If the whole \texttt{string} matches the regular expression \texttt{pattern}, return a corresponding \texttt{match object}. Return \texttt{None} if the string does not match the pattern; note that this is different from a zero-length match.

\textit{New in version 3.4.}

re.\texttt{split}(\texttt{pattern}, \texttt{string}, \texttt{maxsplit}=0, \texttt{flags}=0)

Split \texttt{string} by the occurrences of \texttt{pattern}. If capturing parentheses are used in \texttt{pattern}, then the text of all groups in the pattern are also returned as part of the resulting list. If \texttt{maxsplit} is nonzero, at most \texttt{maxsplit} splits occur, and the remainder of the string is
returned as the final element of the list.

```python
>>> re.split('\W+', 'Words, words, words.

['Words', 'words', 'words', '']

>>> re.split('(\W+)\W+\W+[a-f]+\W+\W+\W+', 'Words, words, words.

['Words', ', ', 'words', ',', ', ', 'words', ',', '.', '', '']

>>> re.split('(\W+)\W+\W+[a-f]+\W+\W+\W+', 'Words, words, words.

['Words', 'words, words.]

>>> re.split('[a-f]+\W+\W+\W+[a-f]+\W+\W+\W+', '0a3B9', flags=re.IGNORECASE

['0', '3', '9']
```

If there are capturing groups in the separator and it matches at the start of the string, the result will start with an empty string. The same holds for the end of the string:

```python
>>> re.split('(\W+)\W+\W+[a-f]+\W+\W+\W+', '...words, words...

[', '...', 'words', ',', ',', 'words', ',', '...', ']

That way, separator components are always found at the same relative indices within the result list.

Note that `split` will never split a string on an empty pattern match. For example:

```python
>>> re.split('x*', 'foo')

['foo']

>>> re.split("(?m)^$", "foo\n\nbar\n")

['foo\n\nbar\n']
```

`Changed in version 3.1:` Added the optional flags argument.

```python
re.**findall**(pattern, string, flags=0)

Return all non-overlapping matches of `pattern` in `string`, as a list of strings. The `string` is scanned left-to-right, and matches are
returned in the order found. If one or more groups are present in the pattern, return a list of groups; this will be a list of tuples if the pattern has more than one group. Empty matches are included in the result unless they touch the beginning of another match.

re.\texttt{finditer}(\texttt{pattern, string, flags=0})

Return an \textit{iterator} yielding \textit{match objects} over all non-overlapping matches for the RE \texttt{pattern} in \texttt{string}. The \texttt{string} is scanned left-to-right, and matches are returned in the order found. Empty matches are included in the result unless they touch the beginning of another match.

re.\texttt{sub}(\texttt{pattern, repl, string, count=0, flags=0})

Return the string obtained by replacing the leftmost non-overlapping occurrences of \texttt{pattern} in \texttt{string} by the replacement \texttt{repl}. If the pattern isn't found, \texttt{string} is returned unchanged. \texttt{repl} can be a string or a function; if it is a string, any backslash escapes in it are processed. That is, \texttt{\n} is converted to a single newline character, \texttt{\r} is converted to a carriage return, and so forth. Unknown escapes such as \texttt{\j} are left alone. Backreferences, such as \texttt{\6}, are replaced with the substring matched by group 6 in the pattern. For example:

```
>>> re.sub(r'def\s+([a-zA-Z_][a-zA-Z_0-9]*)\s*\((\n...    r'static PyObject*\npy_\1(void)\n{',
...    'def myfunc():'
'    static PyObject*\npy_myfunc(void)\n{'
```

If \texttt{repl} is a function, it is called for every non-overlapping occurrence of \texttt{pattern}. The function takes a single match object argument, and returns the replacement string. For example:
The pattern may be a string or an RE object.

The optional argument count is the maximum number of pattern occurrences to be replaced; count must be a non-negative integer. If omitted or zero, all occurrences will be replaced. Empty matches for the pattern are replaced only when not adjacent to a previous match, so sub('x*',' - ','abc') returns '-a-b-c-'.

In string-type repl arguments, in addition to the character escapes and backreferences described above, \g<name> will use the substring matched by the group named name, as defined by the (? P<name>...) syntax. \g<number> uses the corresponding group number; \g<2> is therefore equivalent to \2, but isn't ambiguous in a replacement such as \g<2>0. \20 would be interpreted as a reference to group 20, not a reference to group 2 followed by the literal character '0'. The backreference \g<0> substitutes in the entire substring matched by the RE.

*Changed in version 3.1:* Added the optional flags argument.

re.subn(pattern, repl, string, count=0, flags=0)

Perform the same operation as sub(), but return a tuple (new_string, number_of_subs_made).

*Changed in version 3.1:* Added the optional flags argument.
\texttt{\textbf{re.escape}(string)}

Escape all the characters in pattern except ASCII letters, numbers and \texttt{'}\_\texttt{'}\rt. This is useful if you want to match an arbitrary literal string that may have regular expression metacharacters in it.

\textit{Changed in version 3.3:} The \texttt{'}\_\texttt{'}\rt character is no longer escaped.

\texttt{\textbf{re.purge}()}

Clear the regular expression cache.

\textit{exception} \texttt{re.error}

Exception raised when a string passed to one of the functions here is not a valid regular expression (for example, it might contain unmatched parentheses) or when some other error occurs during compilation or matching. It is never an error if a string contains no match for a pattern.
6.2.3. Regular Expression Objects

Compiled regular expression objects support the following methods and attributes:

\texttt{regex.search(string[, pos[, endpos]])}

Scan through \texttt{string} looking for a location where this regular expression produces a match, and return a corresponding \texttt{match object}. Return \texttt{None} if no position in the string matches the pattern; note that this is different from finding a zero-length match at some point in the string.

The optional second parameter \texttt{pos} gives an index in the string where the search is to start; it defaults to 0. This is not completely equivalent to slicing the string; the '^' pattern character matches at the real beginning of the string and at positions just after a newline, but not necessarily at the index where the search is to start.

The optional parameter \texttt{endpos} limits how far the string will be searched; it will be as if the string is \texttt{endpos} characters long, so only the characters from \texttt{pos} to \texttt{endpos - 1} will be searched for a match. If \texttt{endpos} is less than \texttt{pos}, no match will be found; otherwise, if \texttt{rx} is a compiled regular expression object, \texttt{rx.search(string, 0, 50)} is equivalent to \texttt{rx.search(string[:50], 0)}.

```
>>> pattern = re.compile("d")
>>> pattern.search("dog")  # Match at index 0
<_sre.SRE_Match object; span=(0, 1), match='d'>
>>> pattern.search("dog", 1)  # No match; search
```
regex.\texttt{match}(\textit{string[, pos[, endpos]]})

If zero or more characters at the \textit{beginning} of \textit{string} match this regular expression, return a corresponding \textit{match object}. Return \texttt{None} if the string does not match the pattern; note that this is different from a zero-length match.

The optional \textit{pos} and \textit{endpos} parameters have the same meaning as for the \texttt{search()} method.

```
>>> pattern = re.compile("o")
>>> pattern.match("dog") # No match as "o" is not at the start of "dog".
>>> pattern.match("dog", 1) # Match as "o" is the 2nd character of "dog".
<_sre.SRE_Match object; span=(1, 2), match='o'>
```

If you want to locate a match anywhere in \textit{string}, use \texttt{search()} instead (see also \texttt{search()} \texttt{vs.} \texttt{match()}).

regex.\texttt{fullmatch}(\textit{string[, pos[, endpos]]})

If the whole \textit{string} matches this regular expression, return a corresponding \textit{match object}. Return \texttt{None} if the string does not match the pattern; note that this is different from a zero-length match.

The optional \textit{pos} and \textit{endpos} parameters have the same meaning as for the \texttt{search()} method.

```
>>> pattern = re.compile("o[gh]"
>>> pattern.fullmatch("dog") # No match as "o" is not at the start of "dog".
>>> pattern.fullmatch("ogre") # No match as not the full string matches.
>>> pattern.fullmatch("doggie", 1, 3) # Matches within given limits.
<_sre.SRE_Match object; span=(1, 3), match='og'>
```
New in version 3.4.

regex.split(string, maxsplit=0)

Identical to the split() function, using the compiled pattern.

regex.findall(string[, pos[, endpos]])

Similar to the findall() function, using the compiled pattern, but also accepts optional pos and endpos parameters that limit the search region like for match().

regex.finditer(string[, pos[, endpos]])

Similar to the finditer() function, using the compiled pattern, but also accepts optional pos and endpos parameters that limit the search region like for match().

regex.sub(repl, string, count=0)

Identical to the sub() function, using the compiled pattern.

regex.subn(repl, string, count=0)

Identical to the subn() function, using the compiled pattern.

regex.flags

The regex matching flags. This is a combination of the flags given to compile(), any (?...) inline flags in the pattern, and implicit flags such as UNICODE if the pattern is a Unicode string.

regex.groups

The number of capturing groups in the pattern.

regex.groupindex

A dictionary mapping any symbolic group names defined by (? P<id>) to group numbers. The dictionary is empty if no symbolic
groups were used in the pattern.

**regex.** **pattern**

The pattern string from which the RE object was compiled.
6.2.4. Match Objects

Match objects always have a boolean value of True. Since `match()` and `search()` return None when there is no match, you can test whether there was a match with a simple `if` statement:

```python
match = re.search(pattern, string)
if match:
    process(match)
```

Match objects support the following methods and attributes:

`match. expand(template)`

Return the string obtained by doing backslash substitution on the template string `template`, as done by the `sub()` method. Escapes such as `\n` are converted to the appropriate characters, and numeric backreferences (`\1`, `\2`) and named backreferences (`\g<1>`, `\g<name>`) are replaced by the contents of the corresponding group.

`match. group([group1, ...])`

Returns one or more subgroups of the match. If there is a single argument, the result is a single string; if there are multiple arguments, the result is a tuple with one item per argument. Without arguments, `group1` defaults to zero (the whole match is returned). If a `groupN` argument is zero, the corresponding return value is the entire matching string; if it is in the inclusive range [1..99], it is the string matching the corresponding parenthesized group. If a group number is negative or larger than the number of groups defined in the pattern, an `IndexError` exception is raised. If a group is contained in a part of the pattern that did not match,
the corresponding result is None. If a group is contained in a part of the pattern that matched multiple times, the last match is returned.

```python
>>> m = re.match(r"\w+ \w+", "Isaac Newton, physicist")
>>> m.group(0)  # The entire match
'Isaac Newton'
>>> m.group(1)  # The first parenthesized subexpression
'Isaac'
>>> m.group(2)  # The second parenthesized subexpression
'Newton'
>>> m.group(1, 2)  # Multiple arguments give us a tuple.
('Isaac', 'Newton')
```

If the regular expression uses the (?P<name>...) syntax, the `groupN` arguments may also be strings identifying groups by their group name. If a string argument is not used as a group name in the pattern, an IndexError exception is raised.

A moderately complicated example:

```python
>>> m = re.match(r"(?P<first_name>\w+) (?P<last_name>\w+)", "Malcolm Reynolds")
>>> m.group('first_name')
'Malcolm'
>>> m.group('last_name')
'Reynolds'
```

Named groups can also be referred to by their index:

```python
>>> m.group(1)
'Malcolm'
>>> m.group(2)
'Reynolds'
```
If a group matches multiple times, only the last match is accessible:

```python
>>> m = re.match(r"(\.)+(\.)", "a1b2c3")  # Matches 3 # Returns only
>>> m.group(1)
'c3'
```

match. **groups**(default=None)

Return a tuple containing all the subgroups of the match, from 1 up to however many groups are in the pattern. The *default* argument is used for groups that did not participate in the match; it defaults to *None*.

For example:

```python
>>> m = re.match(r"(\d+)\.(\d+)", "24.1632")
>>> m.groups()
('24', '1632')
```

If we make the decimal place and everything after it optional, not all groups might participate in the match. These groups will default to *None* unless the *default* argument is given:

```python
>>> m = re.match(r"(\d+)\.(\?\d+)？", "24")
>>> m.groups()  # Second group defaults to None
('24', None)
>>> m.groups('0')  # Now, the second group defaults to '0'
('24', '0')
```

match. **groupdict**(default=None)

Return a dictionary containing all the *named* subgroups of the match, keyed by the subgroup name. The *default* argument is used for groups that did not participate in the match; it defaults to *None*. 
For example:

```python
>>> m = re.match(r"(?P<first_name>\w+) (?P<last_name>\w+)", "Malcolm Reynolds")
{'first_name': 'Malcolm', 'last_name': 'Reynolds'}
```

`match.start([group])`

`match.end([group])`

Return the indices of the start and end of the substring matched by `group`; `group` defaults to zero (meaning the whole matched substring). Return `-1` if `group` exists but did not contribute to the match. For a match object `m`, and a group `g` that did contribute to the match, the substring matched by group `g` (equivalent to `m.group(g)`) is

```
m.string[m.start(g):m.end(g)]
```

Note that `m.start(group)` will equal `m.end(group)` if `group` matched a null string. For example, after `m = re.search('b(c?)', 'cba'), m.start(0)` is 1, `m.end(0)` is 2, `m.start(1)` and `m.end(1)` are both 2, and `m.start(2)` raises an `IndexError` exception.

An example that will remove `remove_this` from email addresses:

```python
>>> email = "tony@tiremove_thisger.net"
>>> m = re.search("remove_this", email)
>>> email[:m.start()] + email[m.end():]
'tony@tiger.net'
```

`match.span([group])`

For a match `m`, return the 2-tuple `(m.start(group),`
m.end(group)). Note that if group did not contribute to the match, this is (-1, -1). group defaults to zero, the entire match.

**match.pos**
The value of pos which was passed to the search() or match() method of a *regex object*. This is the index into the string at which the RE engine started looking for a match.

**match.endpos**
The value of endpos which was passed to the search() or match() method of a *regex object*. This is the index into the string beyond which the RE engine will not go.

**match.lastindex**
The integer index of the last matched capturing group, or None if no group was matched at all. For example, the expressions (a)b, ((a)(b)), and ((ab)) will have lastindex == 1 if applied to the string 'ab', while the expression (a)(b) will have lastindex == 2, if applied to the same string.

**match.lastgroup**
The name of the last matched capturing group, or None if the group didn’t have a name, or if no group was matched at all.

**match.re**
The regular expression object whose match() or search() method produced this match instance.

**match.string**
The string passed to match() or search().
6.2.5. Regular Expression Examples

6.2.5.1. Checking for a Pair

In this example, we'll use the following helper function to display match objects a little more gracefully:

```python
def displaymatch(match):
    if match is None:
        return None
    return '<Match: %r, groups=%r>' % (match.group(),)
```

Suppose you are writing a poker program where a player's hand is represented as a 5-character string with each character representing a card, “a” for ace, “k” for king, “q” for queen, “j” for jack, “t” for 10, and “2” through “9” representing the card with that value.

To see if a given string is a valid hand, one could do the following:

```python
>>> valid = re.compile(r'\^[a2-9tjqk]\{5\}$')
>>> displaymatch(valid.match('akt5q'))  # Valid.
'<Match: 'akt5q', groups=()>'
>>> displaymatch(valid.match('akt5e'))  # Invalid.
>>> displaymatch(valid.match('akt'))    # Invalid.
>>> displaymatch(valid.match('727ak'))  # Valid.
'<Match: '727ak', groups=()>'
```

That last hand, "727ak", contained a pair, or two of the same valued cards. To match this with a regular expression, one could use backreferences as such:

```python
>>> pair = re.compile(r'.*(.).*(\1)')
>>> displaymatch(pair.match('717ak'))  # Pair of
```

Note: The backreference \1 is used to match the second occurrence of the same value as the first occurrence.
To find out what card the pair consists of, one could use the `group()` method of the match object in the following manner:

```python
>>> pair.match("717ak").group(1)
'7'
```

# Error because re.match() returns None, which doesn't have a group() method:
```python
>>> pair.match("718ak").group(1)
Traceback (most recent call last):
  File "<pyshell#23>", line 1, in <module>
    re.match(r".*(\.)\1", "718ak").group(1)
AttributeError: 'NoneType' object has no attribute 'group'
```
```python
>>> pair.match("354aa").group(1)
'a'
```

### 6.2.5.2. Simulating scanf()

Python does not currently have an equivalent to `scanf()`. Regular expressions are generally more powerful, though also more verbose, than `scanf()` format strings. The table below offers some more-or-less equivalent mappings between `scanf()` format tokens and regular expressions.

<table>
<thead>
<tr>
<th><code>scanf()</code> Token</th>
<th>Regular Expression</th>
</tr>
</thead>
<tbody>
<tr>
<td><code>%c</code></td>
<td>.</td>
</tr>
<tr>
<td><code>%5c</code></td>
<td>.{5}</td>
</tr>
</tbody>
</table>
To extract the filename and numbers from a string like

```
/usr/sbin/sendmail - 0 errors, 4 warnings
```

you would use a `scanf()` format like

```
%s - %d errors, %d warnings
```

The equivalent regular expression would be

```
(\S+) - (\d+) errors, (\d+) warnings
```

### 6.2.5.3. `search()` vs. `match()`

Python offers two different primitive operations based on regular expressions: `re.match()` checks for a match only at the beginning of the string, while `re.search()` checks for a match anywhere in the string (this is what Perl does by default).

For example:
Regular expressions beginning with `^` can be used with `search()` to restrict the match at the beginning of the string:

```python
g>>> re.match("c", "abcdef")  # No match
>>> re.search("c", "abcdef")  # Match
<_sre.SRE_Match object; span=(2, 3), match='c'>
```

Note however that in MULTILINE mode `match()` only matches at the beginning of the string, whereas using `search()` with a regular expression beginning with `^` will match at the beginning of each line.

```python
g>>> re.match("c", "abcdef")  # No match
>>> re.search("^c", "abcdef")  # No match
>>> re.search("^a", "abcdef")  # Match
<_sre.SRE_Match object; span=(0, 1), match='a'>
```

### 6.2.5.4. Making a Phonebook

`split()` splits a string into a list delimited by the passed pattern. The method is invaluable for converting textual data into data structures that can be easily read and modified by Python as demonstrated in the following example that creates a phonebook.

