the one in the RFC 2231 header is not known by Python; it defaults to 'us-ascii'.

For convenience, if the value passed to collapse_rfc2231_value() is not a tuple, it should be a string and it is returned unquoted.

eemail.utils.decode_params(params)

Decode parameters list according to RFC 2231. params is a sequence of 2-tuples containing elements of the form (content-type, string-value).

Footnotes

[1] Note that the sign of the timezone offset is the opposite of the sign of the time.timezone variable for the same timezone; the latter variable follows the POSIX standard while this module follows RFC 2822.
19.1. **email** — An email and MIME handling package
19.1.12. **email.iterators:** Iterators

Iterating over a message object tree is fairly easy with the `Message.walk` method. The `email.iterators` module provides some useful higher level iterations over message object trees.

```python
email.iterators.body_line_iterator(msg, decode=False)
```

This iterates over all the payloads in all the subparts of `msg`, returning the string payloads line-by-line. It skips over all the subpart headers, and it skips over any subpart with a payload that isn’t a Python string. This is somewhat equivalent to reading the flat text representation of the message from a file using `readline()`, skipping over all the intervening headers.

Optional `decode` is passed through to `Message.get_payload`.

```python
email.iterators.typed_subpart_iterator(msg, maintype='text', subtype=None)
```

This iterates over all the subparts of `msg`, returning only those subparts that match the MIME type specified by `maintype` and `subtype`.

Note that `subtype` is optional; if omitted, then subpart MIME type matching is done only with the main type. `maintype` is optional too; it defaults to `text`.

Thus, by default `typed_subpart_iterator()` returns each subpart that has a MIME type of `text/*`.
The following function has been added as a useful debugging tool. It should \textit{not} be considered part of the supported public interface for the package.

\texttt{email.iterators._structure}(msg, fp=None, level=0, \textit{include_default}=False)

Prints an indented representation of the content types of the message object structure. For example:

\begin{verbatim}
>>> msg = email.message_from_file(somefile)
>>> _structure(msg)
multipart/mixed
  text/plain
  text/plain
  multipart/digest
    message/rfc822
      text/plain
    message/rfc822
      text/plain
    message/rfc822
      text/plain
    message/rfc822
      text/plain
    message/rfc822
      text/plain
  text/plain
\end{verbatim}

Optional \texttt{fp} is a file-like object to print the output to. It must be suitable for Python's \texttt{print()} function. \textit{level} is used internally. \textit{include_default}, if true, prints the default type as well.
19.1. **email** — An email and MIME handling package
19.1.13. **email**: Examples

Here are a few examples of how to use the `email` package to read, write, and send simple email messages, as well as more complex MIME messages.

First, let's see how to create and send a simple text message:

```python
# Import smtplib for the actual sending function
import smtplib

# Import the email modules we'll need
from email.mime.text import MIMEText

# Open a plain text file for reading.  For this example, assume
# the text file contains only ASCII characters.
fp = open(textfile, 'rb')
# Create a text/plain message
msg = MIMEText(fp.read())
fp.close()

# me == the sender's email address
# you == the recipient's email address
msg['Subject'] = 'The contents of %s' % textfile
msg['From'] = me
msg['To'] = you

# Send the message via our own SMTP server.
s = smtplib.SMTP('localhost')
s.send_message(msg)
s.quit()
```

And parsing RFC822 headers can easily be done by the
parse(filename) or parsestr(message_as_string) methods of the Parser() class:

```python
# Import the email modules we'll need
from email.parser import Parser

# If the e-mail headers are in a file, uncomment this line:
# headers = Parser().parse(open(messagefile, 'r'))

# Or for parsing headers in a string, use:
headers = Parser().parsestr('From: <user@example.com>
  To: <someone_else@example.com>
  Subject: Test message
  
  Body would go here')

# Now the header items can be accessed as a dictionary:
print('To: %s' % headers['to'])
print('From: %s' % headers['from'])
print('Subject: %s' % headers['subject'])
```

Here's an example of how to send a MIME message containing a bunch of family pictures that may be residing in a directory:

```python
# Import smtplib for the actual sending function
import smtplib

# Here are the email package modules we'll need
from email.mime.image import MIMEImage
from email.mime.multipart import MIMEMultipart

COMMASPACE = ', '

# Create the container (outer) email message.
msg = MIMEMultipart()
```
msg['Subject'] = 'Our family reunion'
# me == the sender's email address
# family = the list of all recipients' email addresses
msg['From'] = me
msg['To'] = COMMASPACE.join(family)
msg.preamble = 'Our family reunion'

# Assume we know that the image files are all in PNG format
for file in pngfiles:
    # Open the files in binary mode. Let the MIMEImage class automatically
    # guess the specific image type.
    fp = open(file, 'rb')
    img = MIMEImage(fp.read())
    fp.close()
    msg.attach(img)

# Send the email via our own SMTP server.
s = smtplib.SMTP('localhost')
s.send_message(msg)
s.quit()

Here's an example of how to send the entire contents of a directory as an email message: [1]

#!/usr/bin/env python3

"""Send the contents of a directory as a MIME message""

import os
import sys
import smtplib
# For guessing MIME type based on file name extension
import mimetypes

from optparse import OptionParser
from email import encoders
from email.message import Message
from email.mime.audio import MIMEAudio
from email.mime.base import MIMEBase
from email.mime.image import MIMEImage
from email.mime.multipart import MIMEMultipart
from email.mime.text import MIMEText

COMMASPACE = ',', '

def main():
    parser = OptionParser(usage="""\nSend the contents of a directory as a MIME message.

Usage: %prog [options]

Unless the -o option is given, the email is sent by SMTP server, which then does the normal delivery process. Your local machine must be running an SMTP server. """
    parser.add_option('-d', '--directory',
                      type='string', action='store',
                      help='Mail the contents of the directory, otherwise use the current directory. Only the regular files in the directory are sent, and we don’t recurse to subdirectories.'"
                      )
    parser.add_option('-o', '--output',
                      type='string', action='store',
                      help='Print the composed message to FILE instead of sending the message to the SMTP server.'"
                      )
    parser.add_option('-s', '--sender',
                      type='string', action='store',
                      help='The value of the From: header (required)'"
                      )
    parser.add_option('-r', '--recipient',
                      type='string', action='append',
                      default=[], dest='recipients',
                      )
opts, args = parser.parse_args()
if not opts.sender or not opts.recipients:
    parser.print_help()
sys.exit(1)
directory = opts.directory
if not directory:
directory = '.'
# Create the enclosing (outer) message
outer = MIMEMultipart()
outer['Subject'] = 'Contents of directory %s' % outer['To'] = COMMASPACE.join(opts.recipients)
outer['From'] = opts.sender
outer.preamble = 'You will not see this in a MIME-aware mail reader.'
for filename in os.listdir(directory):
    path = os.path.join(directory, filename)
    if not os.path.isfile(path):
        continue
    # Guess the content type based on the file's
    # will be ignored, although we should check # gzip'd or compressed files.
    ctype, encoding = mimetypes.guess_type(path)
    if ctype is None or encoding is not None:
        # No guess could be made, or the file is
        # use a generic bag-of-bits type.
        ctype = 'application/octet-stream'
    maintype, subtype = ctype.split('/', 1)
    if maintype == 'text':
        fp = open(path)
        # Note: we should handle calculating the
        msg = MIMEText(fp.read(), _subtype=subtype)
        fp.close()
    elif maintype == 'image':
        fp = open(path, 'rb')
        msg = MIMEImage(fp.read(), _subtype=subtype)
        fp.close()
elif maintype == 'audio':
    fp = open(path, 'rb')
    msg = MIMEAudio(fp.read(), _subtype=subtype)
    fp.close()
else:
    fp = open(path, 'rb')
    msg = MIMEBase(maintype, subtype)
    msg.set_payload(fp.read())
    fp.close()
    # Encode the payload using Base64
    encoders.encode_base64(msg)
    # Set the filename parameter
    msg.add_header('Content-Disposition', 'attachment')
    outer.attach(msg)
    # Now send or store the message
    composed = outer.as_string()
    if opts.output:
        fp = open(opts.output, 'w')
        fp.write(composed)
        fp.close()
    else:
        s = smtplib.SMTP('localhost')
        s.sendmail(opts.sender, opts.recipients, composed)
        s.quit()

if __name__ == '__main__':
    main()

Here's an example of how to unpack a MIME message like the one above, into a directory of files:

#!/usr/bin/env python3

"""Unpack a MIME message into a directory of files."""
import os
import sys
import email
import errno
import mimetypes

from optparse import OptionParser

def main():
    parser = OptionParser(usage="""Unpack a MIME message into a directory of files."
    Usage: %prog [options] msgfile """
    parser.add_option('-d', '--directory',
                      type='string', action='store',
                      help="""Unpack the MIME message into the named directory, which will be created if it doesn't already exist."""
    )
    opts, args = parser.parse_args()
    if not opts.directory:
        parser.print_help()
        sys.exit(1)

    try:
        msgfile = args[0]
    except IndexError:
        parser.print_help()
        sys.exit(1)

    try:
        os.mkdir(opts.directory)
    except OSError as e:
        # Ignore directory exists error
        if e.errno != errno.EEXIST:
            raise
fp = open(msgfile)
msg = email.message_from_file(fp)
fp.close()

counter = 1
for part in msg.walk():
    # multipart/* are just containers
    if part.get_content_maintype() == 'multipart':
        continue
    # Applications should really sanitize the given
    # email message can't be used to overwrite important
    filename = part.get_filename()
    if not filename:
        ext = mimetypes.guess_extension(part.get_content_type())
        if not ext:
            # Use a generic bag-of-bits extension
            ext = '.bin'
        filename = 'part-%03d%s' % (counter, ext)
    counter += 1
    fp = open(os.path.join(opts.directory, filename))
    fp.write(part.get_payload(decode=True))
    fp.close()

if __name__ == '__main__':
    main()
from email.mime.text import MIMEText

# me == my email address
# you == recipient's email address
me = "my@email.com"
you = "your@email.com"

# Create message container - the correct MIME type is multipart/alternative.
msg = MIME_Multipart('alternative')
msg['Subject'] = "Link"
msg['From'] = me
msg['To'] = you

# Create the body of the message (a plain-text and an HTML version).
text = "Hi!
How are you?
Here is the link you wanted:

<html>
<head></head>
<body>
<p>Hi!<br>
How are you?<br>
Here is the <a href="http://www.python.org">link</a> you wanted.</p>
</body>
</html>

# Record the MIME types of both parts - text/plain and text/html.
part1 = MIMEText(text, 'plain')
part2 = MIMEText(html, 'html')

# Attach parts into message container.
# According to RFC 2046, the last part of a multipart message, in this case
# the HTML message, is best and preferred.
msg.attach(part1)
msg.attach(part2)
Send the message via local SMTP server.

```python
s = smtplib.SMTP('localhost')
# sendmail function takes 3 arguments: sender's address and message to send - here it is sent as one string.
s.sendmail(me, you, msg.as_string())
s.quit()
```

19.2. json — JSON encoder and decoder

JSON (JavaScript Object Notation), specified by RFC 4627, is a lightweight data interchange format based on a subset of JavaScript syntax (ECMA-262 3rd edition).

json exposes an API familiar to users of the standard library marshal and pickle modules.

Encoding basic Python object hierarchies:

```python
>>> import json
>>> json.dumps(['foo', {'bar': ('baz', None, 1.0, 2), 'foo': {"bar": ["baz", null, 1.0, 2)}}])
'"foo", {"bar": ["baz", null, 1.0, 2]})'
>>> print(json.dumps("foo\bar"))
"foo\bar"
>>> print(json.dumps('\u1234'))
'\u1234'
>>> print(json.dumps('\'))
'\'
>>> print(json.dumps({'c': 0, 'b': 0, 'a': 0}, sort_keys=True))
'"a": 0, "b": 0, "c": 0}
>>> from io import StringIO
>>> io = StringIO()
>>> json.dump(['streaming API'], io)
>>> io.getvalue()
'"streaming API"'
```

Compact encoding:

```python
>>> import json
```
Pretty printing:

```python
>>> import json
>>> print(json.dumps({'4': 5, '6': 7}, sort_keys=True,
                   indent=4, separators=(',', ': '))

{   "4": 5,
    "6": 7
}
```

Decoding JSON:

```python
>>> import json
>>> json.loads('"["foo", {"bar": ["baz", null, 1.0, 2]}
            ["foo", {"bar": ["baz", None, 1.0, 2]]}
>>> json.loads('""foo"\"bar"')
"foo\x08ar"
>>> from io import StringIO
>>> io = StringIO('"["streaming API"]"
>>> json.load(io)
['streaming API']
```

Specializing JSON object decoding:

```python
>>> import json
>>> def as_complex(dct):
...     if '__complex__' in dct:
...         return complex(dct['real'], dct['imag'])
...     return dct
...
>>> json.loads('{"__complex__": true, "real": 1, "imag": 2}')
(1+2j)
```
object_hook=as_complex)
(1+2j)

>>> import decimal
>>> json.loads('1.1', parse_float=decimal.Decimal)
Decimal('1.1')

Extending JSONEncoder:

>>> import json
>>> class ComplexEncoder(json.JSONEncoder):
...     def default(self, obj):
...         if isinstance(obj, complex):
...             return [obj.real, obj.imag]
...         # Let the base class default method raise
...         return json.JSONEncoder.default(self, obj)

>>> json.dumps(2 + 1j, cls=ComplexEncoder)
'[2.0, 1.0]'
>>> ComplexEncoder().encode(2 + 1j)
'[2.0, 1.0]'
>>> list(ComplexEncoder().iterencode(2 + 1j))
['[2.0', ',', '1.0', ',', ']']

Using json.tool from the shell to validate and pretty-print:

$ echo '{"json":"obj"}' | python -mjson.tool
{
    "json": "obj"
}
$ echo '{1.2:3.4}' | python -mjson.tool
Expecting property name enclosed in double quotes: }

Note: JSON is a subset of YAML 1.2. The JSON produced by this module’s default settings (in particular, the default separators value)
is also a subset of YAML 1.0 and 1.1. This module can thus also be used as a YAML serializer.
19.2.1. Basic Usage

json.dump(obj, fp, skipkeys=False, ensure_ascii=True, check_circular=True, allow_nan=True, cls=None, indent=None, separators=None, default=None, sort_keys=False, **kw)

Serialize obj as a JSON formatted stream to fp (a supporting file-like object) using this conversion table.

If skipkeys is True (default: False), then dict keys that are not of a basic type (str, int, float, bool, None) will be skipped instead of raising a TypeError.

The json module always produces str objects, not bytes objects. Therefore, fp.write() must support str input.

If ensure_ascii is True (the default), the output is guaranteed to have all incoming non-ASCII characters escaped. If ensure_ascii is False, these characters will be output as-is.

If check_circular is False (default: True), then the circular reference check for container types will be skipped and a circular reference will result in an OverflowError (or worse).

If allow_nan is False (default: True), then it will be a ValueError to serialize out of range float values (nan, inf, -inf) in strict compliance of the JSON specification, instead of using the JavaScript equivalents (NaN, Infinity, -Infinity).

If indent is a non-negative integer or string, then JSON array elements and object members will be pretty-printed with that indent level. An indent level of 0, negative, or "" will only insert newlines.
None (the default) selects the most compact representation. Using a positive integer indent indents that many spaces per level. If `indent` is a string (such as "\t"), that string is used to indent each level.

*Changed in version 3.2:* Allow strings for `indent` in addition to integers.

**Note:** Since the default item separator is ',', the output might include trailing whitespace when `indent` is specified. You can use `separators=('',':')` to avoid this.

If `separators` is an `(item_separator, dict_separator)` tuple, then it will be used instead of the default `('',':')` separators. `('',':')` is the most compact JSON representation.

`default(obj)` is a function that should return a serializable version of `obj` or raise `TypeError`. The default simply raises `TypeError`.

If `sort_keys` is True (default: False), then the output of dictionaries will be sorted by key.

To use a custom `JSONEncoder` subclass (e.g. one that overrides the `default()` method to serialize additional types), specify it with the `cls` kwarg; otherwise `JSONEncoder` is used.

```
json.dumps(obj, skipkeys=False, ensure_ascii=True,
check_circular=True, allow_nan=True, cls=None, indent=None,
separators=None, default=None, sort_keys=False, **kw)
```

Serialize `obj` to a JSON formatted `str` using this *conversion table*. The arguments have the same meaning as in `dump()`.
**Note:** Unlike **pickle** and **marshal**, JSON is not a framed protocol, so trying to serialize multiple objects with repeated calls to **dump()** using the same **fp** will result in an invalid JSON file.

**Note:** Keys in key/value pairs of JSON are always of the type **str**. When a dictionary is converted into JSON, all the keys of the dictionary are coerced to strings. As a result of this, if a dictionary is converted into JSON and then back into a dictionary, the dictionary may not equal the original one. That is, `loads(dumps(x)) != x` if `x` has non-string keys.

```python
json.load(fp, cls=None, object_hook=None, parse_float=None, parse_int=None, parse_constant=None, object_pairs_hook=None, **kw)
```

Deserialize **fp** (a `.read()`-supporting **file-like object** containing a JSON document) to a Python object using this **conversion table**.

**object_hook** is an optional function that will be called with the result of any object literal decoded (a **dict**). The return value of **object_hook** will be used instead of the **dict**. This feature can be used to implement custom decoders (e.g. **JSON-RPC** class hinting).

**object_pairs_hook** is an optional function that will be called with the result of any object literal decoded with an ordered list of pairs. The return value of **object_pairs_hook** will be used instead of the **dict**. This feature can be used to implement custom decoders that rely on the order that the key and value pairs are decoded (for example, **collections.OrderedDict()** will remember the order of insertion). If **object_hook** is also defined, the **object_pairs_hook** takes priority.
Changed in version 3.1: Added support for `object_pairs_hook`.

`parse_float`, if specified, will be called with the string of every JSON float to be decoded. By default, this is equivalent to `float(num_str)`. This can be used to use another datatype or parser for JSON floats (e.g. `decimal.Decimal`).

`parse_int`, if specified, will be called with the string of every JSON int to be decoded. By default, this is equivalent to `int(num_str)`. This can be used to use another datatype or parser for JSON integers (e.g. `float`).

`parse_constant`, if specified, will be called with one of the following strings: '-Infinity', 'Infinity', 'NaN'. This can be used to raise an exception if invalid JSON numbers are encountered.

Changed in version 3.1: `parse_constant` doesn’t get called on ‘null’, ‘true’, ‘false’ anymore.

To use a custom `JSONDecoder` subclass, specify it with the `cls` kwarg; otherwise `JSONDecoder` is used. Additional keyword arguments will be passed to the constructor of the class.

```
json.loads(s, encoding=None, cls=None, object_hook=None,
parse_float=None, parse_int=None, parse_constant=None,
object_pairs_hook=None, **kw)
```

Deserialize `s` (a `str` instance containing a JSON document) to a Python object using this `conversion table`.

The other arguments have the same meaning as in `load()`, except `encoding` which is ignored and deprecated.
19.2.2. Encoders and Decoders

```python
class json.JSONDecoder(object_hook=None, parse_float=None,
parse_int=None, parse_constant=None, strict=True,
object_pairs_hook=None)
```

Simple JSON decoder. Performs the following translations in decoding by default:

<table>
<thead>
<tr>
<th>JSON</th>
<th>Python</th>
</tr>
</thead>
<tbody>
<tr>
<td>object</td>
<td>dict</td>
</tr>
<tr>
<td>array</td>
<td>list</td>
</tr>
<tr>
<td>string</td>
<td>str</td>
</tr>
<tr>
<td>number (int)</td>
<td>int</td>
</tr>
<tr>
<td>number (real)</td>
<td>float</td>
</tr>
<tr>
<td>true</td>
<td>True</td>
</tr>
<tr>
<td>false</td>
<td>False</td>
</tr>
<tr>
<td>null</td>
<td>None</td>
</tr>
</tbody>
</table>

It also understands NaN, Infinity, and -Infinity as their corresponding float values, which is outside the JSON spec.

`object_hook`, if specified, will be called with the result of every JSON object decoded and its return value will be used in place of the given dict. This can be used to provide custom deserializations (e.g. to support JSON-RPC class hinting).

`object_pairs_hook`, if specified will be called with the result of every JSON object decoded with an ordered list of pairs. The return value of `object_pairs_hook` will be used instead of the dict. This feature
can be used to implement custom decoders that rely on the order that the key and value pairs are decoded (for example, collections.OrderedDict() will remember the order of insertion). If *object_hook* is also defined, the *object_pairs_hook* takes priority.

*Changed in version 3.1:* Added support for *object_pairs_hook*.

*parse_float*, if specified, will be called with the string of every JSON float to be decoded. By default, this is equivalent to `float(num_str)`. This can be used to use another datatype or parser for JSON floats (e.g. `decimal.Decimal`).

*parse_int*, if specified, will be called with the string of every JSON int to be decoded. By default, this is equivalent to `int(num_str)`. This can be used to use another datatype or parser for JSON integers (e.g. `float`).

*parse_constant*, if specified, will be called with one of the following strings: `-Infinity`, `Infinity`, `NaN`, `null`, `true`, `false`. This can be used to raise an exception if invalid JSON numbers are encountered.

If *strict* is False (True is the default), then control characters will be allowed inside strings. Control characters in this context are those with character codes in the 0-31 range, including `\t` (tab), `\n`, `\r` and `\0`.

If the data being deserialized is not a valid JSON document, a *ValueError* will be raised.

**decode(s)**

Return the Python representation of s (a *str* instance
containing a JSON document)

**raw_decode**(s)

Decode a JSON document from s (a `str` beginning with a JSON document) and return a 2-tuple of the Python representation and the index in s where the document ended.

This can be used to decode a JSON document from a string that may have extraneous data at the end.

```python
class json.JSONEncoder(skipkeys=False, ensure_ascii=True, check_circular=True, allow_nan=True, sort_keys=False, indent=None, separators=None, default=None)

Extensible JSON encoder for Python data structures.
```

Supports the following objects and types by default:

<table>
<thead>
<tr>
<th>Python</th>
<th>JSON</th>
</tr>
</thead>
<tbody>
<tr>
<td>dict</td>
<td>object</td>
</tr>
<tr>
<td>list, tuple</td>
<td>array</td>
</tr>
<tr>
<td>str</td>
<td>string</td>
</tr>
<tr>
<td>int, float</td>
<td>number</td>
</tr>
<tr>
<td>True</td>
<td>true</td>
</tr>
<tr>
<td>False</td>
<td>false</td>
</tr>
<tr>
<td>None</td>
<td>null</td>
</tr>
</tbody>
</table>

To extend this to recognize other objects, subclass and implement a `default()` method with another method that returns a serializable object for `o` if possible, otherwise it should call the superclass implementation (to raise `TypeError`).
If `skipkeys` is False (the default), then it is a `TypeError` to attempt encoding of keys that are not `str`, `int`, `float` or `None`. If `skipkeys` is True, such items are simply skipped.

If `ensure_ascii` is True (the default), the output is guaranteed to have all incoming non-ASCII characters escaped. If `ensure_ascii` is False, these characters will be output as-is.

If `check_circular` is True (the default), then lists, dicts, and custom encoded objects will be checked for circular references during encoding to prevent an infinite recursion (which would cause an `OverflowError`). Otherwise, no such check takes place.

If `allow_nan` is True (the default), then `NaN`, `Infinity`, and `-Infinity` will be encoded as such. This behavior is not JSON specification compliant, but is consistent with most JavaScript based encoders and decoders. Otherwise, it will be a `ValueError` to encode such floats.

If `sort_keys` is True (default False), then the output of dictionaries will be sorted by key; this is useful for regression tests to ensure that JSON serializations can be compared on a day-to-day basis.

If `indent` is a non-negative integer or string, then JSON array elements and object members will be pretty-printed with that indent level. An indent level of 0, negative, or "" will only insert newlines. None (the default) selects the most compact representation. Using a positive integer indent indents that many spaces per level. If `indent` is a string (such as "\t"), that string is used to indent each level.
Changed in version 3.2: Allow strings for **indent** in addition to integers.

**Note:** Since the default item separator is ",", the output might include trailing whitespace when **indent** is specified. You can use `separators=('\,', '\: ')` to avoid this.

If specified, **separators** should be an `(item_separator, key_separator)` tuple. The default is `('\,', '\: ')`. To get the most compact JSON representation, you should specify `('\,', '\: ')` to eliminate whitespace.

If specified, **default** is a function that gets called for objects that can’t otherwise be serialized. It should return a JSON encodable version of the object or raise a **TypeError**.

**default**(o)

Implement this method in a subclass such that it returns a serializable object for o, or calls the base implementation (to raise a **TypeError**).

For example, to support arbitrary iterators, you could implement default like this:

```python
def default(self, o):
    try:
        iterable = iter(o)
    except TypeError:
        pass
    else:
        return list(iterable)
    # Let the base class default method raise the
    return json.JSONEncoder.default(self, o)
```
**encode(o)**

Return a JSON string representation of a Python data structure, o. For example:

```python
>>> json.JSONEncoder().encode({"foo": ["bar", '
{"foo": ["bar", "baz"]}
```

**iterencode(o)**

Encode the given object, o, and yield each string representation as available. For example:

```python
for chunk in json.JSONEncoder().iterencode(bigobject):
    mysocket.write(chunk)
```
19.2.3. Standard Compliance

The JSON format is specified by RFC 4627. This section details this module’s level of compliance with the RFC. For simplicity, JSONEncoder and JSONDecoder subclasses, and parameters other than those explicitly mentioned, are not considered.

This module does not comply with the RFC in a strict fashion, implementing some extensions that are valid JavaScript but not valid JSON. In particular:

- Top-level non-object, non-array values are accepted and output;
- Infinite and NaN number values are accepted and output;
- Repeated names within an object are accepted, and only the value of the last name-value pair is used.

Since the RFC permits RFC-compliant parsers to accept input texts that are not RFC-compliant, this module’s deserializer is technically RFC-compliant under default settings.

19.2.3.1. Character Encodings

The RFC recommends that JSON be represented using either UTF-8, UTF-16, or UTF-32, with UTF-8 being the default.

As permitted, though not required, by the RFC, this module’s serializer sets ensure_ascii=True by default, thus escaping the output so that the resulting strings only contain ASCII characters.

Other than the ensure_ascii parameter, this module is defined strictly in terms of conversion between Python objects and Unicode strings, and thus does not otherwise address the issue of character
encodings.

### 19.2.3.2. Top-level Non-Object, Non-Array Values

The RFC specifies that the top-level value of a JSON text must be either a JSON object or array (Python `dict` or `list`). This module's deserializer also accepts input texts consisting solely of a JSON null, boolean, number, or string value:

```python
>>> just_a_json_string = "spam and eggs"  # Not by itself a valid JSON text
>>> json.loads(just_a_json_string)
'spam and eggs'
```

This module itself does not include a way to request that such input texts be regarded as illegal. Likewise, this module's serializer also accepts single Python `None`, `bool`, numeric, and `str` values as input and will generate output texts consisting solely of a top-level JSON null, boolean, number, or string value without raising an exception:

```python
>>> neither_a_list_nor_a_dict = "spam and eggs"
>>> json.dumps(neither_a_list_nor_a_dict)  # The result is not a valid JSON text
"spam and eggs"
```

This module's serializer does not itself include a way to enforce the aforementioned constraint.

### 19.2.3.3. Infinite and NaN Number Values

The RFC does not permit the representation of infinite or NaN number values. Despite that, by default, this module accepts and outputs `Infinity`, `-Infinity`, and `NaN` as if they were valid JSON number
literal values:

```python
>>> # Neither of these calls raises an exception, but the results are not valid JSON
>>> json.dumps(float('-inf'))
'-Infinity'
>>> json.dumps(float('nan'))
'NaN'
>>> # Same when deserializing
>>> json.loads('-Infinity')
-inf
>>> json.loads('NaN')
nan
```

In the serializer, the `allow_nan` parameter can be used to alter this behavior. In the deserializer, the `parse_constant` parameter can be used to alter this behavior.

19.2.3.4. Repeated Names Within an Object

The RFC specifies that the names within a JSON object should be unique, but does not specify how repeated names in JSON objects should be handled. By default, this module does not raise an exception; instead, it ignores all but the last name-value pair for a given name:

```python
>>> weird_json = '{"x": 1, "x": 2, "x": 3}'
>>> json.loads(weird_json)
{'x': 3}
```

The `object_pairs_hook` parameter can be used to alter this behavior.
19.3. mailcap — Mailcap file handling

Source code: Lib/mailcap.py

Mailcap files are used to configure how MIME-aware applications such as mail readers and Web browsers react to files with different MIME types. (The name “mailcap” is derived from the phrase “mail capability”.) For example, a mailcap file might contain a line like `video/mpeg; xmpeg %s`. Then, if the user encounters an email message or Web document with the MIME type `video/mpeg`, `%s` will be replaced by a filename (usually one belonging to a temporary file) and the `xmpeg` program can be automatically started to view the file.

The mailcap format is documented in RFC 1524, “A User Agent Configuration Mechanism For Multimedia Mail Format Information,” but is not an Internet standard. However, mailcap files are supported on most Unix systems.

```
mailcap.findmatch(caps, MIMEtype, key='view',
filename='/dev/null', plist=[])
```

Return a 2-tuple; the first element is a string containing the command line to be executed (which can be passed to `os.system()`), and the second element is the mailcap entry for a given MIME type. If no matching MIME type can be found, `(None, None)` is returned.

`key` is the name of the field desired, which represents the type of activity to be performed; the default value is ‘view’, since in the
most common case you simply want to view the body of the MIME-typed data. Other possible values might be 'compose' and 'edit', if you wanted to create a new body of the given MIME type or alter the existing body data. See RFC 1524 for a complete list of these fields.

_filename_ is the filename to be substituted for %s in the command line; the default value is '/dev/null' which is almost certainly not what you want, so usually you'll override it by specifying a filename.

_plist_ can be a list containing named parameters; the default value is simply an empty list. Each entry in the list must be a string containing the parameter name, an equals sign ('='), and the parameter's value. Mailcap entries can contain named parameters like '%{foo}', which will be replaced by the value of the parameter named 'foo'. For example, if the command line _showpartial_ % {id} %{number} %{total} was in a mailcap file, and _plist_ was set to ['id=1', 'number=2', 'total=3'], the resulting command line would be _showpartial 1 2 3_.

In a mailcap file, the “test” field can optionally be specified to test some external condition (such as the machine architecture, or the window system in use) to determine whether or not the mailcap line applies. _findmatch()_ will automatically check such conditions and skip the entry if the check fails.

**mailcap.getcaps()**

Returns a dictionary mapping MIME types to a list of mailcap file entries. This dictionary must be passed to the _findmatch()_ function. An entry is stored as a list of dictionaries, but it shouldn't be necessary to know the details of this representation.
The information is derived from all of the mailcap files found on the system. Settings in the user's mailcap file $HOME/.mailcap will override settings in the system mailcap files /etc/mailcap, /usr/etc/mailcap, and /usr/local/etc/mailcap.

An example usage:

```python
>>> import mailcap
>>> d=mailcap.getcaps()
>>> mailcap.findmatch(d, 'video/mpeg', filename='tmp1223', ('xmpeg tmp1223', {'view': 'xmpeg %s'})
```

19.4. `mailbox` — Manipulate mailboxes in various formats

This module defines two classes, `Mailbox` and `Message`, for accessing and manipulating on-disk mailboxes and the messages they contain. `Mailbox` offers a dictionary-like mapping from keys to messages. `Message` extends the `email.message` module's `Message` class with format-specific state and behavior. Supported mailbox formats are Maildir, mbox, MH, Babyl, and MMDF.

**See also:**

**Module** `email`

Represent and manipulate messages.
19.4.1. **Mailbox objects**

*class* mailbox. **Mailbox**

A mailbox, which may be inspected and modified.

The **Mailbox** class defines an interface and is not intended to be instantiated. Instead, format-specific subclasses should inherit from **Mailbox** and your code should instantiate a particular subclass.

The **Mailbox** interface is dictionary-like, with small keys corresponding to messages. Keys are issued by the **Mailbox** instance with which they will be used and are only meaningful to that **Mailbox** instance. A key continues to identify a message even if the corresponding message is modified, such as by replacing it with another message.

Messages may be added to a **Mailbox** instance using the set-like method **add()** and removed using a **del** statement or the set-like methods **remove()** and **discard()**.

**Mailbox** interface semantics differ from dictionary semantics in some noteworthy ways. Each time a message is requested, a new representation (typically a **Message** instance) is generated based upon the current state of the mailbox. Similarly, when a message is added to a **Mailbox** instance, the provided message representation’s contents are copied. In neither case is a reference to the message representation kept by the **Mailbox** instance.

The default **Mailbox** iterator iterates over message representations, not keys as the default dictionary iterator does. Moreover, modification of a mailbox during iteration is safe and
well-defined. Messages added to the mailbox after an iterator is created will not be seen by the iterator. Messages removed from the mailbox before the iterator yields them will be silently skipped, though using a key from an iterator may result in a `KeyError` exception if the corresponding message is subsequently removed.

**Warning:** Be very cautious when modifying mailboxes that might be simultaneously changed by some other process. The safest mailbox format to use for such tasks is Maildir; try to avoid using single-file formats such as mbox for concurrent writing. If you’re modifying a mailbox, you *must* lock it by calling the `lock()` and `unlock()` methods before reading any messages in the file or making any changes by adding or deleting a message. Failing to lock the mailbox runs the risk of losing messages or corrupting the entire mailbox.

Mailbox instances have the following methods:

`add(message)`

Add `message` to the mailbox and return the key that has been assigned to it.

Parameter `message` may be a `Message` instance, an `email.message.Message` instance, a string, a byte string, or a file-like object (which should be open in binary mode). If `message` is an instance of the appropriate format-specific `Message` subclass (e.g., if it’s an `mboxMessage` instance and this is an `mbox` instance), its format-specific information is used. Otherwise, reasonable defaults for format-specific information are used.

*Changed in version 3.2*: Support for binary input was added.
remove(key)
__delitem__(key)
discard(key)

Delete the message corresponding to key from the mailbox.

If no such message exists, a KeyError exception is raised if the method was called as remove() or __delitem__() but no exception is raised if the method was called as discard(). The behavior of discard() may be preferred if the underlying mailbox format supports concurrent modification by other processes.

__setitem__(key, message)

Replace the message corresponding to key with message. Raise a KeyError exception if no message already corresponds to key.

As with add(), parameter message may be a Message instance, an email.message.Message instance, a string, a byte string, or a file-like object (which should be open in binary mode). If message is an instance of the appropriate format-specific Message subclass (e.g., if it’s an mboxMessage instance and this is an mbox instance), its format-specific information is used. Otherwise, the format-specific information of the message that currently corresponds to key is left unchanged.

iterkeys()
keys()

Return an iterator over all keys if called as iterkeys() or return a list of keys if called as keys().
**itervalues()**

__iter__()

values()

Return an iterator over representations of all messages if called as `itervalues()` or `__iter__()` or return a list of such representations if called as `values()`. The messages are represented as instances of the appropriate format-specific `Message` subclass unless a custom message factory was specified when the `Mailbox` instance was initialized.

**Note:** The behavior of `__iter__()` is unlike that of dictionaries, which iterate over keys.

**iteritems()**

**items()**

Return an iterator over `(key, message)` pairs, where `key` is a key and `message` is a message representation, if called as `iteritems()` or return a list of such pairs if called as `items()`. The messages are represented as instances of the appropriate format-specific `Message` subclass unless a custom message factory was specified when the `Mailbox` instance was initialized.