First, here is the input. Normally it may come from a file, here we are using triple-quoted string syntax:

```python
g>>> text = """Ross McFluff: 834.345.1254 155 Elm Street""
```
Ronald Heathmore: 892.345.3428 436 Finley Avenue
Frank Burger: 925.541.7625 662 South Dogwood Way
Heather Albrecht: 548.326.4584 919 Park Place

The entries are separated by one or more newlines. Now we convert the string into a list with each nonempty line having its own entry:

```python
>>> entries = re.split("\n+", text)
>>> entries
['Ross McFluff: 834.345.1254 155 Elm Street',
 'Ronald Heathmore: 892.345.3428 436 Finley Avenue',
 'Frank Burger: 925.541.7625 662 South Dogwood Way',
 'Heather Albrecht: 548.326.4584 919 Park Place']
```

Finally, split each entry into a list with first name, last name, telephone number, and address. We use the maxsplit parameter of `split()` because the address has spaces, our splitting pattern, in it:

```python
>>> [re.split(":?:\s", entry, 3) for entry in entries]
[['Ross', 'McFluff', '834.345.1254', '155 Elm Street'],
 ['Ronald', 'Heathmore', '892.345.3428', '436 Finley Street'],
 ['Frank', 'Burger', '925.541.7625', '662 South Dogwood Way'],
 ['Heather', 'Albrecht', '548.326.4584', '919 Park Place']]
```

The `:?:` pattern matches the colon after the last name, so that it does not occur in the result list. With a maxsplit of 4, we could separate the house number from the street name:

```python
>>> [re.split(":?:\s", entry, 4) for entry in entries]
[['Ross', 'McFluff', '834.345.1254', '155', 'Elm Street'],
 ['Ronald', 'Heathmore', '892.345.3428', '436', 'Finley Avenue'],
 ['Frank', 'Burger', '925.541.7625', '662', 'South Dogwood Way'],
 ['Heather', 'Albrecht', '548.326.4584', '919', 'Park Place']]
```
6.2.5.5. Text Munging

`sub()` replaces every occurrence of a pattern with a string or the result of a function. This example demonstrates using `sub()` with a function to “munge” text, or randomize the order of all the characters in each word of a sentence except for the first and last characters:

```python
>>> def repl(m):
...     inner_word = list(m.group(2))
...     random.shuffle(inner_word)
...     return m.group(1) + ''.join(inner_word) + m.group(3)

>>> text = "Professor Abdolmalek, please report your absences promptly."
>>> re.sub(r"(\w)(\w+)(\w)" , repl, text)
'Poefsroser Aealmlobdk, pslaee reoprt your abnseces p'
```

6.2.5.6. Finding all Adverbs

`findall()` matches all occurrences of a pattern, not just the first one as `search()` does. For example, if one was a writer and wanted to find all of the adverbs in some text, he or she might use `findall()` in the following manner:

```python
>>> text = "He was carefully disguised but captured quickly by police."
>>> re.findall(r"\\w+ly", text)
['carefully', 'quickly']
```
6.2.5.7. Finding all Adverbs and their Positions

If one wants more information about all matches of a pattern than the matched text, `finditer()` is useful as it provides match objects instead of strings. Continuing with the previous example, if one was a writer who wanted to find all of the adverbs and their positions in some text, he or she would use `finditer()` in the following manner:

```python
text = "He was carefully disguised but captured quickly by police."
for m in re.finditer(r"\w+ly", text):
    ... print('%02d-%02d: %s % (m.start(), m.end()),
07-16: carefully
40-47: quickly
```

6.2.5.8. Raw String Notation

Raw string notation (r"text") keeps regular expressions sane. Without it, every backslash ('\') in a regular expression would have to be prefixed with another one to escape it. For example, the two following lines of code are functionally identical:

```python
>>> re.match(r"\W(.)\1\W", " ff ")
<_sre.SRE_Match object; span=(0, 4), match=' ff '> <<<re.match(r"\\W(.)\\1\\W", " ff ")
<_sre.SRE_Match object; span=(0, 4), match=' ff '>```

When one wants to match a literal backslash, it must be escaped in the regular expression. With raw string notation, this means r"\\\". Without raw string notation, one must use "\\\\", making the following lines of code functionally identical:
6.2.5.9. Writing a Tokenizer

A tokenizer or scanner analyzes a string to categorize groups of characters. This is a useful first step in writing a compiler or interpreter.

The text categories are specified with regular expressions. The technique is to combine those into a single master regular expression and to loop over successive matches:

```python
import collections
import re

Token = collections.namedtuple('Token', ['typ', 'value'])

def tokenize(s):
    keywords = {'IF', 'THEN', 'ENDIF', 'FOR', 'NEXT'}
    token_specification = [
        ('NUMBER', r'\d+(\.\d*)?'),  # Integer or decimal number
        ('ASSIGN', r':='),  # Assignment operator
        ('END', r';'),  # Statement terminator
        ('ID', r'[A-Za-z]+'),  # Identifiers
        ('OP', r'[+\-*/]'),  # Arithmetic operators
        ('NEWLINE', r'\n'),  # Line endings
        ('SKIP', r'[ 	]')  # Skip over spaces and tabs
    ]
    tok_regex = '|'.join('(?P<%s>%s)' % pair for pair in token_specification)
    get_token = re.compile(tok_regex).match
    line = 1
    pos = line_start = 0
    mo = get_token(s)
```
```python
while mo is not None:
    typ = mo.lastgroup
    if typ == 'NEWLINE':
        line_start = pos
        line += 1
    elif typ != 'SKIP':
        val = mo.group(typ)
        if typ == 'ID' and val in keywords:
            typ = val
        yield Token(typ, val, line, mo.start()-1)
        pos = mo.end()
        mo = get_token(s, pos)
    if pos != len(s):
        raise RuntimeError('Unexpected character %r
```
```
statements = '''
    IF quantity THEN
        total := total + price * quantity;
        tax := price * 0.05;
    ENDIF;
    ...
```
```
for token in tokenize(statements):
    print(token)
```
```
The tokenizer produces the following output:
```
Token(typ='IF', value='IF', line=2, column=5)
Token(typ='ID', value='quantity', line=2, column=8)
Token(typ='THEN', value='THEN', line=2, column=17)
Token(typ='ID', value='total', line=3, column=9)
Token(typ='ASSIGN', value=':=', line=3, column=15)
Token(typ='ID', value='total', line=3, column=18)
Token(typ='OP', value='+', line=3, column=24)
Token(typ='ID', value='price', line=3, column=26)
Token(typ='OP', value='*', line=3, column=32)
```
Token(typ='ID', value='quantity', line=3, column=34)
Token(typ='END', value=';', line=3, column=42)

6.3. **difflib** — Helpers for computing deltas

This module provides classes and functions for comparing sequences. It can be used for example, for comparing files, and can produce difference information in various formats, including HTML and context and unified diffs. For comparing directories and files, see also, the `filecmp` module.

```python
class difflib.SequenceMatcher
```

This is a flexible class for comparing pairs of sequences of any type, so long as the sequence elements are *hashable*. The basic algorithm predates, and is a little fancier than, an algorithm published in the late 1980’s by Ratcliff and Obershulp under the hyperbolic name “gestalt pattern matching.” The idea is to find the longest contiguous matching subsequence that contains no “junk” elements (the Ratcliff and Obershulp algorithm doesn’t address junk). The same idea is then applied recursively to the pieces of the sequences to the left and to the right of the matching subsequence. This does not yield minimal edit sequences, but does tend to yield matches that “look right” to people.

**Timing:** The basic Ratcliff-Obershulp algorithm is cubic time in the worst case and quadratic time in the expected case. `SequenceMatcher` is quadratic time for the worst case and has expected-case behavior dependent in a complicated way on how many elements the sequences have in common; best case time is linear.

**Automatic junk heuristic:** `SequenceMatcher` supports a
heuristic that automatically treats certain sequence items as junk. The heuristic counts how many times each individual item appears in the sequence. If an item's duplicates (after the first one) account for more than 1% of the sequence and the sequence is at least 200 items long, this item is marked as “popular” and is treated as junk for the purpose of sequence matching. This heuristic can be turned off by setting the `autojunk` argument to `False` when creating the `SequenceMatcher`.

New in version 3.2: The `autojunk` parameter.

```
class difflib.Differ
```
This is a class for comparing sequences of lines of text, and producing human-readable differences or deltas. Differ uses `SequenceMatcher` both to compare sequences of lines, and to compare sequences of characters within similar (near-matching) lines.

Each line of a `Differ` delta begins with a two-letter code:

<table>
<thead>
<tr>
<th>Code</th>
<th>Meaning</th>
</tr>
</thead>
<tbody>
<tr>
<td><code>-</code></td>
<td>line unique to sequence 1</td>
</tr>
<tr>
<td><code>+</code></td>
<td>line unique to sequence 2</td>
</tr>
<tr>
<td><code>=</code></td>
<td>line common to both sequences</td>
</tr>
<tr>
<td><code>?</code></td>
<td>line not present in either input sequence</td>
</tr>
</tbody>
</table>

Lines beginning with `?` attempt to guide the eye to intraline differences, and were not present in either input sequence. These lines can be confusing if the sequences contain tab characters.

```
class difflib.HtmlDiff
```
This class can be used to create an HTML table (or a complete HTML file containing the table) showing a side by side, line by line comparison of text with inter-line and intra-line change highlights. The table can be generated in either full or contextual difference mode.

The constructor for this class is:

```python
__init__(tabsize=8, wrapcolumn=None, linejunk=None, charjunk=IS_CHARACTER_JUNK)
```

Initializes instance of `HtmlDiff`.

`tabsize` is an optional keyword argument to specify tab stop spacing and defaults to 8.

`wrapcolumn` is an optional keyword to specify column number where lines are broken and wrapped, defaults to `None` where lines are not wrapped.

`linejunk` and `charjunk` are optional keyword arguments passed into `ndiff()` (used by `HtmlDiff` to generate the side by side HTML differences). See `ndiff()` documentation for argument default values and descriptions.

The following methods are public:

```python
make_file(fromlines, tolines, fromdesc='', todesc='', context=False, numlines=5)
```

Compares `fromlines` and `tolines` (lists of strings) and returns a string which is a complete HTML file containing a table showing line by line differences with inter-line and intra-line changes highlighted.
fromdesc and todesc are optional keyword arguments to specify from/to file column header strings (both default to an empty string).

context and numlines are both optional keyword arguments. Set context to True when contextual differences are to be shown, else the default is False to show the full files. numlines defaults to 5. When context is True numlines controls the number of context lines which surround the difference highlights. When context is False numlines controls the number of lines which are shown before a difference highlight when using the “next” hyperlinks (setting to zero would cause the “next” hyperlinks to place the next difference highlight at the top of the browser without any leading context).

make_table(fromlines, tolines, fromdesc='', todesc='', context=False, numlines=5)

Compares fromlines and tolines (lists of strings) and returns a string which is a complete HTML table showing line by line differences with inter-line and intra-line changes highlighted.

The arguments for this method are the same as those for the make_file() method.

Tools/scripts/diff.py is a command-line front-end to this class and contains a good example of its use.

difflib.context_diff(a, b, fromfile='', tofile='', fromfiledate='', tofiledate='', n=3, lineterm='\n')

Compare a and b (lists of strings); return a delta (a generator generating the delta lines) in context diff format.

Context diffs are a compact way of showing just the lines that have
changed plus a few lines of context. The changes are shown in a before/after style. The number of context lines is set by \( n \) which defaults to three.

By default, the diff control lines (those with *** or ---) are created with a trailing newline. This is helpful so that inputs created from \texttt{io.IOBase.readlines()} result in diffs that are suitable for use with \texttt{io.IOBase.writelines()} since both the inputs and outputs have trailing newlines.

For inputs that do not have trailing newlines, set the \texttt{lineterm} argument to "" so that the output will be uniformly newline free.

The context diff format normally has a header for filenames and modification times. Any or all of these may be specified using strings for \texttt{fromfile}, \texttt{tofile}, \texttt{fromfiledate}, and \texttt{tofiledate}. The modification times are normally expressed in the ISO 8601 format. If not specified, the strings default to blanks.

```python
>>> s1 = ['bacon
', 'eggs
', 'ham
', 'guido
'
>>> s2 = ['python
', 'eggy
', 'hamster
', 'guido

>>> for line in context_diff(s1, s2, fromfile='before.py'
... sys.stdout.write(line)
*** before.py
--- after.py
***************
*** 1,4 ****
! bacon
! eggs
! ham
! hamster
```
See *A command-line interface to difflib* for a more detailed example.

```
difflib.get_close_matches(word, possibilities, n=3, cutoff=0.6)
```

Return a list of the best “good enough” matches. `word` is a sequence for which close matches are desired (typically a string), and `possibilities` is a list of sequences against which to match `word` (typically a list of strings).

Optional argument `n` (default 3) is the maximum number of close matches to return; `n` must be greater than 0.

Optional argument `cutoff` (default 0.6) is a float in the range [0, 1]. Possibilities that don’t score at least that similar to `word` are ignored.

The best (no more than `n`) matches among the possibilities are returned in a list, sorted by similarity score, most similar first.

```
>>> get_close_matches('appel', ['ape', 'apple', 'peach'])
['apple', 'ape']
>>> import keyword
>>> get_close_matches('wheel', keyword.kwlist)
['while']
>>> get_close_matches('apple', keyword.kwlist)
[]
>>> get_close_matches('accept', keyword.kwlist)
['except']
```

difflib.**ndiff**(a, b, linejunk=None,
charjunk=IS_CHARACTER_JUNK)

Compare a and b (lists of strings); return a Differ-style delta (a generator generating the delta lines).

Optional keyword parameters linejunk and charjunk are for filter functions (or None):

*linejunk*: A function that accepts a single string argument, and returns true if the string is junk, or false if not. The default is None. There is also a module-level function IS_LINE_JUNK(), which filters out lines without visible characters, except for at most one pound character ("#") – however the underlying SequenceMatcher class does a dynamic analysis of which lines are so frequent as to constitute noise, and this usually works better than using this function.

*charjunk*: A function that accepts a character (a string of length 1), and returns if the character is junk, or false if not. The default is module-level function IS_CHARACTER_JUNK(), which filters out whitespace characters (a blank or tab; note: bad idea to include newline in this!).

Tools/scripts/ndiff.py is a command-line front-end to this function.

```python
>>> diff = ndiff('one\ntwo\nthree\n'.splitlines(1)
...
'ore\ntree\nemu\n'.splitlines(1))
>>> print(''.join(diff), end="")
- one
  ^
+ ore
  ^
- two
- three
```
difflib.restore(sequence, which)

Return one of the two sequences that generated a delta.

Given a sequence produced by Differ.compare() or ndiff(), extract lines originating from file 1 or 2 (parameter which), stripping off line prefixes.

Example:

```python
>>> diff = ndiff('one
two
three').splitlines(1
... 'ore
ntree
nemu').splitlines(1)
>>> diff = list(diff)  # materialize the generated
>>> print('').join(restore(diff, 1)), end=''

one
two
three

>>> print('').join(restore(diff, 2)), end=''

ore
tree
emu
```

difflib.unified_diff(a, b, fromfile='', tofile='', fromfiledate='', tofiledate='', n=3, lineterm=\'\\n\')

Compare a and b (lists of strings); return a delta (a generator generating the delta lines) in unified diff format.

Unified diffs are a compact way of showing just the lines that have changed plus a few lines of context. The changes are shown in a inline style (instead of separate before/after blocks). The number of
context lines is set by \( n \) which defaults to three.

By default, the diff control lines (those with \( \text{---} \), \( +++ \), or \( @@ \)) are created with a trailing newline. This is helpful so that inputs created from \texttt{io.IOBase.readlines()} result in diffs that are suitable for use with \texttt{io.IOBase.writelines()} since both the inputs and outputs have trailing newlines.

For inputs that do not have trailing newlines, set the \texttt{lineterm} argument to "" so that the output will be uniformly newline free.

The context diff format normally has a header for filenames and modification times. Any or all of these may be specified using strings for \texttt{fromfile}, \texttt{tofile}, \texttt{fromfiledate}, and \texttt{tofiledate}. The modification times are normally expressed in the ISO 8601 format. If not specified, the strings default to blanks.

```python
>>> s1 = ['bacon\n', 'eggs\n', 'ham\n', 'guido\n'
>>> s2 = ['python\n', 'eggy\n', 'hamster\n', 'guido

>>> for line in unified_diff(s1, s2, fromfile='before.py'
...
    sys.stdout.write(line)
--- before.py
+++ after.py
@@ -1,4 +1,4 @@
-bacon
-eggs
-ham
+python
+eggy
+hamster
    guided

See \textit{A command-line interface to difflib} for a more detailed example.
difflib.IS_LINE_JUNK(line)

Return true for ignorable lines. The line line is ignorable if line is blank or contains a single '#', otherwise it is not ignorable. Used as a default for parameter linejunk in ndiff() in older versions.

difflib.IS_CHARACTER_JUNK(ch)

Return true for ignorable characters. The character ch is ignorable if ch is a space or tab, otherwise it is not ignorable. Used as a default for parameter charjunk in ndiff().

Pattern Matching: The Gestalt Approach
Discussion of a similar algorithm by John W. Ratcliff and D. E. Metzener. This was published in Dr. Dobb's Journal in July, 1988.
6.3.1. SequenceMatcher Objects

The `SequenceMatcher` class has this constructor:

```python
class difflib.SequenceMatcher(isjunk=None, a='', b='', autojunk=True)
```

Optional argument `isjunk` must be `None` (the default) or a one-argument function that takes a sequence element and returns true if and only if the element is “junk” and should be ignored. Passing `None` for `isjunk` is equivalent to passing `lambda x: 0`; in other words, no elements are ignored. For example, pass:

```python
lambda x: x in " \t"
```

if you’re comparing lines as sequences of characters, and don’t want to synch up on blanks or hard tabs.

The optional arguments `a` and `b` are sequences to be compared; both default to empty strings. The elements of both sequences must be `hashable`.

The optional argument `autojunk` can be used to disable the automatic junk heuristic.

*New in version 3.2:* The `autojunk` parameter.

SequenceMatcher objects get three data attributes: `bjunk` is the set of elements of `b` for which `isjunk` is `True`; `bpopular` is the set of non-junk elements considered popular by the heuristic (if it is not disabled); `b2j` is a dict mapping the remaining elements of `b` to a list of positions where they occur. All three are reset whenever `b` is reset with `set_seqs()` or `set_seq2()`.
New in version 3.2: The `bjunk` and `bpopular` attributes.

`SequenceMatcher` objects have the following methods:

```python
set_seqs(a, b)
```
Set the two sequences to be compared.

`SequenceMatcher` computes and caches detailed information about the second sequence, so if you want to compare one sequence against many sequences, use `set_seq2()` to set the commonly used sequence once and call `set_seq1()` repeatedly, once for each of the other sequences.

```python
set_seq1(a)
```
Set the first sequence to be compared. The second sequence to be compared is not changed.

```python
set_seq2(b)
```
Set the second sequence to be compared. The first sequence to be compared is not changed.

```python
find_longest_match(alo, ahi, blo, bhi)
```
Find longest matching block in `a[alo:ahi]` and `b[blo:bhi]`.

If `isjunk` was omitted or `None`, `find_longest_match()` returns `(i, j, k)` such that `a[i:i+k]` is equal to `b[j:j+k]`, where `alo <= i <= i+k <= ahi` and `blo <= j <= j+k <= bhi`. For all `(i', j', k')` meeting those conditions, the additional conditions `k >= k', i <= i'`, and if `i == i', j <= j'` are also met. In other words, of all maximal matching blocks, return one that starts earliest in `a`,
and of all those maximal matching blocks that start earliest in \( a \), return the one that starts earliest in \( b \).

```python
>>> s = SequenceMatcher(None, "abcd", "abcd abcd
```
and \( j \).

The last triple is a dummy, and has the value \((\text{len}(a),\ \text{len}(b),\ 0)\). It is the only triple with \( n == 0 \). If \((i,\ j,\ n)\) and \((i',\ j',\ n')\) are adjacent triples in the list, and the second is not the last triple in the list, then \( i+n != i' \) or \( j+n != j' \); in other words, adjacent triples always describe non-adjacent equal blocks.

\[
\text{>>}> s = \text{SequenceMatcher(}\text{None, "abxcd", "abcd"}\text{)}
\]
\[
\text{>>}> s.\text{get_matching_blocks()}
\]
\[
[\text{Match(a=0, b=0, size=2), Match(a=3, b=2, size=2), Match(a=5, b=4, size=0)}]
\]

**get_opcodes()**

Return list of 5-tuples describing how to turn \( a \) into \( b \). Each tuple is of the form \((\text{tag, } i1,\ i2,\ j1,\ j2)\). The first tuple has \( i1 == j1 == 0 \), and remaining tuples have \( i1 \) equal to the \( i2 \) from the preceding tuple, and, likewise, \( j1 \) equal to the previous \( j2 \).

The *tag* values are strings, with these meanings:

<table>
<thead>
<tr>
<th>Value</th>
<th>Meaning</th>
</tr>
</thead>
<tbody>
<tr>
<td>'replace'</td>
<td>( a[i1:i2] ) should be replaced by ( b[j1:j2] ).</td>
</tr>
<tr>
<td>'delete'</td>
<td>( a[i1:i2] ) should be deleted. Note that ( j1 == j2 ) in this case.</td>
</tr>
<tr>
<td>'insert'</td>
<td>( b[j1:j2] ) should be inserted at ( a[i1:i1] ). Note that ( i1 == i2 ) in this case.</td>
</tr>
<tr>
<td>'equal'</td>
<td>( a[i1:i2] == b[j1:j2] ) (the subsequences are equal).</td>
</tr>
</tbody>
</table>
For example:

```python
>>> a = "qabxcd"
>>> b = "abycdf"
>>> s = SequenceMatcher(None, a, b)
>>> for tag, i1, i2, j1, j2 in s.get_opcodes():
    print('{:7}			a[{}:{}]	-->	b[{}:{}]	{!r:>8}	-->	{!r}'.format(
        tag, i1, i2, j1, j2, a[i1:i2], b[j1:j2]))
```

**get_grouped_opcodes**(n=3)

Return a generator of groups with up to n lines of context.

Starting with the groups returned by get_opcodes(), this method splits out smaller change clusters and eliminates intervening ranges which have no changes.

The groups are returned in the same format as get_opcodes().

**ratio()**

Return a measure of the sequences' similarity as a float in the range [0, 1].

Where T is the total number of elements in both sequences, and M is the number of matches, this is 2.0*M / T. Note that this is 1.0 if the sequences are identical, and 0.0 if they have nothing in common.

This is expensive to compute if get_matching_blocks() or
get_opcodes() hasn’t already been called, in which case you may want to try quick_ratio() or real_quick_ratio() first to get an upper bound.

**quick_ratio()**

Return an upper bound on ratio() relatively quickly.

**real_quick_ratio()**

Return an upper bound on ratio() very quickly.

The three methods that return the ratio of matching to total characters can give different results due to differing levels of approximation, although quick_ratio() and real_quick_ratio() are always at least as large as ratio():

```python
>>> s = SequenceMatcher(None, "abcd", "bcde")
>>> s.ratio()
0.75
>>> s.quick_ratio()
0.75
>>> s.real_quick_ratio()
1.0
```
6.3.2. SequenceMatcher Examples

This example compares two strings, considering blanks to be “junk”:

```python
>>> s = SequenceMatcher(lambda x: x == " ",
...                        "private Thread currentThread;
...                        "private volatile Thread cur
```

`ratio()` returns a float in [0, 1], measuring the similarity of the sequences. As a rule of thumb, a `ratio()` value over 0.6 means the sequences are close matches:

```python
>>> print(round(s.ratio(), 3))
0.866
```

If you're only interested in where the sequences match, `get_matching_blocks()` is handy:

```python
>>> for block in s.get_matching_blocks():
...     print("a[%d] and b[%d] match for %d elements" % block)
         a[0] and b[0] match for 8 elements
         a[8] and b[17] match for 21 elements
         a[29] and b[38] match for 0 elements
```

Note that the last tuple returned by `get_matching_blocks()` is always a dummy, `(len(a), len(b), 0)`, and this is the only case in which the last tuple element (number of elements matched) is 0.

If you want to know how to change the first sequence into the second, use `get_opcodes()`:

```python
>>> for opcode in s.get_opcodes():
```
...    print("%6s a[%d:%d] b[%d:%d]" % opcode)
    equal a[0:8] b[0:8]
    insert a[8:8] b[8:17]
    equal a[8:29] b[17:38]

See also:

- The `get_close_matches()` function in this module which shows how simple code building on `SequenceMatcher` can be used to do useful work.
- Simple version control recipe for a small application built with `SequenceMatcher`. 
6.3.3. Differ Objects

Note that Differ-generated deltas make no claim to be minimal diffs. To the contrary, minimal diffs are often counter-intuitive, because they synch up anywhere possible, sometimes accidental matches 100 pages apart. Restricting synch points to contiguous matches preserves some notion of locality, at the occasional cost of producing a longer diff.

The Differ class has this constructor:

```python
class difflib.Differ(linejunk=None, charjunk=None)
```

Optional keyword parameters linejunk and charjunk are for filter functions (or None):

- **linejunk**: A function that accepts a single string argument, and returns true if the string is junk. The default is `None`, meaning that no line is considered junk.

- **charjunk**: A function that accepts a single character argument (a string of length 1), and returns true if the character is junk. The default is `None`, meaning that no character is considered junk.

Differ objects are used (deltas generated) via a single method:

```python
compare(a, b)
```

Compare two sequences of lines, and generate the delta (a sequence of lines).

Each sequence must contain individual single-line strings ending with newlines. Such sequences can be obtained from the `readlines()` method of file-like objects. The delta
generated also consists of newline-terminated strings, ready to be printed as-is via the `writelines()` method of a file-like object.
6.3.4. Differ Example

This example compares two texts. First we set up the texts, sequences of individual single-line strings ending with newlines (such sequences can also be obtained from the `readlines()` method of file-like objects):

```python
>>> text1 = ''' 1. Beautiful is better than ugly.
... 2. Explicit is better than implicit.
... 3. Simple is better than complex.
... 4. Complex is better than complicated.
... '''.splitlines(1)
>>> len(text1)
4
>>> text1[0][-1]
'

>>> text2 = ''' 1. Beautiful is better than ugly.
... 3. Simple is better than complex.
... 4. Complicated is better than complex.
... 5. Flat is better than nested.
... '''.splitlines(1)
```

Next we instantiate a Differ object:

```python
>>> d = Differ()
```

Note that when instantiating a `Differ` object we may pass functions to filter out line and character “junk.” See the `Differ()` constructor for details.

Finally, we compare the two:

```python
>>> result = list(d.compare(text1, text2))
```
result is a list of strings, so let's pretty-print it:

```python
>>> from pprint import pprint
>>> pprint(result)
['  1. Beautiful is better than ugly.
  - 2. Explicit is better than implicit.
  - 3. Simple is better than complex.
  + 3. Simple is better than complex.
     ++
  - 4. Complex is better than complicated.
     ^
   ---- ^
  + 4. Complicated is better than complex.
     ++++ ^
     ^
  + 5. Flat is better than nested.
]
```

As a single multi-line string it looks like this:

```python
>>> import sys
>>> sys.stdout.writelines(result)
  1. Beautiful is better than ugly.
  - 2. Explicit is better than implicit.
  - 3. Simple is better than complex.
  + 3. Simple is better than complex.
     ++
  - 4. Complex is better than complicated.
     ^
   ---- ^
  + 4. Complicated is better than complex.
     ++++ ^
     ^
  + 5. Flat is better than nested.
```
6.3.5. A command-line interface to difflib

This example shows how to use difflib to create a diff-like utility. It is also contained in the Python source distribution, as Tools/scripts/diff.py.

""" Command line interface to difflib.py providing a
* ndiff: lists every line and highlights interline changes.
* context: highlights clusters of changes in a before/after format.
* unified: highlights clusters of changes in an inline format.
* html: generates side by side comparison with change highlights.
""

import sys, os, time, difflib, optparse
def main():
    # Configure the option parser
    usage = "usage: %prog [options] fromfile tofile"
    parser = optparse.OptionParser(usage)
    parser.add_option("-c", action="store_true", default=False,
                        help='Produce a context format diff (default)
                        (can use --lines=3)"
    parser.add_option("-u", action="store_true", default=False,
                        help='Produce a unified format diff"
    parser.add_option("-m", action="store_true", default=False,
                        help='Produce an HTML side by side diff (can use --lines=3)"
    parser.add_option("-n", action="store_true", default=False,
                        help='Produce a ndiff format diff"
    parser.add_option("-l", "--lines", type="int", default=3,
                        help='Set number of context lines"

    (options, args) = parser.parse_args()

    if len(args) == 0:
        parser.print_help()
sys.exit(1)

if len(args) != 2:
    parser.error("need to specify both a fromfile and tofile")

n = options.lines
fromfile, tofile = args # as specified in the usage string
# we're passing these as arguments to the diff function
fromdate = time.ctime(os.stat(fromfile).st_mtime)
todate = time.ctime(os.stat(tofile).st_mtime)
with open(fromfile) as fromf, open(tofile) as tof:
    fromlines, tolines = list(fromf), list(tof)

if options.u:
    diff = difflib.unified_diff(fromlines, tolines,
                                 fromdate, todate)
elif options.n:
    diff = difflib.ndiff(fromlines, tolines)
elif options.m:
    diff = difflib.HtmlDiff().make_file(fromlines,
                                          tolines,
                                          fromdate, todate,
                                          numlines)
else:
    diff = difflib.context_diff(fromlines, tolines,
                                 fromdate, todate)

# we're using writelines because diff is a generator
sys.stdout.writelines(diff)

if __name__ == '__main__':
    main()
6.4. **textwrap** — Text wrapping and filling

**Source code:** Lib/textwrap.py

The **textwrap** module provides some convenience functions, as well as **TextWrapper**, the class that does all the work. If you’re just wrapping or filling one or two text strings, the convenience functions should be good enough; otherwise, you should use an instance of **TextWrapper** for efficiency.

**textwrap.wrap**(*text*, *width=70*, **kwargs*)

Wraps the single paragraph in *text* (a string) so every line is at most *width* characters long. Returns a list of output lines, without final newlines.

Optional keyword arguments correspond to the instance attributes of **TextWrapper**, documented below. *width* defaults to 70.

See the **TextWrapper.wrap()** method for additional details on how **wrap()** behaves.

**textwrap.fill**(*text*, *width=70*, **kwargs*)

Wraps the single paragraph in *text*, and returns a single string containing the wrapped paragraph. **fill()** is shorthand for

```
"\n".join(wrap(text, ...))
```

In particular, **fill()** accepts exactly the same keyword arguments as **wrap()**.
textwrap.**shorten**(text, width, **kwargs)**

Collapse and truncate the given text to fit in the given width.

First the whitespace in text is collapsed (all whitespace is replaced by single spaces). If the result fits in the width, it is returned. Otherwise, enough words are dropped from the end so that the remaining words plus the placeholder fit within width:

```
>>> textwrap.shorten("Hello world!", width=12)
'Hello world!'
>>> textwrap.shorten("Hello world!", width=11)
'Hello [...]'  
>>> textwrap.shorten("Hello world", width=10, placeholder='Hello...')
```

Optional keyword arguments correspond to the instance attributes of TextWrapper, documented below. Note that the whitespace is collapsed before the text is passed to the TextWrapper fill() function, so changing the value of tabsize, expand_tabs, drop_whitespace, and replace_whitespace will have no effect.

*New in version 3.4.*

textwrap.**dedent**(text)

Remove any common leading whitespace from every line in text.

This can be used to make triple-quoted strings line up with the left edge of the display, while still presenting them in the source code in indented form.

Note that tabs and spaces are both treated as whitespace, but they are not equal: the lines "hello" and "\thello" are
considered to have no common leading whitespace.

For example:

```python
def test():
    # end first line with \ to avoid the empty line!
s = ''\
    hello
    world
    ''
    print(repr(s))  # prints ' hello\n    print(repr(dedent(s)))  # prints 'hello\n    world''
```

textwrap.**indent**(text, prefix, predicate=None)

Add `prefix` to the beginning of selected lines in `text`. Lines are separated by calling `text.splitlines(True)`. By default, `prefix` is added to all lines that do not consist solely of whitespace (including any line endings).

For example:

```python
>>> s = 'hello\n\n \nworld'
>>> indent(s, '  ')
' hello\n\n \n world'
```

The optional `predicate` argument can be used to control which lines are indented. For example, it is easy to add `prefix` to even empty and whitespace-only lines:

```python
>>> print(indent(s, '+ ', lambda line: True))
+ hello
+ +
```
wrap(), fill() and shorten() work by creating a TextWrapper instance and calling a single method on it. That instance is not reused, so for applications that process many text strings using wrap() and/or fill(), it may be more efficient to create your own TextWrapper object.

Text is preferably wrapped on whitespaces and right after the hyphens in hyphenated words; only then will long words be broken if necessary, unless TextWrapper.break_long_words is set to false.

class textwrap.TextWrapper(**kwargs)

The TextWrapper constructor accepts a number of optional keyword arguments. Each keyword argument corresponds to an instance attribute, so for example

```python
wrapper = TextWrapper(initial_indent="*
")
```

is the same as

```python
wrapper = TextWrapper()
wrapper.initial_indent = "*
"
```

You can re-use the same TextWrapper object many times, and you can change any of its options through direct assignment to instance attributes between uses.

The TextWrapper instance attributes (and keyword arguments to the constructor) are as follows:

**width**

(default: 70) The maximum length of wrapped lines. As long as
there are no individual words in the input text longer than width, TextWrapper guarantees that no output line will be longer than width characters.

**expand_tabs**

(default: True) If true, then all tab characters in text will be expanded to spaces using the expandtabs() method of text.

**tabsize**

(default: 8) If expand_tabs is true, then all tab characters in text will be expanded to zero or more spaces, depending on the current column and the given tab size.

*New in version 3.3.*

**replace_whitespace**

(default: True) If true, after tab expansion but before wrapping, the wrap() method will replace each whitespace character with a single space. The whitespace characters replaced are as follows: tab, newline, vertical tab, formfeed, and carriage return ('\t\n\v\f\r').

**Note:** If expand_tabs is false and replace_whitespace is true, each tab character will be replaced by a single space, which is *not* the same as tab expansion.

**Note:** If replace_whitespace is false, newlines may appear in the middle of a line and cause strange output. For this reason, text should be split into paragraphs (using str.splitlines() or similar) which are wrapped separately.
**drop_whitespace**
(default: `True`) If true, whitespace at the beginning and ending of every line (after wrapping but before indenting) is dropped. Whitespace at the beginning of the paragraph, however, is not dropped if non-whitespace follows it. If whitespace being dropped takes up an entire line, the whole line is dropped.

**initial_indent**
(default: `'` ) String that will be prepended to the first line of wrapped output. Counts towards the length of the first line. The empty string is not indented.

**subsequent_indent**
(default: `'` ) String that will be prepended to all lines of wrapped output except the first. Counts towards the length of each line except the first.

**fix_sentence_endings**
(default: `False`) If true, `TextWrapper` attempts to detect sentence endings and ensure that sentences are always separated by exactly two spaces. This is generally desired for text in a monospaced font. However, the sentence detection algorithm is imperfect: it assumes that a sentence ending consists of a lowercase letter followed by one of `.`, `!`, or `?`, possibly followed by one of `"` or `'`, followed by a space. One problem with this is algorithm is that it is unable to detect the difference between “Dr.” in

```plaintext
[...] Dr. Frankenstein's monster [...]
```

and “Spot.” in
See Spot. See Spot run [...]

fix_sentence_endings is false by default.

Since the sentence detection algorithm relies on string.lowercase for the definition of “lowercase letter,” and a convention of using two spaces after a period to separate sentences on the same line, it is specific to English-language texts.

break_long_words
(default: True) If true, then words longer than width will be broken in order to ensure that no lines are longer than width. If it is false, long words will not be broken, and some lines may be longer than width. (Long words will be put on a line by themselves, in order to minimize the amount by which width is exceeded.)

break_on_hyphens
(default: True) If true, wrapping will occur preferably on whitespaces and right after hyphens in compound words, as it is customary in English. If false, only whitespaces will be considered as potentially good places for line breaks, but you need to set break_long_words to false if you want truly inseparable words. Default behaviour in previous versions was to always allow breaking hyphenated words.

max_lines
(default: None) If not None, then the output will contain at most max_lines lines, with placeholder appearing at the end of the output.
New in version 3.4.

**placeholder**

(default: '[...]') String that will appear at the end of the output text if it has been truncated.

New in version 3.4.

*TextWrapper* also provides some public methods, analogous to the module-level convenience functions:

**wrap(text)**

Wraps the single paragraph in *text* (a string) so every line is at most *width* characters long. All wrapping options are taken from instance attributes of the *TextWrapper* instance. Returns a list of output lines, without final newlines. If the wrapped output has no content, the returned list is empty.

**fill(text)**

Wraps the single paragraph in *text*, and returns a single string containing the wrapped paragraph.
6.5. `unicodedata` — Unicode Database

This module provides access to the Unicode Character Database (UCD) which defines character properties for all Unicode characters. The data contained in this database is compiled from the UCD version 6.3.0.

The module uses the same names and symbols as defined by Unicode Standard Annex #44, “Unicode Character Database”. It defines the following functions:

`unicodedata.lookup(name)`

Look up character by name. If a character with the given name is found, return the corresponding character. If not found, `KeyError` is raised.

*Changed in version 3.3:* Support for name aliases [1] and named sequences [2] has been added.

`unicodedata.name(chr[, default])`

Returns the name assigned to the character `chr` as a string. If no name is defined, `default` is returned, or, if not given, `ValueError` is raised.

`unicodedata.decimal(chr[, default])`

Returns the decimal value assigned to the character `chr` as integer. If no such value is defined, `default` is returned, or, if not given, `ValueError` is raised.
unicodedata.digit(chr[, default])
  Returns the digit value assigned to the character \textit{chr} as integer. If no such value is defined, \textit{default} is returned, or, if not given, \texttt{ValueError} is raised.

unicodedata.numeric(chr[, default])
  Returns the numeric value assigned to the character \textit{chr} as float. If no such value is defined, \textit{default} is returned, or, if not given, \texttt{ValueError} is raised.

unicodedata.category(chr)
  Returns the general category assigned to the character \textit{chr} as string.

unicodedata.bidirectional(chr)
  Returns the bidirectional class assigned to the character \textit{chr} as string. If no such value is defined, an empty string is returned.

unicodedata.combining(chr)
  Returns the canonical combining class assigned to the character \textit{chr} as integer. Returns 0 if no combining class is defined.

unicodedata.east_asian_width(chr)
  Returns the east asian width assigned to the character \textit{chr} as string.

unicodedata.mirrored(chr)
  Returns the mirrored property assigned to the character \textit{chr} as integer. Returns 1 if the character has been identified as a “mirrored” character in bidirectional text, 0 otherwise.

unicodedata.decomposition(chr)
Returns the character decomposition mapping assigned to the character `chr` as string. An empty string is returned in case no such mapping is defined.

`unicodedata.normalize(form, unistr)`

Return the normal form `form` for the Unicode string `unistr`. Valid values for `form` are ‘NFC’, ‘NFKC’, ‘NFD’, and ‘NFKD’.

The Unicode standard defines various normalization forms of a Unicode string, based on the definition of canonical equivalence and compatibility equivalence. In Unicode, several characters can be expressed in various ways. For example, the character U+00C7 (LATIN CAPITAL LETTER C WITH CEDILLA) can also be expressed as the sequence U+0043 (LATIN CAPITAL LETTER C) U+0327 (COMBINING CEDILLA).

For each character, there are two normal forms: normal form C and normal form D. Normal form D (NFD) is also known as canonical decomposition, and translates each character into its decomposed form. Normal form C (NFC) first applies a canonical decomposition, then composes pre-combined characters again.

In addition to these two forms, there are two additional normal forms based on compatibility equivalence. In Unicode, certain characters are supported which normally would be unified with other characters. For example, U+2160 (ROMAN NUMERAL ONE) is really the same thing as U+0049 (LATIN CAPITAL LETTER I). However, it is supported in Unicode for compatibility with existing character sets (e.g. gb2312).

The normal form KD (NFKD) will apply the compatibility decomposition, i.e. replace all compatibility characters with their equivalents. The normal form KC (NFKC) first applies the
compatibility decomposition, followed by the canonical composition.

Even if two unicode strings are normalized and look the same to a human reader, if one has combining characters and the other doesn't, they may not compare equal.

In addition, the module exposes the following constant:

**unicodedata.** \texttt{unidata\_version}

The version of the Unicode database used in this module.

**unicodedata.** \texttt{ucd\_3\_2\_0}

This is an object that has the same methods as the entire module, but uses the Unicode database version 3.2 instead, for applications that require this specific version of the Unicode database (such as IDNA).

Examples:

```python
>>> import unicodedata
>>> unicodedata.lookup('LEFT CURLY BRACKET')
'{'
>>> unicodedata.name('/')
'SOLIDUS'
>>> unicodedata.decimal('9')
9
>>> unicodedata.decimal('a')
Traceback (most recent call last):
  File "<stdin>", line 1, in ?
ValueError: not a decimal
>>> unicodedata.category('A')  # 'L'etter, 'u'ppercase
'Lu'
>>> unicodedata.bidirectional('٠')  # 'A'rabic, 'AN'
```

6.6. **stringprep** — Internet String Preparation

When identifying things (such as host names) in the internet, it is often necessary to compare such identifications for “equality”. Exactly how this comparison is executed may depend on the application domain, e.g. whether it should be case-insensitive or not. It may be also necessary to restrict the possible identifications, to allow only identifications consisting of “printable” characters.

**RFC 3454** defines a procedure for “preparing” Unicode strings in internet protocols. Before passing strings onto the wire, they are processed with the preparation procedure, after which they have a certain normalized form. The RFC defines a set of tables, which can be combined into profiles. Each profile must define which tables it uses, and what other optional parts of the `stringprep` procedure are part of the profile. One example of a `stringprep` profile is `nameprep`, which is used for internationalized domain names.

The module `stringprep` only exposes the tables from RFC 3454. As these tables would be very large to represent them as dictionaries or lists, the module uses the Unicode character database internally. The module source code itself was generated using the `mkstringprep.py` utility.

As a result, these tables are exposed as functions, not as data structures. There are two kinds of tables in the RFC: sets and mappings. For a set, `stringprep` provides the “characteristic function”, i.e. a function that returns true if the parameter is part of the set. For mappings, it provides the mapping function: given the key, it
returns the associated value. Below is a list of all functions available in the module.

**stringprep.in_table_a1(code)**
Determine whether *code* is in tableA.1 (Unassigned code points in Unicode 3.2).

**stringprep.in_table_b1(code)**
Determine whether *code* is in tableB.1 (Commonly mapped to nothing).

**stringprep.map_table_b2(code)**
Return the mapped value for *code* according to tableB.2 (Mapping for case-folding used with NFKC).

**stringprep.map_table_b3(code)**
Return the mapped value for *code* according to tableB.3 (Mapping for case-folding used with no normalization).

**stringprep.in_table_c11(code)**
Determine whether *code* is in tableC.1.1 (ASCII space characters).

**stringprep.in_table_c12(code)**
Determine whether *code* is in tableC.1.2 (Non-ASCII space characters).

**stringprep.in_table_c11_c12(code)**
Determine whether *code* is in tableC.1 (Space characters, union of C.1.1 and C.1.2).

**stringprep.in_table_c21(code)**
Determine whether *code* is in tableC.2.1 (ASCII control characters).
stringprep.\texttt{in\_table\_c22}(\textit{code})

Determine whether \textit{code} is in table\texttt{C.2.2} (Non-ASCII control characters).

stringprep.\texttt{in\_table\_c21\_c22}(\textit{code})

Determine whether \textit{code} is in table\texttt{C.2} (Control characters, union of C.2.1 and C.2.2).

stringprep.\texttt{in\_table\_c3}(\textit{code})

Determine whether \textit{code} is in table\texttt{C.3} (Private use).

stringprep.\texttt{in\_table\_c4}(\textit{code})

Determine whether \textit{code} is in table\texttt{C.4} (Non-character code points).

stringprep.\texttt{in\_table\_c5}(\textit{code})

Determine whether \textit{code} is in table\texttt{C.5} (Surrogate codes).

stringprep.\texttt{in\_table\_c6}(\textit{code})

Determine whether \textit{code} is in table\texttt{C.6} (Inappropriate for plain text).

stringprep.\texttt{in\_table\_c7}(\textit{code})

Determine whether \textit{code} is in table\texttt{C.7} (Inappropriate for canonical representation).

stringprep.\texttt{in\_table\_c8}(\textit{code})

Determine whether \textit{code} is in table\texttt{C.8} (Change display properties or are deprecated).

stringprep.\texttt{in\_table\_c9}(\textit{code})

Determine whether \textit{code} is in table\texttt{C.9} (Tagging characters).

stringprep.\texttt{in\_table\_d1}(\textit{code})
Determine whether \textit{code} is in \texttt{tableD.1} (Characters with bidirectional property “R” or “AL”).

\texttt{stringprep.in_table_d2(code)}

Determine whether \textit{code} is in \texttt{tableD.2} (Characters with bidirectional property “L”).
6.7. readline — GNU readline interface

The `readline` module defines a number of functions to facilitate completion and reading/writing of history files from the Python interpreter. This module can be used directly or via the `rlcompleter` module. Settings made using this module affect the behaviour of both the interpreter’s interactive prompt and the prompts offered by the built-in `input()` function.

**Note:** On MacOS X the `readline` module can be implemented using the `libedit` library instead of GNU readline.

The configuration file for `libedit` is different from that of GNU readline. If you programmatically load configuration strings you can check for the text “libedit” in `readline.__doc__` to differentiate between GNU readline and libedit.

The `readline` module defines the following functions:

- `readline.parse_and_bind(string)`
  Parse and execute single line of a readline init file.

- `readline.get_line_buffer()`
  Return the current contents of the line buffer.

- `readline.insert_text(string)`
  Insert text into the command line.

- `readline.read_init_file([filename])`
Parse a readline initialization file. The default filename is the last filename used.

readline.**read_history_file**([`filename`])

Load a readline history file. The default filename is `~/.history`.

readline.**write_history_file**([`filename`])

Save a readline history file. The default filename is `~/.history`.

readline.**clear_history**()

Clear the current history. (Note: this function is not available if the installed version of GNU readline doesn’t support it.)

readline.**get_history_length**()

Return the desired length of the history file. Negative values imply unlimited history file size.

readline.**set_history_length**(length)

Set the number of lines to save in the history file. `write_history_file()` uses this value to truncate the history file when saving. Negative values imply unlimited history file size.

readline.**get_current_history_length**()

Return the number of lines currently in the history. (This is different from `get_history_length()`, which returns the maximum number of lines that will be written to a history file.)

readline.**get_history_item**(index)

Return the current contents of history item at `index`.

readline.**remove_history_item**(pos)

Remove history item specified by its position from the history.
readline. \texttt{replace\_history\_item}(pos, line)
Replace history item specified by its position with the given line.

readline. \texttt{redisplays}()
Change what's displayed on the screen to reflect the current contents of the line buffer.

readline. \texttt{set\_startup\_hook}([function])
Set or remove the startup\_hook function. If \textit{function} is specified, it will be used as the new startup\_hook function; if omitted or \texttt{None}, any hook function already installed is removed. The startup\_hook function is called with no arguments just before readline prints the first prompt.

readline. \texttt{set\_pre\_input\_hook}([function])
Set or remove the pre\_input\_hook function. If \textit{function} is specified, it will be used as the new pre\_input\_hook function; if omitted or \texttt{None}, any hook function already installed is removed. The pre\_input\_hook function is called with no arguments after the first prompt has been printed and just before readline starts reading input characters.

readline. \texttt{set\_completer}([function])
Set or remove the completer function. If \textit{function} is specified, it will be used as the new completer function; if omitted or \texttt{None}, any completer function already installed is removed. The completer function is called as \texttt{function(text, state)}, for \textit{state} in 0, 1, 2, ..., until it returns a non-string value. It should return the next possible completion starting with \textit{text}.

readline. \texttt{get\_completer}()
Get the completer function, or None if no completer function has been set.

`readline.get_completion_type()`  
Get the type of completion being attempted.

`readline.get_begidx()`  
Get the beginning index of the readline tab-completion scope.

`readline.get_endidx()`  
Get the ending index of the readline tab-completion scope.

`readline.set_completer_delims(string)`  
Set the readline word delimiters for tab-completion.

`readline.get_completer_delims()`  
Get the readline word delimiters for tab-completion.

`readline.set_completion_display_matches_hook([function])`  
Set or remove the completion display function. If `function` is specified, it will be used as the new completion display function; if omitted or None, any completion display function already installed is removed. The completion display function is called as `function(substitution, [matches], longest_match_length)` once each time matches need to be displayed.

`readline.add_history(line)`  
Append a line to the history buffer, as if it was the last line typed.

**See also:**

**Module rlcompleter**
Completion of Python identifiers at the interactive prompt.
6.7.1. Example

The following example demonstrates how to use the `readline` module's history reading and writing functions to automatically load and save a history file named `.python_history` from the user's home directory. The code below would normally be executed automatically during interactive sessions from the user's PYTHONSTARTUP file.

```python
import atexit
import os
import readline

histfile = os.path.join(os.path.expanduser("~"), ".python_history")

try:
    readline.read_history_file(histfile)
except FileNotFoundError:
    pass

atexit.register(readline.write_history_file, histfile)
```

This code is actually automatically run when Python is run in interactive mode (see Readline configuration).

The following example extends the `code.InteractiveConsole` class to support history save/restore.

```python
import atexit
import code
import os
import readline

class HistoryConsole(code.InteractiveConsole):
```
```python
def __init__(self, locals=None, filename='<console>', histfile=os.path.expanduser('~/console-history')):
    code.InteractiveConsole.__init__(self, locals)
    self.init_history(histfile)

def init_history(self, histfile):
    readline.parse_and_bind("tab: complete")
    if hasattr(readline, "read_history_file"):
        try:
            readline.read_history_file(histfile)
        except FileNotFoundError:
            pass
    atexit.register(self.save_history, histfile)

def save_history(self, histfile):
    readline.write_history_file(histfile)
```

Created using Sphinx 1.2.
6.8. **rlcompleter — Completion function for GNU readline**

**Source code:** Lib/rlcompleter.py

The *rlcompleter* module defines a completion function suitable for the *readline* module by completing valid Python identifiers and keywords.

When this module is imported on a Unix platform with the *readline* module available, an instance of the Completer class is automatically created and its `complete()` method is set as the *readline* completer.

Example:

```python
>>> import rlcompleter
>>> import readline
>>> readline.parse_and_bind("tab: complete")
>>> readline.<TAB PRESSED>
readline.__doc__    readline.get_line_buffer(  
readline.__file__   readline.insert_text(  
readline.__name__   readline.parse_and_bind(  
>>> readline.
```

The *rlcompleter* module is designed for use with Python's *interactive mode*. Unless Python is run with the `-S` option, the module is automatically imported and configured (see *Readline configuration*).

On platforms without *readline*, the Completer class defined by
this module can still be used for custom purposes.
6.8.1. Completer Objects

Completer objects have the following method:

Completer.complete(text, state)

Return the state th completion for text.

If called for text that doesn't include a period character ('.'), it will complete from names currently defined in __main__, builtins and keywords (as defined by the keyword module).

If called for a dotted name, it will try to evaluate anything without obvious side-effects (functions will not be evaluated, but it can generate calls to __getattr__() up to the last part, and find matches for the rest via the dir() function. Any exception raised during the evaluation of the expression is caught, silenced and None is returned.
7. Binary Data Services

The modules described in this chapter provide some basic services operations for manipulation of binary data. Other operations on binary data, specifically in relation to file formats and network protocols, are described in the relevant sections.

Some libraries described under *Text Processing Services* also work with either ASCII-compatible binary formats (for example, *re*) or all binary data (for example, *difflib*).

In addition, see the documentation for Python’s built-in binary data types in *Binary Sequence Types — bytes, bytearray, memoryview*.

7.2.5. encodings.idna — Internationalized Domain Names in Applications
7.2.6. encodings.mbcns — Windows ANSI codepage
7.2.7. encodings.utf_8_sig — UTF-8 codec with BOM signature
7.1. **struct** — Interpret bytes as packed binary data

This module performs conversions between Python values and C structs represented as Python `bytes` objects. This can be used in handling binary data stored in files or from network connections, among other sources. It uses *Format Strings* as compact descriptions of the layout of the C structs and the intended conversion to/from Python values.

**Note:** By default, the result of packing a given C struct includes pad bytes in order to maintain proper alignment for the C types involved; similarly, alignment is taken into account when unpacking. This behavior is chosen so that the bytes of a packed struct correspond exactly to the layout in memory of the corresponding C struct. To handle platform-independent data formats or omit implicit pad bytes, use standard size and alignment instead of native size and alignment: see *Byte Order, Size, and Alignment* for details.
7.1.1. Functions and Exceptions

The module defines the following exception and functions:

exception struct.error

Exception raised on various occasions; argument is a string describing what is wrong.

struct.pack(fmt, v1, v2, ...)

Return a bytes object containing the values v1, v2, ... packed according to the format string fmt. The arguments must match the values required by the format exactly.

struct.pack_into(fmt, buffer, offset, v1, v2, ...)

Pack the values v1, v2, ... according to the format string fmt and write the packed bytes into the writable buffer buffer starting at position offset. Note that offset is a required argument.

struct.unpack(fmt, buffer)

Unpack from the buffer buffer (presumably packed by pack(fmt, ...)) according to the format string fmt. The result is a tuple even if it contains exactly one item. The buffer must contain exactly the amount of data required by the format (len(bytes) must equal calcsize(fmt)).

struct.unpack_from(fmt, buffer, offset=0)

Unpack from buffer starting at position offset, according to the format string fmt. The result is a tuple even if it contains exactly one item. buffer must contain at least the amount of data required by the format (len(buffer[offset:]) must be at least calcsize(fmt)).
struct.iter_unpack(fmt, buffer)

Iteratively unpack from the buffer buffer according to the format string fmt. This function returns an iterator which will read equally-sized chunks from the buffer until all its contents have been consumed. The buffer’s size in bytes must be a multiple of the amount of data required by the format, as reflected by calcsize().

Each iteration yields a tuple as specified by the format string.

*New in version 3.4.*

struct.calcsize(fmt)

Return the size of the struct (and hence of the bytes object produced by pack(fmt, ...)) corresponding to the format string fmt.
7.1.2. Format Strings

Format strings are the mechanism used to specify the expected layout when packing and unpacking data. They are built up from Format Characters, which specify the type of data being packed/unpacked. In addition, there are special characters for controlling the Byte Order, Size, and Alignment.

7.1.2.1. Byte Order, Size, and Alignment

By default, C types are represented in the machine's native format and byte order, and properly aligned by skipping pad bytes if necessary (according to the rules used by the C compiler).

Alternatively, the first character of the format string can be used to indicate the byte order, size and alignment of the packed data, according to the following table:

<table>
<thead>
<tr>
<th>Character</th>
<th>Byte order</th>
<th>Size</th>
<th>Alignment</th>
</tr>
</thead>
<tbody>
<tr>
<td>@</td>
<td>native</td>
<td>native</td>
<td>native</td>
</tr>
<tr>
<td>=</td>
<td>native</td>
<td>standard</td>
<td>none</td>
</tr>
<tr>
<td>&lt;</td>
<td>little-endian</td>
<td>standard</td>
<td>none</td>
</tr>
<tr>
<td>&gt;</td>
<td>big-endian</td>
<td>standard</td>
<td>none</td>
</tr>
<tr>
<td>!</td>
<td>network (= big-endian)</td>
<td>standard</td>
<td>none</td>
</tr>
</tbody>
</table>

If the first character is not one of these, '@' is assumed.

Native byte order is big-endian or little-endian, depending on the host system. For example, Intel x86 and AMD64 (x86-64) are little-endian; Motorola 68000 and PowerPC G5 are big-endian; ARM and Intel
Itanium feature switchable endianness (bi-endian). Use `sys.byteorder` to check the endianness of your system.

Native size and alignment are determined using the C compiler’s `sizeof` expression. This is always combined with native byte order.

Standard size depends only on the format character; see the table in the Format Characters section.

Note the difference between `@` and `=`: both use native byte order, but the size and alignment of the latter is standardized.

The form `'!'` is available for those poor souls who claim they can't remember whether network byte order is big-endian or little-endian.

There is no way to indicate non-native byte order (force byte-swapping); use the appropriate choice of `<` or `>`.

Notes:

1. Padding is only automatically added between successive structure members. No padding is added at the beginning or the end of the encoded struct.
2. No padding is added when using non-native size and alignment, e.g. with `<`, `>`, `=`, and `!'`.
3. To align the end of a structure to the alignment requirement of a particular type, end the format with the code for that type with a repeat count count of zero. See Examples.

7.1.2.2. Format Characters

Format characters have the following meaning; the conversion between C and Python values should be obvious given their types. The ‘Standard size’ column refers to the size of the packed value in
bytes when using standard size; that is, when the format string starts with one of '<', '>', '!' or '='. When using native size, the size of the packed value is platform-dependent.

<table>
<thead>
<tr>
<th>Format</th>
<th>C Type</th>
<th>Python type</th>
<th>Standard size</th>
<th>Notes</th>
</tr>
</thead>
<tbody>
<tr>
<td>x</td>
<td>pad byte</td>
<td>no value</td>
<td></td>
<td></td>
</tr>
<tr>
<td>c</td>
<td>char</td>
<td>bytes of length 1</td>
<td>1</td>
<td></td>
</tr>
<tr>
<td>b</td>
<td>signed char</td>
<td>integer</td>
<td>1</td>
<td>(1),(3)</td>
</tr>
<tr>
<td>B</td>

<td>float</td>
<td>8</td>
<td>(5)</td>
</tr>
<tr>
<td>s</td>
<td>char[]</td>
<td>bytes</td>
<td></td>
<td></td>
</tr>
</tbody>
</table>
Changed in version 3.3: Added support for the 'n' and 'N' formats.

Notes:

1. The '?' conversion code corresponds to the _Bool type defined by C99. If this type is not available, it is simulated using a char. In standard mode, it is always represented by one byte.

2. The 'q' and 'Q' conversion codes are available in native mode only if the platform C compiler supports C long long, or, on Windows, __int64. They are always available in standard modes.

3. When attempting to pack a non-integer using any of the integer conversion codes, if the non-integer has a __index__() method then that method is called to convert the argument to an integer before packing.

   Changed in version 3.2: Use of the __index__() method for non-integers is new in 3.2.

4. The 'n' and 'N' conversion codes are only available for the native size (selected as the default or with the '@' byte order character). For the standard size, you can use whichever of the other integer formats fits your application.

5. For the 'f' and 'd' conversion codes, the packed representation uses the IEEE 754 binary32 (for 'f') or binary64 (for 'd') format, regardless of the floating-point format used by the platform.
6. The 'P' format character is only available for the native byte ordering (selected as the default or with the '@' byte order character). The byte order character '=' chooses to use little- or big-endian ordering based on the host system. The struct module does not interpret this as native ordering, so the 'P' format is not available.

A format character may be preceded by an integral repeat count. For example, the format string '4h' means exactly the same as 'hhhh'.

Whitespace characters between formats are ignored; a count and its format must not contain whitespace though.

For the 's' format character, the count is interpreted as the length of the bytes, not a repeat count like for the other format characters; for example, '10s' means a single 10-byte string, while '10c' means 10 characters. If a count is not given, it defaults to 1. For packing, the string is truncated or padded with null bytes as appropriate to make it fit. For unpacking, the resulting bytes object always has exactly the specified number of bytes. As a special case, '0s' means a single, empty string (while '0c' means 0 characters).

When packing a value $x$ using one of the integer formats ('b', 'B', 'h', 'H', 'i', 'I', 'l', 'L', 'q', 'Q'), if $x$ is outside the valid range for that format then `struct.error` is raised.

*Changed in version 3.1*: In 3.0, some of the integer formats wrapped out-of-range values and raised `DeprecationWarning` instead of `struct.error`.

The 'p' format character encodes a “Pascal string”, meaning a short variable-length string stored in a *fixed number of bytes*, given by the
count. The first byte stored is the length of the string, or 255, whichever is smaller. The bytes of the string follow. If the string passed in to \texttt{pack()} is too long (longer than the count minus 1), only the leading \texttt{count-1} bytes of the string are stored. If the string is shorter than \texttt{count-1}, it is padded with null bytes so that exactly count bytes in all are used. Note that for \texttt{unpack()}, the ‘\texttt{p}’ format character consumes \texttt{count} bytes, but that the string returned can never contain more than 255 bytes.

For the ‘\texttt{?}’ format character, the return value is either \texttt{True} or \texttt{False}. When packing, the truth value of the argument object is used. Either 0 or 1 in the native or standard bool representation will be packed, and any non-zero value will be \texttt{True} when unpacking.

7.1.2.3. Examples

\textbf{Note:} All examples assume a native byte order, size, and alignment with a big-endian machine.

A basic example of packing/unpacking three integers:

```python
>>> from struct import *
>>> pack('hhh', 1, 2, 3)
b'\x00\x01\x00\x02\x00\x00\x00\x03'
>>> unpack('hhh', b'\x00\x01\x00\x02\x00\x00\x00\x03')(1, 2, 3)
>>> calcsize('hhh')
8
```

Unpacked fields can be named by assigning them to variables or by wrapping the result in a named tuple:
>>> record = b'raymond \x32\x12\x08\x01\x08'
>>> name, serialnum, school, gradelevel = unpack('<10sHHb', record)

>>> from collections import namedtuple
>>> Student = namedtuple('Student', 'name serialnum school gradelevel')
>>> Student._make(unpack('<10sHHb', record))
Student(name=b'raymond ', serialnum=4658, school=264, gradelevel=8)

The ordering of format characters may have an impact on size since
the padding needed to satisfy alignment requirements is different:

>>> pack('ci', b'*', 0x12131415)
b'*\x00\x00\x00\x12\x13\x14\x15'
>>> pack('ic', 0x12131415, b'*')
b'\x12\x13\x14\x15*
>>> calcsize('ci')
8
>>> calcsize('ic')
5

The following format 'llh0l' specifies two pad bytes at the end,
assuming longs are aligned on 4-byte boundaries:

>>> pack('llh0l', 1, 2, 3)
b'\x00\x00\x00\x01\x00\x00\x00\x02\x00\x03\x00\x00'

This only works when native size and alignment are in effect; standard
size and alignment does not enforce any alignment.

7.1.3. Classes

The `struct` module also defines the following type:

```python
class struct.Struct(format)
```

Return a new Struct object which writes and reads binary data according to the format string `format`. Creating a Struct object once and calling its methods is more efficient than calling the `struct` functions with the same format since the format string only needs to be compiled once.

Compiled Struct objects support the following methods and attributes:

- **pack**($v_1, v_2, ...$)
  Idetical to the `pack()` function, using the compiled format. ($\text{len(result)}$ will equal $\text{self.size}$.)

- **pack_into**($buffer, offset, v_1, v_2, ...$)
  Identical to the `pack_into()` function, using the compiled format.

- **unpack**($buffer$)
  Identical to the `unpack()` function, using the compiled format. ($\text{len(buffer)}$ must equal $\text{self.size}$).

- **unpack_from**($buffer, offset=0$)
  Identical to the `unpack_from()` function, using the compiled format. ($\text{len(buffer[offset:])} \text{ must be at least } \text{self.size}$).
**iter_unpack**(buffer)

Identical to the **iter_unpack()** function, using the compiled format. *(len(buffer)) must be a multiple of self.size).

*New in version 3.4.*

**format**

The format string used to construct this Struct object.

**size**

The calculated size of the struct (and hence of the bytes object produced by the **pack()** method) corresponding to **format**.
7.2. **codecs** — Codec registry and base classes

This module defines base classes for standard Python codecs (encoders and decoders) and provides access to the internal Python codec registry which manages the codec and error handling lookup process.

It defines the following functions:

- `codecs.encode(obj, encoding='utf-8', errors='strict')`
  Encodes `obj` using the codec registered for `encoding`.

  *Errors* may be given to set the desired error handling scheme. The default error handler is *strict* meaning that encoding errors raise `ValueError` (or a more codec specific subclass, such as `UnicodeEncodeError`). Refer to *Codec Base Classes* for more information on codec error handling.

- `codecs.decode(obj, encoding='utf-8', errors='strict')`
  Decodes `obj` using the codec registered for `encoding`.

  *Errors* may be given to set the desired error handling scheme. The default error handler is *strict* meaning that decoding errors raise `ValueError` (or a more codec specific subclass, such as `UnicodeDecodeError`). Refer to *Codec Base Classes* for more information on codec error handling.

- `codecs.register(search_function)`
  Register a codec search function. Search functions are expected to
take one argument, the encoding name in all lower case letters, and return a CodecInfo object having the following attributes:

- **name** The name of the encoding;
- **encode** The stateless encoding function;
- **decode** The stateless decoding function;
- **incrementalencoder** An incremental encoder class or factory function;
- **incrementaldecoder** An incremental decoder class or factory function;
- **streamwriter** A stream writer class or factory function;
- **streamreader** A stream reader class or factory function.

The various functions or classes take the following arguments:

*encode* and *decode*: These must be functions or methods which have the same interface as the *encode()*/*decode()* methods of Codec instances (see *Codec Interface*). The functions/methods are expected to work in a stateless mode.

*incrementalencoder* and *incrementaldecoder*: These have to be factory functions providing the following interface:

```python
factory(errors='strict')
```

The factory functions must return objects providing the interfaces defined by the base classes *IncrementalEncoder* and *IncrementalDecoder*, respectively. Incremental codecs can maintain state.

*streamreader* and *streamwriter*: These have to be factory functions providing the following interface:

```python
factory(stream, errors='strict')
```
The factory functions must return objects providing the interfaces defined by the base classes `StreamReader` and `StreamWriter`, respectively. Stream codecs can maintain state.

Possible values for errors are

- `'strict'`: raise an exception in case of an encoding error
- `'replace'`: replace malformed data with a suitable replacement marker, such as `?` or `�`
- `'ignore'`: ignore malformed data and continue without further notice
- `'xmlcharrefreplace'`: replace with the appropriate XML character reference (for encoding only)
- `'backslashreplace'`: replace with backslashed escape sequences (for encoding only)
- `'surrogateescape'`: on decoding, replace with code points in the Unicode Private Use Area ranging from U+DC80 to U+DCFF. These private code points will then be turned back into the same bytes when the surrogateescape error handler is used when encoding the data. (See [PEP 383](https://www.python.org/dev/peps/pep-0383/) for more.)

as well as any other error handling name defined via `register_error()`.

In case a search function cannot find a given encoding, it should return `None`.

```python
codecs.lookup(encoding)
```

Looks up the codec info in the Python codec registry and returns a `CodecInfo` object as defined above.

Encodings are first looked up in the registry's cache. If not found, the list of registered search functions is scanned. If no `CodecInfo`
object is found, a **LookupError** is raised. Otherwise, the CodecInfo object is stored in the cache and returned to the caller.

To simplify access to the various codecs, the module provides these additional functions which use `lookup()` for the codec lookup:

```python
import codecs

# Get the codec for the given encoding and return its encoder function.
codecs.getencoder(encoding)
```

Look up the codec for the given encoding and return its encoder function.

Raises a **LookupError** in case the encoding cannot be found.

```python
# Get the codec for the given encoding and return its decoder function.
codecs.getdecoder(encoding)
```

Look up the codec for the given encoding and return its decoder function.

Raises a **LookupError** in case the encoding cannot be found.

```python
# Get the codec for the given encoding and return its incremental encoder class or factory function.
codecs.getincrementalencoder(encoding)
```

Look up the codec for the given encoding and return its incremental encoder class or factory function.

Raises a **LookupError** in case the encoding cannot be found or the codec doesn't support an incremental encoder.

```python
# Get the codec for the given encoding and return its incremental decoder class or factory function.
codecs.getincrementaldecoder(encoding)
```

Look up the codec for the given encoding and return its incremental decoder class or factory function.

Raises a **LookupError** in case the encoding cannot be found or the codec doesn't support an incremental decoder.

```python
# Get a reader for the given encoding.
codecs.getreader(encoding)
```
Look up the codec for the given encoding and return its StreamReader class or factory function.

Raises a LookupError in case the encoding cannot be found.

codecs.getwriter(encoding)

Look up the codec for the given encoding and return its StreamWriter class or factory function.

Raises a LookupError in case the encoding cannot be found.

codecs.register_error(name, error_handler)

Register the error handling function error_handler under the name name. error_handler will be called during encoding and decoding in case of an error, when name is specified as the errors parameter.

For encoding error_handler will be called with a UnicodeEncodeError instance, which contains information about the location of the error. The error handler must either raise this or a different exception or return a tuple with a replacement for the unencodable part of the input and a position where encoding should continue. The replacement may be either str or bytes. If the replacement is bytes, the encoder will simply copy them into the output buffer. If the replacement is a string, the encoder will encode the replacement. Encoding continues on original input at the specified position. Negative position values will be treated as being relative to the end of the input string. If the resulting position is out of bound an IndexError will be raised.

Decoding and translating works similar, except UnicodeDecodeError or UnicodeTranslateError will be passed to the handler and that the replacement from the error handler will be put into the output directly.
codecs.**lookup_error**(name)
Return the error handler previously registered under the name name.

Raises a LookupError in case the handler cannot be found.

codecs.**strict_errors**(exception)
Implements the strict error handling: each encoding or decoding error raises a UnicodeError.

codecs.**replace_errors**(exception)
Implements the replace error handling: malformed data is replaced with a suitable replacement character such as '?' in bytestrings and '�' in Unicode strings.

codecs.**ignore_errors**(exception)
Implements the ignore error handling: malformed data is ignored and encoding or decoding is continued without further notice.

codecs.**xmlcharrefreplace_errors**(exception)
Implements the xmlcharrefreplace error handling (for encoding only): the unencodable character is replaced by an appropriate XML character reference.

codecs.**backslashreplace_errors**(exception)
Implements the backslashreplace error handling (for encoding only): the unencodable character is replaced by a backslashed escape sequence.

To simplify working with encoded files or stream, the module also defines these utility functions:
codecs.open(filename, mode[, encoding[, errors[, buffering]]])

Open an encoded file using the given mode and return a wrapped version providing transparent encoding/decoding. The default file mode is 'r' meaning to open the file in read mode.

**Note:** The wrapped version’s methods will accept and return strings only. Bytes arguments will be rejected.

**Note:** Files are always opened in binary mode, even if no binary mode was specified. This is done to avoid data loss due to encodings using 8-bit values. This means that no automatic conversion of b'\n' is done on reading and writing.

*encoding* specifies the encoding which is to be used for the file.

*errors* may be given to define the error handling. It defaults to 'strict' which causes a `ValueError` to be raised in case an encoding error occurs.

*buffering* has the same meaning as for the built-in open() function. It defaults to line buffered.

codecs.EncodedFile(file, data_encoding, file_encoding=None, errors='strict')

Return a wrapped version of file which provides transparent encoding translation.

Bytes written to the wrapped file are interpreted according to the given *data_encoding* and then written to the original file as bytes using the *file_encoding*.

If *file_encoding* is not given, it defaults to *data_encoding*. 
errors may be given to define the error handling. It defaults to 'strict', which causes ValueError to be raised in case an encoding error occurs.

codecs.iterencode(iterator, encoding, errors='strict', **kwargs)
Uses an incremental encoder to iteratively encode the input provided by iterator. This function is a generator. errors (as well as any other keyword argument) is passed through to the incremental encoder.

codecs.iterdecode(iterator, encoding, errors='strict', **kwargs)
Uses an incremental decoder to iteratively decode the input provided by iterator. This function is a generator. errors (as well as any other keyword argument) is passed through to the incremental decoder.

The module also provides the following constants which are useful for reading and writing to platform dependent files:

codecs.BOM
codecs.BOM_BE
codecs.BOM_LE
codecs.BOM_UTF8
codecs.BOM_UTF16
codecs.BOM_UTF16_BE
codecs.BOM_UTF16_LE
codecs.BOM_UTF32
codecs.BOM_UTF32_BE
codecs.BOM_UTF32_LE

These constants define various encodings of the Unicode byte order mark (BOM) used in UTF-16 and UTF-32 data streams to indicate the byte order used in the stream or file and in UTF-8 as a Unicode signature. BOM_UTF16 is either BOM_UTF16_BE or
BOM_UTF16_LE depending on the platform’s native byte order, BOM is an alias for BOM_UTF16, BOM_LE for BOM_UTF16_LE and BOM_BE for BOM_UTF16_BE. The others represent the BOM in UTF-8 and UTF-32 encodings.
7.2.1. Codec Base Classes

The `codecs` module defines a set of base classes which define the interface and can also be used to easily write your own codecs for use in Python.

Each codec has to define four interfaces to make it usable as codec in Python: stateless encoder, stateless decoder, stream reader and stream writer. The stream reader and writers typically reuse the stateless encoder/decoder to implement the file protocols.

The `Codec` class defines the interface for stateless encoders/decoders.

To simplify and standardize error handling, the `encode()` and `decode()` methods may implement different error handling schemes by providing the `errors` string argument. The following string values are defined and implemented by all standard Python codecs:

<table>
<thead>
<tr>
<th>Value</th>
<th>Meaning</th>
</tr>
</thead>
<tbody>
<tr>
<td>'strict'</td>
<td>Raise <code>UnicodeError</code> (or a subclass); this is the default.</td>
</tr>
<tr>
<td>'ignore'</td>
<td>Ignore the character and continue with the next.</td>
</tr>
<tr>
<td>'replace'</td>
<td>Replace with a suitable replacement character; Python will use the official U+FFFD REPLACEMENT CHARACTER for the built-in Unicode codecs on decoding and ‘?’ on encoding.</td>
</tr>
<tr>
<td>'xmlcharrefreplace'</td>
<td>Replace with the appropriate XML character reference (only for encoding).</td>
</tr>
</tbody>
</table>
'backslashreplace' | Replace with backslashed escape sequences (only for encoding).

'surrogateescape' | Replace byte with surrogate U+DCxx, as defined in PEP 383.

In addition, the following error handlers are specific to Unicode encoding schemes:

<table>
<thead>
<tr>
<th>Value</th>
<th>Codec</th>
<th>Meaning</th>
</tr>
</thead>
<tbody>
<tr>
<td>'surrogatepass'</td>
<td>utf-8, utf-16, utf-32, utf-16-be, utf-16-le, utf-32-be, utf-32-le</td>
<td>Allow encoding and decoding of surrogate codes in all the Unicode encoding schemes.</td>
</tr>
</tbody>
</table>

New in version 3.1: The 'surrogateescape' and 'surrogatepass' error handlers.

Changed in version 3.4: The 'surrogatepass' error handlers now works with utf-16* and utf-32* codecs.

The set of allowed values can be extended via register_error().

7.2.1.1. Codec Objects

The Codec class defines these methods which also define the function interfaces of the stateless encoder and decoder:

```
Codec.encode(input[, errors])
```

Encodes the object `input` and returns a tuple (output object, length consumed). Encoding converts a string object to a bytes object using a particular character set encoding (e.g., `cp1252` or `iso-`
errors defines the error handling to apply. It defaults to 'strict' handling.

The method may not store state in the Codec instance. Use StreamCodec for codecs which have to keep state in order to make encoding/decoding efficient.

The encoder must be able to handle zero length input and return an empty object of the output object type in this situation.

Codec. decode(input[, errors])
Decodes the object input and returns a tuple (output object, length consumed). Decoding converts a bytes object encoded using a particular character set encoding to a string object.

input must be a bytes object or one which provides the read-only character buffer interface – for example, buffer objects and memory mapped files.

errors defines the error handling to apply. It defaults to 'strict' handling.

The method may not store state in the Codec instance. Use StreamCodec for codecs which have to keep state in order to make encoding/decoding efficient.

The decoder must be able to handle zero length input and return an empty object of the output object type in this situation.

The IncrementalEncoder and IncrementalDecoder classes provide the basic interface for incremental encoding and decoding.
Encoding/decoding the input isn’t done with one call to the stateless encoder/decoder function, but with multiple calls to the `encode()`/`decode()` method of the incremental encoder/decoder. The incremental encoder/decoder keeps track of the encoding/decoding process during method calls.

The joined output of calls to the `encode()`/`decode()` method is the same as if all the single inputs were joined into one, and this input was encoded/decoded with the stateless encoder/decoder.

### 7.2.1.2. IncrementalEncoder Objects

The `IncrementalEncoder` class is used for encoding an input in multiple steps. It defines the following methods which every incremental encoder must define in order to be compatible with the Python codec registry.