**get(key, default=None)**

__getitem__(key)

Return a representation of the message corresponding to `key`. If no such message exists, `default` is returned if the method was called as `get()` and a `KeyError` exception is raised if the method was called as `__getitem__()`. The message is represented as an instance of the appropriate format-specific `Message` subclass unless a custom message factory was
specified when the Mailbox instance was initialized.

**get_message**(key)
Return a representation of the message corresponding to key as an instance of the appropriate format-specific Message subclass, or raise a KeyError exception if no such message exists.

**get_bytes**(key)
Return a byte representation of the message corresponding to key, or raise a KeyError exception if no such message exists.

*New in version 3.2.*

**get_string**(key)
Return a string representation of the message corresponding to key, or raise a KeyError exception if no such message exists. The message is processed through `email.message.Message` to convert it to a 7bit clean representation.

**get_file**(key)
Return a file-like representation of the message corresponding to key, or raise a KeyError exception if no such message exists. The file-like object behaves as if open in binary mode. This file should be closed once it is no longer needed.

*Changed in version 3.2:* The file object really is a binary file; previously it was incorrectly returned in text mode. Also, the file-like object now supports the context manager protocol: you can use a `with` statement to automatically close it.
**Note:** Unlike other representations of messages, file-like representations are not necessarily independent of the Mailbox instance that created them or of the underlying mailbox. More specific documentation is provided by each subclass.

__contains__(key)
Return True if key corresponds to a message, False otherwise.

__len__()
Return a count of messages in the mailbox.

clear()
Delete all messages from the mailbox.

pop(key, default=None)
Return a representation of the message corresponding to key and delete the message. If no such message exists, return default. The message is represented as an instance of the appropriate format-specific Message subclass unless a custom message factory was specified when the Mailbox instance was initialized.

popitem()
Return an arbitrary (key, message) pair, where key is a key and message is a message representation, and delete the corresponding message. If the mailbox is empty, raise a KeyError exception. The message is represented as an instance of the appropriate format-specific Message subclass unless a custom message factory was specified when the
Mailbox instance was initialized.

**update**(*arg*)
Parameter *arg* should be a *key-to-message* mapping or an iterable of (*key*, *message*) pairs. Updates the mailbox so that, for each given *key* and *message*, the message corresponding to *key* is set to *message* as if by using **setitem**(). As with **setitem**(), each *key* must already correspond to a message in the mailbox or else a *KeyError* exception will be raised, so in general it is incorrect for *arg* to be a Mailbox instance.

**Note:** Unlike with dictionaries, keyword arguments are not supported.

**flush()**
Write any pending changes to the filesystem. For some Mailbox subclasses, changes are always written immediately and **flush()** does nothing, but you should still make a habit of calling this method.

**lock()**
Acquire an exclusive advisory lock on the mailbox so that other processes know not to modify it. An ExternalClashError is raised if the lock is not available. The particular locking mechanisms used depend upon the mailbox format. You should *always* lock the mailbox before making any modifications to its contents.

**unlock()**
Release the lock on the mailbox, if any.
close()

Flush the mailbox, unlock it if necessary, and close any open files. For some Mailbox subclasses, this method does nothing.

19.4.1.1. Maildir

class mailbox.Maildir(dirname, factory=None, create=True)

A subclass of Mailbox for mailboxes in Maildir format. Parameter factory is a callable object that accepts a file-like message representation (which behaves as if opened in binary mode) and returns a custom representation. If factory is None, MaildirMessage is used as the default message representation. If create is True, the mailbox is created if it does not exist.

It is for historical reasons that dirname is named as such rather than path.

Maildir is a directory-based mailbox format invented for the qmail mail transfer agent and now widely supported by other programs. Messages in a Maildir mailbox are stored in separate files within a common directory structure. This design allows Maildir mailboxes to be accessed and modified by multiple unrelated programs without data corruption, so file locking is unnecessary.

Maildir mailboxes contain three subdirectories, namely: tmp, new, and cur. Messages are created momentarily in the tmp subdirectory and then moved to the new subdirectory to finalize delivery. A mail user agent may subsequently move the message to the cur subdirectory and store information about the state of the message in a special “info” section appended to its file name.
Folders of the style introduced by the Courier mail transfer agent are also supported. Any subdirectory of the main mailbox is considered a folder if '.' is the first character in its name. Folder names are represented by Maildir without the leading '.'. Each folder is itself a Maildir mailbox but should not contain other folders. Instead, a logical nesting is indicated using '.' to delimit levels, e.g., “Archived.2005.07”.

Note: The Maildir specification requires the use of a colon (':') in certain message file names. However, some operating systems do not permit this character in file names. If you wish to use a Maildir-like format on such an operating system, you should specify another character to use instead. The exclamation point ('!') is a popular choice. For example:

```python
import mailbox
mailbox.Maildir.colon = '!
```

The colon attribute may also be set on a per-instance basis.

Maildir instances have all of the methods of Mailbox in addition to the following:

**list_folders()**

Return a list of the names of all folders.

**get_folder(folder)**

Return a Maildir instance representing the folder whose name is folder. A NoSuchMailboxError exception is raised if the folder does not exist.

**add_folder(folder)**

Create a folder whose name is folder and return a Maildir
instance representing it.

**remove_folder(folder)**

Delete the folder whose name is `folder`. If the folder contains any messages, a `NotEmptyError` exception will be raised and the folder will not be deleted.

**clean()**

Delete temporary files from the mailbox that have not been accessed in the last 36 hours. The Maildir specification says that mail-reading programs should do this occasionally.

Some **Mailbox** methods implemented by **Maildir** deserve special remarks:

**add(message)**

**__setitem__(key, message)**

**update(arg)**

**Warning:** These methods generate unique file names based upon the current process ID. When using multiple threads, undetected name clashes may occur and cause corruption of the mailbox unless threads are coordinated to avoid using these methods to manipulate the same mailbox simultaneously.

**flush()**

All changes to Maildir mailboxes are immediately applied, so this method does nothing.

**lock()**

**unlock()**

Maildir mailboxes do not support (or require) locking, so these
methods do nothing.

**close()**

`Maildir` instances do not keep any open files and the underlying mailboxes do not support locking, so this method does nothing.

**get_file(key)**

Depending upon the host platform, it may not be possible to modify or remove the underlying message while the returned file remains open.

  Another specification of the format. Describes a common extension for supporting folders.

---

19.4.1.2. **mbox**

```python
class mailbox.mbox(path, factory=None, create=True)
```

A subclass of `Mailbox` for mailboxes in mbox format. Parameter `factory` is a callable object that accepts a file-like message representation (which behaves as if opened in binary mode) and returns a custom representation. If `factory` is None, `mboxMessage` is used as the default message representation. If `create` is True,
the mailbox is created if it does not exist.

The mbox format is the classic format for storing mail on Unix systems. All messages in an mbox mailbox are stored in a single file with the beginning of each message indicated by a line whose first five characters are “From ”.

Several variations of the mbox format exist to address perceived shortcomings in the original. In the interest of compatibility, mbox implements the original format, which is sometimes referred to as mboxo. This means that the Content-Length header, if present, is ignored and that any occurrences of “From ” at the beginning of a line in a message body are transformed to “>From ” when storing the message, although occurrences of “>From ” are not transformed to “From ” when reading the message.

Some Mailbox methods implemented by mbox deserve special remarks:

**get_file(key)**

Using the file after calling flush() or close() on the mbox instance may yield unpredictable results or raise an exception.

**lock()**

**unlock()**

Three locking mechanisms are used—dot locking and, if available, the flock() and lockf() system calls.

An argument for using the original mbox format rather than a variation.

**“mbox” is a family of several mutually incompatible mailbox formats**

A history of mbox variations.

19.4.1.3. **MH**

class mailbox. **MH**(path, factory=None, create=True)

A subclass of Mailbox for mailboxes in MH format. Parameter factory is a callable object that accepts a file-like message representation (which behaves as if opened in binary mode) and returns a custom representation. If factory is None, MHMessage is used as the default message representation. If create is True, the mailbox is created if it does not exist.

MH is a directory-based mailbox format invented for the MH Message Handling System, a mail user agent. Each message in an MH mailbox resides in its own file. An MH mailbox may contain other MH mailboxes (called folders) in addition to messages. Folders may be nested indefinitely. MH mailboxes also support sequences, which are named lists used to logically group messages without moving them to sub-folders. Sequences are defined in a file called `.mh_sequences` in each folder.

The **MH** class manipulates MH mailboxes, but it does not attempt to emulate all of mh's behaviors. In particular, it does not modify and is not affected by the context or `.mh_profile` files that are
used by mh to store its state and configuration.

MH instances have all of the methods of Mailbox in addition to the following:

**list_folders()**
Return a list of the names of all folders.

**get_folder(folder)**
Return an MH instance representing the folder whose name is *folder*. A NoSuchMailboxError exception is raised if the folder does not exist.

**add_folder(folder)**
Create a folder whose name is *folder* and return an MH instance representing it.

**remove_folder(folder)**
Delete the folder whose name is *folder*. If the folder contains any messages, a NotEmptyError exception will be raised and the folder will not be deleted.

**get_sequences()**
Return a dictionary of sequence names mapped to key lists. If there are no sequences, the empty dictionary is returned.

**set_sequences(sequences)**
Re-define the sequences that exist in the mailbox based upon *sequences*, a dictionary of names mapped to key lists, like returned by get_sequences().

**pack()**
Rename messages in the mailbox as necessary to eliminate
gaps in numbering. Entries in the sequences list are updated correspondingly.

**Note:** Already-issued keys are invalidated by this operation and should not be subsequently used.

Some **Mailbox** methods implemented by **MH** deserve special remarks:

```python
remove(key)
__delitem__(key)
discard(key)
```

These methods immediately delete the message. The MH convention of marking a message for deletion by prepending a comma to its name is not used.

```python
lock()
unlock()
```

Three locking mechanisms are used—dot locking and, if available, the `flock()` and `lockf()` system calls. For MH mailboxes, locking the mailbox means locking the `.mh_sequences` file and, only for the duration of any operations that affect them, locking individual message files.

```python
get_file(key)
```

Depending upon the host platform, it may not be possible to remove the underlying message while the returned file remains open.

```python
flush()
```

All changes to MH mailboxes are immediately applied, so this method does nothing.
**close()**

MH instances do not keep any open files, so this method is equivalent to `unlock()`.

A GPL-licensed book on mh and nmh, with some information on the mailbox format.

---

19.4.1.4. **Babyl**

**class** `mailbox`. Babyl(path, factory=None, create=True)

A subclass of Mailbox for mailboxes in Babyl format. Parameter `factory` is a callable object that accepts a file-like message representation (which behaves as if opened in binary mode) and returns a custom representation. If `factory` is None, BabylMessage is used as the default message representation. If `create` is True, the mailbox is created if it does not exist.

Babyl is a single-file mailbox format used by the Rmail mail user agent included with Emacs. The beginning of a message is indicated by a line containing the two characters Control-Underscore ('\037') and Control-L ('\014'). The end of a message is indicated by the start of the next message or, in the case of the last message, a line containing a Control-Underscore ('\037') character.

Messages in a Babyl mailbox have two sets of headers, original
headers and so-called visible headers. Visible headers are typically a subset of the original headers that have been reformatted or abridged to be more attractive. Each message in a Babyl mailbox also has an accompanying list of labels, or short strings that record extra information about the message, and a list of all user-defined labels found in the mailbox is kept in the Babyl options section.

Babyl instances have all of the methods of Mailbox in addition to the following:

**get_labels()**

Return a list of the names of all user-defined labels used in the mailbox.

**Note:** The actual messages are inspected to determine which labels exist in the mailbox rather than consulting the list of labels in the Babyl options section, but the Babyl section is updated whenever the mailbox is modified.

Some Mailbox methods implemented by Babyl deserve special remarks:

**get_file(key)**

In Babyl mailboxes, the headers of a message are not stored contiguously with the body of the message. To generate a file-like representation, the headers and body are copied together into a io.BytesIO instance, which has an API identical to that of a file. As a result, the file-like object is truly independent of the underlying mailbox but does not save memory compared to a string representation.

**lock()**
unlock()

Three locking mechanisms are used—dot locking and, if available, the flock() and lockf() system calls.

The Rmail manual, with some information on Babyl semantics.

19.4.1.5. MMDF

class mailbox. MMDF(path, factory=None, create=True)

A subclass of Mailbox for mailboxes in MMDF format. Parameter factory is a callable object that accepts a file-like message representation (which behaves as if opened in binary mode) and returns a custom representation. If factory is None, MMDFMessage is used as the default message representation. If create is True, the mailbox is created if it does not exist.

MMDF is a single-file mailbox format invented for the Multichannel Memorandum Distribution Facility, a mail transfer agent. Each message is in the same form as an mbox message but is bracketed before and after by lines containing four Control-A (\\001') characters. As with the mbox format, the beginning of each message is indicated by a line whose first five characters are “From ”, but additional occurrences of “From ” are not transformed to “>From ” when storing messages because the extra message separator lines prevent mistaking such occurrences for the starts of subsequent messages.
Some **Mailbox** methods implemented by **MMDF** deserve special remarks:

**get_file**(key)

Using the file after calling `flush()` or `close()` on the **MMDF** instance may yield unpredictable results or raise an exception.

**lock()**

**unlock()**

Three locking mechanisms are used—dot locking and, if available, the `flock()` and `lockf()` system calls.

---

**See also:**

**mmdf man page from tin**

A specification of MMDF format from the documentation of tin, a newsreader.

**MMDF**

A Wikipedia article describing the Multichannel Memorandum Distribution Facility.
19.4.2. **Message** objects

```
class mailbox.Message(message=None)
```

If `message` is omitted, the new instance is created in a default, empty state. If `message` is an `email.message.Message` instance, its contents are copied; furthermore, any format-specific information is converted insofar as possible if `message` is a `Message` instance. If `message` is a string, a byte string, or a file, it should contain an RFC 2822-compliant message, which is read and parsed. Files should be open in binary mode, but text mode files are accepted for backward compatibility.

The format-specific state and behaviors offered by subclasses vary, but in general it is only the properties that are not specific to a particular mailbox that are supported (although presumably the properties are specific to a particular mailbox format). For example, file offsets for single-file mailbox formats and file names for directory-based mailbox formats are not retained, because they are only applicable to the original mailbox. But state such as whether a message has been read by the user or marked as important is retained, because it applies to the message itself.

There is no requirement that `Message` instances be used to represent messages retrieved using `Mailbox` instances. In some situations, the time and memory required to generate `Message` representations might not be acceptable. For such situations, `Mailbox` instances also offer string and file-like representations,
and a custom message factory may be specified when a Mailbox instance is initialized.

19.4.2.1. MaildirMessage

class mailbox.MaildirMessage(message=None)

A message with Maildir-specific behaviors. Parameter message has the same meaning as with the Message constructor.

Typically, a mail user agent application moves all of the messages in the new subdirectory to the cur subdirectory after the first time the user opens and closes the mailbox, recording that the messages are old whether or not they've actually been read. Each message in cur has an “info” section added to its file name to store information about its state. (Some mail readers may also add an “info” section to messages in new.) The “info” section may take one of two forms: it may contain “2,” followed by a list of standardized flags (e.g., “2,FR”) or it may contain “1,” followed by so-called experimental information. Standard flags for Maildir messages are as follows:

<table>
<thead>
<tr>
<th>Flag</th>
<th>Meaning</th>
<th>Explanation</th>
</tr>
</thead>
<tbody>
<tr>
<td>D</td>
<td>Draft</td>
<td>Under composition</td>
</tr>
<tr>
<td>F</td>
<td>Flagged</td>
<td>Marked as important</td>
</tr>
<tr>
<td>P</td>
<td>Passed</td>
<td>Forwarded, resent, or bounced</td>
</tr>
<tr>
<td>R</td>
<td>Replied</td>
<td>Replied to</td>
</tr>
<tr>
<td>S</td>
<td>Seen</td>
<td>Read</td>
</tr>
<tr>
<td>T</td>
<td>Trashed</td>
<td>Marked for subsequent deletion</td>
</tr>
</tbody>
</table>

MaildirMessage instances offer the following methods:
get_subdir()
Return either “new” (if the message should be stored in the new subdirectory) or “cur” (if the message should be stored in the cur subdirectory).

Note: A message is typically moved from new to cur after its mailbox has been accessed, whether or not the message is has been read. A message msg has been read if "S" in msg.get_flags() is True.

set_subdir(subdir)
Set the subdirectory the message should be stored in. Parameter subdir must be either “new” or “cur”.

get_flags()
Return a string specifying the flags that are currently set. If the message complies with the standard Maildir format, the result is the concatenation in alphabetical order of zero or one occurrence of each of 'D', 'F', 'P', 'R', 'S', and 'T'. The empty string is returned if no flags are set or if “info” contains experimental semantics.

set_flags(flags)
Set the flags specified by flags and unset all others.

add_flag(flag)
Set the flag(s) specified by flag without changing other flags. To add more than one flag at a time, flag may be a string of more than one character. The current “info” is overwritten whether or not it contains experimental information rather than flags.

remove_flag(flag)
Unset the flag(s) specified by *flag* without changing other flags. To remove more than one flag at a time, *flag* maybe a string of more than one character. If “info” contains experimental information rather than flags, the current “info” is not modified.

**get_date()**
Return the delivery date of the message as a floating-point number representing seconds since the epoch.

**set_date(date)**
Set the delivery date of the message to *date*, a floating-point number representing seconds since the epoch.

**get_info()**
Return a string containing the “info” for a message. This is useful for accessing and modifying “info” that is experimental (i.e., not a list of flags).

**set_info(info)**
Set “info” to *info*, which should be a string.

When a *MaildirMessage* instance is created based upon an *mboxMessage* or *MMDFMessage* instance, the *Status* and *X-Status* headers are omitted and the following conversions take place:

<table>
<thead>
<tr>
<th>Resulting state</th>
<th><em>mboxMessage</em> or <em>MMDFMessage</em> state</th>
</tr>
</thead>
<tbody>
<tr>
<td>“cur” subdirectory</td>
<td>O flag</td>
</tr>
<tr>
<td>F flag</td>
<td>F flag</td>
</tr>
<tr>
<td>R flag</td>
<td>A flag</td>
</tr>
<tr>
<td>S flag</td>
<td>R flag</td>
</tr>
<tr>
<td>T flag</td>
<td>D flag</td>
</tr>
</tbody>
</table>
When a `MaildirMessage` instance is created based upon an `MHMessage` instance, the following conversions take place:

<table>
<thead>
<tr>
<th>Resulting state</th>
<th>MHMessage state</th>
</tr>
</thead>
<tbody>
<tr>
<td>“cur” subdirectory</td>
<td>“unseen” sequence</td>
</tr>
<tr>
<td>“cur” subdirectory and S flag</td>
<td>no “unseen” sequence</td>
</tr>
<tr>
<td>F flag</td>
<td>“flagged” sequence</td>
</tr>
<tr>
<td>R flag</td>
<td>“replied” sequence</td>
</tr>
</tbody>
</table>

When a `MaildirMessage` instance is created based upon a `BabylMessage` instance, the following conversions take place:

<table>
<thead>
<tr>
<th>Resulting state</th>
<th>BabylMessage state</th>
</tr>
</thead>
<tbody>
<tr>
<td>“cur” subdirectory</td>
<td>“unseen” label</td>
</tr>
<tr>
<td>“cur” subdirectory and S flag</td>
<td>no “unseen” label</td>
</tr>
<tr>
<td>P flag</td>
<td>“forwarded” or “resent” label</td>
</tr>
<tr>
<td>R flag</td>
<td>“answered” label</td>
</tr>
<tr>
<td>T flag</td>
<td>“deleted” label</td>
</tr>
</tbody>
</table>

**19.4.2.2. **`mboxMessage`

```python
class mailbox.mboxMessage(message=None)
A message with mbox-specific behaviors. Parameter `message` has the same meaning as with the `Message` constructor.

Messages in an mbox mailbox are stored together in a single file. The sender’s envelope address and the time of delivery are typically stored in a line beginning with “From ” that is used to indicate the start of a message, though there is considerable...```
variation in the exact format of this data among mbox implementations. Flags that indicate the state of the message, such as whether it has been read or marked as important, are typically stored in Status and X-Status headers.

Conventional flags for mbox messages are as follows:

<table>
<thead>
<tr>
<th>Flag</th>
<th>Meaning</th>
<th>Explanation</th>
</tr>
</thead>
<tbody>
<tr>
<td>R</td>
<td>Read</td>
<td>Read</td>
</tr>
<tr>
<td>O</td>
<td>Old</td>
<td>Previously detected by MUA</td>
</tr>
<tr>
<td>D</td>
<td>Deleted</td>
<td>Marked for subsequent deletion</td>
</tr>
<tr>
<td>F</td>
<td>Flagged</td>
<td>Marked as important</td>
</tr>
<tr>
<td>A</td>
<td>Answered</td>
<td>Replied to</td>
</tr>
</tbody>
</table>

The “R” and “O” flags are stored in the Status header, and the “D”, “F”, and “A” flags are stored in the X-Status header. The flags and headers typically appear in the order mentioned.

mboxMessage instances offer the following methods:

**get_from()**
Return a string representing the “From ” line that marks the start of the message in an mbox mailbox. The leading “From ” and the trailing newline are excluded.

**set_from(from_, time_=None)**
Set the “From ” line to from_, which should be specified without a leading “From ” or trailing newline. For convenience, time_ may be specified and will be formatted appropriately and appended to from_. If time_ is specified, it should be a time.struct_time instance, a tuple suitable for passing to
time.strftime(), or True (to use time.gmtime()).

get_flags()
Return a string specifying the flags that are currently set. If the message complies with the conventional format, the result is the concatenation in the following order of zero or one occurrence of each of 'R', 'O', 'D', 'F', and 'A'.

set_flags(flags)
Set the flags specified by flags and unset all others. Parameter flags should be the concatenation in any order of zero or more occurrences of each of 'R', 'O', 'D', 'F', and 'A'.

add_flag(flag)
Set the flag(s) specified by flag without changing other flags. To add more than one flag at a time, flag may be a string of more than one character.

remove_flag(flag)
Unset the flag(s) specified by flag without changing other flags. To remove more than one flag at a time, flag may be a string of more than one character.

When an mboxMessage instance is created based upon a MaildirMessage instance, a “From ” line is generated based upon the MaildirMessage instance’s delivery date, and the following conversions take place:

<table>
<thead>
<tr>
<th>Resulting state</th>
<th>MaildirMessage state</th>
</tr>
</thead>
<tbody>
<tr>
<td>R flag</td>
<td>S flag</td>
</tr>
<tr>
<td>O flag</td>
<td>“cur” subdirectory</td>
</tr>
<tr>
<td>D flag</td>
<td>T flag</td>
</tr>
<tr>
<td>--------</td>
<td>--------</td>
</tr>
<tr>
<td>F flag</td>
<td>F flag</td>
</tr>
<tr>
<td>A flag</td>
<td>R flag</td>
</tr>
</tbody>
</table>

When an `mboxMessage` instance is created based upon an `MHMessage` instance, the following conversions take place:

<table>
<thead>
<tr>
<th>Resulting state</th>
<th>MHMessage state</th>
</tr>
</thead>
<tbody>
<tr>
<td>R flag and O flag</td>
<td>no “unseen” sequence</td>
</tr>
<tr>
<td>O flag</td>
<td>“unseen” sequence</td>
</tr>
<tr>
<td>F flag</td>
<td>“flagged” sequence</td>
</tr>
<tr>
<td>A flag</td>
<td>“replied” sequence</td>
</tr>
</tbody>
</table>

When an `mboxMessage` instance is created based upon a `BabylMessage` instance, the following conversions take place:

<table>
<thead>
<tr>
<th>Resulting state</th>
<th>BabylMessage state</th>
</tr>
</thead>
<tbody>
<tr>
<td>R flag and O flag</td>
<td>no “unseen” label</td>
</tr>
<tr>
<td>O flag</td>
<td>“unseen” label</td>
</tr>
<tr>
<td>D flag</td>
<td>“deleted” label</td>
</tr>
<tr>
<td>A flag</td>
<td>“answered” label</td>
</tr>
</tbody>
</table>

When a `Message` instance is created based upon an `MMDFMessage` instance, the “From ” line is copied and all flags directly correspond:

<table>
<thead>
<tr>
<th>Resulting state</th>
<th>MMDFMessage state</th>
</tr>
</thead>
<tbody>
<tr>
<td>R flag</td>
<td>R flag</td>
</tr>
<tr>
<td>O flag</td>
<td>O flag</td>
</tr>
</tbody>
</table>
19.4.2.3. **MHMessage**

*class* mailbox. **MHMessage**(*message=None*)

A message with MH-specific behaviors. Parameter *message* has the same meaning as with the **Message** constructor.

MH messages do not support marks or flags in the traditional sense, but they do support sequences, which are logical groupings of arbitrary messages. Some mail reading programs (although not the standard **mh** and **nmh**) use sequences in much the same way flags are used with other formats, as follows:

<table>
<thead>
<tr>
<th>Sequence</th>
<th>Explanation</th>
</tr>
</thead>
<tbody>
<tr>
<td>unseen</td>
<td>Not read, but previously detected by MUA</td>
</tr>
<tr>
<td>replied</td>
<td>Replied to</td>
</tr>
<tr>
<td>flagged</td>
<td>Marked as important</td>
</tr>
</tbody>
</table>

**MHMessage** instances offer the following methods:

**get_sequences()**

Return a list of the names of sequences that include this message.

**set_sequences(sequences)**

Set the list of sequences that include this message.

**add_sequence(sequence)**
Add *sequence* to the list of sequences that include this message.

**remove_sequence**(sequence)
Remove *sequence* from the list of sequences that include this message.

When an **MHMessage** instance is created based upon a **MaildirMessage** instance, the following conversions take place:

<table>
<thead>
<tr>
<th>Resulting state</th>
<th>MaildirMessage state</th>
</tr>
</thead>
<tbody>
<tr>
<td>“unseen” sequence</td>
<td>no S flag</td>
</tr>
<tr>
<td>“replied” sequence</td>
<td>R flag</td>
</tr>
<tr>
<td>“flagged” sequence</td>
<td>F flag</td>
</tr>
</tbody>
</table>

When an **MHMessage** instance is created based upon an **mboxMessage** or **MMDFMessage** instance, the **Status** and **X-Status** headers are omitted and the following conversions take place:

<table>
<thead>
<tr>
<th>Resulting state</th>
<th>mboxMessage or MMDFMessage state</th>
</tr>
</thead>
<tbody>
<tr>
<td>“unseen” sequence</td>
<td>no R flag</td>
</tr>
<tr>
<td>“replied” sequence</td>
<td>A flag</td>
</tr>
<tr>
<td>“flagged” sequence</td>
<td>F flag</td>
</tr>
</tbody>
</table>

When an **MHMessage** instance is created based upon a **BabylMessage** instance, the following conversions take place:

<table>
<thead>
<tr>
<th>Resulting state</th>
<th>BabylMessage state</th>
</tr>
</thead>
<tbody>
<tr>
<td>“unseen” sequence</td>
<td>“unseen” label</td>
</tr>
</tbody>
</table>
19.4.2.4. **BabylMessage**

```python
class mailbox.BabylMessage(message=None)
```

A message with Babyl-specific behaviors. Parameter `message` has the same meaning as with the `Message` constructor.

Certain message labels, called *attributes*, are defined by convention to have special meanings. The attributes are as follows:

<table>
<thead>
<tr>
<th>Label</th>
<th>Explanation</th>
</tr>
</thead>
<tbody>
<tr>
<td>unseen</td>
<td>Not read, but previously detected by MUA</td>
</tr>
<tr>
<td>deleted</td>
<td>Marked for subsequent deletion</td>
</tr>
<tr>
<td>filed</td>
<td>Copied to another file or mailbox</td>
</tr>
<tr>
<td>answered</td>
<td>Replied to</td>
</tr>
<tr>
<td>forwarded</td>
<td>Forwarded</td>
</tr>
<tr>
<td>edited</td>
<td>Modified by the user</td>
</tr>
<tr>
<td>resent</td>
<td>Resent</td>
</tr>
</tbody>
</table>

By default, Rmail displays only visible headers. The `BabylMessage` class, though, uses the original headers because they are more complete. Visible headers may be accessed explicitly if desired.

`BabylMessage` instances offer the following methods:

- **get_labels()**
  
  Return a list of labels on the message.

- **set_labels(labels)**
Set the list of labels on the message to `labels`.

`add_label(label)`

Add `label` to the list of labels on the message.

`remove_label(label)`

Remove `label` from the list of labels on the message.

`get_visible()`

Return an `Message` instance whose headers are the message’s visible headers and whose body is empty.

`set_visible(visible)`

Set the message’s visible headers to be the same as the headers in `message`. Parameter `visible` should be a `Message` instance, an `email.message.Message` instance, a string, or a file-like object (which should be open in text mode).

`update_visible()`

When a `BabylMessage` instance’s original headers are modified, the visible headers are not automatically modified to correspond. This method updates the visible headers as follows: each visible header with a corresponding original header is set to the value of the original header, each visible header without a corresponding original header is removed, and any of `Date`, `From`, `Reply-To`, `To`, `CC`, and `Subject` that are present in the original headers but not the visible headers are added to the visible headers.

When a `BabylMessage` instance is created based upon a `MaildirMessage` instance, the following conversions take place:
<table>
<thead>
<tr>
<th>Resulting state</th>
<th>MaildirMessage state</th>
</tr>
</thead>
<tbody>
<tr>
<td>“unseen” label</td>
<td>no S flag</td>
</tr>
<tr>
<td>“deleted” label</td>
<td>T flag</td>
</tr>
<tr>
<td>“answered” label</td>
<td>R flag</td>
</tr>
<tr>
<td>“forwarded” label</td>
<td>P flag</td>
</tr>
</tbody>
</table>

When a BabylMessage instance is created based upon an mboxMessage or MMDFMessage instance, the Status and X-Status headers are omitted and the following conversions take place:

<table>
<thead>
<tr>
<th>Resulting state</th>
<th>mboxMessage or MMDFMessage state</th>
</tr>
</thead>
<tbody>
<tr>
<td>“unseen” label</td>
<td>no R flag</td>
</tr>
<tr>
<td>“deleted” label</td>
<td>D flag</td>
</tr>
<tr>
<td>“answered” label</td>
<td>A flag</td>
</tr>
</tbody>
</table>

When a BabylMessage instance is created based upon an MHMessage instance, the following conversions take place:

<table>
<thead>
<tr>
<th>Resulting state</th>
<th>MHMessage state</th>
</tr>
</thead>
<tbody>
<tr>
<td>“unseen” label</td>
<td>“unseen” sequence</td>
</tr>
<tr>
<td>“answered” label</td>
<td>“replied” sequence</td>
</tr>
</tbody>
</table>

19.4.2.5. MMDFMessage

```python
class mailbox.MMDFMessage(message=None)
```

A message with MMDF-specific behaviors. Parameter message has the same meaning as with the Message constructor.

As with message in an mbox mailbox, MMDF messages are stored
with the sender’s address and the delivery date in an initial line beginning with “From ”. Likewise, flags that indicate the state of the message are typically stored in Status and X-Status headers.

Conventional flags for MMDF messages are identical to those of mbox message and are as follows:

<table>
<thead>
<tr>
<th>Flag</th>
<th>Meaning</th>
<th>Explanation</th>
</tr>
</thead>
<tbody>
<tr>
<td>R</td>
<td>Read</td>
<td>Read</td>
</tr>
<tr>
<td>O</td>
<td>Old</td>
<td>Previously detected by MUA</td>
</tr>
<tr>
<td>D</td>
<td>Deleted</td>
<td>Marked for subsequent deletion</td>
</tr>
<tr>
<td>F</td>
<td>Flagged</td>
<td>Marked as important</td>
</tr>
<tr>
<td>A</td>
<td>Answered</td>
<td>Replied to</td>
</tr>
</tbody>
</table>

The “R” and “O” flags are stored in the Status header, and the “D”, “F”, and “A” flags are stored in the X-Status header. The flags and headers typically appear in the order mentioned.

**MMDFMessage** instances offer the following methods, which are identical to those offered by **mboxMessage**:  

**get_from()**  
Return a string representing the “From ” line that marks the start of the message in an mbox mailbox. The leading “From ” and the trailing newline are excluded.

**set_from(from_, time_=None)**  
Set the “From ” line to from_, which should be specified without a leading “From ” or trailing newline. For convenience, time_ may be specified and will be formatted appropriately and appended to from_. If time_ is specified, it should be a
time.struct_time instance, a tuple suitable for passing to time.strftime(), or True (to use time.gmtime()).

**get_flags()**
Return a string specifying the flags that are currently set. If the message complies with the conventional format, the result is the concatenation in the following order of zero or one occurrence of each of 'R', 'O', 'D', 'F', and 'A'.

**set_flags(flags)**
Set the flags specified by flags and unset all others. Parameter flags should be the concatenation in any order of zero or more occurrences of each of 'R', 'O', 'D', 'F', and 'A'.

**add_flag(flag)**
Set the flag(s) specified by flag without changing other flags. To add more than one flag at a time, flag may be a string of more than one character.

**remove_flag(flag)**
Unset the flag(s) specified by flag without changing other flags. To remove more than one flag at a time, flag maybe a string of more than one character.

When an MMDFMessage instance is created based upon a MaildirMessage instance, a “From ” line is generated based upon the MaildirMessage instance’s delivery date, and the following conversions take place:

<table>
<thead>
<tr>
<th>Resulting state</th>
<th>MaildirMessage state</th>
</tr>
</thead>
<tbody>
<tr>
<td>R flag</td>
<td>S flag</td>
</tr>
<tr>
<td>O flag</td>
<td>“cur” subdirectory</td>
</tr>
</tbody>
</table>
When an \texttt{MMDFMessage} instance is created based upon an \texttt{MHMessage} instance, the following conversions take place:

<table>
<thead>
<tr>
<th>Resulting state</th>
<th>MHMessage state</th>
</tr>
</thead>
<tbody>
<tr>
<td>R flag and O flag</td>
<td>no “unseen” sequence</td>
</tr>
<tr>
<td>O flag</td>
<td>“unseen” sequence</td>
</tr>
<tr>
<td>F flag</td>
<td>“flagged” sequence</td>
</tr>
<tr>
<td>A flag</td>
<td>“replied” sequence</td>
</tr>
</tbody>
</table>

When an \texttt{MMDFMessage} instance is created based upon a \texttt{BabylMessage} instance, the following conversions take place:

<table>
<thead>
<tr>
<th>Resulting state</th>
<th>BabylMessage state</th>
</tr>
</thead>
<tbody>
<tr>
<td>R flag and O flag</td>
<td>no “unseen” label</td>
</tr>
<tr>
<td>O flag</td>
<td>“unseen” label</td>
</tr>
<tr>
<td>D flag</td>
<td>“deleted” label</td>
</tr>
<tr>
<td>A flag</td>
<td>“answered” label</td>
</tr>
</tbody>
</table>

When an \texttt{MMDFMessage} instance is created based upon an \texttt{mboxMessage} instance, the “From ” line is copied and all flags directly correspond:

<table>
<thead>
<tr>
<th>Resulting state</th>
<th>mboxMessage state</th>
</tr>
</thead>
<tbody>
<tr>
<td>R flag</td>
<td>R flag</td>
</tr>
<tr>
<td>O flag</td>
<td>O flag</td>
</tr>
<tr>
<td>--------</td>
<td>--------</td>
</tr>
<tr>
<td>D flag</td>
<td>D flag</td>
</tr>
<tr>
<td>F flag</td>
<td>F flag</td>
</tr>
<tr>
<td>A flag</td>
<td>A flag</td>
</tr>
</tbody>
</table>
19.4.3. Exceptions

The following exception classes are defined in the mailbox module:

exception mailbox.Error
    The based class for all other module-specific exceptions.

exception mailbox.NoSuchMailboxError
    Raised when a mailbox is expected but is not found, such as when instantiating a Mailbox subclass with a path that does not exist (and with the create parameter set to False), or when opening a folder that does not exist.

exception mailbox.NotEmptyError
    Raised when a mailbox is not empty but is expected to be, such as when deleting a folder that contains messages.

exception mailbox.ExternalClashError
    Raised when some mailbox-related condition beyond the control of the program causes it to be unable to proceed, such as when failing to acquire a lock that another program already holds a lock, or when a uniquely-generated file name already exists.

exception mailbox.FormatError
    Raised when the data in a file cannot be parsed, such as when an MH instance attempts to read a corrupted .mh_sequences file.
19.4.4. Examples

A simple example of printing the subjects of all messages in a mailbox that seem interesting:

```python
import mailbox
for message in mailbox.mbox('~/mbox'):
    subject = message['subject']  # Could possibly be None.
    if subject and 'python' in subject.lower():
        print(subject)
```

To copy all mail from a Babyl mailbox to an MH mailbox, converting all of the format-specific information that can be converted:

```python
import mailbox
import email

list_names = ('python-list', 'python-dev', 'python-bugs')
```

This example sorts mail from several mailing lists into different mailboxes, being careful to avoid mail corruption due to concurrent modification by other programs, mail loss due to interruption of the program, or premature termination due to malformed messages in the mailbox:
boxes = {name: mailbox.mbox('~/email/%s' % name) for name in list_names}

for key in inbox.iterkeys():
    try:
        message = inbox[key]
    except email.Errors.MessageParseError:
        continue  # The message is malformed.

for name in list_names:
    list_id = message['list-id']
    if list_id and name in list_id:
        # Get mailbox to use
        box = boxes[name]

        # Write copy to disk before removing original.
        # If there's a crash, you might duplicate that's better than losing a message completely.
        box.lock()
        box.add(message)
        box.flush()
        box.unlock()

        # Remove original message
        inbox.lock()
        inbox.discard(key)
        inbox.flush()
        inbox.unlock()
        break  # Found destination,

for box in boxes.itervalues():
    box.close()}
19.5. **mimetypes** — Map filenames to MIME types

**Source code:** Lib/mimetypes.py

The `mimetypes` module converts between a filename or URL and the MIME type associated with the filename extension. Conversions are provided from filename to MIME type and from MIME type to filename extension; encodings are not supported for the latter conversion.

The module provides one class and a number of convenience functions. The functions are the normal interface to this module, but some applications may be interested in the class as well.

The functions described below provide the primary interface for this module. If the module has not been initialized, they will call `init()` if they rely on the information `init()` sets up.

`mimetypes.guess_type(url, strict=True)`

Guess the type of a file based on its filename or URL, given by `url`. The return value is a tuple `(type, encoding)` where `type` is None if the type can’t be guessed (missing or unknown suffix) or a string of the form `'type/subtype'`, usable for a MIME `content-type` header.

`encoding` is None for no encoding or the name of the program used to encode (e.g. `compress` or `gzip`). The encoding is suitable for use as a `Content-Encoding` header, not as a `Content-Transfer-Encoding` header. The mappings are table driven. Encoding suffixes are case sensitive; type suffixes are first tried case
sensitively, then case insensitively.

The optional `strict` argument is a flag specifying whether the list of known MIME types is limited to only the official types registered with IANA. When `strict` is `True` (the default), only the IANA types are supported; when `strict` is `False`, some additional non-standard but commonly used MIME types are also recognized.