```python
class codecs.IncrementalEncoder([errors])
```

Constructor for an `IncrementalEncoder` instance.

All incremental encoders must provide this constructor interface. They are free to add additional keyword arguments, but only the ones defined here are used by the Python codec registry.

The `IncrementalEncoder` may implement different error handling schemes by providing the `errors` keyword argument. These parameters are predefined:

- `'strict'` Raise `ValueError` (or a subclass); this is the default.
- `'ignore'` Ignore the character and continue with the next.
- `'replace'` Replace with a suitable replacement character
The `errors` argument will be assigned to an attribute of the same name. Assigning to this attribute makes it possible to switch between different error handling strategies during the lifetime of the IncrementalEncoder object.

The set of allowed values for the `errors` argument can be extended with `register_error()`.

**encode(object[, final])**

Encodes `object` (taking the current state of the encoder into account) and returns the resulting encoded object. If this is the last call to `encode()` `final` must be true (the default is false).

**reset()**

Reset the encoder to the initial state. The output is discarded: call `encode('', final=True)` to reset the encoder and to get the output.

**IncrementalEncoder.getstate()**

Return the current state of the encoder which must be an integer. The implementation should make sure that 0 is the most common state. (States that are more complicated than integers can be converted into an integer by marshaling/pickling the state and encoding the bytes of the resulting string into an integer).

**IncrementalEncoder.setstate(state)**

Set the state of the encoder to `state`. `state` must be an encoder state returned by `getstate()`.

- `'xmlcharrefreplace'` Replace with the appropriate XML character reference
- `'backslashreplace'` Replace with backslashed escape sequences.
7.2.1.3. IncrementalDecoder Objects

The IncrementalDecoder class is used for decoding an input in multiple steps. It defines the following methods which every incremental decoder must define in order to be compatible with the Python codec registry.

```python
class codecs.IncrementalDecoder([errors])
    Constructor for an IncrementalDecoder instance.
```

All incremental decoders must provide this constructor interface. They are free to add additional keyword arguments, but only the ones defined here are used by the Python codec registry.

The IncrementalDecoder may implement different error handling schemes by providing the `errors` keyword argument. These parameters are predefined:

- `'strict'` Raise `ValueError` (or a subclass); this is the default.
- `'ignore'` Ignore the character and continue with the next.
- `'replace'` Replace with a suitable replacement character.

The `errors` argument will be assigned to an attribute of the same name. Assigning to this attribute makes it possible to switch between different error handling strategies during the lifetime of the IncrementalDecoder object.

The set of allowed values for the `errors` argument can be extended with `register_error()`.

```python
decode(object[, final])
    Decodes `object` (taking the current state of the decoder into
account) and returns the resulting decoded object. If this is the last call to `decode()` `final` must be true (the default is false). If `final` is true the decoder must decode the input completely and must flush all buffers. If this isn't possible (e.g. because of incomplete byte sequences at the end of the input) it must initiate error handling just like in the stateless case (which might raise an exception).

**reset()**
Reset the decoder to the initial state.

**getstate()**
Return the current state of the decoder. This must be a tuple with two items, the first must be the buffer containing the still undecoded input. The second must be an integer and can be additional state info. (The implementation should make sure that 0 is the most common additional state info.) If this additional state info is 0 it must be possible to set the decoder to the state which has no input buffered and 0 as the additional state info, so that feeding the previously buffered input to the decoder returns it to the previous state without producing any output. (Additional state info that is more complicated than integers can be converted into an integer by marshaling/pickling the info and encoding the bytes of the resulting string into an integer.)

**setState(state)**
Set the state of the encoder to `state`. `state` must be a decoder state returned by `getstate()`.

The `StreamWriter` and `StreamReader` classes provide generic working interfaces which can be used to implement new encoding
submodules very easily. See encodings.utf_8 for an example of how this is done.

7.2.1.4. StreamWriter Objects

The StreamWriter class is a subclass of Codec and defines the following methods which every stream writer must define in order to be compatible with the Python codec registry.

class codecs.StreamWriter(stream[, errors])

Constructor for a StreamWriter instance.

All stream writers must provide this constructor interface. They are free to add additional keyword arguments, but only the ones defined here are used by the Python codec registry.

stream must be a file-like object open for writing binary data.

The StreamWriter may implement different error handling schemes by providing the errors keyword argument. These parameters are predefined:

- 'strict' Raise ValueError (or a subclass); this is the default.
- 'ignore' Ignore the character and continue with the next.
- 'replace' Replace with a suitable replacement character
- 'xmlcharrefreplace' Replace with the appropriate XML character reference
- 'backslashreplace' Replace with backslashed escape sequences.

The errors argument will be assigned to an attribute of the same name. Assigning to this attribute makes it possible to switch
between different error handling strategies during the lifetime of the StreamWriter object.

The set of allowed values for the errors argument can be extended with `register_error()`.

```python
write(object)

Writes the object's contents encoded to the stream.
```

```python
writelines(list)

Writes the concatenated list of strings to the stream (possibly by reusing the `write()` method).
```

```python
reset()

Flushes and resets the codec buffers used for keeping state.

Calling this method should ensure that the data on the output is put into a clean state that allows appending of new fresh data without having to rescan the whole stream to recover state.
```

In addition to the above methods, the StreamWriter must also inherit all other methods and attributes from the underlying stream.

### 7.2.1.5. StreamReader Objects

The StreamReader class is a subclass of Codec and defines the following methods which every stream reader must define in order to be compatible with the Python codec registry.

```python
class codecs.StreamReader(stream[, errors])

Constructor for a StreamReader instance.
```

All stream readers must provide this constructor interface. They are
free to add additional keyword arguments, but only the ones defined here are used by the Python codec registry.

*stream* must be a file-like object open for reading (binary) data.

The **StreamReader** may implement different error handling schemes by providing the *errors* keyword argument. These parameters are defined:

- **'strict'** Raise **ValueError** (or a subclass); this is the default.
- **'ignore'** Ignore the character and continue with the next.
- **'replace'** Replace with a suitable replacement character.

The *errors* argument will be assigned to an attribute of the same name. Assigning to this attribute makes it possible to switch between different error handling strategies during the lifetime of the **StreamReader** object.

The set of allowed values for the *errors* argument can be extended with **register_error()**.

### **read([size[, chars[, firstline]]])**
Decodes data from the stream and returns the resulting object.

*chars* indicates the number of characters to read from the stream. **read()** will never return more than *chars* characters, but it might return less, if there are not enough characters available.

*size* indicates the approximate maximum number of bytes to read from the stream for decoding purposes. The decoder can modify this setting as appropriate. The default value -1 indicates to read and decode as much as possible. *size* is intended to
prevent having to decode huge files in one step.

*firstline* indicates that it would be sufficient to only return the first line, if there are decoding errors on later lines.

The method should use a greedy read strategy meaning that it should read as much data as is allowed within the definition of the encoding and the given size, e.g. if optional encoding endings or state markers are available on the stream, these should be read too.

**readline**([*size*, *keepends*])
Read one line from the input stream and return the decoded data.

*size*, if given, is passed as size argument to the stream's `read()` method.

If *keepends* is false line-endings will be stripped from the lines returned.

**readlines**([*sizehint*, *keepends*])
Read all lines available on the input stream and return them as a list of lines.

Line-endings are implemented using the codec's decoder method and are included in the list entries if *keepends* is true.

*sizehint*, if given, is passed as the *size* argument to the stream's `read()` method.

**reset**()
Resets the codec buffers used for keeping state.
Note that no stream repositioning should take place. This method is primarily intended to be able to recover from decoding errors.

In addition to the above methods, the `StreamReader` must also inherit all other methods and attributes from the underlying stream.

The next two base classes are included for convenience. They are not needed by the codec registry, but may provide useful in practice.

### 7.2.1.6. StreamReaderWriter Objects

The `StreamReaderWriter` allows wrapping streams which work in both read and write modes.

The design is such that one can use the factory functions returned by the `lookup()` function to construct the instance.

```python
class codecs.StreamReaderWriter(stream, Reader, Writer, errors)
```

Creates a `StreamReaderWriter` instance. `stream` must be a file-like object. `Reader` and `Writer` must be factory functions or classes providing the `StreamReader` and `StreamWriter` interface resp. Error handling is done in the same way as defined for the stream readers and writers.

`StreamReaderWriter` instances define the combined interfaces of `StreamReader` and `StreamWriter` classes. They inherit all other methods and attributes from the underlying stream.

### 7.2.1.7. StreamRecoder Objects
The **StreamRecoder** provide a frontend - backend view of encoding data which is sometimes useful when dealing with different encoding environments.

The design is such that one can use the factory functions returned by the `lookup()` function to construct the instance.

```python
class codecs.StreamRecoder(stream, encode, decode, Reader, Writer, errors):
    Creates a StreamRecoder instance which implements a two-way conversion: `encode` and `decode` work on the frontend (the input to `read()` and output of `write()`) while `Reader` and `Writer` work on the backend (reading and writing to the stream).

    You can use these objects to do transparent direct recodings from e.g. Latin-1 to UTF-8 and back.

    `stream` must be a file-like object.

    `encode`, `decode` must adhere to the Codec interface. `Reader`, `Writer` must be factory functions or classes providing objects of the `StreamReader` and `StreamWriter` interface respectively.

    `encode` and `decode` are needed for the frontend translation, `Reader` and `Writer` for the backend translation.

    Error handling is done in the same way as defined for the stream readers and writers.

    StreamRecoder instances define the combined interfaces of `StreamReader` and `StreamWriter` classes. They inherit all other methods and attributes from the underlying stream.
```
7.2.2. Encodings and Unicode

Strings are stored internally as sequences of codepoints in range $0 - 10FFFF$ (see PEP 393 for more details about the implementation). Once a string object is used outside of CPU and memory, CPU endianness and how these arrays are stored as bytes become an issue. Transforming a string object into a sequence of bytes is called encoding and recreating the string object from the sequence of bytes is known as decoding. There are many different methods for how this transformation can be done (these methods are also called encodings). The simplest method is to map the codepoints 0-255 to the bytes $0x0 - 0xff$. This means that a string object that contains codepoints above $U+00FF$ can’t be encoded with this method (which is called 'latin-1' or 'iso-8859-1'). `str.encode()` will raise a `UnicodeEncodeError` that looks like this: `UnicodeEncodeError: latin-1 codec can't encode character '\u1234' in position 3: ordinal not in range(256).

There’s another group of encodings (the so called charmap encodings) that choose a different subset of all Unicode code points and how these codepoints are mapped to the bytes $0x0 - 0xff$. To see how this is done simply open e.g. `encodings/cp1252.py` (which is an encoding that is used primarily on Windows). There’s a string constant with 256 characters that shows you which character is mapped to which byte value.

All of these encodings can only encode 256 of the 1114112 codepoints defined in Unicode. A simple and straightforward way that can store each Unicode code point, is to store each codepoint as four consecutive bytes. There are two possibilities: store the bytes in big endian or in little endian order. These two encodings are called UTF-
32-BE and UTF-32-LE respectively. Their disadvantage is that if e.g. you use UTF-32-BE on a little endian machine you will always have to swap bytes on encoding and decoding. UTF-32 avoids this problem: bytes will always be in natural endianness. When these bytes are read by a CPU with a different endianness, then bytes have to be swapped though. To be able to detect the endianness of a UTF-16 or UTF-32 byte sequence, there's the so called BOM ("Byte Order Mark"). This is the Unicode character U+FEFF. This character can be prepended to every UTF-16 or UTF-32 byte sequence. The byte swapped version of this character (0xFFFE) is an illegal character that may not appear in a Unicode text. So when the first character in an UTF-16 or UTF-32 byte sequence appears to be a U+FFFE the bytes have to be swapped on decoding. Unfortunately the character U+FEFF had a second purpose as a ZERO WIDTH NO-BREAK SPACE: a character that has no width and doesn't allow a word to be split. It can e.g. be used to give hints to a ligature algorithm. With Unicode 4.0 using U+FEFF as a ZERO WIDTH NO-BREAK SPACE has been deprecated (with U+2060 (WORD JOINER) assuming this role). Nevertheless Unicode software still must be able to handle U+FEFF in both roles: as a BOM it's a device to determine the storage layout of the encoded bytes, and vanishes once the byte sequence has been decoded into a string; as a ZERO WIDTH NO-BREAK SPACE it's a normal character that will be decoded like any other.

There's another encoding that is able to encoding the full range of Unicode characters: UTF-8. UTF-8 is an 8-bit encoding, which means there are no issues with byte order in UTF-8. Each byte in a UTF-8 byte sequence consists of two parts: marker bits (the most significant bits) and payload bits. The marker bits are a sequence of zero to four 1 bits followed by a 0 bit. Unicode characters are encoded like this (with x being payload bits, which when concatenated give the Unicode
The least significant bit of the Unicode character is the rightmost x bit.

As UTF-8 is an 8-bit encoding no BOM is required and any U+FEFF character in the decoded string (even if it's the first character) is treated as a **ZERO WIDTH NO-BREAK SPACE**.

Without external information it's impossible to reliably determine which encoding was used for encoding a string. Each charmap encoding can decode any random byte sequence. However that's not possible with UTF-8, as UTF-8 byte sequences have a structure that doesn't allow arbitrary byte sequences. To increase the reliability with which a UTF-8 encoding can be detected, Microsoft invented a variant of UTF-8 (that Python 2.5 calls "utf-8-sig") for its Notepad program: Before any of the Unicode characters is written to the file, a UTF-8 encoded BOM (which looks like this as a byte sequence: 0xef, 0xbb, 0xbf) is written. As it's rather improbable that any charmap encoded file starts with these byte values (which would e.g. map to

LATIN SMALL LETTER I WITH DIAERESIS
RIGHT-POINTING DOUBLE ANGLE QUOTATION MARK
in iso-8859-1), this increases the probability that a utf-8-sig encoding can be correctly guessed from the byte sequence. So here the BOM is not used to be able to determine the byte order used for generating the byte sequence, but as a signature that helps in guessing the encoding. On encoding the utf-8-sig codec will write 0xef, 0xbb, 0xbf as the first three bytes to the file. On decoding utf-8-sig will skip those three bytes if they appear as the first three bytes in the file. In UTF-8, the use of the BOM is discouraged and should generally be avoided.
7.2.3. Standard Encodings

Python comes with a number of codecs built-in, either implemented as C functions or with dictionaries as mapping tables. The following table lists the codecs by name, together with a few common aliases, and the languages for which the encoding is likely used. Neither the list of aliases nor the list of languages is meant to be exhaustive. Notice that spelling alternatives that only differ in case or use a hyphen instead of an underscore are also valid aliases; therefore, e.g. 'utf-8' is a valid alias for the 'utf_8' codec.

<table>
<thead>
<tr>
<th>Codec</th>
<th>Aliases</th>
<th>Languages</th>
</tr>
</thead>
<tbody>
<tr>
<td>an ISO 8859 codeset</td>
<td></td>
<td></td>
</tr>
<tr>
<td>a Microsoft Windows code page, which is typically derived from a 8859 codeset, but replaces control characters with additional graphic characters</td>
<td></td>
<td></td>
</tr>
<tr>
<td>an IBM EBCDIC code page</td>
<td></td>
<td></td>
</tr>
<tr>
<td>an IBM PC code page, which is ASCII compatible</td>
<td></td>
<td></td>
</tr>
</tbody>
</table>

CPython implementation detail: Some common encodings can bypass the codecs lookup machinery to improve performance. These optimization opportunities are only recognized by CPython for a limited set of aliases: utf-8, utf8, latin-1, latin1, iso-8859-1, mbc (Windows only), ascii, utf-16, and utf-32. Using alternative spellings for these encodings may result in slower execution.

Many of the character sets support the same languages. They vary in individual characters (e.g. whether the EURO SIGN is supported or not), and in the assignment of characters to code positions. For the European languages in particular, the following variants typically exist:

*Changed in version 3.4:* The utf-16* and utf-32* encoders no longer allow surrogate code points (U+D800–U+DFFF) to be encoded. The utf-32* decoders no longer decode byte sequences that correspond to surrogate code points.
7.2.4. Python Specific Encodings

A number of predefined codecs are specific to Python, so their codec names have no meaning outside Python. These are listed in the tables below based on the expected input and output types (note that while text encodings are the most common use case for codecs, the underlying codec infrastructure supports arbitrary data transforms rather than just text encodings). For asymmetric codecs, the stated purpose describes the encoding direction.

7.2.4.1. Text Encodings

The following codecs provide `str` to `bytes` encoding and `bytes-like object` to `str` decoding, similar to the Unicode text encodings.

<table>
<thead>
<tr>
<th>Codec</th>
<th>Aliases</th>
<th>Purpose</th>
</tr>
</thead>

</tbody>
</table>

In addition to `bytes-like objects`, 'base64_codec' also accepts ASCII-only instances of `str` for decoding.

**New in version 3.2:** Restoration of the binary transforms.

**Changed in version 3.4:** Restoration of the aliases for the binary transforms.

### 7.2.4.3. Text Transforms

The following codec provides a text transform: a `str` to `str` mapping.
<table>
<thead>
<tr>
<th>Codec</th>
<th>Aliases</th>
<th>Purpose</th>
</tr>
</thead>
<tbody>
<tr>
<td>rot_13</td>
<td>rot13</td>
<td>Returns the Caesar-cypher encryption of the operand</td>
</tr>
</tbody>
</table>

*New in version 3.2:* Restoration of the `rot_13` text transform.

*Changed in version 3.4:* Restoration of the `rot13` alias.
7.2.5. **encodings.idna — Internationalized Domain Names in Applications**

This module implements **RFC 3490** (Internationalized Domain Names in Applications) and **RFC 3492** (Nameprep: A Stringprep Profile for Internationalized Domain Names (IDN)). It builds upon the `punycode` encoding and `stringprep`.

These RFCs together define a protocol to support non-ASCII characters in domain names. A domain name containing non-ASCII characters (such as `www.Alliancefrançaise.nu`) is converted into an ASCII-compatible encoding (ACE, such as `www.xn--alliancefranaise-npb.nu`). The ACE form of the domain name is then used in all places where arbitrary characters are not allowed by the protocol, such as DNS queries, HTTP Host fields, and so on. This conversion is carried out in the application; if possible invisible to the user: The application should transparently convert Unicode domain labels to IDNA on the wire, and convert back ACE labels to Unicode before presenting them to the user.

Python supports this conversion in several ways: the `idna` codec performs conversion between Unicode and ACE, separating an input string into labels based on the separator characters defined in section 3.1 (1) of **RFC 3490** and converting each label to ACE as required, and conversely separating an input byte string into labels based on the . separator and converting any ACE labels found into unicode. Furthermore, the `socket` module transparently converts Unicode host names to ACE, so that applications need not be concerned about converting host names themselves when they pass them to the socket.
module. On top of that, modules that have host names as function parameters, such as `http.client` and `ftplib`, accept Unicode host names (`http.client` then also transparently sends an IDNA hostname in the `Host` field if it sends that field at all).

When receiving host names from the wire (such as in reverse name lookup), no automatic conversion to Unicode is performed: Applications wishing to present such host names to the user should decode them to Unicode.

The module `encodings.idna` also implements the nameprep procedure, which performs certain normalizations on host names, to achieve case-insensitivity of international domain names, and to unify similar characters. The nameprep functions can be used directly if desired.

`encodings.idna.nameprep(label)`

Return the nameprepped version of `label`. The implementation currently assumes query strings, so `AllowUnassigned` is true.

`encodings.idna.ToASCII(label)`

Convert a label to ASCII, as specified in RFC 3490. `UseSTD3ASCIIRules` is assumed to be false.

`encodings.idna.ToUnicode(label)`

Convert a label to Unicode, as specified in RFC 3490.
7.2.6. **encodings.mbc** — Windows ANSI codepage

Encode operand according to the ANSI codepage (CP_ACP).

Availability: Windows only.

*Changed in version 3.3:* Support any error handler.

*Changed in version 3.2:* Before 3.2, the *errors* argument was ignored; 'replace' was always used to encode, and 'ignore' to decode.
7.2.7. **encodings.utf_8_sig — UTF-8 codec with BOM signature**

This module implements a variant of the UTF-8 codec: On encoding a UTF-8 encoded BOM will be prepended to the UTF-8 encoded bytes. For the stateful encoder this is only done once (on the first write to the byte stream). For decoding an optional UTF-8 encoded BOM at the start of the data will be skipped.
8. Data Types

The modules described in this chapter provide a variety of specialized data types such as dates and times, fixed-type arrays, heap queues, synchronized queues, and sets.

Python also provides some built-in data types, in particular, `dict`, `list`, `set` and `frozenset`, and `tuple`. The `str` class is used to hold Unicode strings, and the `bytes` class is used to hold binary data.

The following modules are documented in this chapter:

- **8.1. datetime — Basic date and time types**
  - 8.1.1. Available Types
  - 8.1.2. timedelta Objects
  - 8.1.3. date Objects
  - 8.1.4. datetime Objects
  - 8.1.5. time Objects
  - 8.1.6. tzinfo Objects
  - 8.1.7. timezone Objects
  - 8.1.8. strftime() and strptime() Behavior
- **8.2. calendar — General calendar-related functions**
- **8.3. collections — Container datatypes**
  - 8.3.1. ChainMap objects
    - 8.3.1.1. ChainMap Examples and Recipes
  - 8.3.2. Counter objects
  - 8.3.3. deque objects
    - 8.3.3.1. deque Recipes
  - 8.3.4. defaultdict objects
    - 8.3.4.1. defaultdict Examples
  - 8.3.5. namedtuple() Factory Function for Tuples with
Named Fields
- 8.3.6. OrderedDict objects
  - 8.3.6.1. OrderedDict Examples and Recipes
- 8.3.7. UserDict objects
- 8.3.8. UserList objects
- 8.3.9. UserString objects
- 8.4. collections.abc — Abstract Base Classes for Containers
  - 8.4.1. Collections Abstract Base Classes
- 8.5. heapq — Heap queue algorithm
  - 8.5.1. Basic Examples
  - 8.5.2. Priority Queue Implementation Notes
  - 8.5.3. Theory
- 8.6. bisect — Array bisection algorithm
  - 8.6.1. Searching Sorted Lists
  - 8.6.2. Other Examples
- 8.7. array — Efficient arrays of numeric values
- 8.8. weakref — Weak references
  - 8.8.1. Weak Reference Objects
  - 8.8.2. Example
  - 8.8.3. Finalizer Objects
  - 8.8.4. Comparing finalizers with __del__() methods
- 8.9. types — Dynamic type creation and names for built-in types
  - 8.9.1. Dynamic Type Creation
  - 8.9.2. Standard Interpreter Types
  - 8.9.3. Additional Utility Classes and Functions
- 8.10. copy — Shallow and deep copy operations
- 8.11. pprint — Data pretty printer
  - 8.11.1. PrettyPrinter Objects
  - 8.11.2. Example
- 8.12. reprlib — Alternate repr() implementation
  - 8.12.1. Repr Objects
  - 8.12.2. Subclassing Repr Objects
- 8.13. enum — Support for enumerations
8.13.1. Module Contents
8.13.2. Creating an Enum
8.13.3. Programmatic access to enumeration members and their attributes
8.13.4. Duplicating enum members and values
8.13.5. Ensuring unique enumeration values
8.13.6. Iteration
8.13.7. Comparisons
8.13.8. Allowed members and attributes of enumerations
8.13.9. Restricted subclassing of enumerations
8.13.10. Pickling
8.13.11. Functional API
8.13.12. Derived Enumerations
   8.13.12.1. IntEnum
   8.13.12.2. Others
8.13.13. Interesting examples
   8.13.13.1. AutoNumber
   8.13.13.2. OrderedEnum
   8.13.13.3. DuplicateFreeEnum
   8.13.13.4. Planet
8.13.14. How are Enums different?
   8.13.14.2. Enum Members (aka instances)
   8.13.14.3. Finer Points
8.1. `datetime` — Basic date and time types

The `datetime` module supplies classes for manipulating dates and times in both simple and complex ways. While date and time arithmetic is supported, the focus of the implementation is on efficient attribute extraction for output formatting and manipulation. For related functionality, see also the `time` and `calendar` modules.

There are two kinds of date and time objects: “naive” and “aware”.

An aware object has sufficient knowledge of applicable algorithmic and political time adjustments, such as time zone and daylight saving time information, to locate itself relative to other aware objects. An aware object is used to represent a specific moment in time that is not open to interpretation [1].

A naive object does not contain enough information to unambiguously locate itself relative to other date/time objects. Whether a naive object represents Coordinated Universal Time (UTC), local time, or time in some other timezone is purely up to the program, just like it is up to the program whether a particular number represents metres, miles, or mass. Naive objects are easy to understand and to work with, at the cost of ignoring some aspects of reality.

For applications requiring aware objects, `datetime` and `time` objects have an optional time zone information attribute, `tzinfo`, that can be set to an instance of a subclass of the abstract `tzinfo` class. These `tzinfo` objects capture information about the offset from UTC time, the time zone name, and whether Daylight Saving Time is in effect.
Note that only one concrete `tzinfo` class, the `timezone` class, is supplied by the `datetime` module. The `timezone` class can represent simple timezones with fixed offset from UTC, such as UTC itself or North American EST and EDT timezones. Supporting timezones at deeper levels of detail is up to the application. The rules for time adjustment across the world are more political than rational, change frequently, and there is no standard suitable for every application aside from UTC.

The `datetime` module exports the following constants:

```python
datetime.MINYEAR

The smallest year number allowed in a `date` or `datetime` object. `MINYEAR` is 1.

datetime.MAXYEAR

The largest year number allowed in a `date` or `datetime` object. `MAXYEAR` is 9999.
```

See also:

**Module** `calendar`

General calendar related functions.

**Module** `time`

Time access and conversions.
8.1.1. Available Types

class datetime.date
An idealized naive date, assuming the current Gregorian calendar always was, and always will be, in effect. Attributes: year, month, and day.

class datetime.time
An idealized time, independent of any particular day, assuming that every day has exactly 24*60*60 seconds (there is no notion of “leap seconds” here). Attributes: hour, minute, second, microsecond, and tzinfo.

class datetime.datetime
A combination of a date and a time. Attributes: year, month, day, hour, minute, second, microsecond, and tzinfo.

class datetime.timedelta
A duration expressing the difference between two date, time, or datetime instances to microsecond resolution.

class datetime.tzinfo
An abstract base class for time zone information objects. These are used by the datetime and time classes to provide a customizable notion of time adjustment (for example, to account for time zone and/or daylight saving time).

class datetime.timezone
A class that implements the tzinfo abstract base class as a fixed offset from the UTC.
New in version 3.2.

Objects of these types are immutable.

Objects of the **date** type are always naive.

An object of type **time** or **datetime** may be naive or aware. A **datetime** object \( d \) is aware if \( d.tzinfo \) is not \( \text{None} \) and \( d.tzinfo.utcoffset(d) \) does not return \( \text{None} \). If \( d.tzinfo \) is \( \text{None} \), or if \( d.tzinfo \) is not \( \text{None} \) but \( d.tzinfo.utcoffset(d) \) returns \( \text{None} \), \( d \) is naive. A **time** object \( t \) is aware if \( t.tzinfo \) is not \( \text{None} \) and \( t.tzinfo.utcoffset(\text{None}) \) does not return \( \text{None} \). Otherwise, \( t \) is naive.

The distinction between naive and aware doesn't apply to **timedelta** objects.

Subclass relationships:

```
object
timedelta
tzinfo
timezone
time
date
datetime
```
8.1.2. `timedelta` Objects

A `timedelta` object represents a duration, the difference between two dates or times.

```python
class datetime.timedelta(days=0, seconds=0, microseconds=0, milliseconds=0, minutes=0, hours=0, weeks=0)
```

All arguments are optional and default to 0. Arguments may be integers or floats, and may be positive or negative.

Only `days`, `seconds` and `microseconds` are stored internally. Arguments are converted to those units:

- A millisecond is converted to 1000 microseconds.
- A minute is converted to 60 seconds.
- An hour is converted to 3600 seconds.
- A week is converted to 7 days.

and `days`, `seconds` and `microseconds` are then normalized so that the representation is unique, with

- \(0 \leq \text{microseconds} < 1000000\)
- \(0 \leq \text{seconds} < 3600 \times 24\) (the number of seconds in one day)
- \(-999999999 \leq \text{days} \leq 999999999\)

If any argument is a float and there are fractional microseconds, the fractional microseconds left over from all arguments are combined and their sum is rounded to the nearest microsecond using round-half-to-even tiebreaker. If no argument is a float, the conversion and normalization processes are exact (no information is lost).

If the normalized value of `days` lies outside the indicated range,
OverflowError is raised.

Note that normalization of negative values may be surprising at first. For example,

```python
>>> from datetime import timedelta
>>> d = timedelta(microseconds=-1)
>>> (d.days, d.seconds, d.microseconds)
(-1, 86399, 999999)
```

Class attributes are:

`timedelta.min`

The most negative `timedelta` object, `timedelta(-999999999)`.

`timedelta.max`

The most positive `timedelta` object, `timedelta(days=999999999, hours=23, minutes=59, seconds=59, microseconds=999999)`.

`timedelta.resolution`

The smallest possible difference between non-equal `timedelta` objects, `timedelta(microseconds=1)`.

Note that, because of normalization, `timedelta.max > -timedelta.min`. `-timedelta.max` is not representable as a `timedelta` object.

Instance attributes (read-only):

<table>
<thead>
<tr>
<th>Attribute</th>
<th>Value</th>
</tr>
</thead>
<tbody>
<tr>
<td>Between -999999999 and 999999999</td>
<td></td>
</tr>
</tbody>
</table>
Supported operations:

<table>
<thead>
<tr>
<th>Operation</th>
<th>Result</th>
</tr>
</thead>
<tbody>
<tr>
<td>( t1 = t2 + t3 )</td>
<td>Sum of ( t2 ) and ( t3 ). Afterwards ( t1-t2 == t3 ) and ( t1-t3 == t2 ) are true. (1)</td>
</tr>
<tr>
<td>( t1 = t2 - t3 )</td>
<td>Difference of ( t2 ) and ( t3 ). Afterwards ( t1 == t2 - t3 ) and ( t2 == t1 + t3 ) are true. (1)</td>
</tr>
<tr>
<td>( t1 = t2 \times i ) or ( t1 = i \times t2 )</td>
<td>Delta multiplied by an integer. Afterwards ( t1 // i == t2 ) is true, provided ( i \neq 0 ).</td>
</tr>
<tr>
<td>( t1 = t2 \times f ) or ( t1 = f \times t2 )</td>
<td>Delta multiplied by a float. The result is rounded to the nearest multiple of \texttt{timedelta.resolution} using round-half-to-even.</td>
</tr>
<tr>
<td>( f = t2 / t3 )</td>
<td>Division (3) of ( t2 ) by ( t3 ). Returns a \texttt{float} object.</td>
</tr>
<tr>
<td>( t1 = t2 / f ) or ( t1 = t2 / i )</td>
<td>Delta divided by a float or an int. The result is rounded to the nearest multiple of \texttt{timedelta.resolution} using round-half-to-even.</td>
</tr>
<tr>
<td>( t1 = t2 // i ) or ( t1 = t2 // t3 )</td>
<td>The floor is computed and the remainder (if any) is thrown away. In the second case, an integer is returned. (3)</td>
</tr>
<tr>
<td></td>
<td>The remainder is computed as a</td>
</tr>
</tbody>
</table>
\[ t_1 = t_2 \% t_3 \]

\begin{tabular}{|l|p{0.7\textwidth}|}
\hline
\texttt{t1 = t2 \% t3} & \texttt{timedelta} object. (3) \\
\hline
\texttt{q, r = divmod(t1, t2)} & Computes the quotient and the remainder: \( q = t_1 \div t_2 \) (3) and \( r = t_1 \% t_2 \). \( q \) is an integer and \( r \) is a \texttt{timedelta} object. \\
\hline
\texttt{+t1} & Returns a \texttt{timedelta} object with the same value. (2) \\
\hline
\texttt{-t1} & equivalent to \texttt{timedelta(-t1.days, -t1.seconds, -t1.microseconds)}, and to \( t_1 \times -1 \). (1)(4) \\
\hline
\texttt{abs(t)} & equivalent to \( +t \) when \( t \text{.days} \geq 0 \), and to \( -t \) when \( t \text{.days} < 0 \). (2) \\
\hline
\texttt{str(t)} & Returns a string in the form \([D \text{ day[s]}, ]\text{[H]H:MM:SS[.UUUUUU]}, \) where \( D \) is negative for negative \( t \). (5) \\
\hline
\texttt{repr(t)} & Returns a string in the form \texttt{datetime.timedelta(D[, S[, U]]]), where \( D \) is negative for negative \( t \). (5) \\
\hline
\end{tabular}

Notes:

1. This is exact, but may overflow.
2. This is exact, and cannot overflow.
3. Division by 0 raises \texttt{ZeroDivisionError}.
4. \texttt{-timedelta.max} is not representable as a \texttt{timedelta} object.
5. String representations of \texttt{timedelta} objects are normalized similarly to their internal representation. This leads to somewhat
unusual results for negative timedeltas. For example:

```python
>>> timedelta(hours=-5)
datetime.timedelta(-1, 68400)
>>> print(_)
-1 day, 19:00:00
```

In addition to the operations listed above `timedelta` objects support certain additions and subtractions with `date` and `datetime` objects (see below).

*Changed in version 3.2:* Floor division and true division of a `timedelta` object by another `timedelta` object are now supported, as are remainder operations and the `divmod()` function. True division and multiplication of a `timedelta` object by a `float` object are now supported.

Comparisons of `timedelta` objects are supported with the `timedelta` object representing the smaller duration considered to be the smaller timedelta. In order to stop mixed-type comparisons from falling back to the default comparison by object address, when a `timedelta` object is compared to an object of a different type, `TypeError` is raised unless the comparison is `==` or `!=`. The latter cases return `False` or `True`, respectively.

`timedelta` objects are `hashable` (usable as dictionary keys), support efficient pickling, and in Boolean contexts, a `timedelta` object is considered to be true if and only if it isn’t equal to `timedelta(0)`.

Instance methods:

`timedelta.total_seconds()`

Return the total number of seconds contained in the duration.
Equivalent to \( \text{td} / \text{timedelta(seconds=1)} \).

Note that for very large time intervals (greater than 270 years on most platforms) this method will lose microsecond accuracy.

*New in version 3.2.*

Example usage:

```python
>>> from datetime import timedelta
>>> year = timedelta(days=365)
... another_year = timedelta(weeks=40, days=84, hours=20, minutes=50, seconds=600)
... year.total_seconds()
31536000.0
>>> year == another_year
True
>>> ten_years = 10 * year
>>> ten_years, ten_years.days // 365
datetime.timedelta(3650), 10
>>> nine_years = ten_years - year
>>> nine_years, nine_years.days // 365
datetime.timedelta(3285), 9
>>> three_years = nine_years // 3;
>>> three_years, three_years.days // 365
datetime.timedelta(1095), 3
>>> abs(three_years - ten_years) == 2 * three_years
True
```
8.1.3. date Objects

A date object represents a date (year, month and day) in an idealized calendar, the current Gregorian calendar indefinitely extended in both directions. January 1 of year 1 is called day number 1, January 2 of year 1 is called day number 2, and so on. This matches the definition of the “proleptic Gregorian” calendar in Dershowitz and Reingold’s book Calendrical Calculations, where it’s the base calendar for all computations. See the book for algorithms for converting between proleptic Gregorian ordinals and many other calendar systems.

class datetime.date(year, month, day)

All arguments are required. Arguments may be integers, in the following ranges:

- MINYEAR <= year <= MAXYEAR
- 1 <= month <= 12
- 1 <= day <= number of days in the given month and year

If an argument outside those ranges is given, ValueError is raised.

Other constructors, all class methods:

classmethod date.today()

Return the current local date. This is equivalent to
date.fromtimestamp(time.time()).

classmethod date.fromtimestamp(timestamp)

Return the local date corresponding to the POSIX timestamp, such as is returned by time.time(). This may raise
OverflowError, if the timestamp is out of the range of values supported by the platform C localtime() function, and OSError on localtime() failure. It's common for this to be restricted to years from 1970 through 2038. Note that on non-POSIX systems that include leap seconds in their notion of a timestamp, leap seconds are ignored by fromtimestamp().

Changed in version 3.3: Raise OverflowError instead of ValueError if the timestamp is out of the range of values supported by the platform C localtime() function. Raise OSError instead of ValueError on localtime() failure.

classmethod date.fromordinal(ordinal)

Return the date corresponding to the proleptic Gregorian ordinal, where January 1 of year 1 has ordinal 1. ValueError is raised unless 1 <= ordinal <= date.max.toordinal(). For any date d, date.fromordinal(d.toordinal()) == d.

Class attributes:

date.min

The earliest representable date, date(MINYEAR, 1, 1).

date.max

The latest representable date, date(MAXYEAR, 12, 31).

date.resolution

The smallest possible difference between non-equal date objects, timedelta(days=1).