```
mimetypes.guess_all_extensions(type, strict=True)
```

Guess the extensions for a file based on its MIME type, given by `type`. The return value is a list of strings giving all possible filename extensions, including the leading dot (`'.'`). The extensions are not guaranteed to have been associated with any particular data stream, but would be mapped to the MIME type `type` by `guess_type()`.

The optional `strict` argument has the same meaning as with the `guess_type()` function.

```
mimetypes.guess_extension(type, strict=True)
```

Guess the extension for a file based on its MIME type, given by `type`. The return value is a string giving a filename extension, including the leading dot (`'.'`). The extension is not guaranteed to have been associated with any particular data stream, but would be mapped to the MIME type `type` by `guess_type()` If no extension can be guessed for `type`, `None` is returned.

The optional `strict` argument has the same meaning as with the `guess_type()` function.

Some additional functions and data items are available for controlling the behavior of the module.
mimetypes.**init**(files=None)

Initialize the internal data structures. If given, *files* must be a sequence of file names which should be used to augment the default type map. If omitted, the file names to use are taken from *knownfiles*; on Windows, the current registry settings are loaded. Each file named in *files* or *knownfiles* takes precedence over those named before it. Calling *init()* repeatedly is allowed.

Specifying an empty list for *files* will prevent the system defaults from being applied: only the well-known values will be present from a built-in list.

*Changed in version 3.2:* Previously, Windows registry settings were ignored.

mimetypes.**read_mime_types**(filename)

Load the type map given in the file *filename*, if it exists. The type map is returned as a dictionary mapping filename extensions, including the leading dot ('.'), to strings of the form 'type/subtype'. If the file *filename* does not exist or cannot be read, None is returned.

mimetypes.**add_type**(type, ext, strict=True)

Add a mapping from the MIME type *type* to the extension *ext*. When the extension is already known, the new type will replace the old one. When the type is already known the extension will be added to the list of known extensions.

When *strict* is True (the default), the mapping will added to the official MIME types, otherwise to the non-standard ones.

mimetypes.**init**
Flag indicating whether or not the global data structures have been initialized. This is set to True by `init()`.

**mimetypes.knownfiles**
List of type map file names commonly installed. These files are typically named `mime.types` and are installed in different locations by different packages.

**mimetypes.suffix_map**
Dictionary mapping suffixes to suffixes. This is used to allow recognition of encoded files for which the encoding and the type are indicated by the same extension. For example, the `.tgz` extension is mapped to `.tar.gz` to allow the encoding and type to be recognized separately.

**mimetypes.encodings_map**
Dictionary mapping filename extensions to encoding types.

**mimetypes.types_map**
Dictionary mapping filename extensions to MIME types.

**mimetypes.common_types**
Dictionary mapping filename extensions to non-standard, but commonly found MIME types.

An example usage of the module:

```python
>>> import mimetypes
>>> mimetypes.init()
>>> mimetypes.knownfiles
['/etc/mime.types', '/etc/httpd/mime.types', ...]
>>> mimetypes.suffix_map['.tgz']
'.tar.gz'
>>> mimetypes.encodings_map['.gz']
```
'gzip'

>>> mimetypes.types_map['.tgz']
'application/x-tar-gz'
19.5.1. MimeTypes Objects

The `MimeTypes` class may be useful for applications which may want more than one MIME-type database; it provides an interface similar to the one of the `mimetypes` module.

```python
class mimetypes.MimeTypes(filenames=(), strict=True)
```

This class represents a MIME-types database. By default, it provides access to the same database as the rest of this module. The initial database is a copy of that provided by the module, and may be extended by loading additional `mime.types`-style files into the database using the `read()` or `readfp()` methods. The mapping dictionaries may also be cleared before loading additional data if the default data is not desired.

The optional `filenames` parameter can be used to cause additional files to be loaded “on top” of the default database.

`MimeTypes.suffix_map`

Dictionary mapping suffixes to suffixes. This is used to allow recognition of encoded files for which the encoding and the type are indicated by the same extension. For example, the `.tgz` extension is mapped to `.tar.gz` to allow the encoding and type to be recognized separately. This is initially a copy of the global `suffix_map` defined in the module.

`MimeTypes.encodings_map`

Dictionary mapping filename extensions to encoding types. This is initially a copy of the global `encodings_map` defined in the module.
MimeTypes. **types_map**

Tuple containing two dictionaries, mapping filename extensions to MIME types: the first dictionary is for the non-standards types and the second one is for the standard types. They are initialized by `common_types` and `types_map`.

MimeTypes. **types_map_inv**

Tuple containing two dictionaries, mapping MIME types to a list of filename extensions: the first dictionary is for the non-standards types and the second one is for the standard types. They are initialized by `common_types` and `types_map`.

MimeTypes. **guess_extension**(type, strict=True)

Similar to the `guess_extension()` function, using the tables stored as part of the object.

MimeTypes. **guess_type**(url, strict=True)

Similar to the `guess_type()` function, using the tables stored as part of the object.

MimeTypes. **guess_all_extensions**(type, strict=True)

Similar to the `guess_all_extensions()` function, using the tables stored as part of the object.

MimeTypes. **read**(filename, strict=True)

Load MIME information from a file named `filename`. This uses `readfp()` to parse the file.

If `strict` is True, information will be added to list of standard types, else to the list of non-standard types.

MimeTypes. **readfp**(fp, strict=True)
Load MIME type information from an open file `fp`. The file must have the format of the standard `mime.types` files.

If `strict` is True, information will be added to the list of standard types, else to the list of non-standard types.

```python
MimeTypes.read_windows_registry(strict=True)
```

Load MIME type information from the Windows registry. Availability: Windows.

If `strict` is True, information will be added to the list of standard types, else to the list of non-standard types.

*New in version 3.2.*
19.6. base64 — RFC 3548: Base16, Base32, Base64 Data Encodings

This module provides data encoding and decoding as specified in RFC 3548. This standard defines the Base16, Base32, and Base64 algorithms for encoding and decoding arbitrary binary strings into ASCII-only byte strings that can be safely sent by email, used as parts of URLs, or included as part of an HTTP POST request. The encoding algorithm is not the same as the uuencode program.

There are two interfaces provided by this module. The modern interface supports encoding and decoding ASCII byte string objects using all three alphabets. Additionally, the decoding functions of the modern interface also accept Unicode strings containing only ASCII characters. The legacy interface provides for encoding and decoding to and from file-like objects as well as byte strings, but only using the Base64 standard alphabet.

*Changed in version 3.3:* ASCII-only Unicode strings are now accepted by the decoding functions of the modern interface.

The modern interface provides:

```python
base64. b64encode(s, altchars=None)
```

Encode a byte string using Base64.

s is the string to encode. Optional altchars must be a string of at least length 2 (additional characters are ignored) which specifies an alternative alphabet for the + and / characters. This allows an
application to e.g. generate URL or filesystem safe Base64 strings. The default is None, for which the standard Base64 alphabet is used.

The encoded byte string is returned.

```python
base64.b64decode(s, altchars=None, validate=False)
```

Decode a Base64 encoded byte string.

`s` is the byte string to decode. Optional `altchars` must be a string of at least length 2 (additional characters are ignored) which specifies the alternative alphabet used instead of the + and / characters.

The decoded string is returned. A `binascii.Error` exception is raised if `s` is incorrectly padded.

If `validate` is False (the default), non-base64-alphabet characters are discarded prior to the padding check. If `validate` is True, non-base64-alphabet characters in the input result in a `binascii.Error`.

```python
base64.standard_b64encode(s)
```

Encode byte string `s` using the standard Base64 alphabet.

```python
base64.standard_b64decode(s)
```

Decode byte string `s` using the standard Base64 alphabet.

```python
base64.urlsafe_b64encode(s)
```

Encode byte string `s` using a URL-safe alphabet, which substitutes - instead of + and _ instead of / in the standard Base64 alphabet. The result can still contain =.

```python
base64.urlsafe_b64decode(s)
```
Decode byte string s using a URL-safe alphabet, which substitutes - instead of + and _ instead of / in the standard Base64 alphabet.

**base64. b32encode(s)**

Encode a byte string using Base32. s is the string to encode. The encoded string is returned.

**base64. b32decode(s, casefold=False, map01=None)**

Decode a Base32 encoded byte string.

s is the byte string to decode. Optional casefold is a flag specifying whether a lowercase alphabet is acceptable as input. For security purposes, the default is False.

**RFC 3548** allows for optional mapping of the digit 0 (zero) to the letter O (oh), and for optional mapping of the digit 1 (one) to either the letter I (eye) or letter L (el). The optional argument map01 when not None, specifies which letter the digit 1 should be mapped to (when map01 is not None, the digit 0 is always mapped to the letter O). For security purposes the default is None, so that 0 and 1 are not allowed in the input.

The decoded byte string is returned. A *binascii.Error* is raised if s were incorrectly padded or if there are non-alphabet characters present in the string.

**base64. b16encode(s)**

Encode a byte string using Base16.

s is the string to encode. The encoded byte string is returned.

**base64. b16decode(s, casefold=False)**

Decode a Base16 encoded byte string.
s is the string to decode. Optional \textit{casefold} is a flag specifying whether a lowercase alphabet is acceptable as input. For security purposes, the default is False.

The decoded byte string is returned. A \texttt{TypeError} is raised if \texttt{s} were incorrectly padded or if there are non-alphabet characters present in the string.

The legacy interface:

\texttt{base64.decode(input, output)}

Decode the contents of the binary \texttt{input} file and write the resulting binary data to the \texttt{output} file. \texttt{input} and \texttt{output} must be \texttt{file objects}. \texttt{input} will be read until \texttt{input.read()} returns an empty bytes object.

\texttt{base64.decodebytes(s)}
\texttt{base64.decodestring(s)}

Decode the byte string \texttt{s}, which must contain one or more lines of \texttt{base64} encoded data, and return a byte string containing the resulting binary data. \texttt{decodestring} is a deprecated alias.

\texttt{New in version 3.1.}

\texttt{base64.encode(input, output)}

Encode the contents of the binary \texttt{input} file and write the resulting \texttt{base64} encoded data to the \texttt{output} file. \texttt{input} and \texttt{output} must be \texttt{file objects}. \texttt{input} will be read until \texttt{input.read()} returns an empty bytes object. \texttt{encode()} returns the encoded data plus a trailing newline character (b'\n').

\texttt{base64.encodebytes(s)}
\texttt{base64.encodestring(s)}
Encode the byte string \( s \), which can contain arbitrary binary data, and return a byte string containing one or more lines of base64-encoded data. `encodebytes()` returns a string containing one or more lines of base64-encoded data always including an extra trailing newline (b'\n'). `encodestring` is a deprecated alias.

An example usage of the module:

```python
>>> import base64
>>> encoded = base64.b64encode(b'data to be encoded')
>>> encoded
b'ZGF0YSB0byBiZSBmNmVzZGVk'
>>> data = base64.b64decode(encoded)
>>> data
b'data to be encoded'
```

See also:

**Module** binascii

Support module containing ASCII-to-binary and binary-to-ASCII conversions.

**RFC 1521** - MIME (Multipurpose Internet Mail Extensions) Part One: Mechanisms for Specifying and Describing the Format of Internet Message Bodies

Section 5.2, “Base64 Content-Transfer-Encoding,” provides the definition of the base64 encoding.
19.7. **binhex** — Encode and decode binhex4 files

This module encodes and decodes files in binhex4 format, a format allowing representation of Macintosh files in ASCII. Only the data fork is handled.

The *binhex* module defines the following functions:

`binhex.binhex(input, output)`

Convert a binary file with filename `input` to binhex file `output`. The `output` parameter can either be a filename or a file-like object (any object supporting a `write()` and `close()` method).

`binhex.hexbin(input, output)`

Decode a binhex file `input`. `input` may be a filename or a file-like object supporting `read()` and `close()` methods. The resulting file is written to a file named `output`, unless the argument is None in which case the output filename is read from the binhex file.

The following exception is also defined:

`exception binhex.Error`

Exception raised when something can’t be encoded using the binhex format (for example, a filename is too long to fit in the filename field), or when input is not properly encoded binhex data.

**See also:**

**Module binascii**

Support module containing ASCII-to-binary and binary-to-ASCII
conversions.
19.7.1. Notes

There is an alternative, more powerful interface to the coder and decoder, see the source for details.

If you code or decode textfiles on non-Macintosh platforms they will still use the old Macintosh newline convention (carriage-return as end of line).

As of this writing, `hexbin()` appears to not work in all cases.
19.8. **binascii** — Convert between binary and ASCII

The *binascii* module contains a number of methods to convert between binary and various ASCII-encoded binary representations. Normally, you will not use these functions directly but use wrapper modules like *uu*, *base64*, or *binhex* instead. The *binascii* module contains low-level functions written in C for greater speed that are used by the higher-level modules.

**Note:** *a2b_* functions accept Unicode strings containing only ASCII characters. Other functions only accept *bytes-like objects* (such as *bytes*, *bytearray* and other objects that support the buffer protocol).

*Changed in version 3.3:* ASCII-only unicode strings are now accepted by the *a2b_* functions.

The *binascii* module defines the following functions:

*binascii*. **a2b_uu**(string)

Convert a single line of uuencoded data back to binary and return the binary data. Lines normally contain 45 (binary) bytes, except for the last line. Line data may be followed by whitespace.

*binascii*. **b2a_uu**(data)

Convert binary data to a line of ASCII characters, the return value is the converted line, including a newline char. The length of *data* should be at most 45.
binascii.\texttt{a2b\_base64}(\texttt{string})

Convert a block of base64 data back to binary and return the binary data. More than one line may be passed at a time.

binascii.\texttt{b2a\_base64}(\texttt{data})

Convert binary data to a line of ASCII characters in base64 coding. The return value is the converted line, including a newline char. The length of \texttt{data} should be at most 57 to adhere to the base64 standard.

binascii.\texttt{a2b\_qp}(\texttt{string}, \texttt{header=}False)

Convert a block of quoted-printable data back to binary and return the binary data. More than one line may be passed at a time. If the optional argument \texttt{header} is present and true, underscores will be decoded as spaces.

\textit{Changed in version 3.2:} Accept only bytestring or bytearray objects as input.

binascii.\texttt{b2a\_qp}(\texttt{data}, \texttt{quotetabs=}False, \texttt{istext=}True, \texttt{header=}False)

Convert binary data to a line(s) of ASCII characters in quoted-printable encoding. The return value is the converted line(s). If the optional argument \texttt{quotetabs} is present and true, all tabs and spaces will be encoded. If the optional argument \texttt{istext} is present and true, newlines are not encoded but trailing whitespace will be encoded. If the optional argument \texttt{header} is present and true, spaces will be encoded as underscores per RFC1522. If the optional argument \texttt{header} is present and false, newline characters will be encoded as well; otherwise linefeed conversion might corrupt the binary data stream.

binascii.\texttt{a2b\_hqx}(\texttt{string})
Convert binhex4 formatted ASCII data to binary, without doing RLE-decompression. The string should contain a complete number of binary bytes, or (in case of the last portion of the binhex4 data) have the remaining bits zero.

```
binascii.rledecode_hqx(data)
```

Perform RLE-decompression on the data, as per the binhex4 standard. The algorithm uses 0x90 after a byte as a repeat indicator, followed by a count. A count of 0 specifies a byte value of 0x90. The routine returns the decompressed data, unless data input data ends in an orphaned repeat indicator, in which case the Incomplete exception is raised.

*Changed in version 3.2:* Accept only bytestring or bytearray objects as input.

```
binascii.rlecode_hqx(data)
```

Perform binhex4 style RLE-compression on data and return the result.

```
binascii.b2a_hqx(data)
```

Perform hexbin4 binary-to-ASCII translation and return the resulting string. The argument should already be RLE-coded, and have a length divisible by 3 (except possibly the last fragment).

```
binascii.crc_hqx(data, crc)
```

Compute the binhex4 crc value of data, starting with an initial crc and returning the result.

```
binascii.crc32(data[, crc])
```

Compute CRC-32, the 32-bit checksum of data, starting with an initial crc. This is consistent with the ZIP file checksum. Since the
algorithm is designed for use as a checksum algorithm, it is not suitable for use as a general hash algorithm. Use as follows:

```python
print(binascii.crc32(b"hello world"))
# Or, in two pieces:
crc = binascii.crc32(b"hello")
crc = binascii.crc32(b" world", crc) & 0xffffffff
print('crc32 = {:#010x}'.format(crc))
```

**Note:** To generate the same numeric value across all Python versions and platforms use crc32(data) & 0xffffffff. If you are only using the checksum in packed binary format this is not necessary as the return value is the correct 32bit binary representation regardless of sign.

`binascii.b2a_hex(data)`
`binascii.hexlify(data)`

Return the hexadecimal representation of the binary `data`. Every byte of `data` is converted into the corresponding 2-digit hex representation. The resulting string is therefore twice as long as the length of `data`.

`binascii.a2b_hex(hexstr)`
`binascii.unhexlify(hexstr)`

Return the binary data represented by the hexadecimal string `hexstr`. This function is the inverse of `b2a_hex()`. `hexstr` must contain an even number of hexadecimal digits (which can be upper or lower case), otherwise a `TypeError` is raised.

*Changed in version 3.2:* Accept only bytestring or bytearray objects as input.
exception binascii.**Error**

Exception raised on errors. These are usually programming errors.

exception binascii.**Incomplete**

Exception raised on incomplete data. These are usually not programming errors, but may be handled by reading a little more data and trying again.

**See also:**

**Module base64**

Support for base64 encoding used in MIME email messages.

**Module binhex**

Support for the binhex format used on the Macintosh.

**Module uu**

Support for UU encoding used on Unix.

**Module quopri**

Support for quoted-printable encoding used in MIME email messages.
19.9. `quopri` — Encode and decode MIME quoted-printable data

**Source code:** Lib/quopri.py

This module performs quoted-printable transport encoding and decoding, as defined in RFC 1521: “MIME (Multipurpose Internet Mail Extensions) Part One: Mechanisms for Specifying and Describing the Format of Internet Message Bodies”. The quoted-printable encoding is designed for data where there are relatively few nonprintable characters; the base64 encoding scheme available via the base64 module is more compact if there are many such characters, as when sending a graphics file.

`quopri.decode(input, output, header=False)`

Decode the contents of the `input` file and write the resulting decoded binary data to the `output` file. `input` and `output` must be file objects. `input` will be read until `input.readline()` returns an empty string. If the optional argument `header` is present and true, underscore will be decoded as space. This is used to decode “Q”-encoded headers as described in RFC 1522: “MIME (Multipurpose Internet Mail Extensions) Part Two: Message Header Extensions for Non-ASCII Text”.

`quopri.encode(input, output, quotetabs, header=False)`

Encode the contents of the `input` file and write the resulting quoted-printable data to the `output` file. `input` and `output` must be file objects.
objects. input will be read until input.readline() returns an empty string. quotetabs is a flag which controls whether to encode embedded spaces and tabs; when true it encodes such embedded whitespace, and when false it leaves them unencoded. Note that spaces and tabs appearing at the end of lines are always encoded, as per RFC 1521. header is a flag which controls if spaces are encoded as underscores as per RFC 1522.

quopri. **decodestring**(s, header=False)
Like decode(), except that it accepts a source string and returns the corresponding decoded string.

quopri. **encodestring**(s, quotetabs=False, header=False)
Like encode(), except that it accepts a source string and returns the corresponding encoded string. quotetabs and header are optional (defaulting to False), and are passed straight through to encode().

Module base64
  Encode and decode MIME base64 data
19.10. uu — Encode and decode uuencode files

Source code: Lib/uu.py

This module encodes and decodes files in uuencode format, allowing arbitrary binary data to be transferred over ASCII-only connections. Wherever a file argument is expected, the methods accept a file-like object. For backwards compatibility, a string containing a pathname is also accepted, and the corresponding file will be opened for reading and writing; the pathname '-' is understood to mean the standard input or output. However, this interface is deprecated; it's better for the caller to open the file itself, and be sure that, when required, the mode is 'rb' or 'wb' on Windows.

This code was contributed by Lance Ellinghouse, and modified by Jack Jansen.

The uu module defines the following functions:

uu.encode(in_file, out_file, name=None, mode=None)

Uuencode file in_file into file out_file. The uuencoded file will have the header specifying name and mode as the defaults for the results of decoding the file. The default defaults are taken from in_file, or '-' and 0o666 respectively.

uu.decode(in_file, out_file=None, mode=None, quiet=False)

This call decodes uuencoded file in_file placing the result on file out_file. If out_file is a pathname, mode is used to set the permission bits if the file must be created. Defaults for out_file and
mode are taken from the uuencode header. However, if the file specified in the header already exists, a uu.Error is raised.

decode() may print a warning to standard error if the input was produced by an incorrect uuencoder and Python could recover from that error. Setting quiet to a true value silences this warning.

exception uu.Error
Subclass of Exception, this can be raised by uu.decode() under various situations, such as described above, but also including a badly formatted header, or truncated input file.

20.1. `html` — HyperText Markup Language support

**Source code:** `Lib/html/__init__.py`

This module defines utilities to manipulate HTML.

```python
html.escape(s, quote=True)
```

Convert the characters `&`, `<`, and `>` in string `s` to HTML-safe sequences. Use this if you need to display text that might contain such characters in HTML. If the optional flag `quote` is true, the characters `"` and `'` are also translated; this helps for inclusion in an HTML attribute value delimited by quotes, as in `<a href="...">`.

*New in version 3.2.*

Submodules in the `html` package are:

- `html.parser` — HTML/XHTML parser with lenient parsing mode
- `html.entities` — HTML entity definitions
20.2. html.parser — Simple HTML and XHTML parser

Source code: Lib/html/parser.py

This module defines a class HTMLParser which serves as the basis for parsing text files formatted in HTML (HyperText Mark-up Language) and XHTML.

```python
class html.parser.HTMLParser(strict=False)
    Create a parser instance. If strict is False (the default), the parser will accept and parse invalid markup. If strict is True the parser will raise an HTMLParseError exception instead [1] when it's not able to parse the markup. The use of strict=True is discouraged and the strict argument is deprecated.
```

An HTMLParser instance is fed HTML data and calls handler methods when start tags, end tags, text, comments, and other markup elements are encountered. The user should subclass HTMLParser and override its methods to implement the desired behavior.

This parser does not check that end tags match start tags or call the end-tag handler for elements which are closed implicitly by closing an outer element.

_changed in version 3.2:_ strict keyword added.

_Deprecated since version 3.3, will be removed in version 3.5:_ The strict argument and the strict mode have been deprecated. The
parser is now able to accept and parse invalid markup too.

An exception is defined as well:

```
exception html.parser.HTMLParseError
```

Exception raised by the `HTMLParser` class when it encounters an error while parsing and `strict` is `True`. This exception provides three attributes: `msg` is a brief message explaining the error, `lineno` is the number of the line on which the broken construct was detected, and `offset` is the number of characters into the line at which the construct starts.

```
Deprecated since version 3.3, will be removed in version 3.5: This exception has been deprecated because it's never raised by the parser (when the default non-strict mode is used).
```
20.2.1. Example HTML Parser Application

As a basic example, below is a simple HTML parser that uses the `HTMLParser` class to print out start tags, end tags, and data as they are encountered:

```python
from html.parser import HTMLParser

class MyHTMLParser(HTMLParser):
    def handle_starttag(self, tag, attrs):
        print("Encountered a start tag: ", tag)
    def handle_endtag(self, tag):
        print("Encountered an end tag : ", tag)
    def handle_data(self, data):
        print("Encountered some data : ", data)

parser = MyHTMLParser(strict=False)
parser.feed('<!--html--><head><title>Test</title></head>'
'<!--body--><h1>Parse me!</h1></body><!--html-->'

The output will then be:

Encountered a start tag: html
Encountered a start tag: head
Encountered a start tag: title
Encountered some data : Test
Encountered an end tag : title
Encountered an end tag : head
Encountered a start tag: body
Encountered a start tag: h1
Encountered some data : Parse me!
Encountered an end tag : h1
Encountered an end tag : body
Encountered an end tag : html
20.2.2. **HTMLParser** Methods

**HTMLParser** instances have the following methods:

**HTMLParser.**`feed(data)`
Feed some text to the parser. It is processed insofar as it consists of complete elements; incomplete data is buffered until more data is fed or `close()` is called. `data` must be `str`.

**HTMLParser.**`close()`
Force processing of all buffered data as if it were followed by an end-of-file mark. This method may be redefined by a derived class to define additional processing at the end of the input, but the redefined version should always call the **HTMLParser** base class method `close()`.

**HTMLParser.**`reset()`
Reset the instance. Loses all unprocessed data. This is called implicitly at instantiation time.

**HTMLParser.**`getpos()`
Return current line number and offset.

**HTMLParser.**`get_starttag_text()`
Return the text of the most recently opened start tag. This should not normally be needed for structured processing, but may be useful in dealing with HTML “as deployed” or for re-generating input with minimal changes (whitespace between attributes can be preserved, etc.).

The following methods are called when data or markup elements are
encountered and they are meant to be overridden in a subclass. The base class implementations do nothing (except for `handle_startendtag()`):

**HTMLParser.** `handle_starttag(tag, attrs)`

This method is called to handle the start of a tag (e.g. `<div id="main">`).

The `tag` argument is the name of the tag converted to lower case. The `attrs` argument is a list of `(name, value)` pairs containing the attributes found inside the tag’s `<>` brackets. The `name` will be translated to lower case, and quotes in the `value` have been removed, and character and entity references have been replaced.

For instance, for the tag `<A HREF="http://www.cwi.nl/"`, this method would be called as `handle_starttag('a', [('href', 'http://www.cwi.nl/')])`.

All entity references from `html.entities` are replaced in the attribute values.

**HTMLParser.** `handle_endtag(tag)`

This method is called to handle the end tag of an element (e.g. `</div>`).

The `tag` argument is the name of the tag converted to lower case.

**HTMLParser.** `handle_startendtag(tag, attrs)`

Similar to `handle_starttag()`, but called when the parser encounters an XHTML-style empty tag (`<img ... />`). This method may be overridden by subclasses which require this particular lexical information; the default implementation simply
calls `handle_starttag()` and `handle_endtag()`.

**HTMLParser.** `handle_data(data)`

This method is called to process arbitrary data (e.g. text nodes and the content of `<script>...</script>` and `<style>...</style>`).

**HTMLParser.** `handle_entityref(name)`

This method is called to process a named character reference of the form `&name;` (e.g. `&gt;`), where `name` is a general entity reference (e.g. `'gt'`).

**HTMLParser.** `handle_charref(name)`

This method is called to process decimal and hexadecimal numeric character references of the form `&#NNN;` and `&#xNNN;`. For example, the decimal equivalent for `&gt;` is `&#62;`, whereas the hexadecimal is `&#x3E;`; in this case the method will receive '62' or 'x3E'.

**HTMLParser.** `handle_comment(data)`

This method is called when a comment is encountered (e.g. `<!-- comment -->`).

For example, the comment `<!-- comment -->` will cause this method to be called with the argument `'comment'`.

The content of Internet Explorer conditional comments (condcoms) will also be sent to this method, so, for `<!--[if IE 9]>IE9-specific content<![endif]-->`, this method will receive `'[if IE 9]>IE-specific content<![endif]'`.

**HTMLParser.** `handle_decl(decl)`
This method is called to handle an HTML doctype declaration (e.g. `<!DOCTYPE html>`).

The `decl` parameter will be the entire contents of the declaration inside the `<!...>` markup (e.g. `'DOCTYPE html'`).

**HTMLParser.**`handle_pi(data)`

Method called when a processing instruction is encountered. The `data` parameter will contain the entire processing instruction. For example, for the processing instruction `<?proc color='red'>`, this method would be called as `handle_pi("proc color='red'")`. It is intended to be overridden by a derived class; the base class implementation does nothing.

**Note:** The **HTMLParser** class uses the SGML syntactic rules for processing instructions. An XHTML processing instruction using the trailing '?' will cause the '?' to be included in `data`.

**HTMLParser.**`unknown_decl(data)`

This method is called when an unrecognized declaration is read by the parser.

The `data` parameter will be the entire contents of the declaration inside the `<![...]>` markup. It is sometimes useful to be overridden by a derived class. The base class implementation raises an **HTMLParseError** when `strict` is True.
20.2.3. Examples

The following class implements a parser that will be used to illustrate more examples:

```python
from html.parser import HTMLParser
from html.entities import name2codepoint

class MyHTMLParser(HTMLParser):
    def handle_starttag(self, tag, attrs):
        print("Start tag:", tag)
        for attr in attrs:
            print("  attr:", attr)
    def handle_endtag(self, tag):
        print("End tag :", tag)
    def handle_data(self, data):
        print("Data :", data)
    def handle_comment(self, data):
        print("Comment :", data)
    def handle_entityref(self, name):
        c = chr(name2codepoint[name])
        print("Named ent:", c)
    def handle_charref(self, name):
        if name.startswith('x'):
            c = chr(int(name[1:], 16))
        else:
            c = chr(int(name))
        print("Num ent :", c)
    def handle_decl(self, data):
        print("Decl :", data)

parser = MyHTMLParser(strict=False)
```

Parsing a doctype:
Parsing an element with a few attributes and a title:

```python
>>> parser.feed('&lt;img src=&quot;python-logo.png&quot; alt=&quot;The Python logo&quot;&gt;')
Start tag: img
attr: ('src', 'python-logo.png')
attr: ('alt', 'The Python logo')

>>> parser.feed('&lt;h1&gt;Python&lt;/h1&gt;')
Start tag: h1
Data : Python
End tag : h1
```

The content of `<script>` and `<style>` elements is returned as is, without further parsing:

```python
>>> parser.feed('&lt;style type=&quot;text/css&quot;&gt;#python { color: green }&lt;/style&gt;')
Start tag: style
attr: ('type', 'text/css')
Data : #python { color: green }
End tag : style

>>> parser.feed('&lt;script type=&quot;text/javascript&quot;&gt;
...   &quot;alert(&quot;&lt;strong&gt;hello!&lt;/strong&gt;&quot;);&lt;/script&gt;')
Start tag: script
attr: ('type', 'text/javascript')
Data : alert("&lt;strong&gt;hello!&lt;/strong&gt;");
End tag : script
```

Parsing comments:
Parsing named and numeric character references and converting them to the correct char (note: these 3 references are all equivalent to ‘>’):

Feeding incomplete chunks to `feed()` works, but `handle_data()` might be called more than once:

Parsing invalid HTML (e.g. unquoted attributes) also works:
Footnotes

For backward compatibility reasons strict mode does not raise exceptions for all non-compliant HTML. That is, some invalid HTML is tolerated even in strict mode.

[1]
20.3. html.entities — Definitions of HTML general entities

Source code: Lib/html/entities.py

This module defines four dictionaries, html5, name2codepoint, codepoint2name, and entitydefs.

html.entities.html5

A dictionary that maps HTML5 named character references [1] to the equivalent Unicode character(s), e.g. `html5['gt;'] == '>'. Note that the trailing semicolon is included in the name (e.g. 'gt;'), however some of the names are accepted by the standard even without the semicolon: in this case the name is present with and without the ';'..

New in version 3.3.

html.entities.entitydefs

A dictionary mapping XHTML 1.0 entity definitions to their replacement text in ISO Latin-1.

html.entities.name2codepoint

A dictionary that maps HTML entity names to the Unicode codepoints.

html.entities.codepoint2name

A dictionary that maps Unicode codepoints to HTML entity names.
Footnotes

20.4. XML Processing Modules

Python’s interfaces for processing XML are grouped in the xml package.

Warning: The XML modules are not secure against erroneous or maliciously constructed data. If you need to parse untrusted or unauthenticated data see XML vulnerabilities.

It is important to note that modules in the xml package require that there be at least one SAX-compliant XML parser available. The Expat parser is included with Python, so the xml.parsers.expat module will always be available.

The documentation for the xml.dom and xml.sax packages are the definition of the Python bindings for the DOM and SAX interfaces.

The XML handling submodules are:

- xml.etree.ElementTree: the ElementTree API, a simple and lightweight
- xml.dom: the DOM API definition
- xml.dom.minidom: a lightweight DOM implementation
- xml.dom.pulldom: support for building partial DOM trees
- xml.sax: SAX2 base classes and convenience functions
- xml.parsers.expat: the Expat parser binding
20.5. XML vulnerabilities

The XML processing modules are not secure against maliciously constructed data. An attacker can abuse vulnerabilities for e.g. denial of service attacks, to access local files, to generate network connections to other machines, or to or circumvent firewalls. The attacks on XML abuse unfamiliar features like inline DTD (document type definition) with entities.

The following table gives an overview of the known attacks and if the various modules are vulnerable to them.

<table>
<thead>
<tr>
<th>kind</th>
<th>sax</th>
<th>etree</th>
<th>minidom</th>
<th>pulldom</th>
<th>xmlrpc</th>
</tr>
</thead>
<tbody>
<tr>
<td>billion laughs</td>

<td>No</td>
<td>No</td>
<td>No</td>
<td>Yes</td>
</tr>
</tbody>
</table>

1. xml.etree.ElementTree doesn’t expand external entities and raises a ParserError when an entity occurs.
2. xml.dom.minidom doesn’t expand external entities and simply returns the unexpanded entity verbatim.
3. xmlrpcclient doesn’t expand external entities and omits them.

billion laughs / exponential entity expansion

The Billion Laughs attack – also known as exponential entity expansion – uses multiple levels of nested entities. Each entity refers to another entity several times, the final entity definition
contains a small string. Eventually the small string is expanded to several gigabytes. The exponential expansion consumes lots of CPU time, too.

**quadratic blowup entity expansion**

A quadratic blowup attack is similar to a *Billion Laughs* attack; it abuses entity expansion, too. Instead of nested entities it repeats one large entity with a couple of thousand chars over and over again. The attack isn’t as efficient as the exponential case but it avoids triggering countermeasures of parsers against heavily nested entities.

**external entity expansion**

Entity declarations can contain more than just text for replacement. They can also point to external resources by public identifiers or system identifiers. System identifiers are standard URIs or can refer to local files. The XML parser retrieves the resource with e.g. HTTP or FTP requests and embeds the content into the XML document.

**DTD retrieval**

Some XML libraries like Python’s mod:`xml.dom.pulldom` retrieve document type definitions from remote or local locations. The feature has similar implications as the external entity expansion issue.

**decompression bomb**

The issue of decompression bombs (aka *ZIP bomb*) apply to all XML libraries that can parse compressed XML stream like gzipped HTTP streams or LZMA-ed files. For an attacker it can reduce the amount of transmitted data by three magnitudes or more.

The documentation of *defusedxml* on PyPI has further information about all known attack vectors with examples and references.
20.5.1. defused packages

defusedxml is a pure Python package with modified subclasses of all stdlib XML parsers that prevent any potentially malicious operation. The courses of action are recommended for any server code that parses untrusted XML data. The package also ships with example exploits and an extended documentation on more XML exploits like xpath injection.

defusedexpat provides a modified libexpat and patched replacment pyexpat extension module with countermeasures against entity expansion DoS attacks. Defusedexpat still allows a sane and configurable amount of entity expansions. The modifications will be merged into future releases of Python.

The workarounds and modifications are not included in patch releases as they break backward compatibility. After all inline DTD and entity expansion are well-definied XML features.
20.6. `xml.etree.ElementTree` — The ElementTree XML API

The `xml.etree.ElementTree` module implements a simple and efficient API for parsing and creating XML data.

*Changed in version 3.3:* This module will use a fast implementation whenever available. The `xml.etree.cElementTree` module is deprecated.

**Warning:** The `xml.etree.ElementTree` module is not secure against maliciously constructed data. If you need to parse untrusted or unauthenticated data see [XML vulnerabilities](https://xml.etree.org).
20.6.1. Tutorial

This is a short tutorial for using `xml.etree.ElementTree` (ET in short). The goal is to demonstrate some of the building blocks and basic concepts of the module.

20.6.1.1. XML tree and elements

XML is an inherently hierarchical data format, and the most natural way to represent it is with a tree. ET has two classes for this purpose - `ElementTree` represents the whole XML document as a tree, and `Element` represents a single node in this tree. Interactions with the whole document (reading and writing to/from files) are usually done on the `ElementTree` level. Interactions with a single XML element and its sub-elements are done on the `Element` level.

20.6.1.2. Parsing XML

We'll be using the following XML document as the sample data for this section:

```xml
<?xml version="1.0"?>
<data>
    <country name="Liechtenstein">
        <rank>1</rank>
        <year>2008</year>
        <gdppc>141100</gdppc>
        <neighbor name="Austria" direction="E"/>
        <neighbor name="Switzerland" direction="W"/>
    </country>
    <country name="Singapore">
        <rank>4</rank>
    </country>
</data>
```
We can import this data by reading from a file:

```python
import xml.etree.ElementTree as ET
tree = ET.parse('country_data.xml')
root = tree.getroot()
```

Or directly from a string:

```python
root = ET.fromstring(country_data_as_string)
```

`fromstring()` parses XML from a string directly into an `Element`, which is the root element of the parsed tree. Other parsing functions may create an `ElementTree`. Check the documentation to be sure.

As an `Element`, `root` has a tag and a dictionary of attributes:

```python
>>> root.tag
'data'
>>> root.attrib
{} 
```

It also has children nodes over which we can iterate:
for child in root:
...
print(child.tag, child.attrib)
...
country {'name': 'Liechtenstein'}
country {'name': 'Singapore'}
country {'name': 'Panama'}

Children are nested, and we can access specific child nodes by index:

root[0][1].text
'2008'

20.6.1.3. Finding interesting elements

Element has some useful methods that help iterate recursively over all the sub-tree below it (its children, their children, and so on). For example, Element.iter():

for neighbor in root.iter('neighbor'):
...
print(neighbor.attrib)
...
{'name': 'Austria', 'direction': 'E'}
{'name': 'Switzerland', 'direction': 'W'}
{'name': 'Malaysia', 'direction': 'N'}
{'name': 'Costa Rica', 'direction': 'W'}
{'name': 'Colombia', 'direction': 'E'}

Element.findall() finds only elements with a tag which are direct children of the current element. Element.find() finds the first child with a particular tag, and Element.text accesses the element’s text content. Element.get() accesses the element’s attributes:

for country in root.findall('country'):
More sophisticated specification of which elements to look for is possible by using *XPath*.

20.6.1.4. Modifying an XML File

*ElementTree* provides a simple way to build XML documents and write them to files. The *ElementTree.write()* method serves this purpose.

Once created, an *Element* object may be manipulated by directly changing its fields (such as *Element.text*), adding and modifying attributes (*Element.set()* method), as well as adding new children (for example with *Element.append()*).

Let's say we want to add one to each country's rank, and add an updated attribute to the rank element:

```python
>>> for rank in root.iter('rank):
...     new_rank = int(rank.text) + 1
...     rank.text = str(new_rank)
...     rank.set('updated', 'yes')
... 
>>> tree.write('output.xml')
```

Our XML now looks like this:

```
... rank = country.find('rank').text
... name = country.get('name')
... print(name, rank)
...
Liechtenstein 1
Singapore 4
Panama 68
```
We can remove elements using `Element.remove()`. Let's say we want to remove all countries with a rank higher than 50:

```python
>>> for country in root.findall('country'):
...    rank = int(country.find('rank').text)
...    if rank > 50:
...        root.remove(country)
...>>> tree.write('output.xml')
```

Our XML now looks like this:
20.6.1.5. Building XML documents

The SubElement() function also provides a convenient way to create new sub-elements for a given element:

```python
>>> a = ET.Element('a')
>>> b = ET.SubElement(a, 'b')
>>> c = ET.SubElement(a, 'c')
>>> d = ET.SubElement(c, 'd')
>>> ET.dump(a)
<a><b /></c><d /></a>
```

20.6.1.6. Additional resources

See http://effbot.org/zone/element-index.htm for tutorials and links to other docs.
20.6.2. XPath support

This module provides limited support for *XPath expressions* for locating elements in a tree. The goal is to support a small subset of the abbreviated syntax; a full XPath engine is outside the scope of the module.

20.6.2.1. Example

Here's an example that demonstrates some of the XPath capabilities of the module. We'll be using the `countrydata` XML document from the *Parsing XML* section:

```python
import xml.etree.ElementTree as ET

root = ET.fromstring(countrydata)

# Top-level elements
root.findall(".")

# All 'neighbor' grand-children of 'country' children
# elements
root.findall("./country/neighbor")

# Nodes with name='Singapore' that have a 'year' child
root.findall("./year/..[@name='Singapore']")

# 'year' nodes that are children of nodes with name=
root.findall("./*[@name='Singapore']/year")

# All 'neighbor' nodes that are the second child of
root.findall("./neighbor[2]")"
## 20.6.2.2. Supported XPath syntax

<table>
<thead>
<tr>
<th>Syntax</th>
<th>Meaning</th>
</tr>
</thead>
<tbody>
<tr>
<td>tag</td>
<td>Selects all child elements with the given tag. For example, spam selects all child elements named spam, spam/egg selects all grandchildren named egg in all children named spam.</td>
</tr>
<tr>
<td>*</td>
<td>Selects all child elements. For example, */egg selects all grandchildren named egg.</td>
</tr>
<tr>
<td>.</td>
<td>Selects the current node. This is mostly useful at the beginning of the path, to indicate that it’s a relative path.</td>
</tr>
<tr>
<td>//</td>
<td>Selects all subelements, on all levels beneath the current element. For example, ../egg selects all egg elements in the entire tree.</td>
</tr>
<tr>
<td>..</td>
<td>Selects the parent element. Returns None if the path attempts to reach the ancestors of the start element (the element find was called on).</td>
</tr>
<tr>
<td>[@attrib]</td>
<td>Selects all elements that have the given attribute.</td>
</tr>
<tr>
<td>[@attrib='value']</td>
<td>Selects all elements for which the given attribute has the given value. The value cannot contain quotes.</td>
</tr>
<tr>
<td>[tag]</td>
<td>Selects all elements that have a child named tag. Only immediate children are supported.</td>
</tr>
<tr>
<td></td>
<td>Selects all elements that are located at the given position. The position can be either</td>
</tr>
<tr>
<td>position</td>
<td>an integer (1 is the first position), the expression <code>last()</code> (for the last position), or a position relative to the last position (e.g. <code>last()-1</code>).</td>
</tr>
</tbody>
</table>

Predicates (expressions within square brackets) must be preceded by a tag name, an asterisk, or another predicate. `position` predicates must be preceded by a tag name.
20.6.3. Reference

20.6.3.1. Functions

```python
xml.etree.ElementTree.Comment(text=None)
```
Comment element factory. This factory function creates a special element that will be serialized as an XML comment by the standard serializer. The comment string can be either a bytestring or a Unicode string. `text` is a string containing the comment string. Returns an element instance representing a comment.

```python
xml.etree.ElementTree.dump(elem)
```
Writes an element tree or element structure to sys.stdout. This function should be used for debugging only.

The exact output format is implementation dependent. In this version, it's written as an ordinary XML file.

`elem` is an element tree or an individual element.

```python
xml.etree.ElementTree.fromstring(text)
```
Parses an XML section from a string constant. Same as `XML()`.

`text` is a string containing XML data. Returns an `Element` instance.

```python
xml.etree.ElementTree.fromstringlist(sequence, parser=None)
```
Parses an XML document from a sequence of string fragments. `sequence` is a list or other sequence containing XML data fragments. `parser` is an optional parser instance. If not given, the standard `XMLParser` parser is used. Returns an `Element` instance.
New in version 3.2.

```
xml.etree.ElementTree.iselement(element)
```

Checks if an object appears to be a valid element object. `element` is an element instance. Returns a true value if this is an element object.

```
xml.etree.ElementTree.iterparse(source, events=None, parser=None)
```

Parses an XML section into an element tree incrementally, and reports what’s going on to the user. `source` is a filename or file object containing XML data. `events` is a list of events to report back. The supported events are the strings "start", "end", "start-ns" and "end-ns" (the “ns” events are used to get detailed namespace information). If `events` is omitted, only "end" events are reported. `parser` is an optional parser instance. If not given, the standard XMLParser parser is used. `parser` can only use the default TreeBuilder as a target. Returns an iterator providing (event, elem) pairs.

**Note:** `iterparse()` only guarantees that it has seen the “>” character of a starting tag when it emits a “start” event, so the attributes are defined, but the contents of the text and tail attributes are undefined at that point. The same applies to the element children; they may or may not be present. If you need a fully populated element, look for “end” events instead.

```
xml.etree.ElementTree.parse(source, parser=None)
```

Parses an XML section into an element tree. `source` is a filename or file object containing XML data. `parser` is an optional parser
instance. If not given, the standard `XMLParser` parser is used. Returns an `ElementTree` instance.

```python
xml.etree.ElementTree.ProcessingInstruction(target, text=None)
```

PI element factory. This factory function creates a special element that will be serialized as an XML processing instruction. `target` is a string containing the PI target. `text` is a string containing the PI contents, if given. Returns an element instance, representing a processing instruction.

```python
xml.etree.ElementTree.register_namespace(prefix, uri)
```

Registers a namespace prefix. The registry is global, and any existing mapping for either the given prefix or the namespace URI will be removed. `prefix` is a namespace prefix. `uri` is a namespace uri. Tags and attributes in this namespace will be serialized with the given prefix, if at all possible.

*New in version 3.2.*

```python
xml.etree.ElementTree.SubElement(parent, tag, attrib={}, **extra)
```

Subelement factory. This function creates an element instance, and appends it to an existing element.

The element name, attribute names, and attribute values can be either bytestrings or Unicode strings. `parent` is the parent element. `tag` is the subelement name. `attrib` is an optional dictionary, containing element attributes. `extra` contains additional attributes, given as keyword arguments. Returns an element instance.

```python
xml.etree.ElementTree.tostring(element, encoding="us-ascii", method="xml")
```
Generates a string representation of an XML element, including all subelements. `element` is an `Element` instance. `encoding` [1] is the output encoding (default is US-ASCII). Use `encoding="unicode"` to generate a Unicode string (otherwise, a bytestring is generated). `method` is either "xml", "html" or "text" (default is "xml"). Returns an (optionally) encoded string containing the XML data.

```python
xml.etree.ElementTree.tostringlist(element, encoding="us-ascii", method="xml")
```

Generates a string representation of an XML element, including all subelements. `element` is an `Element` instance. `encoding` [1] is the output encoding (default is US-ASCII). Use `encoding="unicode"` to generate a Unicode string (otherwise, a bytestring is generated). `method` is either "xml", "html" or "text" (default is "xml"). Returns a list of (optionally) encoded strings containing the XML data. It does not guarantee any specific sequence, except that `"".join(tostringlist(element)) == tostring(element)`. New in version 3.2.

```python
xml.etree.ElementTree.XML(text, parser=None)
```

Parses an XML section from a string constant. This function can be used to embed “XML literals” in Python code. `text` is a string containing XML data. `parser` is an optional parser instance. If not given, the standard `XMLParser` parser is used. Returns an `Element` instance.

```python
xml.etree.ElementTree.XMLID(text, parser=None)
```

Parses an XML section from a string constant, and also returns a dictionary which maps from element id:s to elements. `text` is a
string containing XML data. parser is an optional parser instance. If not given, the standard XMLParser parser is used. Returns a tuple containing an Element instance and a dictionary.

20.6.3.2. Element Objects

class xml.etree.ElementTree.Element(tag, attrib={}, **extra)

Element class. This class defines the Element interface, and provides a reference implementation of this interface.

The element name, attribute names, and attribute values can be either bytestrings or Unicode strings. tag is the element name. attrib is an optional dictionary, containing element attributes. extra contains additional attributes, given as keyword arguments.

tag
A string identifying what kind of data this element represents (the element type, in other words).

text
The text attribute can be used to hold additional data associated with the element. As the name implies this attribute is usually a string but may be any application-specific object. If the element is created from an XML file the attribute will contain any text found between the element tags.

tail
The tail attribute can be used to hold additional data associated with the element. This attribute is usually a string but may be any application-specific object. If the element is created from an XML file the attribute will contain any text found after the element’s end tag and before the next tag.
**attrib**

A dictionary containing the element’s attributes. Note that while the `attrib` value is always a real mutable Python dictionary, an ElementTree implementation may choose to use another internal representation, and create the dictionary only if someone asks for it. To take advantage of such implementations, use the dictionary methods below whenever possible.

The following dictionary-like methods work on the element attributes.

**clear()**

Resets an element. This function removes all subelements, clears all attributes, and sets the text and tail attributes to `None`.

**get**(key, default=`None`)

Gets the element attribute named `key`.

Returns the attribute value, or `default` if the attribute was not found.

**items()**

Returns the element attributes as a sequence of (name, value) pairs. The attributes are returned in an arbitrary order.

**keys()**

Returns the elements attribute names as a list. The names are returned in an arbitrary order.

**set**(key, value)

Set the attribute `key` on the element to `value`. 
The following methods work on the element’s children (subelements).

**append**(subelement)

Adds the element *subelement* to the end of this element’s internal list of subelements. Raises *TypeError* if *subelement* is not an *Element*.

**extend**(subelements)

Appends *subelements* from a sequence object with zero or more elements. Raises *TypeError* if a subelement is not an *Element*.

*New in version 3.2.*

**find**(match, namespaces=None)

Finds the first subelement matching *match*. *match* may be a tag name or a *path*. Returns an element instance or None. *namespaces* is an optional mapping from namespace prefix to full name.

**.findall**(match, namespaces=None)

Finds all matching subelements, by tag name or *path*. Returns a list containing all matching elements in document order. *namespaces* is an optional mapping from namespace prefix to full name.

**findtext**(match, default=None, namespaces=None)

Finds text for the first subelement matching *match*. *match* may be a tag name or a *path*. Returns the text content of the first matching element, or *default* if no element was found. Note that if the matching element has no text content an empty string is
returned. *namespaces* is an optional mapping from namespace prefix to full name.

**getchildren()**

*Deprecated since version 3.2:* Use `list(elem)` or iteration.

**getiterator**(tag=\texttt{None})

*Deprecated since version 3.2:* Use method `Element.iter()` instead.

**insert**(index, subelement)

Inserts *subelement* at the given position in this element. Raises `TypeError` if *subelement* is not an `Element`.

**iter**(tag=\texttt{None})

Creates a tree iterator with the current element as the root. The iterator iterates over this element and all elements below it, in document (depth first) order. If *tag* is not None or `'*'`, only elements whose tag equals *tag* are returned from the iterator. If the tree structure is modified during iteration, the result is undefined.

*New in version 3.2.*

**iterfind**(match, namespaces=\texttt{None})

Finds all matching subelements, by tag name or *path*. Returns an iterable yielding all matching elements in document order. *namespaces* is an optional mapping from namespace prefix to full name.

*New in version 3.2.*
**itertext()**

Creates a text iterator. The iterator loops over this element and all subelements, in document order, and returns all inner text.

*New in version 3.2.*

**makeelement**(tag, attrib)

Creates a new element object of the same type as this element. Do not call this method, use the `SubElement()` factory function instead.

**remove**(subelement)

Removes `subelement` from the element. Unlike the find* methods this method compares elements based on the instance identity, not on tag value or contents.

**Element** objects also support the following sequence type methods for working with subelements: **__delitem__()**, **__getitem__()**, **__setitem__()**, **__len__()**.

Caution: Elements with no subelements will test as False. This behavior will change in future versions. Use specific `len(elem)` or `elem is None` test instead.

```python
element = root.find('foo')

if not element:  # careful!
    print("element not found, or element has no s

if element is None:
    print("element not found")
```
20.6.3.3. ElementTree Objects

class xml.etree.ElementTree.**ElementTree**(element=None, file=None)

ElementTree wrapper class. This class represents an entire element hierarchy, and adds some extra support for serialization to and from standard XML.

*element* is the root element. The tree is initialized with the contents of the XML *file* if given.

__setroot__(*element*)

Replaces the root element for this tree. This discards the current contents of the tree, and replaces it with the given element. Use with care. *element* is an element instance.

**find**(match, namespaces=None)

Same as **Element.find()**, starting at the root of the tree.

**findall**(match, namespaces=None)

Same as **Element.findall()**, starting at the root of the tree.

**findtext**(match, default=None, namespaces=None)

Same as **Element.findtext()**, starting at the root of the tree.

**getiterator**(tag=None)

*Deprecated* since version 3.2: Use method **ElementTree.iter()** instead.

**getroot**()
Returns the root element for this tree.

iter(tag=None)
Creates and returns a tree iterator for the root element. The iterator loops over all elements in this tree, in section order. tag is the tag to look for (default is to return all elements)

iterfind(match, namespaces=None)
Same as Element.iterfind(), starting at the root of the tree.

New in version 3.2.

parse(source, parser=None)
Loads an external XML section into this element tree. source is a file name or file object. parser is an optional parser instance. If not given, the standard XMLParser parser is used. Returns the section root element.

write(file, encoding="us-ascii", xml_declaration=None, default_namespace=None, method="xml")
Writes the element tree to a file, as XML. file is a file name, or a file object opened for writing. encoding [1] is the output encoding (default is US-ASCII). xml_declaration controls if an XML declaration should be added to the file. Use False for never, True for always, None for only if not US-ASCII or UTF-8 or Unicode (default is None). default_namespace sets the default XML namespace (for “xmlns”). method is either "xml", "html" or "text" (default is "xml").

The output is either a string (str) or binary (bytes). This is controlled by the encoding argument. If encoding is
"unicode", the output is a string; otherwise, it's binary. Note that this may conflict with the type of file if it's an open file object; make sure you do not try to write a string to a binary stream and vice versa.

This is the XML file that is going to be manipulated:

```xml
<html>
  <head>
    <title>Example page</title>
  </head>
  <body>
    <p>Moved to <a href="http://example.org/">example.org</a> or <a href="http://example.com/">example.com</a></p>
  </body>
</html>
```

Example of changing the attribute “target” of every link in first paragraph:

```python
>>> from xml.etree.ElementTree import ElementTree
>>> tree = ElementTree()
>>> tree.parse("index.xhtml")
<Element 'html' at 0xb77e6fac>
>>> p = tree.find("body/p")  # Finds first occurrence
>>> p
<Element 'p' at 0xb77ec26c>
>>> links = list(p.iter("a"))  # Returns list of all links
>>> links
[<Element 'a' at 0xb77ec2ac>, <Element 'a' at 0xb77ec22c>]
>>> for i in links:  # Iterates through all links
...    i.attrib["target"] = "blank"
>>> tree.write("output.xhtml")
```
20.6.3.4. QName Objects

```python
class xml.etree.ElementTree.QName(text_or_uri, tag=None)
```

QName wrapper. This can be used to wrap a QName attribute value, in order to get proper namespace handling on output. `text_or_uri` is a string containing the QName value, in the form `{uri}local`, or, if the tag argument is given, the URI part of a QName. If `tag` is given, the first argument is interpreted as an URI, and this argument is interpreted as a local name. `QName` instances are opaque.

20.6.3.5. TreeBuilder Objects

```python
class xml.etree.ElementTree.TreeBuilder(element_factory=None)
```

Generic element structure builder. This builder converts a sequence of start, data, and end method calls to a well-formed element structure. You can use this class to build an element structure using a custom XML parser, or a parser for some other XML-like format. `element_factory`, when given, must be a callable accepting two positional arguments: a tag and a dict of attributes. It is expected to return a new element instance.

```python
close()
```

Flushes the builder buffers, and returns the toplevel document element. Returns an `Element` instance.

```python
data(data)
```

Adds text to the current element. `data` is a string. This should be either a bytestring, or a Unicode string.
end(tag)
Closes the current element. tag is the element name. Returns the closed element.

start(tag, attrs)
Opens a new element. tag is the element name. attrs is a dictionary containing element attributes. Returns the opened element.

In addition, a custom TreeBuilder object can provide the following method:

doctype(name, pubid, system)
Handles a doctype declaration. name is the doctype name. pubid is the public identifier. system is the system identifier. This method does not exist on the default TreeBuilder class.

New in version 3.2.

20.6.3.6. XMLParser Objects

class xml.etree.ElementTree.XMLParser(html=0,
target=None, encoding=None)
Element structure builder for XML source data, based on the expat parser. html are predefined HTML entities. This flag is not supported by the current implementation. target is the target object. If omitted, the builder uses an instance of the standard TreeBuilder class. encoding [1] is optional. If given, the value overrides the encoding specified in the XML file.

close()
Finishes feeding data to the parser. Returns the result of calling
the `close()` method of the `target` passed during construction; by default, this is the toplevel document element.

**doctype**(*name, pubid, system*)

*Deprecated since version 3.2:* Define the `TreeBuilder.doctype()` method on a custom `TreeBuilder` target.

**feed**(*data*)

Feeds data to the parser. `data` is encoded data.

`XMLParser.feed()` calls `target`'s `start()` method for each opening tag, its `end()` method for each closing tag, and data is processed by method `data()`. `XMLParser.close()` calls `target`'s method `close()`. `XMLParser` can be used not only for building a tree structure. This is an example of counting the maximum depth of an XML file:

```python
>>> from xml.etree.ElementTree import XMLParser
>>> class MaxDepth:
...     # The target
...     maxDepth = 0
...     depth = 0
...     def start(self, tag, attrib):
...         # Called
...         self.depth += 1
...         if self.depth > self.maxDepth:
...             self.maxDepth = self.depth
...     def end(self, tag):
...         # Called
...         self.depth -= 1
...     def data(self, data):
...         pass  # We do not need to do anything with data
...     def close(self):
...         # Called when all data has been processed
...         return self.maxDepth
...
>>> target = MaxDepth()
```
>>> parser = XMLParser(target=target)
>>> exampleXml = ""
... <a>
...  <b>
...  </b>
...  <b>
...   <c>
...  </c>
...   <d>
...  </d>
... </b>
... </a>"
>>> parser.feed(exampleXml)
>>> parser.close()
4

20.6.3.7. Exceptions

class xml.etree.ElementTree.ParseError
XML parse error, raised by the various parsing methods in this module when parsing fails. The string representation of an instance of this exception will contain a user-friendly error message. In addition, it will have the following attributes available:

code
A numeric error code from the expat parser. See the documentation of xml.parsers.expat for the list of error codes and their meanings.

position
A tuple of line, column numbers, specifying where the error occurred.
The encoding string included in XML output should conform to the appropriate standards. For example, “UTF-8” is valid, but “UTF8” is not. See http://www.w3.org/TR/2006/REC-xml11-20060816/#NT-EncodingDecl and http://www.iana.org/assignments/character-sets.
20.7. `xml.dom` — The Document Object Model API

The Document Object Model, or “DOM,” is a cross-language API from the World Wide Web Consortium (W3C) for accessing and modifying XML documents. A DOM implementation presents an XML document as a tree structure, or allows client code to build such a structure from scratch. It then gives access to the structure through a set of objects which provided well-known interfaces.

The DOM is extremely useful for random-access applications. SAX only allows you a view of one bit of the document at a time. If you are looking at one SAX element, you have no access to another. If you are looking at a text node, you have no access to a containing element. When you write a SAX application, you need to keep track of your program’s position in the document somewhere in your own code. SAX does not do it for you. Also, if you need to look ahead in the XML document, you are just out of luck.

Some applications are simply impossible in an event driven model with no access to a tree. Of course you could build some sort of tree yourself in SAX events, but the DOM allows you to avoid writing that code. The DOM is a standard tree representation for XML data.

The Document Object Model is being defined by the W3C in stages, or “levels” in their terminology. The Python mapping of the API is substantially based on the DOM Level 2 recommendation.

DOM applications typically start by parsing some XML into a DOM. How this is accomplished is not covered at all by DOM Level 1, and Level 2 provides only limited improvements: There is a
DOMImplementation object class which provides access to Document creation methods, but no way to access an XML reader/parser/Document builder in an implementation-independent way. There is also no well-defined way to access these methods without an existing Document object. In Python, each DOM implementation will provide a function `getDOMImplementation()`. DOM Level 3 adds a Load/Store specification, which defines an interface to the reader, but this is not yet available in the Python standard library.

Once you have a DOM document object, you can access the parts of your XML document through its properties and methods. These properties are defined in the DOM specification; this portion of the reference manual describes the interpretation of the specification in Python.

The specification provided by the W3C defines the DOM API for Java, ECMAScript, and OMG IDL. The Python mapping defined here is based in large part on the IDL version of the specification, but strict compliance is not required (though implementations are free to support the strict mapping from IDL). See section Conformance for a detailed discussion of mapping requirements.

See also:

**Document Object Model (DOM) Level 2 Specification**

The W3C recommendation upon which the Python DOM API is based.

**Document Object Model (DOM) Level 1 Specification**

The W3C recommendation for the DOM supported by `xml.dom.minidom`.

**Python Language Mapping Specification**
This specifies the mapping from OMG IDL to Python.
20.7.1. Module Contents

The `xml.dom` contains the following functions:

- **`registerDOMImplementation(name, factory)`**
  Register the `factory` function with the name `name`. The factory function should return an object which implements the DOMImplementation interface. The factory function can return the same object every time, or a new one for each call, as appropriate for the specific implementation (e.g. if that implementation supports some customization).

- **`getDOMImplementation(name=None, features=())`**
  Return a suitable DOM implementation. The `name` is either well-known, the module name of a DOM implementation, or None. If it is not None, imports the corresponding module and returns a DOMImplementation object if the import succeeds. If no name is given, and if the environment variable PYTHON_DOM is set, this variable is used to find the implementation.

  If name is not given, this examines the available implementations to find one with the required feature set. If no implementation can be found, raise an `ImportError`. The features list must be a sequence of `(feature, version)` pairs which are passed to the hasFeature() method on available DOMImplementation objects.

Some convenience constants are also provided:

- **`EMPTY_NAMESPACE`**
  The value used to indicate that no namespace is associated with a
node in the DOM. This is typically found as the namespaceURI of a node, or used as the namespaceURI parameter to a namespaces-specific method.

`xml.dom.XML_NAMESPACE`

The namespace URI associated with the reserved prefix `xml`, as defined by Namespaces in XML (section 4).

`xml.dom.XMLNS_NAMESPACE`

The namespace URI for namespace declarations, as defined by Document Object Model (DOM) Level 2 Core Specification (section 1.1.8).

`xml.dom.XHTML_NAMESPACE`

The URI of the XHTML namespace as defined by XHTML 1.0: The Extensible HyperText Markup Language (section 3.1.1).

In addition, `xml.dom` contains a base Node class and the DOM exception classes. The Node class provided by this module does not implement any of the methods or attributes defined by the DOM specification; concrete DOM implementations must provide those. The Node class provided as part of this module does provide the constants used for the nodeType attribute on concrete Node objects; they are located within the class rather than at the module level to conform with the DOM specifications.
20.7.2. Objects in the DOM

The definitive documentation for the DOM is the DOM specification from the W3C.

Note that DOM attributes may also be manipulated as nodes instead of as simple strings. It is fairly rare that you must do this, however, so this usage is not yet documented.

<table>

</tbody>
</table>
An additional section describes the exceptions defined for working with the DOM in Python.

20.7.2.1. DOMImplementation Objects

The DOMImplementation interface provides a way for applications to determine the availability of particular features in the DOM they are using. DOM Level 2 added the ability to create new Document and DocumentType objects using the DOMImplementation as well.

DOMImplementation.

- **hasFeature** *(feature, version)*
  
  Return true if the feature identified by the pair of strings feature and version is implemented.

- **createDocument** *(namespaceUri, qualifiedName,doctype)*
Return a new Document object (the root of the DOM), with a child Element object having the given namespaceUri and qualifiedName. The doctype must be a DocumentType object created by createDocumentType(), or None. In the Python DOM API, the first two arguments can also be None in order to indicate that no Element child is to be created.

DOMImplementation.createDocumentType(qualifiedName, publicId, systemId)

Return a new DocumentType object that encapsulates the given qualifiedName, publicId, and systemId strings, representing the information contained in an XML document type declaration.

20.7.2.2. Node Objects

All of the components of an XML document are subclasses of Node.

Node.nodeType

An integer representing the node type. Symbolic constants for the types are on the Node object: ELEMENT_NODE, ATTRIBUTE_NODE, TEXT_NODE, CDATA_SECTION_NODE, ENTITY_NODE, PROCESSING_INSTRUCTION_NODE, COMMENT_NODE, DOCUMENT_NODE, DOCUMENT_TYPE_NODE, NOTATION_NODE. This is a read-only attribute.

Node.parentNode

The parent of the current node, or None for the document node. The value is always a Node object or None. For Element nodes, this will be the parent element, except for the root element, in which case it will be the Document object. For Attr nodes, this is always None. This is a read-only attribute.
Node. **attributes**
A NamedNodeMap of attribute objects. Only elements have actual values for this; others provide None for this attribute. This is a read-only attribute.

Node. **previousSibling**
The node that immediately precedes this one with the same parent. For instance the element with an end-tag that comes just before the *self* element’s start-tag. Of course, XML documents are made up of more than just elements so the previous sibling could be text, a comment, or something else. If this node is the first child of the parent, this attribute will be None. This is a read-only attribute.

Node. **nextSibling**
The node that immediately follows this one with the same parent. See also **previousSibling**. If this is the last child of the parent, this attribute will be None. This is a read-only attribute.

Node. **childNodes**
A list of nodes contained within this node. This is a read-only attribute.

Node. **firstChild**
The first child of the node, if there are any, or None. This is a read-only attribute.

Node. **lastChild**
The last child of the node, if there are any, or None. This is a read-only attribute.

Node. **localName**
The part of the **tagName** following the colon if there is one, else
the entire tagName. The value is a string.

Node. prefix
The part of the tagName preceding the colon if there is one, else the empty string. The value is a string, or None.

Node. namespaceURI
The namespace associated with the element name. This will be a string or None. This is a read-only attribute.

Node. nodeName
This has a different meaning for each node type; see the DOM specification for details. You can always get the information you would get here from another property such as the tagName property for elements or the name property for attributes. For all node types, the value of this attribute will be either a string or None. This is a read-only attribute.

Node. nodeValue
This has a different meaning for each node type; see the DOM specification for details. The situation is similar to that with nodeName. The value is a string or None.

Node. hasAttributes()
Returns true if the node has any attributes.

Node. hasChildNodes()
Returns true if the node has any child nodes.

Node. isSameNode(other)
Returns true if other refers to the same node as this node. This is especially useful for DOM implementations which use any sort of
proxy architecture (because more than one object can refer to the same node).

**Note:** This is based on a proposed DOM Level 3 API which is still in the “working draft” stage, but this particular interface appears uncontroversial. Changes from the W3C will not necessarily affect this method in the Python DOM interface (though any new W3C API for this would also be supported).

Node. **appendChild**(newChild)
Add a new child node to this node at the end of the list of children, returning `newChild`. If the node was already in the tree, it is removed first.

Node. **insertBefore**(newChild, refChild)
Insert a new child node before an existing child. It must be the case that `refChild` is a child of this node; if not, `ValueError` is raised. `newChild` is returned. If `refChild` is None, it inserts `newChild` at the end of the children's list.

Node. **removeChild**(oldChild)
Remove a child node. `oldChild` must be a child of this node; if not, `ValueError` is raised. `oldChild` is returned on success. If `oldChild` will not be used further, its `unlink()` method should be called.

Node. **replaceChild**(newChild, oldChild)
Replace an existing node with a new node. It must be the case that `oldChild` is a child of this node; if not, `ValueError` is raised.

Node. **normalize**()
Join adjacent text nodes so that all stretches of text are stored as single `Text` instances. This simplifies processing text from a DOM
tree for many applications.

Node .cloneNode (deep)

Clone this node. Setting deep means to clone all child nodes as well. This returns the clone.

20.7.2.3. NodeList Objects

A NodeList represents a sequence of nodes. These objects are used in two ways in the DOM Core recommendation: the Element objects provides one as its list of child nodes, and the getElementsByTagName() and getElementsByTagNameNS() methods of Node return objects with this interface to represent query results.

The DOM Level 2 recommendation defines one method and one attribute for these objects:

NodeList .item (i)

Return the i'th item from the sequence, if there is one, or None. The index i is not allowed to be less then zero or greater than or equal to the length of the sequence.

NodeList .length

The number of nodes in the sequence.

In addition, the Python DOM interface requires that some additional support is provided to allow NodeList objects to be used as Python sequences. All NodeList implementations must include support for __len__() and __getitem__(); this allows iteration over the NodeList in for statements and proper support for the len() built-in function.
If a DOM implementation supports modification of the document, the NodeList implementation must also support the `__setitem__()` and `__delitem__()` methods.

### 20.7.2.4. DocumentType Objects

Information about the notations and entities declared by a document (including the external subset if the parser uses it and can provide the information) is available from a DocumentType object. The DocumentType for a document is available from the Document object's doctype attribute; if there is no `DOCTYPE` declaration for the document, the document's doctype attribute will be set to `None` instead of an instance of this interface.

DocumentType is a specialization of Node, and adds the following attributes:

**DocumentType**. `publicId`
- The public identifier for the external subset of the document type definition. This will be a string or `None`.

**DocumentType**. `systemId`
- The system identifier for the external subset of the document type definition. This will be a URI as a string, or `None`.

**DocumentType**. `internalSubset`
- A string giving the complete internal subset from the document. This does not include the brackets which enclose the subset. If the document has no internal subset, this should be `None`.

**DocumentType**. `name`
- The name of the root element as given in the `DOCTYPE`
declaration, if present.

DocumentType. **entities**
This is a NamedNodeMap giving the definitions of external entities. For entity names defined more than once, only the first definition is provided (others are ignored as required by the XML recommendation). This may be None if the information is not provided by the parser, or if no entities are defined.

DocumentType. **notations**
This is a NamedNodeMap giving the definitions of notations. For notation names defined more than once, only the first definition is provided (others are ignored as required by the XML recommendation). This may be None if the information is not provided by the parser, or if no notations are defined.

20.7.2.5. Document Objects

A Document represents an entire XML document, including its constituent elements, attributes, processing instructions, comments etc. Remember that it inherits properties from Node.

Document. **documentElement**
The one and only root element of the document.

Document. **createElement**(tagName)
Create and return a new element node. The element is not inserted into the document when it is created. You need to explicitly insert it with one of the other methods such as insertBefore() or appendChild().

Document. **createElementNS**(namespaceURI, tagName)
Create and return a new element with a namespace. The `tagName` may have a prefix. The element is not inserted into the document when it is created. You need to explicitly insert it with one of the other methods such as `insertBefore()` or `appendChild()`.

**Document.createTextNode(data)**
Create and return a text node containing the data passed as a parameter. As with the other creation methods, this one does not insert the node into the tree.

**Document.createComment(data)**
Create and return a comment node containing the data passed as a parameter. As with the other creation methods, this one does not insert the node into the tree.

**Document.createProcessingInstruction(target, data)**
Create and return a processing instruction node containing the `target` and `data` passed as parameters. As with the other creation methods, this one does not insert the node into the tree.

**Document.createAttribute(name)**
Create and return an attribute node. This method does not associate the attribute node with any particular element. You must use `setAttributeNode()` on the appropriate Element object to use the newly created attribute instance.

**Document.createAttributeNS(namespaceURI, qualifiedName)**
Create and return an attribute node with a namespace. The `tagName` may have a prefix. This method does not associate the attribute node with any particular element. You must use `setAttributeNode()` on the appropriate Element object to
use the newly created attribute instance.

Document. **getElementsByTagName**(tagName)
  Search for all descendants (direct children, children’s children, etc.) with a particular element type name.

Document. **getElementsByTagNameNS**(namespaceURI, localName)
  Search for all descendants (direct children, children’s children, etc.) with a particular namespace URI and localname. The localname is the part of the namespace after the prefix.

20.7.2.6. Element Objects

Element is a subclass of Node, so inherits all the attributes of that class.

Element. **tagName**
  The element type name. In a namespace-using document it may have colons in it. The value is a string.

Element. **getElementsByTagName**(tagName)
  Same as equivalent method in the Document class.

Element. **getElementsByTagNameNS**(namespaceURI, localName)
  Same as equivalent method in the Document class.

Element. **hasAttribute**(name)
  Returns true if the element has an attribute named by name.

Element. **hasAttributeNS**(namespaceURI, localName)
Returns true if the element has an attribute named by namespaceURI and localName.

Element.getAttribute(name)

Return the value of the attribute named by name as a string. If no such attribute exists, an empty string is returned, as if the attribute had no value.

Element.getAttributeNode(attrname)

Return the Attr node for the attribute named by attrname.

Element.getAttributeNS(namespaceURI, localName)

Return the value of the attribute named by namespaceURI and localName as a string. If no such attribute exists, an empty string is returned, as if the attribute had no value.

Element.getAttributeNodeNS(namespaceURI, localName)

Return an attribute value as a node, given a namespaceURI and localName.

Element.removeAttribute(name)

Remove an attribute by name. If there is no matching attribute, a NotFoundErr is raised.

Element.removeAttributeNode(oldAttr)

Remove and return oldAttr from the attribute list, if present. If oldAttr is not present, NotFoundErr is raised.

Element.removeAttributeNS(namespaceURI, localName)

Remove an attribute by name. Note that it uses a localName, not a qname. No exception is raised if there is no matching attribute.

Element.setAttribute(name, value)
Set an attribute value from a string.

**Element**. `setAttributeNode(newAttr)`

Add a new attribute node to the element, replacing an existing attribute if necessary if the name attribute matches. If a replacement occurs, the old attribute node will be returned. If `newAttr` is already in use, `InuseAttributeErr` will be raised.

**Element**. `setAttributeNodeNS(newAttr)`

Add a new attribute node to the element, replacing an existing attribute if necessary if the namespaceURI and `localName` attributes match. If a replacement occurs, the old attribute node will be returned. If `newAttr` is already in use, `InuseAttributeErr` will be raised.

**Element**. `setAttributeNS(namespaceURI, qname, value)`

Set an attribute value from a string, given a `namespaceURI` and a `qname`. Note that a qname is the whole attribute name. This is different than above.

### 20.7.2.7. Attr Objects

`Attr` inherits from `Node`, so inherits all its attributes.

**Attr**. `name`

The attribute name. In a namespace-using document it may include a colon.

**Attr**. `localName`

The part of the name following the colon if there is one, else the entire name. This is a read-only attribute.
Attr. **prefix**

The part of the name preceding the colon if there is one, else the empty string.

Attr. **value**

The text value of the attribute. This is a synonym for the `nodeValue` attribute.

### 20.7.2.8. NamedNodeMap Objects

NamedNodeMap does *not* inherit from Node.

NamedNodeMap. **length**

The length of the attribute list.

NamedNodeMap. **item(index)**

Return an attribute with a particular index. The order you get the attributes in is arbitrary but will be consistent for the life of a DOM. Each item is an attribute node. Get its value with the value attribute.

There are also experimental methods that give this class more mapping behavior. You can use them or you can use the standardized `getAttribute*()` family of methods on the Element objects.

### 20.7.2.9. Comment Objects

Comment represents a comment in the XML document. It is a subclass of Node, but cannot have child nodes.

Comment. **data**

The content of the comment as a string. The attribute contains all
characters between the leading `<!-` and trailing `-->`, but does not include them.

### 20.7.2.10. Text and CDATASection Objects

The Text interface represents text in the XML document. If the parser and DOM implementation support the DOM’s XML extension, portions of the text enclosed in CDATA marked sections are stored in CDATASection objects. These two interfaces are identical, but provide different values for the nodeType attribute.

These interfaces extend the Node interface. They cannot have child nodes.

**Text.data**

The content of the text node as a string.

**Note:** The use of a CDATASection node does not indicate that the node represents a complete CDATA marked section, only that the content of the node was part of a CDATA section. A single CDATA section may be represented by more than one node in the document tree. There is no way to determine whether two adjacent CDATASection nodes represent different CDATA marked sections.

### 20.7.2.11. ProcessingInstruction Objects

Represents a processing instruction in the XML document; this inherits from the Node interface and cannot have child nodes.

**ProcessingInstruction.target**

The content of the processing instruction up to the first whitespace
character. This is a read-only attribute.

**ProcessingInstruction.data**

The content of the processing instruction following the first whitespace character.

### 20.7.2.12. Exceptions

The DOM Level 2 recommendation defines a single exception, **DOMException**, and a number of constants that allow applications to determine what sort of error occurred. **DOMException** instances carry a **code** attribute that provides the appropriate value for the specific exception.

The Python DOM interface provides the constants, but also expands the set of exceptions so that a specific exception exists for each of the exception codes defined by the DOM. The implementations must raise the appropriate specific exception, each of which carries the appropriate value for the **code** attribute.

*exception* *xml.dom.DOMException*

Base exception class used for all specific DOM exceptions. This exception class cannot be directly instantiated.

*exception* *xml.dom.DomstringSizeErr*

Raised when a specified range of text does not fit into a string. This is not known to be used in the Python DOM implementations, but may be received from DOM implementations not written in Python.

*exception* *xml.dom.HierarchyRequestErr*

Raised when an attempt is made to insert a node where the node type is not allowed.
exception xml.dom.**IndexSizeErr**
Raised when an index or size parameter to a method is negative or exceeds the allowed values.

exception xml.dom.**InuseAttributeErr**
Raised when an attempt is made to insert an Attr node that is already present elsewhere in the document.

exception xml.dom.**InvalidAccessErr**
Raised if a parameter or an operation is not supported on the underlying object.

exception xml.dom.**InvalidCharacterErr**
This exception is raised when a string parameter contains a character that is not permitted in the context it’s being used in by the XML 1.0 recommendation. For example, attempting to create an Element node with a space in the element type name will cause this error to be raised.

exception xml.dom.**InvalidModificationErr**
Raised when an attempt is made to modify the type of a node.

exception xml.dom.**InvalidStateErr**
Raised when an attempt is made to use an object that is not defined or is no longer usable.

exception xml.dom.**NamespaceErr**
If an attempt is made to change any object in a way that is not permitted with regard to the Namespaces in XML recommendation, this exception is raised.

exception xml.dom.**NotFoundErr**
Exception when a node does not exist in the referenced context.
For example, `NamedNodeMap.removeNamedItem()` will raise this if the node passed in does not exist in the map.

*exception* `xml.dom.NotSupportedException`
Raised when the implementation does not support the requested type of object or operation.

*exception* `xml.dom.NoDataAllowedErr`
This is raised if data is specified for a node which does not support data.

*exception* `xml.dom.NoModificationAllowedErr`
Raised on attempts to modify an object where modifications are not allowed (such as for read-only nodes).

*exception* `xml.dom.SyntaxErr`
Raised when an invalid or illegal string is specified.

*exception* `xml.dom.WrongDocumentErr`
Raised when a node is inserted in a different document than it currently belongs to, and the implementation does not support migrating the node from one document to the other.

The exception codes defined in the DOM recommendation map to the exceptions described above according to this table:

<table>
<thead>
<tr>
<th>Constant</th>
<th>Exception</th>
</tr>
</thead>
<tbody>
<tr>
<td>DOMSTRING_SIZE_ERR</td>
<td>DomstringSizeErr</td>
</tr>
<tr>
<td>HIERARCHY_REQUEST_ERR</td>

</tbody>
</table>
20.7.3. Conformance

This section describes the conformance requirements and relationships between the Python DOM API, the W3C DOM recommendations, and the OMG IDL mapping for Python.

20.7.3.1. Type Mapping

The IDL types used in the DOM specification are mapped to Python types according to the following table.

<table>
<thead>
<tr>
<th>IDL Type</th>
<th>Python Type</th>
</tr>
</thead>
<tbody>
<tr>
<td>boolean</td>
<td>bool or int</td>
</tr>
<tr>
<td>int</td>
<td>int</td>
</tr>
<tr>
<td>long int</td>
<td>int</td>
</tr>
<tr>
<td>unsigned int</td>
<td>int</td>
</tr>
<tr>
<td>DOMString</td>
<td>str or bytes</td>
</tr>
<tr>
<td>null</td>
<td>None</td>
</tr>
</tbody>
</table>

20.7.3.2. Accessor Methods

The mapping from OMG IDL to Python defines accessor functions for IDL attribute declarations in much the way the Java mapping does. Mapping the IDL declarations

```plaintext
readonly attribute string someValue;
attribute string anotherValue;
```

yields three accessor functions: a “get” method for `someValue`
&_get_someValue(), and “get” and “set” methods for anotherValue (_get_anotherValue() and _set_anotherValue()). The mapping, in particular, does not require that the IDL attributes are accessible as normal Python attributes: object.someValue is not required to work, and may raise an AttributeError.

The Python DOM API, however, does require that normal attribute access work. This means that the typical surrogates generated by Python IDL compilers are not likely to work, and wrapper objects may be needed on the client if the DOM objects are accessed via CORBA. While this does require some additional consideration for CORBA DOM clients, the implementers with experience using DOM over CORBA from Python do not consider this a problem. Attributes that are declared readonly may not restrict write access in all DOM implementations.

In the Python DOM API, accessor functions are not required. If provided, they should take the form defined by the Python IDL mapping, but these methods are considered unnecessary since the attributes are accessible directly from Python. “Set” accessors should never be provided for readonly attributes.

The IDL definitions do not fully embody the requirements of the W3C DOM API, such as the notion of certain objects, such as the return value of getElementsByTagName(), being “live”. The Python DOM API does not require implementations to enforce such requirements.
20.8. **xml.dom.minidom** — Minimal DOM implementation

**Source code:** Lib/xml/dom/minidom.py

`xml.dom.minidom` is a minimal implementation of the Document Object Model interface, with an API similar to that in other languages. It is intended to be simpler than the full DOM and also significantly smaller. Users who are not already proficient with the DOM should consider using the `xml.etree.ElementTree` module for their XML processing instead.

**Warning:** The `xml.dom.minidom` module is not secure against maliciously constructed data. If you need to parse untrusted or unauthenticated data see *XML vulnerabilities*.

DOM applications typically start by parsing some XML into a DOM. With `xml.dom.minidom`, this is done through the parse functions:

```python
from xml.dom.minidom import parse, parseString

dom1 = parse('c:"\temp\mydata.xml')  # parse an XML

datasource = open('c:"\temp\mydata.xml')
dom2 = parse(datasource)  # parse an open file

dom3 = parseString('<myxml>Some data<empty/> some more data</myxml>')
```

The `parse()` function can take either a filename or an open file.
object.

```
xml.dom.minidom.parse(filename_or_file, parser=None, bufsize=None)
```

Return a Document from the given input. `filename_or_file` may be either a file name, or a file-like object. `parser`, if given, must be a SAX2 parser object. This function will change the document handler of the parser and activate namespace support; other parser configuration (like setting an entity resolver) must have been done in advance.

If you have XML in a string, you can use the `parseString()` function instead:

```
xml.dom.minidom.parseString(string, parser=None)
```

Return a Document that represents the `string`. This method creates a `io.StringIO` object for the string and passes that on to `parse()`.

Both functions return a `Document` object representing the content of the document.

What the `parse()` and `parseString()` functions do is connect an XML parser with a “DOM builder” that can accept parse events from any SAX parser and convert them into a DOM tree. The name of the functions are perhaps misleading, but are easy to grasp when learning the interfaces. The parsing of the document will be completed before these functions return; it’s simply that these functions do not provide a parser implementation themselves.

You can also create a Document by calling a method on a “DOM Implementation” object. You can get this object either by calling the
getDOMImplementation() function in the xml.dom package or the xml.dom.minidom module. Once you have a Document, you can add child nodes to it to populate the DOM:

```python
from xml.dom.minidom import getDOMImplementation

impl = getDOMImplementation()

newdoc = impl.createDocument(None, "some_tag", None)
top_element = newdoc.documentElement
text = newdoc.createTextNode('Some textual content.')
top_element.appendChild(text)
```

Once you have a DOM document object, you can access the parts of your XML document through its properties and methods. These properties are defined in the DOM specification. The main property of the document object is the documentElement property. It gives you the main element in the XML document: the one that holds all others. Here is an example program:

```python
dom3 = parseString("<myxml>Some data</myxml>"")
assert dom3.documentElement.tagName == "myxml"
```

When you are finished with a DOM tree, you may optionally call the unlink() method to encourage early cleanup of the now-unneeded objects. unlink() is a xml.dom.minidom-specific extension to the DOM API that renders the node and its descendants are essentially useless. Otherwise, Python’s garbage collector will eventually take care of the objects in the tree.

See also:

Document Object Model (DOM) Level 1 Specification
The W3C recommendation for the DOM supported by xml.dom.minidom.
20.8.1. DOM Objects

The definition of the DOM API for Python is given as part of the `xml.dom` module documentation. This section lists the differences between the API and `xml.dom.minidom`.

**Node. `unlink()`**

Break internal references within the DOM so that it will be garbage collected on versions of Python without cyclic GC. Even when cyclic GC is available, using this can make large amounts of memory available sooner, so calling this on DOM objects as soon as they are no longer needed is good practice. This only needs to be called on the Document object, but may be called on child nodes to discard children of that node.

You can avoid calling this method explicitly by using the `with` statement. The following code will automatically unlink `dom` when the `with` block is exited:

```python
with xml.dom.minidom.parse(datasource) as dom:
    ... # Work with dom.
```

**Node. `writexml(writer, indent='', addindent='', newl='')`**

Write XML to the writer object. The writer should have a `write()` method which matches that of the file object interface. The `indent` parameter is the indentation of the current node. The `addindent` parameter is the incremental indentation to use for subnodes of the current one. The `newl` parameter specifies the string to use to terminate newlines.

For the Document node, an additional keyword argument
encoding can be used to specify the encoding field of the XML header.

Node. `toxml(encoding=None)`
Return a string or byte string containing the XML represented by the DOM node.

With an explicit encoding [1] argument, the result is a byte string in the specified encoding. With no encoding argument, the result is a Unicode string, and the XML declaration in the resulting string does not specify an encoding. Encoding this string in an encoding other than UTF-8 is likely incorrect, since UTF-8 is the default encoding of XML.

Node. `toprettyxml(indent='', newl='', encoding='')`
Return a pretty-printed version of the document. indent specifies the indentation string and defaults to a tabulator; newl specifies the string emitted at the end of each line and defaults to \
.

The encoding argument behaves like the corresponding argument of toxml().
This example program is a fairly realistic example of a simple program. In this particular case, we do not take much advantage of the flexibility of the DOM.

```python
import xml.dom.minidom

document = """
<slideshow>
<title>Demo slideshow</title>
<slide><title>Slide title</title>
<point>This is a demo</point>
<point>Of a program for processing slides</point>
</slide>

<slide><title>Another demo slide</title>
<point>It is important</point>
<point>To have more than</point>
<point>one slide</point>
</slide>
</slideshow>
""

dom = xml.dom.minidom.parseString(document)

def getText(nodelist):
    rc = []
    for node in nodelist:
        if node.nodeType == node.TEXT_NODE:
            rc.append(node.data)
    return ''.join(rc)

def handleSlideshow(slideshow):
    print("<html>")
```
handleSlideshowTitle(slideshow.getElementsByTagName("slide"))
slides = slideshow.getElementsByTagName("slide")
handleToc(slides)
handleSlides(slides)
print("</html>"

def handleSlides(slides):
    for slide in slides:
        handleSlide(slide)

def handleSlide(slide):
    handleSlideTitle(slide.getElementsByTagName("title"))
    handlePoints(slide.getElementsByTagName("point"))

def handleSlideshowTitle(title):
    print("<title>%s</title>" % getText(title.childNodes))

def handleSlideTitle(title):
    print("<h2>%s</h2>" % getText(title.childNodes))

def handlePoints(points):
    print("<ul>"
    for point in points:
        handlePoint(point)
    print("</ul>"

def handlePoint(point):
    print("<li>%s</li>" % getText(point.childNodes))

def handleToc(slides):
    for slide in slides:
        title = slide.getElementsByTagName("title")
        print("<p>%s</p>" % getText(title.childNodes))

handleSlideshow(dom)
20.8.3. minidom and the DOM standard

The xml.dom.minidom module is essentially a DOM 1.0-compatible DOM with some DOM 2 features (primarily namespace features).

Usage of the DOM interface in Python is straight-forward. The following mapping rules apply:

- Interfaces are accessed through instance objects. Applications should not instantiate the classes themselves; they should use the creator functions available on the Document object. Derived interfaces support all operations (and attributes) from the base interfaces, plus any new operations.
- Operations are used as methods. Since the DOM uses only `in` parameters, the arguments are passed in normal order (from left to right). There are no optional arguments. `void` operations return `None`.
- IDL attributes map to instance attributes. For compatibility with the OMG IDL language mapping for Python, an attribute `foo` can also be accessed through accessor methods `_get_foo()` and `_set_foo()`. `readonly` attributes must not be changed; this is not enforced at runtime.
- The types `short int`, `unsigned int`, `unsigned long`, and `boolean` all map to Python integer objects.
- The type `DOMString` maps to Python strings. `xml.dom.minidom` supports either bytes or strings, but will normally produce strings. Values of type `DOMString` may also be `None` where allowed to have the IDL `null` value by the DOM specification from the W3C.
- `const` declarations map to variables in their respective scope (e.g. `xml.dom.minidom.Node.PROCESSING_INSTRUCTION_NODE`):
they must not be changed.

- **DOMException** is currently not supported in `xml.dom.minidom`. Instead, `xml.dom.minidom` uses standard Python exceptions such as `TypeError` and `AttributeError`.
- NodeList objects are implemented using Python's built-in list type. These objects provide the interface defined in the DOM specification, but with earlier versions of Python they do not support the official API. They are, however, much more “Pythonic” than the interface defined in the W3C recommendations.

The following interfaces have no implementation in `xml.dom.minidom`:

- DOMTimeStamp
- DocumentType
- DOMImplementation
- CharacterData
- CDATASection
- Notation
- Entity
- EntityReference
- DocumentFragment

Most of these reflect information in the XML document that is not of general utility to most DOM users.

**Footnotes**

The encoding name included in the XML output should conform to the appropriate standards. For example, “UTF-8” is valid, but “UTF8” is not valid in an XML document’s declaration, even though Python accepts it as an encoding name. See [http://www.w3.org/TR/2006/REC-xml11-20060816/#NT-EncodingDecl](http://www.w3.org/TR/2006/REC-xml11-20060816/#NT- EncodingDecl) and [http://www.iana.org/assignments/character-](http://www.iana.org/assignments/character-)
sets.
20.9. `xml.dom.pulldom` — Support for building partial DOM trees

**Source code:** `Lib/xml/dom/pulldom.py`

The `xml.dom.pulldom` module provides a “pull parser” which can also be asked to produce DOM-accessible fragments of the document where necessary. The basic concept involves pulling “events” from a stream of incoming XML and processing them. In contrast to SAX which also employs an event-driven processing model together with callbacks, the user of a pull parser is responsible for explicitly pulling events from the stream, looping over those events until either processing is finished or an error condition occurs.

**Warning:** The `xml.dom.pulldom` module is not secure against maliciously constructed data. If you need to parse untrusted or unauthenticated data see *XML vulnerabilities*.

Example:

```python
from xml.dom import pulldom

doc = pulldom.parse('sales_items.xml')
for event, node in doc:
    if event == pulldom.START_ELEMENT and node.tagName if int(node.getAttribute('price')) > 50:
        doc.expandNode(node)
        print(node.toxml())
```
event is a constant and can be one of:

- START_ELEMENT
- END_ELEMENT
- COMMENT
- START_DOCUMENT
- END_DOCUMENT
- CHARACTERS
- PROCESSING_INSTRUCTION
- IGNORABLE_WHITESPACE

node is a object of type xml.dom.minidom.Document, xml.dom.minidom.Element or xml.dom.minidom.Text.

Since the document is treated as a “flat” stream of events, the document “tree” is implicitly traversed and the desired elements are found regardless of their depth in the tree. In other words, one does not need to consider hierarchical issues such as recursive searching of the document nodes, although if the context of elements were important, one would either need to maintain some context-related state (i.e. remembering where one is in the document at any given point) or to make use of the DOMEventStream.expandNode() method and switch to DOM-related processing.

class xml.dom.pulldom.PullDom(documentFactory=None)
    Subclass of xml.sax.handler.ContentHandler.

class xml.dom.pulldom.SAX2DOM(documentFactory=None)
    Subclass of xml.sax.handler.ContentHandler.

xml.dom.pulldom.parse(stream_or_string, parser=None, bufsize=None)
Return a **DOMEventStream** from the given input. *stream_or_string* may be either a file name, or a file-like object. *parser*, if given, must be a **XMLReader** object. This function will change the document handler of the parser and activate namespace support; other parser configuration (like setting an entity resolver) must have been done in advance.

If you have XML in a string, you can use the **parseString()** function instead:

```python
xml.dom.pulldom.parseString(string, parser=None)
```

Return a **DOMEventStream** that represents the (Unicode) *string*.

```python
xml.dom.pulldom.default_bufsize
```

Default value for the *bufsize* parameter to **parse()**.

The value of this variable can be changed before calling **parse()** and the new value will take effect.
20.9.1. DOMEventStream Objects

class xml.dom.pulldom.DOMEventStream(stream, parser, bufsize)

getEvent()
Return a tuple containing event and the current node as
xml.dom.minidom.Document if event equals
START_DOCUMENT, xml.dom.minidom.Element if event
equals START_ELEMENT or END_ELEMENT or
xml.dom.minidom.Text if event equals CHARACTERS. The
current node does not contain informations about its children,
unless expandNode() is called.

expandNode(node)
Expands all children of node into node. Example:

```python
xml = '<html><title>Foo</title> <p>Some text <div>and more</div></p>'
doc = pulldom.parseString(xml)
for event, node in doc:
    if event == pulldom.START_ELEMENT and node:
        # Following statement only prints '<p/>
        print(node.toxml())
        doc.exandNode(node)
        # Following statement prints node with
        print(node.toxml())
```

reset()
20.10. xml.sax — Support for SAX2 parsers

The xml.sax package provides a number of modules which implement the Simple API for XML (SAX) interface for Python. The package itself provides the SAX exceptions and the convenience functions which will be most used by users of the SAX API.

**Warning:** The xml.sax module is not secure against maliciously constructed data. If you need to parse untrusted or unauthenticated data see [XML vulnerabilities](#).

The convenience functions are:

```python
xml.sax.make_parser(parser_list=[])  
Create and return a SAX XMLReader object. The first parser found will be used. If parser_list is provided, it must be a sequence of strings which name modules that have a function named create_parser(). Modules listed in parser_list will be used before modules in the default list of parsers.
```

```python
xml.sax.parse(filename_or_stream, handler, error_handler=handler.ErrorHandler())
Create a SAX parser and use it to parse a document. The document, passed in as filename_or_stream, can be a filename or a file object. The handler parameter needs to be a SAX ContentHandler instance. If error_handler is given, it must be a SAX ErrorHandler instance; if omitted, SAXParseException will be raised on all errors. There is no return value; all work must
be done by the *handler* passed in.

```python
def xml.sax.parseString(string, handler, error_handler=None):
```

Similar to `parse()`, but parses from a buffer `string` received as a parameter.

A typical SAX application uses three kinds of objects: readers, handlers and input sources. “Reader” in this context is another term for parser, i.e. some piece of code that reads the bytes or characters from the input source, and produces a sequence of events. The events then get distributed to the handler objects, i.e. the reader invokes a method on the handler. A SAX application must therefore obtain a reader object, create or open the input sources, create the handlers, and connect these objects all together. As the final step of preparation, the reader is called to parse the input. During parsing, methods on the handler objects are called based on structural and syntactic events from the input data.

For these objects, only the interfaces are relevant; they are normally not instantiated by the application itself. Since Python does not have an explicit notion of interface, they are formally introduced as classes, but applications may use implementations which do not inherit from the provided classes. The `InputSource`, `Locator`, `Attributes`, `AttributesNS`, and `XMLReader` interfaces are defined in the module `xml.sax.xmlreader`. The handler interfaces are defined in `xml.sax.handler`. For convenience, `InputSource` (which is often instantiated directly) and the handler classes are also available from `xml.sax`. These interfaces are described below.

In addition to these classes, `xml.sax` provides the following exception classes.
**exception xml.sax.SAXException**(msg, exception=None)

Encapsulate an XML error or warning. This class can contain basic error or warning information from either the XML parser or the application: it can be subclassed to provide additional functionality or to add localization. Note that although the handlers defined in the **ErrorHandler** interface receive instances of this exception, it is not required to actually raise the exception — it is also useful as a container for information.

When instantiated, `msg` should be a human-readable description of the error. The optional `exception` parameter, if given, should be None or an exception that was caught by the parsing code and is being passed along as information.

This is the base class for the other SAX exception classes.

**exception xml.sax.SAXParseException**(msg, exception, locator)

Subclass of **SAXException** raised on parse errors. Instances of this class are passed to the methods of the SAX **ErrorHandler** interface to provide information about the parse error. This class supports the SAX **Locator** interface as well as the **SAXException** interface.

**exception xml.sax.SAXNotRecognizedException**(msg, exception=None)

Subclass of **SAXException** raised when a SAX **XMLReader** is confronted with an unrecognized feature or property. SAX applications and extensions may use this class for similar purposes.

**exception xml.sax.SAXNotSupportedException**(msg,
Subclass of `SAXException` raised when a SAX `XMLReader` is asked to enable a feature that is not supported, or to set a property to a value that the implementation does not support. SAX applications and extensions may use this class for similar purposes.

**See also:**

**SAX: The Simple API for XML**
This site is the focal point for the definition of the SAX API. It provides a Java implementation and online documentation. Links to implementations and historical information are also available.

**Module** `xml.sax.handler`
Definitions of the interfaces for application-provided objects.

**Module** `xml.sax.saxutils`
Convenience functions for use in SAX applications.

**Module** `xml.sax.xmlreader`
Definitions of the interfaces for parser-provided objects.
20.10.1. SAXException Objects

The `SAXException` exception class supports the following methods:

**SAXException.getMessage()**

Return a human-readable message describing the error condition.

**SAXException.getException()**

Return an encapsulated exception object, or None.
20.11. **xml.sax.handler** — Base classes for SAX handlers

The SAX API defines four kinds of handlers: content handlers, DTD handlers, error handlers, and entity resolvers. Applications normally only need to implement those interfaces whose events they are interested in; they can implement the interfaces in a single object or in multiple objects. Handler implementations should inherit from the base classes provided in the module `xml.sax.handler`, so that all methods get default implementations.

```python
class xml.sax.handler.ContentHandler
    This is the main callback interface in SAX, and the one most important to applications. The order of events in this interface mirrors the order of the information in the document.

class xml.sax.handler.DTDHandler
    Handle DTD events.
    This interface specifies only those DTD events required for basic parsing (unparsed entities and attributes).

class xml.sax.handler.EntityResolver
    Basic interface for resolving entities. If you create an object implementing this interface, then register the object with your Parser, the parser will call the method in your object to resolve all external entities.

class xml.sax.handler.ErrorHandler
    Interface used by the parser to present error and warning messages to the application. The methods of this object control
whether errors are immediately converted to exceptions or are handled in some other way.

In addition to these classes, \texttt{xml.sax.handler} provides symbolic constants for the feature and property names.

\texttt{xml.sax.handler.feature_namespaces}

\texttt{value: "http://xml.org/sax/features/namespaces"}

true: Perform Namespace processing.
false: Optionally do not perform Namespace processing (implies namespace-prefixes; default).
access: (parsing) read-only; (not parsing) read/write

\texttt{xml.sax.handler.feature_namespace_prefixes}

\texttt{value: "http://xml.org/sax/features/namespace-prefixes"}

true: Report the original prefixed names and attributes used for Namespace declarations.
false: Do not report attributes used for Namespace declarations, and optionally do not report original prefixed names (default).
access: (parsing) read-only; (not parsing) read/write

\texttt{xml.sax.handler.feature_string_interning}

\texttt{value: "http://xml.org/sax/features/string-interning"}

true: All element names, prefixes, attribute names, Namespace URIs, and local names are interned using the built-in intern function.
false: Names are not necessarily interned, although they may be (default).
access: (parsing) read-only; (not parsing) read/write

\texttt{xml.sax.handler.feature_validation}

\texttt{value: "http://xml.org/sax/features/validation"}
true: Report all validation errors (implies external-general-entities and external-parameter-entities).
false: Do not report validation errors.
access: (parsing) read-only; (not parsing) read/write

xml.sax.handler.feature_external_ges
value: "http://xml.org/sax/features/external-general-entities"
true: Include all external general (text) entities.
false: Do not include external general entities.
access: (parsing) read-only; (not parsing) read/write

xml.sax.handler.feature_external_pes
value: "http://xml.org/sax/features/external-parameter-entities"
true: Include all external parameter entities, including the external DTD subset.
false: Do not include any external parameter entities, even the external DTD subset.
access: (parsing) read-only; (not parsing) read/write

xml.sax.handler.all_features
List of all features.

xml.sax.handler.property_lexical_handler
value: "http://xml.org/sax/properties/lexical-handler"
data type: xml.sax.sax2lib.LexicalHandler (not supported in Python 2)
description: An optional extension handler for lexical events like comments.
access: read/write

xml.sax.handler.property_declaration_handler
value: "http://xml.org/sax/properties/declaration-handler"
data type: xml.sax.sax2libDeclHandler (not supported in Python 2)
description: An optional extension handler for DTD-related events other than notations and unparsed entities.
access: read/write

xml.sax.handler.property_dom_node
value: "http://xml.org/sax/properties/dom-node"
data type: org.w3c.dom.Node (not supported in Python 2)
description: When parsing, the current DOM node being visited if this is a DOM iterator; when not parsing, the root DOM node for iteration.
access: (parsing) read-only; (not parsing) read/write

xml.sax.handler.property_xml_string
value: "http://xml.org/sax/properties/xml-string"
data type: String
description: The literal string of characters that was the source for the current event.
access: read-only

xml.sax.handler.all_properties
List of all known property names.
20.11.1. ContentHandler Objects

Users are expected to subclass `ContentHandler` to support their application. The following methods are called by the parser on the appropriate events in the input document:

`ContentHandler.setDocumentLocator(locator)`

Called by the parser to give the application a locator for locating the origin of document events.

SAX parsers are strongly encouraged (though not absolutely required) to supply a locator: if it does so, it must supply the locator to the application by invoking this method before invoking any of the other methods in the DocumentHandler interface.

The locator allows the application to determine the end position of any document-related event, even if the parser is not reporting an error. Typically, the application will use this information for reporting its own errors (such as character content that does not match an application’s business rules). The information returned by the locator is probably not sufficient for use with a search engine.

Note that the locator will return correct information only during the invocation of the events in this interface. The application should not attempt to use it at any other time.

`ContentHandler.startDocument()`

Receive notification of the beginning of a document.

The SAX parser will invoke this method only once, before any other methods in this interface or in DTDHandler (except for `setDocumentLocator()`).
ContentHandler.\texttt{endDocument()}
Receive notification of the end of a document.

The SAX parser will invoke this method only once, and it will be the last method invoked during the parse. The parser shall not invoke this method until it has either abandoned parsing (because of an unrecoverable error) or reached the end of input.

ContentHandler.\texttt{startPrefixMapping}(\textit{prefix, uri})
Begin the scope of a prefix-URI Namespace mapping.

The information from this event is not necessary for normal Namespace processing: the SAX XML reader will automatically replace prefixes for element and attribute names when the \texttt{feature_namespaces} feature is enabled (the default).

There are cases, however, when applications need to use prefixes in character data or in attribute values, where they cannot safely be expanded automatically; the \texttt{startPrefixMapping()} and \texttt{endPrefixMapping()} events supply the information to the application to expand prefixes in those contexts itself, if necessary.

Note that \texttt{startPrefixMapping()} and \texttt{endPrefixMapping()} events are not guaranteed to be properly nested relative to each other: all \texttt{startPrefixMapping()} events will occur before the corresponding \texttt{startElement()} event, and all \texttt{endPrefixMapping()} events will occur after the corresponding \texttt{endElement()} event, but their order is not guaranteed.

ContentHandler.\texttt{endPrefixMapping}(\textit{prefix})
End the scope of a prefix-URI mapping.

See \texttt{startPrefixMapping()} for details. This event will always
occur after the corresponding endElement() event, but the order of endPrefixMapping() events is not otherwise guaranteed.

**ContentHandler.startElement**(name, attrs)
Signals the start of an element in non-namespace mode.

The name parameter contains the raw XML 1.0 name of the element type as a string and the attrs parameter holds an object of the Attributes interface (see *The Attributes Interface*) containing the attributes of the element. The object passed as attrs may be re-used by the parser; holding on to a reference to it is not a reliable way to keep a copy of the attributes. To keep a copy of the attributes, use the copy() method of the attrs object.

**ContentHandler.endElement**(name)
Signals the end of an element in non-namespace mode.

The name parameter contains the name of the element type, just as with the startElement() event.

**ContentHandler.startElementNS**(name, qname, attrs)
Signals the start of an element in namespace mode.

The name parameter contains the name of the element type as a (uri, localname) tuple, the qname parameter contains the raw XML 1.0 name used in the source document, and the attrs parameter holds an instance of the AttributesNS interface (see *The AttributesNS Interface*) containing the attributes of the element. If no namespace is associated with the element, the uri component of name will be None. The object passed as attrs may be re-used by the parser; holding on to a reference to it is not a reliable way to keep a copy of the attributes. To keep a copy of the
attributes, use the `copy()` method of the `attrs` object.

Parsers may set the `qname` parameter to `None`, unless the `feature_namespace_prefixes` feature is activated.

**ContentHandler**. `endElementNS(name, qname)`
Signals the end of an element in namespace mode.

The `name` parameter contains the name of the element type, just as with the `startElementNS()` method, likewise the `qname` parameter.

**ContentHandler**. `characters(content)`
Receive notification of character data.

The Parser will call this method to report each chunk of character data. SAX parsers may return all contiguous character data in a single chunk, or they may split it into several chunks; however, all of the characters in any single event must come from the same external entity so that the Locator provides useful information.

`content` may be a string or bytes instance; the `expat` reader module always produces strings.

**Note:** The earlier SAX 1 interface provided by the Python XML Special Interest Group used a more Java-like interface for this method. Since most parsers used from Python did not take advantage of the older interface, the simpler signature was chosen to replace it. To convert old code to the new interface, use `content` instead of slicing content with the old `offset` and `length` parameters.

**ContentHandler**. `ignorableWhitespace(whitespace)`
Receive notification of ignorable whitespace in element content.

Validating Parsers must use this method to report each chunk of ignorable whitespace (see the W3C XML 1.0 recommendation, section 2.10): non-validating parsers may also use this method if they are capable of parsing and using content models.

SAX parsers may return all contiguous whitespace in a single chunk, or they may split it into several chunks; however, all of the characters in any single event must come from the same external entity, so that the Locator provides useful information.

**ContentHandler.** `processingInstruction(target, data)`
Receive notification of a processing instruction.

The Parser will invoke this method once for each processing instruction found: note that processing instructions may occur before or after the main document element.

A SAX parser should never report an XML declaration (XML 1.0, section 2.8) or a text declaration (XML 1.0, section 4.3.1) using this method.

**ContentHandler.** `skippedEntity(name)`
Receive notification of a skipped entity.

The Parser will invoke this method once for each entity skipped. Non-validating processors may skip entities if they have not seen the declarations (because, for example, the entity was declared in an external DTD subset). All processors may skip external entities, depending on the values of the `feature_external_ges` and the `feature_external_pes` properties.
20.11.2. DTDHandler Objects

**DTDHandler** instances provide the following methods:

**`DTDHandler.notationDecl(name, publicId, systemId)`**
Handle a notation declaration event.

**`DTDHandler.unparsedEntityDecl(name, publicId, systemId, ndata)`**
Handle an unparsed entity declaration event.
20.11.3. EntityResolver Objects

EntityResolver. **resolveEntity**(*publicId, systemId*)

Resolve the system identifier of an entity and return either the system identifier to read from as a string, or an InputSource to read from. The default implementation returns *systemId*. 
20.11.4. ErrorHandler Objects

Objects with this interface are used to receive error and warning information from the XMLReader. If you create an object that implements this interface, then register the object with your XMLReader, the parser will call the methods in your object to report all warnings and errors. There are three levels of errors available: warnings, (possibly) recoverable errors, and unrecoverable errors. All methods take a SAXParseException as the only parameter. Errors and warnings may be converted to an exception by raising the passed-in exception object.

ErrorHandler.error(exception)

Called when the parser encounters a recoverable error. If this method does not raise an exception, parsing may continue, but further document information should not be expected by the application. Allowing the parser to continue may allow additional errors to be discovered in the input document.

ErrorHandler.fatalError(exception)

Called when the parser encounters an error it cannot recover from; parsing is expected to terminate when this method returns.

ErrorHandler.warning(exception)

Called when the parser presents minor warning information to the application. Parsing is expected to continue when this method returns, and document information will continue to be passed to the application. Raising an exception in this method will cause parsing to end.
20.12. xml.sax.saxutils — SAX Utilities

The module `xml.sax.saxutils` contains a number of classes and functions that are commonly useful when creating SAX applications, either in direct use, or as base classes.

`xml.sax.saxutils.escape(data, entities={})`

Escape `&`, `<`, and `>` in a string of data.

You can escape other strings of data by passing a dictionary as the optional `entities` parameter. The keys and values must all be strings; each key will be replaced with its corresponding value. The characters `&`, `<` and `>` are always escaped, even if `entities` is provided.

`xml.sax.saxutils.unescape(data, entities={})`

Unescape `&amp;`, `&lt;`, and `&gt;` in a string of data.

You can unescape other strings of data by passing a dictionary as the optional `entities` parameter. The keys and values must all be strings; each key will be replaced with its corresponding value. `&amp;`, `&lt;`, and `&gt;` are always unescaped, even if `entities` is provided.

`xml.sax.saxutils.quoteattr(data, entities={})`

Similar to `escape()`, but also prepares `data` to be used as an attribute value. The return value is a quoted version of `data` with any additional required replacements. `quoteattr()` will select a quote character based on the content of `data`, attempting to avoid
encoding any quote characters in the string. If both single- and double-quote characters are already in data, the double-quote characters will be encoded and data will be wrapped in double-quotes. The resulting string can be used directly as an attribute value:

>>> print("<element attr=%s>" % quoteattr("ab ' cd &quot; ef")

This function is useful when generating attribute values for HTML or any SGML using the reference concrete syntax.

class xml.sax.saxutils.XMLGenerator(out=None, encoding='iso-8859-1', short_empty_elements=False)

This class implements the ContentHandler interface by writing SAX events back into an XML document. In other words, using an XMLGenerator as the content handler will reproduce the original document being parsed. out should be a file-like object which will default to sys.stdout. encoding is the encoding of the output stream which defaults to 'iso-8859-1'. short_empty_elements controls the formatting of elements that contain no content: if False (the default) they are emitted as a pair of start/end tags, if set to True they are emitted as a single self-closed tag.

New in version 3.2: The short_empty_elements parameter.

class xml.sax.saxutils.XMLFilterBase(base)

This class is designed to sit between an XMLReader and the client application’s event handlers. By default, it does nothing but pass requests up to the reader and events on to the handlers unmodified, but subclasses can override specific methods to modify the event stream or the configuration requests as they pass
xml.sax.saxutils.prepare_input_source(source, base='')

This function takes an input source and an optional base URL and returns a fully resolved InputSource object ready for reading. The input source can be given as a string, a file-like object, or an InputSource object; parsers will use this function to implement the polymorphic source argument to their parse() method.
20.13. `xml.sax.xmlreader` — Interface for XML parsers

SAX parsers implement the `XMLReader` interface. They are implemented in a Python module, which must provide a function `create_parser()`. This function is invoked by `xml.sax.make_parser()` with no arguments to create a new parser object.

```python
class xml.sax.xmlreader.XMLReader
    Base class which can be inherited by SAX parsers.
```

```python
class xml.sax.xmlreader.IncrementalParser
    In some cases, it is desirable not to parse an input source at once, but to feed chunks of the document as they get available. Note that the reader will normally not read the entire file, but read it in chunks as well; still `parse()` won't return until the entire document is processed. So these interfaces should be used if the blocking behaviour of `parse()` is not desirable.

    When the parser is instantiated it is ready to begin accepting data from the feed method immediately. After parsing has been finished with a call to close the reset method must be called to make the parser ready to accept new data, either from feed or using the `parse` method.

    Note that these methods must *not* be called during parsing, that is, after `parse` has been called and before it returns.

    By default, the class also implements the `parse` method of the
```
XMLReader interface using the feed, close and reset methods of the IncrementalParser interface as a convenience to SAX 2.0 driver writers.

```python
class xml.sax.xmlreader.Locator

Interface for associating a SAX event with a document location. A locator object will return valid results only during calls to DocumentHandler methods; at any other time, the results are unpredictable. If information is not available, methods may return None.
```

```python
class xml.sax.xmlreader.InputSource(system_id=None)

Encapsulation of the information needed by the XMLReader to read entities.

This class may include information about the public identifier, system identifier, byte stream (possibly with character encoding information) and/or the character stream of an entity.

Applications will create objects of this class for use in the XMLReader.parse() method and for returning from EntityResolver.resolveEntity.

An InputSource belongs to the application, the XMLReader is not allowed to modify InputSource objects passed to it from the application, although it may make copies and modify those.
```

```python
class xml.sax.xmlreader.AttributesImpl(attrs)

This is an implementation of the Attributes interface (see section The Attributes Interface). This is a dictionary-like object which represents the element attributes in a startElement() call. In addition to the most useful dictionary operations, it supports a number of other methods as described by the interface. Objects
of this class should be instantiated by readers; \textit{attrs} must be a
dictionary-like object containing a mapping from attribute names to
attribute values.

\texttt{class xml.sax.xmlreader.\textit{AttributesNSImpl}(attrs,}
\texttt{qnames)}

Namespace-aware variant of \textit{AttributesImpl}, which will be
passed to \texttt{startElementNS()}. It is derived from
\textit{AttributesImpl}, but understands attribute names as two-tuples
of \textit{namespaceURI} and \textit{localname}. In addition, it provides a number
of methods expecting qualified names as they appear in the
original document. This class implements the \textit{AttributesNS}
interface (see section \textit{The AttributesNS Interface}).
20.13.1. XMLReader Objects

The XMLReader interface supports the following methods:

XMLReader. `parse(source)`
Process an input source, producing SAX events. The `source` object can be a system identifier (a string identifying the input source – typically a file name or an URL), a file-like object, or an `InputSource` object. When `parse()` returns, the input is completely processed, and the parser object can be discarded or reset. As a limitation, the current implementation only accepts byte streams; processing of character streams is for further study.

XMLReader. `getContentHandler()`
Return the current `ContentHandler`.

XMLReader. `setContentHandler(handler)`
Set the current `ContentHandler`. If no `ContentHandler` is set, content events will be discarded.

XMLReader. `getDTDHandler()`
Return the current `DTDHandler`.

XMLReader. `setDTDHandler(handler)`
Set the current `DTDHandler`. If no `DTDHandler` is set, DTD events will be discarded.

XMLReader. `getEntityResolver()`
Return the current `EntityResolver`.

XMLReader. `setEntityResolver(handler)`
Set the current `EntityResolver`. If no `EntityResolver` is set, attempts to resolve an external entity will result in opening the system identifier for the entity, and fail if it is not available.

**XMLReader**. `getErrorHandler()`  
Return the current `ErrorHandler`.

**XMLReader**. `setErrorHandler(handler)`  
Set the current error handler. If no `ErrorHandler` is set, errors will be raised as exceptions, and warnings will be printed.

**XMLReader**. `setLocale(locale)`  
Allow an application to set the locale for errors and warnings.

SAX parsers are not required to provide localization for errors and warnings; if they cannot support the requested locale, however, they must raise a SAX exception. Applications may request a locale change in the middle of a parse.

**XMLReader**. `getFeature(featurename)`  
Return the current setting for feature `featurename`. If the feature is not recognized, `SAXNotRecognizedException` is raised. The well-known featurenames are listed in the module `xml.sax.handler`.

**XMLReader**. `setFeature(featurename, value)`  
Set the `featurename` to `value`. If the feature is not recognized, `SAXNotRecognizedException` is raised. If the feature or its setting is not supported by the parser, `SAXNotSupportedException` is raised.

**XMLReader**. `getProperty(propertyname)`
Return the current setting for property `propertyname`. If the property is not recognized, a SAXNotRecognizedException is raised. The well-known property names are listed in the module `xml.sax.handler`.

`XMLReader.setProperty(propertyname, value)`

Set the `propertyname` to `value`. If the property is not recognized, SAXNotRecognizedException is raised. If the property or its setting is not supported by the parser, SAXNotSupportedException is raised.
20.13.2. IncrementalParser Objects

Instances of `IncrementalParser` offer the following additional methods:

`IncrementalParser.feed(data)`
- Process a chunk of `data`.

`IncrementalParser.close()`
- Assume the end of the document. That will check well-formedness conditions that can be checked only at the end, invoke handlers, and may clean up resources allocated during parsing.

`IncrementalParser.reset()`
- This method is called after close has been called to reset the parser so that it is ready to parse new documents. The results of calling `parse` or `feed` after close without calling `reset` are undefined.
20.13.3. Locator Objects

Instances of Locator provide these methods:

Locator. `getColumnNumber()`
   Return the column number where the current event ends.

Locator. `getLineNumber()`
   Return the line number where the current event ends.

Locator. `getPublicId()`
   Return the public identifier for the current event.

Locator. `getSystemId()`
   Return the system identifier for the current event.
20.13.4. InputSource Objects

InputSource. **setPublicId**(id)
Sets the public identifier of this InputSource.

InputSource. **getPublicId**()
Returns the public identifier of this InputSource.

InputSource. **setSystemId**(id)
Sets the system identifier of this InputSource.

InputSource. **getSystemId**()
Returns the system identifier of this InputSource.

InputSource. **setEncoding**(encoding)
Sets the character encoding of this InputSource.

The encoding must be a string acceptable for an XML encoding declaration (see section 4.3.3 of the XML recommendation).

The encoding attribute of the InputSource is ignored if the InputSource also contains a character stream.

InputSource. **getEncoding**()
Get the character encoding of this InputSource.

InputSource. **setByteStream**(bytefile)
Set the byte stream (a Python file-like object which does not perform byte-to-character conversion) for this input source.

The SAX parser will ignore this if there is also a character stream specified, but it will use a byte stream in preference to opening a
URI connection itself.

If the application knows the character encoding of the byte stream, it should set it with the setEncoding method.

InputSource. **getByteStream()**
Get the byte stream for this input source.

The getEncoding method will return the character encoding for this byte stream, or None if unknown.

InputSource. **setCharacterStream(charfile)**
Set the character stream for this input source. (The stream must be a Python 1.6 Unicode-wrapped file-like that performs conversion to strings.)

If there is a character stream specified, the SAX parser will ignore any byte stream and will not attempt to open a URI connection to the system identifier.

InputSource. **getCharacterStream()**
Get the character stream for this input source.
20.13.5. The Attributes Interface

Attributes objects implement a portion of the *mapping protocol*, including the methods `copy()`, `get()`, `__contains__()`, `items()`, `keys()`, and `values()`. The following methods are also provided:

**Attributes.** `getLength()`

Return the number of attributes.

**Attributes.** `getNames()`

Return the names of the attributes.

**Attributes.** `getType(name)`

Returns the type of the attribute `name`, which is normally `'CDATA'`.

**Attributes.** `getValue(name)`

Return the value of attribute `name`. 
20.13.6. The AttributesNS Interface

This interface is a subtype of the Attributes interface (see section *The Attributes Interface*). All methods supported by that interface are also available on AttributesNS objects.

The following methods are also available:

AttributesNS. `getValueByQName(name)`
   Return the value for a qualified name.

AttributesNS. `getNameByQName(name)`
   Return the `(namespace, localname)` pair for a qualified name.

AttributesNS. `getQNameByName(name)`
   Return the qualified name for a `(namespace, localname)` pair.

AttributesNS. `getQNames()`
   Return the qualified names of all attributes.
Warning: The pyexpat module is not secure against maliciously constructed data. If you need to parse untrusted or unauthenticated data see *XML vulnerabilities*.

The `xml.parsers.expat` module is a Python interface to the Expat non-validating XML parser. The module provides a single extension type, `xmlparser`, that represents the current state of an XML parser. After an `xmlparser` object has been created, various attributes of the object can be set to handler functions. When an XML document is then fed to the parser, the handler functions are called for the character data and markup in the XML document.

This module uses the pyexpat module to provide access to the Expat parser. Direct use of the pyexpat module is deprecated.

This module provides one exception and one type object:

`exception xml.parsers.expat.ExpatError`

The exception raised when Expat reports an error. See section *ExpatError Exceptions* for more information on interpreting Expat errors.

`exception xml.parsers.expat.error`

Alias for `ExpatError`.

`xml.parsers.expat.XMLParserType`

The type of the return values from the `ParserCreate()` function.
The `xml.parsers.expat` module contains two functions:

```python
xml.parsers.expat.ErrorString(errno)
```

Returns an explanatory string for a given error number `errno`.

```python
xml.parsers.expat.ParserCreate(encoding=None, namespace_separator=None)
```

Creates and returns a new `xmlparser` object. `encoding`, if specified, must be a string naming the encoding used by the XML data. Expat doesn't support as many encodings as Python does, and its repertoire of encodings can't be extended; it supports UTF-8, UTF-16, ISO-8859-1 (Latin1), and ASCII. If `encoding` [1] is given it will override the implicit or explicit encoding of the document.

Expat can optionally do XML namespace processing for you, enabled by providing a value for `namespace_separator`. The value must be a one-character string; a `ValueError` will be raised if the string has an illegal length (None is considered the same as omission). When namespace processing is enabled, element type names and attribute names that belong to a namespace will be expanded. The element name passed to the element handlers `StartElementHandler` and `EndElementHandler` will be the concatenation of the namespace URI, the namespace separator character, and the local part of the name. If the namespace separator is a zero byte (chr(0)) then the namespace URI and the local part will be concatenated without any separator.

For example, if `namespace_separator` is set to a space character (" ") and the following document is parsed:

```xml
<?xml version="1.0"?>
<root xmlns = "http://default-namespace.org/"
     xmlns:py = "http://www.python.org/ns/">
```
StartElementHandler will receive the following strings for each element:

http://default-namespace.org/ root
http://www.python.org/ns/ elem1
elem2

See also:

The Expat XML Parser
  Home page of the Expat project.
20.14.1. XMLParser Objects

xmlparser objects have the following methods:

xmlparser.Parse(data[, isfinal])
    Parses the contents of the string data, calling the appropriate handler functions to process the parsed data. isfinal must be true on the final call to this method. data can be the empty string at any time.

xmlparser.ParseFile(file)
    Parse XML data reading from the object file. file only needs to provide the read(nbytes) method, returning the empty string when there’s no more data.

xmlparser.SetBase(base)
    Sets the base to be used for resolving relative URIs in system identifiers in declarations. Resolving relative identifiers is left to the application: this value will be passed through as the base argument to the ExternalEntityRefHandler(), NotationDeclHandler(), and UnparsedEntityDeclHandler() functions.

xmlparser.GetBase()
    Returns a string containing the base set by a previous call to SetBase(), or None if SetBase() hasn’t been called.

xmlparser.GetInputContext()
    Returns the input data that generated the current event as a string. The data is in the encoding of the entity which contains the text. When called while an event handler is not active, the return value
is None.

```xml
xmlparser.**ExternalEntityParserCreate**(context[, encoding])
```

Create a “child” parser which can be used to parse an external parsed entity referred to by content parsed by the parent parser. The `context` parameter should be the string passed to the `ExternalEntityRefHandler()` handler function, described below. The child parser is created with the `ordered_attributes` and `specified_attributes` set to the values of this parser.

```xml
xmlparser.**SetParamEntityParsing**(flag)
```

Control parsing of parameter entities (including the external DTD subset). Possible `flag` values are `XML_PARAM_ENTITY_PARSING_NEVER`, `XML_PARAM_ENTITY_PARSING_UNLESS_STANDALONE` and `XML_PARAM_ENTITY_PARSING_ALWAYS`. Return true if setting the flag was successful.

```xml
xmlparser.**UseForeignDTD**(flag)
```

Calling this with a true value for `flag` (the default) will cause Expat to call the `ExternalEntityRefHandler` with `None` for all arguments to allow an alternate DTD to be loaded. If the document does not contain a document type declaration, the `ExternalEntityRefHandler` will still be called, but the `StartDoctypeDeclHandler` and `EndDoctypeDeclHandler` will not be called.

Passing a false value for `flag` will cancel a previous call that passed a true value, but otherwise has no effect.
This method can only be called before the `Parse()` or `ParseFile()` methods are called; calling it after either of those have been called causes `ExpatError` to be raised with the `code` attribute set to `errors.codes[errors.XML_ERROR_CANT_CHANGE_FEATURE_`

`xmlparser` objects have the following attributes:

`xmlparser.buffer_size`

The size of the buffer used when `buffer_text` is true. A new buffer size can be set by assigning a new integer value to this attribute. When the size is changed, the buffer will be flushed.

`xmlparser.buffer_text`

Setting this to true causes the `xmlparser` object to buffer textual content returned by Expat to avoid multiple calls to the `CharacterDataHandler()` callback whenever possible. This can improve performance substantially since Expat normally breaks character data into chunks at every line ending. This attribute is false by default, and may be changed at any time.

`xmlparser.buffer_used`

If `buffer_text` is enabled, the number of bytes stored in the buffer. These bytes represent UTF-8 encoded text. This attribute has no meaningful interpretation when `buffer_text` is false.

`xmlparser.ordered_attributes`

Setting this attribute to a non-zero integer causes the attributes to be reported as a list rather than a dictionary. The attributes are presented in the order found in the document text. For each attribute, two list entries are presented: the attribute name and the attribute value. (Older versions of this module also used this
format.) By default, this attribute is false; it may be changed at any time.

**xmlparser.specified_attributes**

If set to a non-zero integer, the parser will report only those attributes which were specified in the document instance and not those which were derived from attribute declarations. Applications which set this need to be especially careful to use what additional information is available from the declarations as needed to comply with the standards for the behavior of XML processors. By default, this attribute is false; it may be changed at any time.

The following attributes contain values relating to the most recent error encountered by an xmlparser object, and will only have correct values once a call to Parse() or ParseFile() has raised a `xml.parsers.expat.ExpatError` exception.

**xmlparser.ErrorByteIndex**

Byte index at which an error occurred.

**xmlparser.ErrorCode**

Numeric code specifying the problem. This value can be passed to the `ErrorString()` function, or compared to one of the constants defined in the `errors` object.

**xmlparser.ErrorColumnNumber**

Column number at which an error occurred.

**xmlparser.ErrorLineNumber**

Line number at which an error occurred.

The following attributes contain values relating to the current parse location in an xmlparser object. During a callback reporting a parse
event they indicate the location of the first of the sequence of characters that generated the event. When called outside of a callback, the position indicated will be just past the last parse event (regardless of whether there was an associated callback).

`xmlparser.CurrentByteIndex`  
Current byte index in the parser input.

`xmlparser.CurrentColumnNumber`  
Current column number in the parser input.

`xmlparser.CurrentLineNumber`  
Current line number in the parser input.

Here is the list of handlers that can be set. To set a handler on an `xmlparser` object `o`, use `o.handlername = func`. `handlername` must be taken from the following list, and `func` must be a callable object accepting the correct number of arguments. The arguments are all strings, unless otherwise stated.

`xmlparser.XmlDeclHandler(version, encoding, standalone)`  
Called when the XML declaration is parsed. The XML declaration is the (optional) declaration of the applicable version of the XML recommendation, the encoding of the document text, and an optional “standalone” declaration. `version` and `encoding` will be strings, and `standalone` will be 1 if the document is declared standalone, 0 if it is declared not to be standalone, or -1 if the standalone clause was omitted. This is only available with Expat version 1.95.0 or newer.

`xmlparser.StartDoctypeDeclHandler(doctypeName, systemId, publicId, has_internal_subset)`  
Called when Expat begins parsing the document type declaration
The doctypeName is provided exactly as presented. The systemId and publicId parameters give the system and public identifiers if specified, or None if omitted. has_internal_subset will be true if the document contains and internal document declaration subset. This requires Expat version 1.2 or newer.

```
xmllparser.EndDoctypeDeclHandler()
```
Called when Expat is done parsing the document type declaration. This requires Expat version 1.2 or newer.

```
xmllparser.ElementDeclHandler(name, model)
```
Called once for each element type declaration. name is the name of the element type, and model is a representation of the content model.

```
xmllparser.AttlistDeclHandler(elname, attname, type, default, required)
```
Called for each declared attribute for an element type. If an attribute list declaration declares three attributes, this handler is called three times, once for each attribute. elname is the name of the element to which the declaration applies and attname is the name of the attribute declared. The attribute type is a string passed as type; the possible values are 'CDATA', 'ID', 'IDREF', ... default gives the default value for the attribute used when the attribute is not specified by the document instance, or None if there is no default value (#IMPLIED values). If the attribute is required to be given in the document instance, required will be true. This requires Expat version 1.95.0 or newer.

```
xmllparser.StartElementHandler(name, attributes)
```
Called for the start of every element. name is a string containing
the element name, and attributes is the element attributes. If ordered_attributes is true, this is a list (see ordered_attributes for a full description). Otherwise it's a dictionary mapping names to values.

```
xmlparser.EndElementHandler(name)
```

Called for the end of every element.

```
xmlparser.ProcessingInstructionHandler(target, data)
```

Called for every processing instruction.

```
xmlparser.CharacterDataHandler(data)
```

Called for character data. This will be called for normal character data, CDATA marked content, and ignorable whitespace. Applications which must distinguish these cases can use the StartCdataSectionHandler, EndCdataSectionHandler, and ElementDeclHandler callbacks to collect the required information.

```
xmlparser.UnparsedEntityDeclHandler(entityName, base, systemId, publicId, notationName)
```

Called for unparsed (NDATA) entity declarations. This is only present for version 1.2 of the Expat library; for more recent versions, use EntityDeclHandler instead. (The underlying function in the Expat library has been declared obsolete.)

```
xmlparser.EntityDeclHandler(entityName, is_parameter_entity, value, base, systemId, publicId, notationName)
```

Called for all entity declarations. For parameter and internal entities, value will be a string giving the declared contents of the entity; this will be None for external entities. The notationName
parameter will be None for parsed entities, and the name of the notation for unparsed entities. is_parameter_entity will be true if the entity is a parameter entity or false for general entities (most applications only need to be concerned with general entities). This is only available starting with version 1.95.0 of the Expat library.

```python
def xmlparser.NotationDeclHandler(notationName, base, systemId, publicId):
    """Called for notation declarations. notationName, base, and systemId, and publicId are strings if given. If the public identifier is omitted, publicId will be None."
```

```python
def xmlparser.StartNamespaceDeclHandler(prefix, uri):
    """Called when an element contains a namespace declaration. Namespace declarations are processed before the StartElementHandler is called for the element on which declarations are placed."
```

```python
def xmlparser.EndNamespaceDeclHandler(prefix):
    """Called when the closing tag is reached for an element that contained a namespace declaration. This is called once for each namespace declaration on the element in the reverse of the order for which the StartNamespaceDeclHandler was called to indicate the start of each namespace declaration's scope. Calls to this handler are made after the correspondingEndElementHandler for the end of the element."
```

```python
def xmlparser.CommentHandler(data):
    """Called for comments. data is the text of the comment, excluding the leading '<!--' and trailing '-->'."
```

```python
def xmlparser.StartCdataSectionHandler():
    """""
```
Called at the start of a CDATA section. This and
EndCdataSectionHandler are needed to be able to identify the
syntactical start and end for CDATA sections.

`xmlparser.EndCdataSectionHandler()`
Called at the end of a CDATA section.

`xmlparser.DefaultHandler(data)`
Called for any characters in the XML document for which no
applicable handler has been specified. This means characters that
are part of a construct which could be reported, but for which no
handler has been supplied.

`xmlparser.DefaultHandlerExpand(data)`
This is the same as the `DefaultHandler()`, but doesn't inhibit
expansion of internal entities. The entity reference will not be
passed to the default handler.

`xmlparser.NotStandaloneHandler()`
Called if the XML document hasn't been declared as being a
standalone document. This happens when there is an external
subset or a reference to a parameter entity, but the XML
declaration does not set standalone to `yes` in an XML declaration.
If this handler returns 0, then the parser will raise an
XML_ERROR_NOT_STANDALONE error. If this handler is not set, no
exception is raised by the parser for this condition.

`xmlparser.ExternalEntityRefHandler(context, base, systemId, publicId)`
Called for references to external entities. `base` is the current base,
as set by a previous call to `SetBase()`. The public and system
identifiers, `systemId` and `publicId`, are strings if given; if the public
identifier is not given, \texttt{publicId} will be None. The \texttt{context} value is opaque and should only be used as described below.

For external entities to be parsed, this handler must be implemented. It is responsible for creating the sub-parser using \texttt{ExternalEntityParserCreate(context)}, initializing it with the appropriate callbacks, and parsing the entity. This handler should return an integer; if it returns \texttt{0}, the parser will raise an \texttt{XML\_ERROR\_EXTERNAL\_ENTITY\_HANDLING} error, otherwise parsing will continue.

If this handler is not provided, external entities are reported by the \texttt{DefaultHandler} callback, if provided.
20.14.2. ExpatError Exceptions

*ExpatError* exceptions have a number of interesting attributes:

**ExpatError.code**
Expat's internal error number for the specific error. The *errors.messages* dictionary maps these error numbers to Expat's error messages. For example:

```python
from xml.parsers.expat import ParserCreate, ExpatError
p = ParserCreate()
try:
    p.Parse(some_xml_document)
except ExpatError as err:
    print("Error:", errors.messages[err.code])
```

The *errors* module also provides error message constants and a dictionary *codes* mapping these messages back to the error codes, see below.

**ExpatError.lineno**
Line number on which the error was detected. The first line is numbered 1.

**ExpatError.offset**
Character offset into the line where the error occurred. The first column is numbered 0.
20.14.3. Example

The following program defines three handlers that just print out their arguments.

```python
import xml.parsers.expat

# 3 handler functions
def start_element(name, attrs):
    print('Start element:', name, attrs)
def end_element(name):
    print('End element:', name)
def char_data(data):
    print('Character data:', repr(data))

p = xml.parsers.expat.ParserCreate()
p.StartElementHandler = start_element
p.EndElementHandler = end_element
p.CharacterDataHandler = char_data

p.Parse("""<?xml version="1.0"?>
<parent id="top"><child1 name="paul">Text goes here</child1>
<child2 name="fred">More text</child2>
</parent>""", 1)
```

The output from this program is:

```plaintext
Start element: parent {'id': 'top'}
Start element: child1 {'name': 'paul'}
Character data: 'Text goes here'
End element: child1
Character data: '
'
Start element: child2 {'name': 'fred'}
```
Character data: 'More text'
End element: child2
Character data: '
'
End element: parent
20.14.4. Content Model Descriptions

Content modules are described using nested tuples. Each tuple contains four values: the type, the quantifier, the name, and a tuple of children. Children are simply additional content module descriptions.

The values of the first two fields are constants defined in the `xml.parsers.expat.model` module. These constants can be collected in two groups: the model type group and the quantifier group.

The constants in the model type group are:

- `xml.parsers.expat.model.XML_CTYPE_ANY`
  - The element named by the model name was declared to have a content model of `ANY`.

- `xml.parsers.expat.model.XML_CTYPE_CHOICE`
  - The named element allows a choice from a number of options; this is used for content models such as `(A | B | C)`.

- `xml.parsers.expat.model.XML_CTYPE_EMPTY`
  - Elements which are declared to be `EMPTY` have this model type.

- `xml.parsers.expat.model.XML_CTYPE_MIXED`

- `xml.parsers.expat.model.XML_CTYPE_NAME`

- `xml.parsers.expat.model.XML_CTYPE_SEQ`
  - Models which represent a series of models which follow one after the other are indicated with this model type. This is used for models such as `(A, B, C)`.

The constants in the quantifier group are:
xml.parsers.expat.model.XML_CQUANT_NONE
   No modifier is given, so it can appear exactly once, as for A.

xml.parsers.expat.model.XML_CQUANT_OPT
   The model is optional: it can appear once or not at all, as for A?.

xml.parsers.expat.model.XML_CQUANT_PLUS
   The model must occur one or more times (like A+).

xml.parsers.expat.model.XML_CQUANT_REP
   The model must occur zero or more times, as for A*. 
20.14.5. Expat error constants

The following constants are provided in the `xml.parsers.expat.errors` module. These constants are useful in interpreting some of the attributes of the ExpatError exception objects raised when an error has occurred. Since for backwards compatibility reasons, the constants' value is the error message and not the numeric error code, you do this by comparing its `code` attribute with `errors.codes[errors.XML_ERROR_CONSTANT_NAME]`.

The `errors` module has the following attributes:

`xml.parsers.expat.errors.codes`

A dictionary mapping numeric error codes to their string descriptions.

*New in version 3.2.*

`xml.parsers.expat.errors.messages`

A dictionary mapping string descriptions to their error codes.

*New in version 3.2.*

`xml.parsers.expat.errors.XML_ERROR_ASYNC_ENTITY`

An entity reference in an attribute value referred to an external entity instead of an internal entity.

`xml.parsers.expat.errors.XML_ERROR_ATTRIBUTE_EXTERNAL_ENTITY_REF`

A character reference referred to a character which is illegal in XML
(for example, character \0, or ‘&\#0;’).

xml.parsers.expat.errors.XML_ERROR_BINARY_ENTITY
An entity reference referred to an entity which was declared with a notation, so cannot be parsed.

xml.parsers.expat.errors.XML_ERROR_DUPLICATE_ATTRIBUTE
An attribute was used more than once in a start tag.

xml.parsers.expat.errors.XML_ERROR_INCORRECT_ENCODING
xml.parsers.expat.errors.XML_ERROR_INVALID_TOKEN
  Raised when an input byte could not properly be assigned to a character; for example, a NUL byte (value \0) in a UTF-8 input stream.

xml.parsers.expat.errors.XML_ERROR_JUNK_AFTER_DOC_ELEMENT
Something other than whitespace occurred after the document element.

xml.parsers.expat.errors.XML_ERROR_MISPLACED_XML_PI
An XML declaration was found somewhere other than the start of the input data.

xml.parsers.expat.errors.XML_ERROR_NO_ELEMENTS
The document contains no elements (XML requires all documents to contain exactly one top-level element).

xml.parsers.expat.errors.XML_ERROR_NO_MEMORY
Expat was not able to allocate memory internally.

xml.parsers.expat.errors.XML_ERROR_PARAM_ENTITY_REF
A parameter entity reference was found where it was not allowed.
An incomplete character was found in the input.

An entity reference contained another reference to the same entity; possibly via a different name, and possibly indirectly.

Some unspecified syntax error was encountered.

An end tag did not match the innermost open start tag.

Some token (such as a start tag) was not closed before the end of the stream or the next token was encountered.

A reference was made to a entity which was not defined.

The document encoding is not supported by Expat.

A CDATA marked section was not closed.

The parser determined that the document was not “standalone” though it declared itself to be in the XML declaration, and the NotStandaloneHandler was set and returned 0.

The parser encountered an unexpected state.
An operation was requested that requires DTD support to be compiled in, but Expat was configured without DTD support. This should never be reported by a standard build of the `xml.parsers.expat` module.

A behavioral change was requested after parsing started that can only be changed before parsing has started. This is (currently) only raised by `UseForeignDTD()`.

An undeclared prefix was found when namespace processing was enabled.

The document attempted to remove the namespace declaration associated with a prefix.

A parameter entity contained incomplete markup.

The document contained no document element at all.

There was an error parsing a text declaration in an external entity.

Characters were found in the public id that are not allowed.
The requested operation was made on a suspended parser, but isn’t allowed. This includes attempts to provide additional input or to stop the parser.

```python
xml.parsers.expat.errors.XML_ERROR_NOT_SUSPENDED
```

An attempt to resume the parser was made when the parser had not been suspended.

```python
xml.parsers.expat.errors.XML_ERROR_ABORTED
```

This should not be reported to Python applications.

```python
xml.parsers.expat.errors.XML_ERROR_FINISHED
```

The requested operation was made on a parser which was finished parsing input, but isn’t allowed. This includes attempts to provide additional input or to stop the parser.

```python
xml.parsers.expat.errors.XML_ERROR_SUSPEND_PE
```

Footnotes

[1] The encoding string included in XML output should conform to the appropriate standards. For example, “UTF-8” is valid, but “UTF8” is not. See [http://www.w3.org/TR/2006/REC-xml11-20060816/#NT-EncodingDecl](http://www.w3.org/TR/2006/REC-xml11-20060816/#NT-EncodingDecl) and [http://www.iana.org/assignments/character-sets](http://www.iana.org/assignments/character-sets).
21. Internet Protocols and Support

The modules described in this chapter implement Internet protocols and support for related technology. They are all implemented in Python. Most of these modules require the presence of the system-dependent module `socket`, which is currently supported on most popular platforms. Here is an overview:

- **21.1. webbrowser — Convenient Web-browser controller**
  - 21.1.1. Browser Controller Objects
- **21.2. cgi — Common Gateway Interface support**
  - 21.2.1. Introduction
  - 21.2.2. Using the cgi module
  - 21.2.3. Higher Level Interface
  - 21.2.4. Functions
  - 21.2.5. Caring about security
  - 21.2.6. Installing your CGI script on a Unix system
  - 21.2.7. Testing your CGI script
  - 21.2.8. Debugging CGI scripts
  - 21.2.9. Common problems and solutions
- **21.3. cgitb — Traceback manager for CGI scripts**
- **21.4. wsgiref — WSGI Utilities and Reference Implementation**
  - 21.4.1. wsgiref.util — WSGI environment utilities
  - 21.4.2. wsgiref.headers — WSGI response header tools
  - 21.4.3. wsgiref.simple_server — a simple WSGI HTTP server
  - 21.4.4. wsgiref.validate — WSGI conformance checker
  - 21.4.5. wsgiref.handlers — server/gateway base classes
  - 21.4.6. Examples
- **21.5. urllib — URL handling modules**
- **21.6. urllib.request — Extensible library for opening URLs**
  - 21.6.1. Request Objects
- 21.6.2. OpenerDirector Objects
- 21.6.3. BaseHandler Objects
- 21.6.4. HTTPRedirectHandler Objects
- 21.6.5. HTTPCookieProcessor Objects
- 21.6.6. ProxyHandler Objects
- 21.6.7. HTTPPasswordMgr Objects
- 21.6.8. AbstractBasicAuthHandler Objects
- 21.6.9. HTTPBasicAuthHandler Objects
- 21.6.10. ProxyBasicAuthHandler Objects
- 21.6.11. AbstractDigestAuthHandler Objects
- 21.6.12. HTTPDigestAuthHandler Objects
- 21.6.13. ProxyDigestAuthHandler Objects
- 21.6.14. HTTPHandler Objects
- 21.6.15. HTTPSHandler Objects
- 21.6.16. FileHandler Objects
- 21.6.17. FTPHandler Objects
- 21.6.18. CacheFTPHandler Objects
- 21.6.19. UnknownHandler Objects
- 21.6.20. HTTPErrorProcessor Objects
- 21.6.21. Examples
- 21.6.22. Legacy interface
- 21.6.23. urllib.request Restrictions

- 21.7. urllib.response — Response classes used by urllib
- 21.8. urllib.parse — Parse URLs into components
  - 21.8.1. URL Parsing
  - 21.8.2. Parsing ASCII Encoded Bytes
  - 21.8.3. Structured Parse Results
  - 21.8.4. URL Quoting
- 21.9. urllib.error — Exception classes raised by urllib.request
- 21.10. urllib.robotparser — Parser for robots.txt
- 21.11. http — HTTP modules
  - 21.12.1. HTTPConnection Objects
- 21.12.2. HTTPResponse Objects
- 21.12.3. Examples
- 21.12.4. HTTPMessage Objects

- 21.13. ftplib — FTP protocol client
  - 21.13.1. FTP Objects
  - 21.13.2. FTP_TLS Objects

- 21.14. poplib — POP3 protocol client
  - 21.14.1. POP3 Objects
  - 21.14.2. POP3 Example

- 21.15. imaplib — IMAP4 protocol client
  - 21.15.1. IMAP4 Objects
  - 21.15.2. IMAP4 Example

- 21.16. nntplib — NNTP protocol client
  - 21.16.1. NNTP Objects
    - 21.16.1.1. Attributes
    - 21.16.1.2. Methods
  - 21.16.2. Utility functions

- 21.17. smtplib — SMTP protocol client
  - 21.17.1. SMTP Objects
  - 21.17.2. SMTP Example

- 21.18. smtpd — SMTP Server
  - 21.18.1. SMTPServer Objects
  - 21.18.2. DebuggingServer Objects
  - 21.18.3. PureProxy Objects
  - 21.18.4. MailmanProxy Objects
  - 21.18.5. SMTPChannel Objects

- 21.19. telnetlib — Telnet client
  - 21.19.1. Telnet Objects
  - 21.19.2. Telnet Example

- 21.20. uuid — UUID objects according to RFC 4122
  - 21.20.1. Example

- 21.21. socketserver — A framework for network servers
  - 21.21.1. Server Creation Notes
• 21.21.2. Server Objects
• 21.21.3. RequestHandler Objects
• 21.21.4. Examples
  ■ 21.21.4.1. socketserver.TCPServer Example
  ■ 21.21.4.2. socketserver.UDPServer Example
  ■ 21.21.4.3. Asynchronous Mixins
• 21.22. http.server — HTTP servers
• 21.23. http.cookies — HTTP state management
  ○ 21.23.1. Cookie Objects
  ○ 21.23.2. Morsel Objects
  ○ 21.23.3. Example
• 21.24. http.cookiejar — Cookie handling for HTTP clients
  ○ 21.24.2. FileCookieJar subclasses and co-operation with web browsers
  ○ 21.24.3. CookiePolicy Objects
  ○ 21.24.4. DefaultCookiePolicy Objects
  ○ 21.24.5. Cookie Objects
  ○ 21.24.6. Examples
• 21.25. xmlrpc — XMLRPC server and client modules
• 21.26. xmlrpc.client — XML-RPC client access
  ○ 21.26.2. DateTime Objects
  ○ 21.26.3. Binary Objects
  ○ 21.26.4. Fault Objects
  ○ 21.26.5. ProtocolError Objects
  ○ 21.26.6. MultiCall Objects
  ○ 21.26.7. Convenience Functions
  ○ 21.26.9. Example of Client and Server Usage
• 21.27. xmlrpc.server — Basic XML-RPC servers
  ○ 21.27.1. SimpleXMLRPCServer Objects
    ■ 21.27.1.1. SimpleXMLRPCServer Example
  ○ 21.27.2. CGIXMLRPCRequestHandler
- 21.27.3. Documenting XMLRPC server
- 21.27.4. DocXMLRPCServer Objects
- 21.27.5. DocCGIXMLRPCRequestHandler
- 21.28. ipaddress — IPv4/IPv6 manipulation library
  - 21.28.1. Convenience factory functions
  - 21.28.2. IP Addresses
    - 21.28.2.1. Address objects
    - 21.28.2.2. Conversion to Strings and Integers

  - 21.28.5. Other Module Level Functions
  - 21.28.6. Custom Exceptions
21.1. webbrowser — Convenient Web-browser controller

Source code: Lib/webbrowser.py

The webbrowser module provides a high-level interface to allow displaying Web-based documents to users. Under most circumstances, simply calling the `open()` function from this module will do the right thing.

Under Unix, graphical browsers are preferred under X11, but text-mode browsers will be used if graphical browsers are not available or an X11 display isn’t available. If text-mode browsers are used, the calling process will block until the user exits the browser.

If the environment variable `BROWSER` exists, it is interpreted to override the platform default list of browsers, as a `os.pathsep`-separated list of browsers to try in order. When the value of a list part contains the string `%%s`, then it is interpreted as a literal browser command line to be used with the argument URL substituted for `%%s`; if the part does not contain `%%s`, it is simply interpreted as the name of the browser to launch. [1]

For non-Unix platforms, or when a remote browser is available on Unix, the controlling process will not wait for the user to finish with the browser, but allow the remote browser to maintain its own windows on the display. If remote browsers are not available on Unix, the controlling process will launch a new browser and wait.

The script `webbrowser` can be used as a command-line interface for
the module. It accepts an URL as the argument. It accepts the following optional parameters: -n opens the URL in a new browser window, if possible; -t opens the URL in a new browser page (“tab”). The options are, naturally, mutually exclusive. Usage example:

```
python -m webbrowser -t "http://www.python.org"
```

The following exception is defined:

```
exception webbrowser.Error
```

Exception raised when a browser control error occurs.

The following functions are defined:

```
webbrowser.open(url, new=0, autoraise=True)
```

Display `url` using the default browser. If `new` is 0, the `url` is opened in the same browser window if possible. If `new` is 1, a new browser window is opened if possible. If `new` is 2, a new browser page (“tab”) is opened if possible. If `autoraise` is True, the window is raised if possible (note that under many window managers this will occur regardless of the setting of this variable).

Note that on some platforms, trying to open a filename using this function, may work and start the operating system's associated program. However, this is neither supported nor portable.

```
webbrowser.open_new(url)
```

Open `url` in a new window of the default browser, if possible, otherwise, open `url` in the only browser window.

```
webbrowser.open_new_tab(url)
```

Open `url` in a new page (“tab”) of the default browser, if possible, otherwise equivalent to `open_new()`.
webbrowser.get(using=None)

Return a controller object for the browser type using. If using is None, return a controller for a default browser appropriate to the caller's environment.

webbrowser.register(name, constructor, instance=None)

Register the browser type name. Once a browser type is registered, the get() function can return a controller for that browser type. If instance is not provided, or is None, constructor will be called without parameters to create an instance when needed. If instance is provided, constructor will never be called, and may be None.

This entry point is only useful if you plan to either set the BROWSER variable or call get() with a nonempty argument matching the name of a handler you declare.

A number of browser types are predefined. This table gives the type names that may be passed to the get() function and the corresponding instantiations for the controller classes, all defined in this module.

<td></td>
</tr>
</tbody>
</table>

Notes:

1. “Konqueror” is the file manager for the KDE desktop environment for Unix, and only makes sense to use if KDE is running. Some way of reliably detecting KDE would be nice; the KDEDIR variable is not sufficient. Note also that the name “kfm” is used even when using the konqueror command with KDE 2 — the implementation selects the best strategy for running Konqueror.
2. Only on Windows platforms.
3. Only on Mac OS X platform.

*New in version 3.3:* Support for Chrome/Chromium has been added.

Here are some simple examples:

```python
url = 'http://docs.python.org/

# Open URL in a new tab, if a browser window is already open.
webbrowser.open_new_tab(url)

# Open URL in new window, raising the window if possible.
webbrowser.open_new(url)
```
21.1.1. Browser Controller Objects

Browser controllers provide these methods which parallel three of the module-level convenience functions:

controller.**open**(url, new=0, autoraise=True)

Display url using the browser handled by this controller. If new is 1, a new browser window is opened if possible. If new is 2, a new browser page (“tab”) is opened if possible.

controller.**open_new**(url)

Open url in a new window of the browser handled by this controller, if possible, otherwise, open url in the only browser window. Alias open_new().

controller.**open_new_tab**(url)

Open url in a new page (“tab”) of the browser handled by this controller, if possible, otherwise equivalent to open_new().

Footnotes

[1] Executables named here without a full path will be searched in the directories given in the PATH environment variable.
21.2. **cgi** — Common Gateway Interface support

**Source code:** Lib/cgi.py

Support module for Common Gateway Interface (CGI) scripts.

This module defines a number of utilities for use by CGI scripts written in Python.
21.2.1. Introduction

A CGI script is invoked by an HTTP server, usually to process user input submitted through an HTML `<FORM>` or `<ISINDEX>` element.

Most often, CGI scripts live in the server’s special `cgi-bin` directory. The HTTP server places all sorts of information about the request (such as the client’s hostname, the requested URL, the query string, and lots of other goodies) in the script’s shell environment, executes the script, and sends the script's output back to the client.

The script's input is connected to the client too, and sometimes the form data is read this way; at other times the form data is passed via the “query string” part of the URL. This module is intended to take care of the different cases and provide a simpler interface to the Python script. It also provides a number of utilities that help in debugging scripts, and the latest addition is support for file uploads from a form (if your browser supports it).

The output of a CGI script should consist of two sections, separated by a blank line. The first section contains a number of headers, telling the client what kind of data is following. Python code to generate a minimal header section looks like this:

```python
print("Content-Type: text/html") # HTML is followed
print() # blank line, end of headers
```

The second section is usually HTML, which allows the client software to display nicely formatted text with header, in-line images, etc. Here's Python code that prints a simple piece of HTML:

```python
print("<TITLE>CGI script output</TITLE>")
```
print("<H1>This is my first CGI script</H1>")
print("Hello, world!")
21.2.2. Using the cgi module

Begin by writing `import cgi`.

When you write a new script, consider adding these lines:

```python
import cgitb
cgitb.enable()
```

This activates a special exception handler that will display detailed reports in the Web browser if any errors occur. If you’d rather not show the guts of your program to users of your script, you can have the reports saved to files instead, with code like this:

```python
import cgitb
cgitb.enable(display=0, logdir="/path/to/logdir")
```

It’s very helpful to use this feature during script development. The reports produced by `cgitb` provide information that can save you a lot of time in tracking down bugs. You can always remove the `cgitb` line later when you have tested your script and are confident that it works correctly.

To get at submitted form data, use the `FieldStorage` class. If the form contains non-ASCII characters, use the `encoding` keyword parameter set to the value of the encoding defined for the document. It is usually contained in the META tag in the HEAD section of the HTML document or by the `Content-Type` header). This reads the form contents from the standard input or the environment (depending on the value of various environment variables set according to the CGI standard). Since it may consume standard input, it should be instantiated only once.
The FieldStorage instance can be indexed like a Python dictionary. It allows membership testing with the `in` operator, and also supports the standard dictionary method `keys()` and the built-in function `len()`. Form fields containing empty strings are ignored and do not appear in the dictionary; to keep such values, provide a true value for the optional `keep_blank_values` keyword parameter when creating the FieldStorage instance.

For instance, the following code (which assumes that the Content-Type header and blank line have already been printed) checks that the fields `name` and `addr` are both set to a non-empty string:

```python
form = cgi.FieldStorage()
if "name" not in form or "addr" not in form:
    print("<H1>Error</H1>"
    print("Please fill in the name and addr fields.
    return
print("<p>name: ", form["name"].value)
print("<p>addr: ", form["addr"].value)
...further form processing here...
```

Here the fields, accessed through `form[key]`, are themselves instances of FieldStorage (or MiniFieldStorage, depending on the form encoding). The value attribute of the instance yields the string value of the field. The `getvalue()` method returns this string value directly; it also accepts an optional second argument as a default to return if the requested key is not present.

If the submitted form data contains more than one field with the same name, the object retrieved by `form[key]` is not a FieldStorage or MiniFieldStorage instance but a list of such instances. Similarly, in this situation, `form.getvalue(key)` would return a list of strings. If
you expect this possibility (when your HTML form contains multiple fields with the same name), use the `getlist()` method, which always returns a list of values (so that you do not need to special-case the single item case). For example, this code concatenates any number of username fields, separated by commas:

```python
value = form.getlist("username")
usernames = ",".join(value)
```

If a field represents an uploaded file, accessing the value via the value attribute or the `getvalue()` method reads the entire file in memory as bytes. This may not be what you want. You can test for an uploaded file by testing either the `filename` attribute or the `file` attribute. You can then read the data at leisure from the `file` attribute (the `read()` and `readline()` methods will return bytes):

```python
fileitem = form["userfile"]
if fileitem.file:
    # It's an uploaded file; count lines
    linecount = 0
    while True:
        line = fileitem.file.readline()
        if not line: break
        linecount = linecount + 1
```

If an error is encountered when obtaining the contents of an uploaded file (for example, when the user interrupts the form submission by clicking on a Back or Cancel button) the done attribute of the object for the field will be set to the value -1.

The file upload draft standard entertains the possibility of uploading multiple files from one field (using a recursive `multipart/*` encoding). When this occurs, the item will be a dictionary-like `FieldStorage`
item. This can be determined by testing its type attribute, which should be *multipart/form-data* (or perhaps another MIME type matching *multipart/*). In this case, it can be iterated over recursively just like the top-level form object.

When a form is submitted in the “old” format (as the query string or as a single data part of type *application/x-www-form-urlencoded*), the items will actually be instances of the class MiniFieldStorage. In this case, the list, file, and filename attributes are always None.

A form submitted via POST that also has a query string will contain both FieldStorage and MiniFieldStorage items.
21.2.3. Higher Level Interface

The previous section explains how to read CGI form data using the FieldStorage class. This section describes a higher level interface which was added to this class to allow one to do it in a more readable and intuitive way. The interface doesn’t make the techniques described in previous sections obsolete — they are still useful to process file uploads efficiently, for example.

The interface consists of two simple methods. Using the methods you can process form data in a generic way, without the need to worry whether only one or more values were posted under one name.

In the previous section, you learned to write following code anytime you expected a user to post more than one value under one name:

```python
item = form.getvalue("item")
if isinstance(item, list):
    # The user is requesting more than one item.
else:
    # The user is requesting only one item.
```

This situation is common for example when a form contains a group of multiple checkboxes with the same name:

```html
<input type="checkbox" name="item" value="1" />  
<input type="checkbox" name="item" value="2" />
```

In most situations, however, there’s only one form control with a particular name in a form and then you expect and need only one value associated with this name. So you write a script containing for example this code:
The problem with the code is that you should never expect that a client will provide valid input to your scripts. For example, if a curious user appends another `user=foo` pair to the query string, then the script would crash, because in this situation the `form.getvalue("user")` method call returns a list instead of a string. Calling the `upper()` method on a list is not valid (since lists do not have a method of this name) and results in an `AttributeError` exception.

Therefore, the appropriate way to read form data values was to always use the code which checks whether the obtained value is a single value or a list of values. That's annoying and leads to less readable scripts.

A more convenient approach is to use the methods `getfirst()` and `getlist()` provided by this higher level interface.

**FieldStorage.getfirst(name, default=None)**

This method always returns only one value associated with form field `name`. The method returns only the first value in case that more values were posted under such name. Please note that the order in which the values are received may vary from browser to browser and should not be counted on. [1] If no such form field or value exists then the method returns the value specified by the optional parameter `default`. This parameter defaults to None if not specified.

**FieldStorage.getlist(name)**

This method always returns a list of values associated with form field `name`. The method returns an empty list if no such form field or value exists for `name`. It returns a list consisting of one item if
only one such value exists.

Using these methods you can write nice compact code:

```python
import cgi
form = cgi.FieldStorage()
user = form.getfirst("user", "").upper()  # This way it's safe.
for item in form.getlist("item"):
    do_something(item)
```
21.2.4. Functions

These are useful if you want more control, or if you want to employ some of the algorithms implemented in this module in other circumstances.

```python
cgi.parse(fp=None, environ=os.environ,
          keep_blank_values=False, strict_parsing=False)
```

Parse a query in the environment or from a file (the file defaults to `sys.stdin`). The `keep_blank_values` and `strict_parsing` parameters are passed to `urllib.parse.parse_qs()` unchanged.

```python
cgi.parse_qs(qs, keep_blank_values=False, strict_parsing=False)
```

This function is deprecated in this module. Use `urllib.parse.parse_qs()` instead. It is maintained here only for backward compatibility.

```python
cgi.parse_qsl(qs, keep_blank_values=False, strict_parsing=False)
```

This function is deprecated in this module. Use `urllib.parse.parse_qs()` instead. It is maintained here only for backward compatibility.

```python
cgi.parse_multipart(fp, pdict)
```

Parse input of type `multipart/form-data` (for file uploads). Arguments are `fp` for the input file and `pdict` for a dictionary containing other parameters in the `Content-Type` header.

Returns a dictionary just like `urllib.parse.parse_qs()` keys
are the field names, each value is a list of values for that field. This is easy to use but not much good if you are expecting megabytes to be uploaded — in that case, use the FieldStorage class instead which is much more flexible.

Note that this does not parse nested multipart parts — use FieldStorage for that.

cgi.\texttt{parse\_header}(string)
Parse a MIME header (such as Content-Type) into a main value and a dictionary of parameters.

cgi.\texttt{test}()
Robust test CGI script, usable as main program. Writes minimal HTTP headers and formats all information provided to the script in HTML form.

cgi.\texttt{print\_environ}()
Format the shell environment in HTML.

cgi.\texttt{print\_form}(form)
Format a form in HTML.

cgi.\texttt{print\_directory}()
Format the current directory in HTML.

cgi.\texttt{print\_environ\_usage}()
Print a list of useful (used by CGI) environment variables in HTML.

cgi.\texttt{escape}(s, quote=False)
Convert the characters ' & ', '<' and '>' in string s to HTML-safe sequences. Use this if you need to display text that might contain such characters in HTML. If the optional flag quote is true, the
quotation mark character (") is also translated; this helps for inclusion in an HTML attribute value delimited by double quotes, as in `<a href="...">`. Note that single quotes are never translated.

*Deprecated since version 3.2*: This function is unsafe because *quote* is false by default, and therefore deprecated. Use `html.escape()` instead.
There’s one important rule: if you invoke an external program (via the os.system() or os.popen() functions, or others with similar functionality), make very sure you don’t pass arbitrary strings received from the client to the shell. This is a well-known security hole whereby clever hackers anywhere on the Web can exploit a gullible CGI script to invoke arbitrary shell commands. Even parts of the URL or field names cannot be trusted, since the request doesn’t have to come from your form!

To be on the safe side, if you must pass a string gotten from a form to a shell command, you should make sure the string contains only alphanumeric characters, dashes, underscores, and periods.
21.2.6. Installing your CGI script on a Unix system

Read the documentation for your HTTP server and check with your local system administrator to find the directory where CGI scripts should be installed; usually this is in a directory `cgi-bin` in the server tree.

Make sure that your script is readable and executable by “others”; the Unix file mode should be `0o755` octal (use `chmod 0755 filename`). Make sure that the first line of the script contains `#!` starting in column 1 followed by the pathname of the Python interpreter, for instance:

```
#!/usr/local/bin/python
```

Make sure the Python interpreter exists and is executable by “others”. Make sure that any files your script needs to read or write are readable or writable, respectively, by “others” — their mode should be `0o644` for readable and `0o666` for writable. This is because, for security reasons, the HTTP server executes your script as user “nobody”, without any special privileges. It can only read (write, execute) files that everybody can read (write, execute). The current directory at execution time is also different (it is usually the server’s `cgi-bin` directory) and the set of environment variables is also different from what you get when you log in. In particular, don’t count on the shell’s search path for executables (PATH) or the Python module search path (`PYTHONPATH`) to be set to anything interesting.

If you need to load modules from a directory which is not on Python’s
default module search path, you can change the path in your script, before importing other modules. For example:

```python
import sys
sys.path.insert(0, "/usr/home/joe/lib/python")
sys.path.insert(0, "/usr/local/lib/python")
```

(This way, the directory inserted last will be searched first!)

Instructions for non-Unix systems will vary; check your HTTP server’s documentation (it will usually have a section on CGI scripts).
21.2.7. Testing your CGI script

Unfortunately, a CGI script will generally not run when you try it from the command line, and a script that works perfectly from the command line may fail mysteriously when run from the server. There’s one reason why you should still test your script from the command line: if it contains a syntax error, the Python interpreter won’t execute it at all, and the HTTP server will most likely send a cryptic error to the client.

Assuming your script has no syntax errors, yet it does not work, you have no choice but to read the next section.
21.2.8. Debugging CGI scripts

First of all, check for trivial installation errors — reading the section above on installing your CGI script carefully can save you a lot of time. If you wonder whether you have understood the installation procedure correctly, try installing a copy of this module file (cgi.py) as a CGI script. When invoked as a script, the file will dump its environment and the contents of the form in HTML form. Give it the right mode etc, and send it a request. If it's installed in the standard cgi-bin directory, it should be possible to send it a request by entering a URL into your browser of the form:

```
http://yourhostname/cgi-bin/cgi.py?name=Joe+Blow&addr=At+Home
```

If this gives an error of type 404, the server cannot find the script — perhaps you need to install it in a different directory. If it gives another error, there's an installation problem that you should fix before trying to go any further. If you get a nicely formatted listing of the environment and form content (in this example, the fields should be listed as “addr" with value “At Home” and “name” with value “Joe Blow"), the cgi.py script has been installed correctly. If you follow the same procedure for your own script, you should now be able to debug it.

The next step could be to call the cgi module’s test() function from your script: replace its main code with the single statement

```
cgi.test()
```

This should produce the same results as those gotten from installing the cgi.py file itself.
When an ordinary Python script raises an unhandled exception (for whatever reason: of a typo in a module name, a file that can’t be opened, etc.), the Python interpreter prints a nice traceback and exits. While the Python interpreter will still do this when your CGI script raises an exception, most likely the traceback will end up in one of the HTTP server’s log files, or be discarded altogether.

Fortunately, once you have managed to get your script to execute some code, you can easily send tracebacks to the Web browser using the cgitb module. If you haven’t done so already, just add the lines:

```python
import cgitb
cgitb.enable()
```

to the top of your script. Then try running it again; when a problem occurs, you should see a detailed report that will likely make apparent the cause of the crash.

If you suspect that there may be a problem in importing the cgitb module, you can use an even more robust approach (which only uses built-in modules):

```python
import sys
sys.stderr = sys.stdout
print("Content-Type: text/plain")
print()
...your code here...
```

This relies on the Python interpreter to print the traceback. The content type of the output is set to plain text, which disables all HTML processing. If your script works, the raw HTML will be displayed by your client. If it raises an exception, most likely after the first two lines have been printed, a traceback will be displayed. Because no HTML
interpretation is going on, the traceback will be readable.
21.2.9. Common problems and solutions

- Most HTTP servers buffer the output from CGI scripts until the script is completed. This means that it is not possible to display a progress report on the client's display while the script is running.
- Check the installation instructions above.
- Check the HTTP server's log files. (`tail -f logfile` in a separate window may be useful!)
- Always check a script for syntax errors first, by doing something like `python script.py`.
- If your script does not have any syntax errors, try adding `import cgitb; cgitb.enable()` to the top of the script.
- When invoking external programs, make sure they can be found. Usually, this means using absolute path names — `PATH` is usually not set to a very useful value in a CGI script.
- When reading or writing external files, make sure they can be read or written by the userid under which your CGI script will be running: this is typically the userid under which the web server is running, or some explicitly specified userid for a web server's `suexec` feature.
- Don’t try to give a CGI script a set-uid mode. This doesn’t work on most systems, and is a security liability as well.

Footnotes

Note that some recent versions of the HTML specification do not state what order the field values should be supplied in, but knowing whether a request was received from a conforming browser, or even from a browser at all, is tedious and error-prone.

[1]
21. Internet Protocols and Support
21.3. **cgitb** — Traceback manager for CGI scripts

The **cgitb** module provides a special exception handler for Python scripts. (Its name is a bit misleading. It was originally designed to display extensive traceback information in HTML for CGI scripts. It was later generalized to also display this information in plain text.) After this module is activated, if an uncaught exception occurs, a detailed, formatted report will be displayed. The report includes a traceback showing excerpts of the source code for each level, as well as the values of the arguments and local variables to currently running functions, to help you debug the problem. Optionally, you can save this information to a file instead of sending it to the browser.

To enable this feature, simply add this to the top of your CGI script:

```python
import cgitb
cgitb.enable()
```

The options to the `enable()` function control whether the report is displayed in the browser and whether the report is logged to a file for later analysis.

```python
cgitb.enable(display=1, logdir=None, context=5, format="html")
```

This function causes the **cgitb** module to take over the interpreter's default handling for exceptions by setting the value of `sys.excepthook`.

The optional argument `display` defaults to 1 and can be set to 0 to suppress sending the traceback to the browser. If the argument...
logdir is present, the traceback reports are written to files. The value of logdir should be a directory where these files will be placed. The optional argument context is the number of lines of context to display around the current line of source code in the traceback; this defaults to 5. If the optional argument format is "html", the output is formatted as HTML. Any other value forces plain text output. The default value is "html".

cgitb.handler(info=None)

This function handles an exception using the default settings (that is, show a report in the browser, but don’t log to a file). This can be used when you’ve caught an exception and want to report it using cgitb. The optional info argument should be a 3-tuple containing an exception type, exception value, and traceback object, exactly like the tuple returned by sys.exc_info(). If the info argument is not supplied, the current exception is obtained from sys.exc_info().
21.4. wsgiref — WSGI Utilities and Reference Implementation

The Web Server Gateway Interface (WSGI) is a standard interface between web server software and web applications written in Python. Having a standard interface makes it easy to use an application that supports WSGI with a number of different web servers.

Only authors of web servers and programming frameworks need to know every detail and corner case of the WSGI design. You don’t need to understand every detail of WSGI just to install a WSGI application or to write a web application using an existing framework.

wsgiref is a reference implementation of the WSGI specification that can be used to add WSGI support to a web server or framework. It provides utilities for manipulating WSGI environment variables and response headers, base classes for implementing WSGI servers, a demo HTTP server that serves WSGI applications, and a validation tool that checks WSGI servers and applications for conformance to the WSGI specification (PEP 3333).

See http://www.wsgi.org for more information about WSGI, and links to tutorials and other resources.
21.4.1. wsgiref.util – WSGI environment utilities

This module provides a variety of utility functions for working with WSGI environments. A WSGI environment is a dictionary containing HTTP request variables as described in PEP 3333. All of the functions taking an environ parameter expect a WSGI-compliant dictionary to be supplied; please see PEP 3333 for a detailed specification.

wsgiref.util.guess_scheme(environ)

Return a guess for whether wsgi.url_scheme should be “http” or “https”, by checking for a HTTPS environment variable in the environ dictionary. The return value is a string.

This function is useful when creating a gateway that wraps CGI or a CGI-like protocol such as FastCGI. Typically, servers providing such protocols will include a HTTPS variable with a value of “1” “yes”, or “on” when a request is received via SSL. So, this function returns “https” if such a value is found, and “http” otherwise.

wsgiref.util.request_uri(environ, include_query=True)

Return the full request URI, optionally including the query string, using the algorithm found in the “URL Reconstruction” section of PEP 3333. If include_query is false, the query string is not included in the resulting URI.

wsgiref.util.application_uri(environ)

Similar to request_uri(), except that the PATH_INFO and QUERY_STRING variables are ignored. The result is the base URI of the application object addressed by the request.
wsgiref.util.shift_path_info(environ)
Shift a single name from PATH_INFO to SCRIPT_NAME and return the name. The environ dictionary is modified in-place; use a copy if you need to keep the original PATH_INFO or SCRIPT_NAME intact.

If there are no remaining path segments in PATH_INFO, None is returned.

Typically, this routine is used to process each portion of a request URI path, for example to treat the path as a series of dictionary keys. This routine modifies the passed-in environment to make it suitable for invoking another WSGI application that is located at the target URI. For example, if there is a WSGI application at /foo, and the request URI path is /foo/bar/baz, and the WSGI application at /foo calls shift_path_info(), it will receive the string “bar”, and the environment will be updated to be suitable for passing to a WSGI application at /foo/bar. That is, SCRIPT_NAME will change from /foo to /foo/bar, and PATH_INFO will change from /bar/baz to /baz.

When PATH_INFO is just a “/”, this routine returns an empty string and appends a trailing slash to SCRIPT_NAME, even though empty path segments are normally ignored, and SCRIPT_NAME doesn't normally end in a slash. This is intentional behavior, to ensure that an application can tell the difference between URIs ending in /x from ones ending in /x/ when using this routine to do object traversal.

wsgiref.util.setup_testing_defaults(environ)
Update environ with trivial defaults for testing purposes.

This routine adds various parameters required for WSGI, including
HTTP_HOST, SERVER_NAME, SERVER_PORT, REQUEST_METHOD, SCRIPT_NAME, PATH_INFO, and all of the PEP 3333-defined \texttt{wsgi.*} variables. It only supplies default values, and does not replace any existing settings for these variables.

This routine is intended to make it easier for unit tests of WSGI servers and applications to set up dummy environments. It should NOT be used by actual WSGI servers or applications, since the data is fake!

Example usage:

```python
from wsgiref.util import setup_testing_defaults
from wsgiref.simple_server import make_server

# A relatively simple WSGI application. It's going to print out the
# environment dictionary after being updated by setup_testing_defaults.

def simple_app(environ, start_response):
    setup_testing_defaults(environ)

    status = '200 OK'
    headers = [('Content-type', 'text/plain; charset=utf-8')]

    start_response(status, headers)
    ret = ['%s: %s
' % (key, value) for key, value in environ.items()]
    return ret

httpd = make_server('', 8000, simple_app)
print("Serving on port 8000...")
httpd.serve_forever()
```

In addition to the environment functions above, the \texttt{wsgiref.util}
module also provides these miscellaneous utilities:

\texttt{wsgiref.util.is\_hop\_by\_hop(header\_name)}

Return true if ‘header\_name’ is an HTTP/1.1 “Hop-by-Hop” header, as defined by \texttt{RFC 2616}.

\texttt{class wsgiref.util.FileWrapper(filelike, blksize=8192)}

A wrapper to convert a file-like object to an \texttt{iterator}. The resulting objects support both \texttt{__getitem__() and \_\_iter\_\_()} iteration styles, for compatibility with Python 2.1 and Jython. As the object is iterated over, the optional \texttt{blksize} parameter will be repeatedly passed to the \texttt{filelike} object’s \texttt{read()} method to obtain bytestrings to yield. When \texttt{read()} returns an empty bytestring, iteration is ended and is not resumable.

If \texttt{filelike} has a \texttt{close()} method, the returned object will also have a \texttt{close()} method, and it will invoke the \texttt{filelike} object’s \texttt{close()} method when called.

Example usage:

```
from io import StringIO
from wsgiref.util import FileWrapper

# We're using a StringIO-buffer for as the file-like
filelike = StringIO("This is an example file-like
wrapper = FileWrapper(filelike, blksize=5)

for chunk in wrapper:
    print(chunk)
```
21.4.2. `wsgiref.headers` – WSGI response header tools

This module provides a single class, `Headers`, for convenient manipulation of WSGI response headers using a mapping-like interface.

```python
class wsgiref.headers.Headers(headers)
```

Create a mapping-like object wrapping `headers`, which must be a list of header name/value tuples as described in PEP 3333.

`Headers` objects support typical mapping operations including `__getitem__()`, `get()`, `__setitem__()`, `setdefault()`, `__delitem__()` and `__contains__()`. For each of these methods, the key is the header name (treated case-insensitively), and the value is the first value associated with that header name. Setting a header deletes any existing values for that header, then adds a new value at the end of the wrapped header list. Headers’ existing order is generally maintained, with new headers added to the end of the wrapped list.

Unlike a dictionary, `Headers` objects do not raise an error when you try to get or delete a key that isn’t in the wrapped header list. Getting a non-existent header just returns `None`, and deleting a non-existent header does nothing.

`Headers` objects also support `keys()`, `values()`, and `items()` methods. The lists returned by `keys()` and `items()` can include the same key more than once if there is a multi-valued header. The `len()` of a `Headers` object is the same as the length of its `items()`, which is the same as the length of the wrapped header...
list. In fact, the `items()` method just returns a copy of the wrapped header list.

Calling `bytes()` on a `Headers` object returns a formatted bytestring suitable for transmission as HTTP response headers. Each header is placed on a line with its value, separated by a colon and a space. Each line is terminated by a carriage return and line feed, and the bytestring is terminated with a blank line.

In addition to their mapping interface and formatting features, `Headers` objects also have the following methods for querying and adding multi-valued headers, and for adding headers with MIME parameters:

**get_all**(name)

Return a list of all the values for the named header.

The returned list will be sorted in the order they appeared in the original header list or were added to this instance, and may contain duplicates. Any fields deleted and re-inserted are always appended to the header list. If no fields exist with the given name, returns an empty list.

**add_header**(name, value, **_params)

Add a (possibly multi-valued) header, with optional MIME parameters specified via keyword arguments.

`name` is the header field to add. Keyword arguments can be used to set MIME parameters for the header field. Each parameter must be a string or `None`. Underscores in parameter names are converted to dashes, since dashes are illegal in Python identifiers, but many MIME parameter names include dashes. If the parameter value is a string, it is added to the
header value parameters in the form `name="value"`. If it is None, only the parameter name is added. (This is used for MIME parameters without a value.) Example usage:

```python
h.add_header('content-disposition', 'attachment')
```

The above will add a header that looks like this:

```
Content-Disposition: attachment; filename="bud.
```
21.4.3. **wsgiref.simple_server** – a simple WSGI HTTP server

This module implements a simple HTTP server (based on `http.server`) that serves WSGI applications. Each server instance serves a single WSGI application on a given host and port. If you want to serve multiple applications on a single host and port, you should create a WSGI application that parses `PATH_INFO` to select which application to invoke for each request. (E.g., using the `shift_path_info()` function from `wsgiref.util`.)

```

wsgiref.simple_server.make_server(host, port, app, server_class=WSGIServer, handler_class=WSGIRequestHandler)

Create a new WSGI server listening on host and port, accepting connections for app. The return value is an instance of the supplied server_class, and will process requests using the specified handler_class. app must be a WSGI application object, as defined by PEP 3333.

Example usage:

```

from wsgiref.simple_server import make_server, demo_app

httpd = make_server('', 8000, demo_app)
print("Serving HTTP on port 8000...")

# Respond to requests until process is killed
httpd.serve_forever()

# Alternative: serve one request, then exit
httpd.handle_request()
```
wsgiref.simple_server.demo_app(environ, start_response)

This function is a small but complete WSGI application that returns a text page containing the message “Hello world!” and a list of the key/value pairs provided in the `environ` parameter. It's useful for verifying that a WSGI server (such as `wsgiref.simple_server`) is able to run a simple WSGI application correctly.

class wsgiref.simple_server.WSGIServer(server_address, RequestHandlerClass)

Create a `WSGIServer` instance. `server_address` should be a (host, port) tuple, and `RequestHandlerClass` should be the subclass of `http.server.BaseHTTPRequestHandler` that will be used to process requests.

You do not normally need to call this constructor, as the `make_server()` function can handle all the details for you.

`WSGIServer` is a subclass of `http.server.HTTPServer`, so all of its methods (such as `serve_forever()` and `handle_request()`) are available. `WSGIServer` also provides these WSGI-specific methods:

set_app(application)

Sets the callable `application` as the WSGI application that will receive requests.

get_app()

Returns the currently-set application callable.

Normally, however, you do not need to use these additional methods, as `set_app()` is normally called by `make_server()`,
and the \texttt{get\_app()} exists mainly for the benefit of request handler instances.

\begin{verbatim}
class wsgiref.simple_server.WSGIRequestHandler(request, client_address, server)
    Create an HTTP handler for the given \textit{request} (i.e. a socket), 
    \textit{client_address} (a \texttt{(host, port)} tuple), and \textit{server} (\texttt{WSGIServer} instance).

    You do not need to create instances of this class directly; they are automatically created as needed by \texttt{WSGIServer} objects. You can, however, subclass this class and supply it as a \textit{handler\_class} to the \texttt{make\_server()} function. Some possibly relevant methods for overriding in subclasses:

    \textbf{get\_environ()}
    Returns a dictionary containing the WSGI environment for a request. The default implementation copies the contents of the \texttt{WSGIServer} object's base\_environ dictionary attribute and then adds various headers derived from the HTTP request. Each call to this method should return a new dictionary containing all of the relevant CGI environment variables as specified in \texttt{PEP 3333}.

    \textbf{get\_stderr()}
    Return the object that should be used as the \texttt{wsgi.errors} stream. The default implementation just returns \texttt{sys.stderr}.

    \textbf{handle()}
    Process the HTTP request. The default implementation creates a handler instance using a \texttt{wsgiref.handlers} class to
\end{verbatim}
implement the actual WSGI application interface.
21.4.4. `wsgiref.validate` — WSGI conformance checker

When creating new WSGI application objects, frameworks, servers, or middleware, it can be useful to validate the new code's conformance using `wsgiref.validate`. This module provides a function that creates WSGI application objects that validate communications between a WSGI server or gateway and a WSGI application object, to check both sides for protocol conformance.

Note that this utility does not guarantee complete PEP 3333 compliance; an absence of errors from this module does not necessarily mean that errors do not exist. However, if this module does produce an error, then it is virtually certain that either the server or application is not 100% compliant.

This module is based on the `paste.lint` module from Ian Bicking's "Python Paste" library.

`wsgiref.validate.validator(application)`

Wrap `application` and return a new WSGI application object. The returned application will forward all requests to the original `application`, and will check that both the `application` and the server invoking it are conforming to the WSGI specification and to RFC 2616.

Any detected nonconformance results in an `AssertionError` being raised; note, however, that how these errors are handled is server-dependent. For example, `wsgiref.simple_server` and other servers based on `wsgiref.handlers` (that don't override the error handling methods to do something else) will simply output
a message that an error has occurred, and dump the traceback to sys.stderr or some other error stream.

This wrapper may also generate output using the warnings module to indicate behaviors that are questionable but which may not actually be prohibited by PEP 3333. Unless they are suppressed using Python command-line options or the warnings API, any such warnings will be written to sys.stderr (not wsgi.errors, unless they happen to be the same object).

Example usage:

```python
from wsgiref.validate import validator
from wsgiref.simple_server import make_server

# Our callable object which is intentionally not standard, so the validator is going to break
def simple_app(environ, start_response):
    status = '200 OK'  # HTTP Status
    headers = [('Content-type', 'text/plain')]  # HTTP Headers
    start_response(status, headers)

    # This is going to break because we need to return a list, and the validator is going to inform us
    return b'Hello World'

# This is the application wrapped in a validator
validator_app = validator(simple_app)

httpd = make_server('', 8000, validator_app)
print("Listening on port 8000....")
httpd.serve_forever()
```
21.4.5. **wsgiref.handlers** – server/gateway base classes

This module provides base handler classes for implementing WSGI servers and gateways. These base classes handle most of the work of communicating with a WSGI application, as long as they are given a CGI-like environment, along with input, output, and error streams.

*class wsgiref.handlers.CGIHandler*

CGI-based invocation via `sys.stdin`, `sys.stdout`, `sys.stderr` and `os.environ`. This is useful when you have a WSGI application and want to run it as a CGI script. Simply invoke `CGIHandler().run(app)`, where `app` is the WSGI application object you wish to invoke.

This class is a subclass of `BaseCGIHandler` that sets `wsgi.run_once` to true, `wsgi.multithread` to false, and `wsgi.multiprocess` to true, and always uses `sys` and `os` to obtain the necessary CGI streams and environment.

*class wsgiref.handlers.IISCGIHandler*

A specialized alternative to `CGIHandler`, for use when deploying on Microsoft's IIS web server, without having set the config `allowPathInfo` option (IIS>=7) or `metabase allowPathInfoForScriptMappings` (IIS<7).

By default, IIS gives a `PATH_INFO` that duplicates the `SCRIPT_NAME` at the front, causing problems for WSGI applications that wish to implement routing. This handler strips any such duplicated path.
IIS can be configured to pass the correct PATH_INFO, but this causes another bug where PATH_TRANSLATED is wrong. Luckily this variable is rarely used and is not guaranteed by WSGI. On IIS<7, though, the setting can only be made on a vhost level, affecting all other script mappings, many of which break when exposed to the PATH_TRANSLATED bug. For this reason IIS<7 is almost never deployed with the fix. (Even IIS7 rarely uses it because there is still no UI for it.)

There is no way for CGI code to tell whether the option was set, so a separate handler class is provided. It is used in the same way as CGIHandler, i.e., by calling IISCGIHandler().run(app), where app is the WSGI application object you wish to invoke.

New in version 3.2.

class wsgiref.handlers.BaseCGIHandler(stdin, stdout, stderr, environ, multithread=True, multiprocess=False)

Similar to CGIHandler, but instead of using the sys and os modules, the CGI environment and I/O streams are specified explicitly. The multithread and multiprocess values are used to set the wsgi.multithread and wsgi.multiprocess flags for any applications run by the handler instance.

This class is a subclass of SimpleHandler intended for use with software other than HTTP "origin servers". If you are writing a gateway protocol implementation (such as CGI, FastCGI, SCGI, etc.) that uses a Status: header to send an HTTP status, you probably want to subclass this instead of SimpleHandler.

class wsgiref.handlers.SimpleHandler(stdin, stdout, stderr, environ, multithread=True, multiprocess=False)
Similar to `BaseCGIHandler`, but designed for use with HTTP origin servers. If you are writing an HTTP server implementation, you will probably want to subclass this instead of `BaseCGIHandler`.

This class is a subclass of `BaseHandler`. It overrides the `__init__()`, `get_stdin()`, `get_stderr()`, `add_cgi_vars()`, `_write()`, and `_flush()` methods to support explicitly setting the environment and streams via the constructor. The supplied environment and streams are stored in the `stdin`, `stdout`, `stderr`, and `environ` attributes.

```python
class wsgiref.handlers.BaseHandler

This is an abstract base class for running WSGI applications. Each instance will handle a single HTTP request, although in principle you could create a subclass that was reusable for multiple requests.

`BaseHandler` instances have only one method intended for external use:

```python
run(app)
```

Run the specified WSGI application, `app`.

All of the other `BaseHandler` methods are invoked by this method in the process of running the application, and thus exist primarily to allow customizing the process.

The following methods MUST be overridden in a subclass:

```python
_write(data)
```

Buffer the bytes `data` for transmission to the client. It's okay if this method actually transmits the data; `BaseHandler` just
separates write and flush operations for greater efficiency when the underlying system actually has such a distinction.

__flush__

Force buffered data to be transmitted to the client. It’s okay if this method is a no-op (i.e., if __write__() actually sends the data).

get_stdin()

Return an input stream object suitable for use as the wsgi.input of the request currently being processed.

get_stderr()

Return an output stream object suitable for use as the wsgi.errors of the request currently being processed.

add_cgi_vars()

Insert CGI variables for the current request into the environ attribute.

Here are some other methods and attributes you may wish to override. This list is only a summary, however, and does not include every method that can be overridden. You should consult the docstrings and source code for additional information before attempting to create a customized BaseHandler subclass.

Attributes and methods for customizing the WSGI environment:

wsgi_multithread

The value to be used for the wsgi.multithread environment variable. It defaults to true in BaseHandler, but may have a different default (or be set by the constructor) in the other subclasses.
wsgi_multiprocess
The value to be used for the wsgi.multiprocess environment variable. It defaults to true in BaseHandler, but may have a different default (or be set by the constructor) in the other subclasses.

wsgi_run_once
The value to be used for the wsgi.run_once environment variable. It defaults to false in BaseHandler, but CGIHandler sets it to true by default.

os_environ
The default environment variables to be included in every request's WSGI environment. By default, this is a copy of os.environ at the time that wsgiref.handlers was imported, but subclasses can either create their own at the class or instance level. Note that the dictionary should be considered read-only, since the default value is shared between multiple classes and instances.

server_software
If the origin_server attribute is set, this attribute's value is used to set the default SERVER_SOFTWARE WSGI environment variable, and also to set a default Server: header in HTTP responses. It is ignored for handlers (such as BaseCGIHandler and CGIHandler) that are not HTTP origin servers.

Changed in version 3.3: The term “Python” is replaced with implementation specific term like “CPython”, “Jython” etc.
get_scheme()
Return the URL scheme being used for the current request. The default implementation uses the guess_scheme() function from wsgiref.util to guess whether the scheme should be “http” or “https”, based on the current request's environ variables.

setup_environ()
Set the environ attribute to a fully-populated WSGI environment. The default implementation uses all of the above methods and attributes, plus the get_stdin(), get_stderr(), and add_cgi_vars() methods and the wsgi_file_wrapper attribute. It also inserts a SERVER_SOFTWARE key if not present, as long as the origin_server attribute is a true value and the server_software attribute is set.

Methods and attributes for customizing exception handling:

log_exception(exc_info)
Log the exc_info tuple in the server log. exc_info is a (type, value, traceback) tuple. The default implementation simply writes the traceback to the request's wsgi.errors stream and flushes it. Subclasses can override this method to change the format or retarget the output, mail the traceback to an administrator, or whatever other action may be deemed suitable.

traceback_limit
The maximum number of frames to include in tracebacks output by the default log_exception() method. If None, all frames
are included.

**error_output**(environ, start_response)
This method is a WSGI application to generate an error page for the user. It is only invoked if an error occurs before headers are sent to the client.

This method can access the current error information using `sys.exc_info()`, and should pass that information to `start_response` when calling it (as described in the “Error Handling” section of [PEP 3333](https://www.python.org/dev/peps/pep-0333/)).

The default implementation just uses the `error_status`, `error_headers`, and `error_body` attributes to generate an output page. Subclasses can override this to produce more dynamic error output.

Note, however, that it's not recommended from a security perspective to spit out diagnostics to any old user; ideally, you should have to do something special to enable diagnostic output, which is why the default implementation doesn’t include any.

**error_status**
The HTTP status used for error responses. This should be a status string as defined in [PEP 3333](https://www.python.org/dev/peps/pep-0333/); it defaults to a 500 code and message.

**error_headers**
The HTTP headers used for error responses. This should be a list of WSGI response headers ((name, value) tuples), as described in [PEP 3333](https://www.python.org/dev/peps/pep-0333/). The default list just sets the content type to `text/plain`. 
**error_body**

The error response body. This should be an HTTP response body bytestring. It defaults to the plain text, “A server error occurred. Please contact the administrator.”

Methods and attributes for PEP 3333’s “Optional Platform-Specific File Handling” feature:

**wsgi_file_wrapper**

A `wsgi.file_wrapper` factory, or None. The default value of this attribute is the `wsgiref.util.FileWrapper` class.

**sendfile()**

Override to implement platform-specific file transmission. This method is called only if the application's return value is an instance of the class specified by the `wsgi_file_wrapper` attribute. It should return a true value if it was able to successfully transmit the file, so that the default transmission code will not be executed. The default implementation of this method just returns a false value.

Miscellaneous methods and attributes:

**origin_server**

This attribute should be set to a true value if the handler's `__write()` and `__flush()` are being used to communicate directly to the client, rather than via a CGI-like gateway protocol that wants the HTTP status in a special `Status:` header.

This attribute's default value is true in `BaseHandler`, but false in `BaseCGIHandler` and `CGIHandler`.

**http_version**
If `origin_server` is true, this string attribute is used to set the HTTP version of the response set to the client. It defaults to "1.0".

**wsgiref.handlers.read_environ()**

Transcode CGI variables from `os.environ` to PEP 3333 “bytes in unicode” strings, returning a new dictionary. This function is used by `CGIHandler` and `IISCGIHandler` in place of directly using `os.environ`, which is not necessarily WSGI-compliant on all platforms and web servers using Python 3 – specifically, ones where the OS's actual environment is Unicode (i.e. Windows), or ones where the environment is bytes, but the system encoding used by Python to decode it is anything other than ISO-8859-1 (e.g. Unix systems using UTF-8).

If you are implementing a CGI-based handler of your own, you probably want to use this routine instead of just copying values out of `os.environ` directly.

*New in version 3.2.*
This is a working “Hello World” WSGI application:

```python
from wsgiref.simple_server import make_server

def hello_world_app(environ, start_response):
    status = '200 OK'  # HTTP Status
    headers = [('Content-type', 'text/plain; charset=utf-8')]
    start_response(status, headers)

    return [b'Hello World']

httpd = make_server('', 8000, hello_world_app)
print("Serving on port 8000...")

# Serve until process is killed
httpd.serve_forever()
```

Last updated on Nov 11, 2013. Found a bug?
Created using Sphinx 1.0.7.
21.5. `urllib` — URL handling modules

`urllib` is a package that collects several modules for working with URLs:

- `urllib.request` for opening and reading URLs
- `urllib.error` containing the exceptions raised by `urllib.request`
- `urllib.parse` for parsing URLs
- `urllib.robotparser` for parsing robots.txt files
21.6. `urllib.request` — Extensible library for opening URLs

The `urllib.request` module defines functions and classes which help in opening URLs (mostly HTTP) in a complex world — basic and digest authentication, redirections, cookies and more.

The `urllib.request` module defines the following functions:

`urllib.request.urlopen(url, data=None[, timeout], *,
  cafile=None, capath=None, cadefault=False)`

Open the URL `url`, which can be either a string or a `Request` object.

`data` must be a bytes object specifying additional data to be sent to the server, or None if no such data is needed. `data` may also be an iterable object and in that case Content-Length value must be specified in the headers. Currently HTTP requests are the only ones that use `data`; the HTTP request will be a POST instead of a GET when the `data` parameter is provided.

`data` should be a buffer in the standard `application/x-www-form-urlencoded` format. The `urllib.parse.urlencode()` function takes a mapping or sequence of 2-tuples and returns a string in this format. It should be encoded to bytes before being used as the `data` parameter. The charset parameter in Content-Type header may be used to specify the encoding. If charset parameter is not sent with the Content-Type header, the server following the HTTP
1.1 recommendation may assume that the data is encoded in ISO-8859-1 encoding. It is advisable to use charset parameter with encoding used in Content-Type header with the Request.

urllib.request module uses HTTP/1.1 and includes Connection:close header in its HTTP requests.

The optional timeout parameter specifies a timeout in seconds for blocking operations like the connection attempt (if not specified, the global default timeout setting will be used). This actually only works for HTTP, HTTPS and FTP connections.

The optional cafile and capath parameters specify a set of trusted CA certificates for HTTPS requests. cafile should point to a single file containing a bundle of CA certificates, whereas capath should point to a directory of hashed certificate files. More information can be found in ssl.SSLContext.load_verify_locations().

The cadefault parameter specifies whether to fall back to loading a default certificate store defined by the underlying OpenSSL library if the cafile and capath parameters are omitted. This will only work on some non-Windows platforms.

**Warning:** If neither cafile nor capath is specified, and cadefault is False, an HTTPS request will not do any verification of the server’s certificate.

For http and https urls, this function returns a http.client.HTTPResponse object which has the following HTTPResponse Objects methods.

For ftp, file, and data urls and requests explicity handled by legacy URLopener and FancyURLopener classes, this function returns
a `urllib.response.addinfourl` object which can work as
context manager and has methods such as

- `geturl()` — return the URL of the resource retrieved,
  commonly used to determine if a redirect was followed
- `info()` — return the meta-information of the page, such as
  headers, in the form of an
  `email.message_from_string()` instance (see Quick
  Reference to HTTP Headers)
- `getcode()` – return the HTTP status code of the response.

Raises `URLError` on errors.

Note that None may be returned if no handler handles the request
(though the default installed global `OpenerDirector` uses
`UnknownHandler` to ensure this never happens).

In addition, if proxy settings are detected (for example, when a
`*_proxy` environment variable like `http_proxy` is set),
`ProxyHandler` is default installed and makes sure the requests
are handled through the proxy.

The legacy `urllib.urlopen` function from Python 2.6 and earlier
has been discontinued; `urllib.request.urlopen()`
corresponds to the old `urllib2.urlopen`. Proxy handling, which
was done by passing a dictionary parameter to `urllib.urlopen`,
can be obtained by using `ProxyHandler` objects.

*Changed in version 3.2*: `cafile` and `capath` were added.

*Changed in version 3.2*: HTTPS virtual hosts are now supported if
possible (that is, if `ssl.HAS_SNI` is true).

*New in version 3.2*: `data` can be an iterable object.
Changed in version 3.3: cadefault was added.

urllib.request.install_opener(opener)

Install an OpenerDirector instance as the default global opener. Installing an opener is only necessary if you want urlopen to use that opener; otherwise, simply call OpenerDirector.open() instead of urlopen(). The code does not check for a real OpenerDirector, and any class with the appropriate interface will work.

urllib.request.build_opener([handler,...])

Return an OpenerDirector instance, which chains the handlers in the order given. handlers can be either instances of BaseHandler, or subclasses of BaseHandler (in which case it must be possible to call the constructor without any parameters). Instances of the following classes will be in front of the handlers, unless the handlers contain them, instances of them or subclasses of them: ProxyHandler (if proxy settings are detected), UnknownHandler, HTTPHandler, HTTPDefaultErrorHandler, HTTPRedirectHandler, FTPHandler, FileHandler, HTTPErrorProcessor.

If the Python installation has SSL support (i.e., if the ssl module can be imported), HTTPSHandler will also be added.

A BaseHandler subclass may also change its handler_order attribute to modify its position in the handlers list.

urllib.request.pathname2url(path)

Convert the pathname path from the local syntax for a path to the form used in the path component of a URL. This does not produce a complete URL. The return value will already be quoted using the
quote() function.

urllib.request.url2pathname(path)
Convert the path component path from a percent-encoded URL to the local syntax for a path. This does not accept a complete URL. This function uses unquote() to decode path.

urllib.request.getproxies()
This helper function returns a dictionary of scheme to proxy server URL mappings. It scans the environment for variables named <scheme>_proxy, in a case insensitive approach, for all operating systems first, and when it cannot find it, looks for proxy information from Mac OS X System Configuration for Mac OS X and Windows Systems Registry for Windows.

The following classes are provided:

class urllib.request.Request(url, data=None, headers={}, origin_req_host=None, unverifiable=False, method=None)
This class is an abstraction of a URL request.

url should be a string containing a valid URL.

data must be a bytes object specifying additional data to send to the server, or None if no such data is needed. Currently HTTP requests are the only ones that use data; the HTTP request will be a POST instead of a GET when the data parameter is provided. data should be a buffer in the standard application/x-www-form-urlencoded format.

The urllib.parse.urlencode() function takes a mapping or sequence of 2-tuples and returns a string in this format. It should be encoded to bytes before being used as the data parameter. The
charset parameter in `Content-Type` header may be used to specify the encoding. If charset parameter is not sent with the Content-Type header, the server following the HTTP 1.1 recommendation may assume that the data is encoded in ISO-8859-1 encoding. It is advisable to use charset parameter with encoding used in `Content-Type` header with the `Request`.

`headers` should be a dictionary, and will be treated as if `add_header()` was called with each key and value as arguments. This is often used to “spoof” the `User-Agent` header, which is used by a browser to identify itself – some HTTP servers only allow requests coming from common browsers as opposed to scripts. For example, Mozilla Firefox may identify itself as "Mozilla/5.0 (X11; U; Linux i686) Gecko/20071127 Firefox/2.0.0.11", while urllib's default user agent string is "Python-urllib/2.6" (on Python 2.6).

An example of using `Content-Type` header with `data` argument would be sending a dictionary like `{"Content-Type":"application/x-www-form-urlencoded; charset=utf-8"}`

The final two arguments are only of interest for correct handling of third-party HTTP cookies:

`origin_req_host` should be the request-host of the origin transaction, as defined by RFC 2965. It defaults to `http.cookiejar.request_host(self)`. This is the host name or IP address of the original request that was initiated by the user. For example, if the request is for an image in an HTML document, this should be the request-host of the request for the page containing the image.
unverifiable should indicate whether the request is unverifiable, as defined by RFC 2965. It defaults to False. An unverifiable request is one whose URL the user did not have the option to approve. For example, if the request is for an image in an HTML document, and the user had no option to approve the automatic fetching of the image, this should be true.

method should be a string that indicates the HTTP request method that will be used (e.g. 'HEAD'). Its value is stored in the method attribute and is used by get_method().

Changed in version 3.3: Request.method argument is added to the Request class.

class urllib.request.OpenerDirector
    The OpenerDirector class opens URLs via BaseHandlers chained together. It manages the chaining of handlers, and recovery from errors.

class urllib.request.BaseHandler
    This is the base class for all registered handlers — and handles only the simple mechanics of registration.

class urllib.request.HTTPDefaultErrorHandler
    A class which defines a default handler for HTTP error responses; all responses are turned into HTTPError exceptions.

class urllib.request.HTTPRedirectHandler
    A class to handle redirections.

class urllib.request.HTTPCookieProcessor(cookiejar=None)
    A class to handle HTTP Cookies.
**class urllib.request.ProxyHandler**(proxies=None)

Causes requests to go through a proxy. If **proxies** is given, it must be a dictionary mapping protocol names to URLs of proxies. The default is to read the list of proxies from the environment variables `<protocol>_proxy`. If no proxy environment variables are set, then in a Windows environment proxy settings are obtained from the registry's Internet Settings section, and in a Mac OS X environment proxy information is retrieved from the OS X System Configuration Framework.

To disable autodetected proxy pass an empty dictionary.

**class urllib.request.HTTPPasswordMgr**

Keep a database of (realm, uri) -> (user, password) mappings.

**class urllib.request.HTTPPasswordMgrWithDefaultRealm**

Keep a database of (realm, uri) -> (user, password) mappings. A realm of None is considered a catch-all realm, which is searched if no other realm fits.

**class urllib.request.AbstractBasicAuthHandler**(password_mgr=None)

This is a mixin class that helps with HTTP authentication, both to the remote host and to a proxy. **password_mgr**, if given, should be something that is compatible with HTTPPasswordMgr; refer to section HTTPPasswordMgr Objects for information on the interface that must be supported.

**class urllib.request.HTTPBasicAuthHandler**(password_mgr=None)

Handle authentication with the remote host. **password_mgr**, if
given, should be something that is compatible with HTTPPasswordMgr; refer to section HTTPPasswordMgr Objects for information on the interface that must be supported. HTTPBasicAuthHandler will raise a ValueError when presented with a wrong Authentication scheme.

class
urllib.request.ProxyBasicAuthHandler(password_mgr=None)
Handle authentication with the proxy. password_mgr, if given, should be something that is compatible with HTTPPasswordMgr; refer to section HTTPPasswordMgr Objects for information on the interface that must be supported.

class
urllib.request.AbstractDigestAuthHandler(password_mgr=None)
This is a mixin class that helps with HTTP authentication, both to the remote host and to a proxy. password_mgr, if given, should be something that is compatible with HTTPPasswordMgr; refer to section HTTPPasswordMgr Objects for information on the interface that must be supported.

class
urllib.request.HTTPDigestAuthHandler(password_mgr=None)
Handle authentication with the remote host. password_mgr, if given, should be something that is compatible with HTTPPasswordMgr; refer to section HTTPPasswordMgr Objects for information on the interface that must be supported. When both Digest Authentication Handler and Basic Authentication Handler are both added, Digest Authentication is always tried first. If the Digest Authentication returns a 40x response again, it is sent to Basic Authentication handler to Handle. This Handler method will raise a ValueError when presented with an authentication
scheme other than Digest or Basic.

*Changed in version 3.3:* Raise `ValueError` on unsupported Authentication Scheme.

```python
class urllib.request.ProxyDigestAuthHandler(password_mgr=None):
    Handle authentication with the proxy. `password_mgr`, if given, should be something that is compatible with `HTTPPasswordMgr`; refer to section `HTTPPasswordMgr Objects` for information on the interface that must be supported.

class urllib.request.HTTPHandler:
    A class to handle opening of HTTP URLs.

class urllib.request.HTTPSHandler(debuglevel=0, context=None, check_hostname=None):
    A class to handle opening of HTTPS URLs. `context` and `check_hostname` have the same meaning as in `http.client.HTTPSConnection`.

    *Changed in version 3.2:* context and check_hostname were added.

class urllib.request.FileHandler:
    Open local files.

class urllib.request.FTPHandler:
    Open FTP URLs.

class urllib.request.CacheFTPHandler:
    Open FTP URLs, keeping a cache of open FTP connections to minimize delays.

class urllib.request.UnknownHandler:
```
A catch-all class to handle unknown URLs.

class urllib.request.HTTPErrorProcessor
    Process HTTP error responses.
21.6.1. Request Objects

The following methods describe Request’s public interface, and so all may be overridden in subclasses. It also defines several public attributes that can be used by clients to inspect the parsed request.

Request. `full_url`
   The original URL passed to the constructor.

Request. `type`
   The URI scheme.

Request. `host`
   The URI authority, typically a host, but may also contain a port separated by a colon.

Request. `origin_req_host`
   The original host for the request, without port.

Request. `selector`
   The URI path. If the Request uses a proxy, then selector will be the full url that is passed to the proxy.

Request. `data`
   The entity body for the request, or None if not specified.

Request. `unverifiable`
   boolean, indicates whether the request is unverifiable as defined by RFC 2965.

Request. `method`
   The HTTP request method to use. This value is used by
get_method() to override the computed HTTP request method that would otherwise be returned. This attribute is initialized with the value of the method argument passed to the constructor.

New in version 3.3.

Request.get_method()
Return a string indicating the HTTP request method. If Request.method is not None, return its value, otherwise return 'GET' if Request.data is None, or 'POST' if it's not. This is only meaningful for HTTP requests.

Changed in version 3.3: get_method now looks at the value of Request.method.

Request.add_header(key, val)
Add another header to the request. Headers are currently ignored by all handlers except HTTP handlers, where they are added to the list of headers sent to the server. Note that there cannot be more than one header with the same name, and later calls will overwrite previous calls in case the key collides. Currently, this is no loss of HTTP functionality, since all headers which have meaning when used more than once have a (header-specific) way of gaining the same functionality using only one header.

Request.add_unredirected_header(key, header)
Add a header that will not be added to a redirected request.

Request.has_header(header)
Return whether the instance has the named header (checks both regular and unredirected).

Request.get_full_url()
Return the URL given in the constructor.

Request.\texttt{set\_proxy}(\textit{host}, \textit{type})

Prepare the request by connecting to a proxy server. The \textit{host} and \textit{type} will replace those of the instance, and the instance's selector will be the original URL given in the constructor.

Request.\texttt{add\_data}(\textit{data})

Set the Request data to \textit{data}. This is ignored by all handlers except HTTP handlers — and there it should be a byte string, and will change the request to be POST rather than GET. Deprecated in 3.3, use Request.\texttt{data}.

\textit{Deprecated since version 3.3, will be removed in version 3.4.}

Request.\texttt{has\_data}()

Return whether the instance has a non-None data. Deprecated in 3.3, use Request.\texttt{data}.

\textit{Deprecated since version 3.3, will be removed in version 3.4.}

Request.\texttt{get\_data}()

Return the instance's data. Deprecated in 3.3, use Request.\texttt{data}.

\textit{Deprecated since version 3.3, will be removed in version 3.4.}

Request.\texttt{get\_type}()

Return the type of the URL — also known as the scheme. Deprecated in 3.3, use Request.\texttt{type}. 

**Deprecated since version 3.3, will be removed in version 3.4.**

Request. `get_host()`

Return the host to which a connection will be made. Deprecated in 3.3, use `Request.host`.

**Deprecated since version 3.3, will be removed in version 3.4.**

Request. `get_selector()`

Return the selector — the part of the URL that is sent to the server. Deprecated in 3.3, use `Request.selector`.

**Deprecated since version 3.3, will be removed in version 3.4.**

Request. `get_header(header_name, default=None)`

Return the value of the given header. If the header is not present, return the default value.

Request. `header_items()`

Return a list of tuples (header_name, header_value) of the Request headers.

Request. `set_proxy(host, type)`

Request. `get_origin_req_host()`

Return the request-host of the origin transaction, as defined by RFC 2965. See the documentation for the `Request` constructor. Deprecated in 3.3, use `Request.origin_req_host`.

**Deprecated since version 3.3, will be removed in version 3.4.**
Request.is_unverifiable()

Return whether the request is unverifiable, as defined by RFC 2965. See the documentation for the Request constructor. Deprecated in 3.3, use Request.unverifiable.

*Deprecated since version 3.3, will be removed in version 3.4.*
21.6.2. OpenerDirector Objects

**OpenerDirector** instances have the following methods:

**OpenerDirector.** `add_handler(handler)`

*handler* should be an instance of **BaseHandler**. The following methods are searched, and added to the possible chains (note that HTTP errors are a special case).

- `protocol_open()` — signal that the handler knows how to open *protocol* URLs.
- `http_error_type()` — signal that the handler knows how to handle HTTP errors with HTTP error code *type*.
- `protocol_error()` — signal that the handler knows how to handle errors from (non-http) *protocol*.
- `protocol_request()` — signal that the handler knows how to pre-process *protocol* requests.
- `protocol_response()` — signal that the handler knows how to post-process *protocol* responses.

**OpenerDirector.** `open(url, data=None[, timeout])`

Open the given *url* (which can be a request object or a string), optionally passing the given *data*. Arguments, return values and exceptions raised are the same as those of `urlopen()` (which simply calls the `open()` method on the currently installed global **OpenerDirector**). The optional *timeout* parameter specifies a timeout in seconds for blocking operations like the connection attempt (if not specified, the global default timeout setting will be used). The timeout feature actually works only for HTTP, HTTPS and FTP connections).
OpenerDirector.error(proto, *args)

Handle an error of the given protocol. This will call the registered error handlers for the given protocol with the given arguments (which are protocol specific). The HTTP protocol is a special case which uses the HTTP response code to determine the specific error handler; refer to the http_error_*() methods of the handler classes.

Return values and exceptions raised are the same as those of urlopen().

OpenerDirector objects open URLs in three stages:

The order in which these methods are called within each stage is determined by sorting the handler instances.

1. Every handler with a method named like protocol_request() has that method called to pre-process the request.

2. Handlers with a method named like protocol_open() are called to handle the request. This stage ends when a handler either returns a non-None value (ie. a response), or raises an exception (usually URLError). Exceptions are allowed to propagate.

In fact, the above algorithm is first tried for methods named default_open(). If all such methods return None, the algorithm is repeated for methods named like protocol_open(). If all such methods return None, the algorithm is repeated for methods named unknown_open().

Note that the implementation of these methods may involve calls of the parent OpenerDirector instance’s open() and
error() methods.

3. Every handler with a method named like protocol_response() has that method called to post-process the response.
21.6.3. BaseHandler Objects