Instance attributes (read-only):

date.year
Between `MINYEAR` and `MAXYEAR` inclusive.

`date.month`
Between 1 and 12 inclusive.

`date.day`
Between 1 and the number of days in the given month of the given year.

Supported operations:

<table>
<thead>
<tr>
<th>Operation</th>
<th>Result</th>
</tr>
</thead>
<tbody>
<tr>
<td><code>date2 = date1 + timedelta</code></td>
<td><code>date2</code> is <code>timedelta.days</code> days removed from <code>date1</code>. (1)</td>
</tr>
<tr>
<td><code>date2 = date1 - timedelta</code></td>
<td>Computes <code>date2</code> such that <code>date2 + timedelta == date1</code>. (2)</td>
</tr>
<tr>
<td><code>timedelta = date1 - date2</code></td>
<td>(3)</td>
</tr>
<tr>
<td><code>date1 &lt; date2</code></td>
<td><code>date1</code> is considered less than <code>date2</code> when <code>date1</code> precedes <code>date2</code> in time. (4)</td>
</tr>
</tbody>
</table>

Notes:

1. `date2` is moved forward in time if `timedelta.days > 0`, or backward if `timedelta.days < 0`. Afterward `date2 - date1 == timedelta.days`. `timedelta.seconds` and `timedelta.microseconds` are ignored. `OverflowError` is raised if `date2.year` would be smaller than `MINYEAR` or larger than `MAXYEAR`.

2. This isn’t quite equivalent to `date1 + (-timedelta)`, because `-timedelta` in isolation can overflow in cases where `date1 - timedelta` does not. `timedelta.seconds` and
timedelta.microseconds are ignored.
3. This is exact, and cannot overflow. timedelta.seconds and timedelta.microseconds are 0, and date2 + timedelta == date1 after.
4. In other words, date1 < date2 if and only if date1.toordinal() < date2.toordinal(). In order to stop comparison from falling back to the default scheme of comparing object addresses, date comparison normally raises TypeError if the other comparand isn't also a date object. However, NotImplemented is returned instead if the other comparand has a timetuple() attribute. This hook gives other kinds of date objects a chance at implementing mixed-type comparison. If not, when a date object is compared to an object of a different type, TypeError is raised unless the comparison is == or !=. The latter cases return False or True, respectively.

Dates can be used as dictionary keys. In Boolean contexts, all date objects are considered to be true.

Instance methods:

date.replace(year, month, day)
Return a date with the same value, except for those parameters given new values by whichever keyword arguments are specified. For example, if d == date(2002, 12, 31), then d.replace(day=26) == date(2002, 12, 26).

date.timetuple()
Return a time.struct_time such as returned by time.localtime(). The hours, minutes and seconds are 0, and the DST flag is -1. d.timetuple() is equivalent to time.struct_time((d.year, d.month, d.day, 0, 0,
0, d.weekday(), yday, -1)), where yday =

\[ yday = d.toordinal() - \text{date}(d.year, 1, 1).toordinal() + 1 \]

is the day number within the current year starting with 1 for January 1st.

\section*{date.toordinal()}

Return the proleptic Gregorian ordinal of the date, where January 1 of year 1 has ordinal 1. For any date object \( d \),

\[ \text{date.fromordinal}(d.toordinal()) = d. \]

\section*{date.weekday()}

Return the day of the week as an integer, where Monday is 0 and Sunday is 6. For example, \( \text{date}(2002, 12, 4).weekday() = 2 \), a Wednesday. See also \text{isoweekday()}.

\section*{date.isoweekday()}

Return the day of the week as an integer, where Monday is 1 and Sunday is 7. For example, \( \text{date}(2002, 12, 4).isoweekday() = 3 \), a Wednesday. See also \text{weekday()}, \text{isocalendar()}.

\section*{date.isocalendar()}

Return a 3-tuple, (ISO year, ISO week number, ISO weekday).

The ISO calendar is a widely used variant of the Gregorian calendar.

See http://www.phys.uu.nl/~vgent/calendar/isocalendar.htm for a good explanation.

The ISO year consists of 52 or 53 full weeks, and where a week starts on a Monday and ends on a Sunday. The first week of an ISO year is the first (Gregorian) calendar week of a year containing
a Thursday. This is called week number 1, and the ISO year of that Thursday is the same as its Gregorian year.

For example, 2004 begins on a Thursday, so the first week of ISO year 2004 begins on Monday, 29 Dec 2003 and ends on Sunday, 4 Jan 2004, so that `date(2003, 12, 29).isocalendar() == (2004, 1, 1)` and `date(2004, 1, 4).isocalendar() == (2004, 1, 7)`.

date. **isoformat**()

Return a string representing the date in ISO 8601 format, ‘YYYY-MM-DD’. For example, `date(2002, 12, 4).isoformat() == '2002-12-04'`.

date. **__str__**()

For a date `d`, `str(d)` is equivalent to `d.isoformat()`.

date. **ctime**()

Return a string representing the date, for example `date(2002, 12, 4).ctime() == 'Wed Dec 4 00:00:00 2002'`. `d.ctime()` is equivalent to `time.ctime(time.mktime(d.timetuple()))` on platforms where the native C `ctime()` function (which `time.ctime()` invokes, but which `date.ctime()` does not invoke) conforms to the C standard.

date. **strftime**(format)

Return a string representing the date, controlled by an explicit format string. Format codes referring to hours, minutes or seconds will see 0 values. For a complete list of formatting directives, see `strftime()` and `strptime()` Behavior.
date.__format__(format)

Same as date.strftime(). This makes it possible to specify format string for a date object when using str.format(). For a complete list of formatting directives, see strftime() and strptime().

Behavior.

Example of counting days to an event:

```python
>>> import time
>>> from datetime import date
>>> today = date.today()
>>> today
datetime.date(2007, 12, 5)
>>> today == date.fromtimestamp(time.time())
True
>>> my_birthday = date(today.year, 6, 24)
>>> if my_birthday < today:
...    my_birthday = my_birthday.replace(year=today.year)
>>> my_birthday
datetime.date(2008, 6, 24)
>>> time_to_birthday = abs(my_birthday - today)
>>> time_to_birthday.days
202
```

Example of working with date:

```python
>>> from datetime import date
>>> d = date.fromordinal(730920)  # 730920th day after 1.1.0001
>>> d
datetime.date(2002, 3, 11)
>>> t = d.timetuple()
>>> for i in t:
...    print(i)
2002  # year
3  # month
```
11              # day
0
0
0
0
# weekday (0 = Monday)
70              # 70th day in the year
-1
>>> ic = d.isocalendar()
>>> for i in ic:
    ...    print(i)
2002            # ISO year
11              # ISO week number
1               # ISO day number (1 = Monday)
>>> d.isoformat()
'2002-03-11'
>>> d.strftime("%d/%m/%y")
'11/03/02'
>>> d.strftime("%A %d. %B %Y")
'Monday 11. March 2002'
>>> 'The {1} is {0:%d}, the {2} is {0:%B}'.format(d)
'The day is 11, the month is March.'
8.1.4. **datetime** Objects

A **datetime** object is a single object containing all the information from a **date** object and a **time** object. Like a **date** object, **datetime** assumes the current Gregorian calendar extended in both directions; like a time object, **datetime** assumes there are exactly 3600*24 seconds in every day.

Constructor:

```python
class datetime.datetime(year, month, day, hour=0, minute=0, second=0, microsecond=0, tzinfo=None)
```

The year, month and day arguments are required. `tzinfo` may be `None`, or an instance of a `tzinfo` subclass. The remaining arguments may be integers, in the following ranges:

- `MINYEAR <= year <= MAXYEAR`
- `1 <= month <= 12`
- `1 <= day <= number of days in the given month and year`
- `0 <= hour < 24`
- `0 <= minute < 60`
- `0 <= second < 60`
- `0 <= microsecond < 1000000`

If an argument outside those ranges is given, `ValueError` is raised.

Other constructors, all class methods:

```python
classmethod datetime.today()"
```

Return the current local datetime, with `tzinfo None`. This is
equivalent to `datetime.fromtimestamp(time.time())`. See also `now()`, `fromtimestamp()`.

classmethod `datetime.now(tz=None)`

Return the current local date and time. If optional argument `tz` is `None` or not specified, this is like `today()`, but, if possible, supplies more precision than can be gotten from going through a `time.time()` timestamp (for example, this may be possible on platforms supplying the C `gettimeofday()` function).

Else `tz` must be an instance of a class `tzinfo` subclass, and the current date and time are converted to `tz`'s time zone. In this case the result is equivalent to `tz.fromutc(datetime.utcnow().replace(tzinfo=tz))`. See also `today()`, `utcnow()`.

classmethod `datetime.utcnow()`

Return the current UTC date and time, with `tzinfo` `None`. This is like `now()`, but returns the current UTC date and time, as a naive `datetime` object. An aware current UTC datetime can be obtained by calling `datetime.now(timezone.utc)`. See also `now()`.

classmethod `datetime.fromtimestamp(timestamp, tz=None)`

Return the local date and time corresponding to the POSIX timestamp, such as is returned by `time.time()`. If optional argument `tz` is `None` or not specified, the timestamp is converted to the platform's local date and time, and the returned `datetime` object is naive.

Else `tz` must be an instance of a class `tzinfo` subclass, and the
timestamp is converted to tz's time zone. In this case the result is equivalent to
tz.fromutc(datetime.utcfromtimestamp(timestamp).replace(tzinfo=tz))

fromtimestamp() may raise OverflowError, if the timestamp is out of the range of values supported by the platform C localtime() or gmtime() functions, and OSError on localtime() or gmtime() failure. It's common for this to be restricted to years in 1970 through 2038. Note that on non-POSIX systems that include leap seconds in their notion of a timestamp, leap seconds are ignored by fromtimestamp(), and then it's possible to have two timestamps differing by a second that yield identical datetime objects. See also utcfromtimestamp().

Changed in version 3.3: Raise OverflowError instead of ValueError if the timestamp is out of the range of values supported by the platform C localtime() or gmtime() functions. Raise OSError instead of ValueError on localtime() or gmtime() failure.

classmethod datetime.utcfromtimestamp(timestamp)
Return the UTC datetime corresponding to the POSIX timestamp, with tzinfo None. This may raise OverflowError, if the timestamp is out of the range of values supported by the platform C gmtime() function, and OSError on gmtime() failure. It's common for this to be restricted to years in 1970 through 2038. See also fromtimestamp().

On the POSIX compliant platforms, utcfromtimestamp(timestamp) is equivalent to the following expression:
\[
\text{datetime}(1970, 1, 1) + \text{timedelta(seconds=timestamp)}
\]

*Changed in version 3.3:* Raise `OverflowError` instead of `ValueError` if the timestamp is out of the range of values supported by the platform C `gmtime()` function. Raise `OSError` instead of `ValueError` on `gmtime()` failure.

**classmethod `datetime.fromordinal(ordinal)`**

Return the `datetime` corresponding to the proleptic Gregorian ordinal, where January 1 of year 1 has ordinal 1. `ValueError` is raised unless \[1 \leq \text{ordinal} \leq \text{datetime.max.toordinal}().\] The hour, minute, second and microsecond of the result are all 0, and `tzinfo` is `None`.

**classmethod `datetime.combine(date, time)`**

Return a new `datetime` object whose date components are equal to the given `date` object's, and whose time components and `tzinfo` attributes are equal to the given `time` object's. For any `datetime` object \(d\), \(d == \text{datetime.combine}(d.date(), d.timetz())\). If `date` is a `datetime` object, its time components and `tzinfo` attributes are ignored.

**classmethod `datetime.strptime(date_string, format)`**

Return a `datetime` corresponding to `date_string`, parsed according to `format`. This is equivalent to `datetime(* (time.strptime(date_string, format)[0:6]))`. `ValueError` is raised if the `date_string` and `format` can't be parsed by `time.strptime()` or if it returns a value which isn't a time tuple. For a complete list of formatting directives, see `strftime()` and `strptime()` Behavior.
Class attributes:

datetime.min
The earliest representable datetime, `datetime(MINYEAR, 1, 1, tzinfo=None)`.

datetime.max
The latest representable datetime, `datetime(MAXYEAR, 12, 31, 23, 59, 59, 999999, tzinfo=None)`.

datetime.resolution
The smallest possible difference between non-equal datetime objects, `timedelta(microseconds=1)`.

Instance attributes (read-only):

datetime.year
Between MINYEAR and MAXYEAR inclusive.

datetime.month
Between 1 and 12 inclusive.

datetime.day
Between 1 and the number of days in the given month of the given year.

datetime.hour
In range(24).

datetime.minute
In range(60).

datetime.second
In `range(60)`.

`datetime.microsecond`

In `range(1000000)`.

`datetime.tzinfo`

The object passed as the `tzinfo` argument to the `datetime` constructor, or `None` if none was passed.

Supported operations:

<table>
<thead>
<tr>
<th>Operation</th>
<th>Result</th>
</tr>
</thead>
<tbody>
<tr>
<td><code>datetime2 = datetime1 + timedelta</code></td>
<td>(1)</td>
</tr>
<tr>
<td><code>datetime2 = datetime1 - timedelta</code></td>
<td>(2)</td>
</tr>
<tr>
<td><code>timedelta = datetime1 - datetime2</code></td>
<td>(3)</td>
</tr>
<tr>
<td><code>datetime1 &lt; datetime2</code></td>
<td>Compares <code>datetime</code> to <code>datetime</code> (4)</td>
</tr>
</tbody>
</table>

1. `datetime2` is a duration of `timedelta` removed from `datetime1`, moving forward in time if `timedelta.days > 0`, or backward if `timedelta.days < 0`. The result has the same `tzinfo` attribute as the input `datetime`, and `datetime2 - datetime1 == timedelta` after. `OverflowError` is raised if `datetime2.year` would be smaller than `MINYEAR` or larger than `MAXYEAR`. Note that no time zone adjustments are done even if the input is an aware object.

2. Computes the `datetime2` such that `datetime2 + timedelta == datetime1`. As for addition, the result has the same `tzinfo`
attribute as the input datetime, and no time zone adjustments are done even if the input is aware. This isn't quite equivalent to \( \text{datetime1} + (-\text{timedelta}) \), because \(-\text{timedelta}\) in isolation can overflow in cases where \( \text{datetime1} - \text{timedelta} \) does not.

3. Subtraction of a \texttt{datetime} from a \texttt{datetime} is defined only if both operands are naive, or if both are aware. If one is aware and the other is naive, \texttt{TypeError} is raised.

If both are naive, or both are aware and have the same \texttt{tzinfo} attribute, the \texttt{tzinfo} attributes are ignored, and the result is a \texttt{timedelta} object \( t \) such that \( \text{datetime2} + t \equiv \text{datetime1} \). No time zone adjustments are done in this case.

If both are aware and have different \texttt{tzinfo} attributes, \( a - b \) acts as if \( a \) and \( b \) were first converted to naive UTC datetimes first. The result is \( (a.\text{replace(tzinfo=None)} - a.\text{utcoffset()}) - (b.\text{replace(tzinfo=None)} - b.\text{utcoffset()}) \) except that the implementation never overflows.

4. \texttt{datetime1} is considered less than \texttt{datetime2} when \texttt{datetime1} precedes \texttt{datetime2} in time.

If one comparand is naive and the other is aware, \texttt{TypeError} is raised if an order comparison is attempted. For equality comparisons, naive instances are never equal to aware instances.

If both comparands are aware, and have the same \texttt{tzinfo} attribute, the common \texttt{tzinfo} attribute is ignored and the base datetimes are compared. If both comparands are aware and have different \texttt{tzinfo} attributes, the comparands are first adjusted by
subtracting their UTC offsets (obtained from self.utcoffset()).

*Changed in version 3.3:* Equality comparisons between naive and aware `datetime` instances don’t raise `TypeError`.

**Note:** In order to stop comparison from falling back to the default scheme of comparing object addresses, `datetime` comparison normally raises `TypeError` if the other comparand isn't also a `datetime` object. However, `NotImplemented` is returned instead if the other comparand has a `timetuple()` attribute. This hook gives other kinds of date objects a chance at implementing mixed-type comparison. If not, when a `datetime` object is compared to an object of a different type, `TypeError` is raised unless the comparison is `==` or `!=`. The latter cases return `False` or `True`, respectively.

`datetime` objects can be used as dictionary keys. In Boolean contexts, all `datetime` objects are considered to be true.

Instance methods:

`datetime.date()`
Return `date` object with same year, month and day.

`datetime.time()`
Return `time` object with same hour, minute, second and microsecond. `tzinfo` is `None`. See also method `timetz()`.

`datetime.timetz()`
Return `time` object with same hour, minute, second, microsecond, and `tzinfo` attributes. See also method `time()`.
datetime.replace(year[, month[, day[, hour[, minute[, second[, microsecond[, tzinfo]]]]]]])

Return a datetime with the same attributes, except for those attributes given new values by whichever keyword arguments are specified. Note that tzinfo=None can be specified to create a naive datetime from an aware datetime with no conversion of date and time data.

datetime.astimezone(tz=None)

Return a datetime object with new tzinfo attribute tz, adjusting the date and time data so the result is the same UTC time as self, but in tz's local time.

If provided, tz must be an instance of a tzinfo subclass, and its utcoffset() and dst() methods must not return None. self must be aware (self.tzinfo must not be None, and self.utcoffset() must not return None).

If called without arguments (or with tz=None) the system local timezone is assumed. The tzinfo attribute of the converted datetime instance will be set to an instance of timezone with the zone name and offset obtained from the OS.

If self.tzinfo is tz, self.astimezone(tz) is equal to self: no adjustment of date or time data is performed. Else the result is local time in time zone tz, representing the same UTC time as self: after astz = dt.astimezone(tz), astz - astz.utcoffset() will usually have the same date and time data as dt - dt.utcoffset(). The discussion of class tzinfo explains the cases at Daylight Saving Time transition
boundaries where this cannot be achieved (an issue only if tz models both standard and daylight time).

If you merely want to attach a time zone object tz to a datetime dt without adjustment of date and time data, use dt.replace(tzinfo=tz). If you merely want to remove the time zone object from an aware datetime dt without conversion of date and time data, use dt.replace(tzinfo=None).

Note that the default tzinfo.fromutc() method can be overridden in a tzinfo subclass to affect the result returned by astimezone(). Ignoring error cases, astimezone() acts like:

```python
def astimezone(self, tz):
    if self.tzinfo is tz:
        return self
    utc = (self - self.utcoffset()).replace(tzinfo=None)
    return tz.fromutc(utc)
```

*Changed in version 3.3:* tz now can be omitted.

datetime.utcoffset()

If tzinfo is None, returns None, else returns self.tzinfo.utcoffset(self), and raises an exception if the latter doesn't return None, or a timedelta object representing a whole number of minutes with magnitude less than one day.

datetime.dst()

If tzinfo is None, returns None, else returns
self.tzinfo.dst(self), and raises an exception if the latter doesn't return None, or a `timedelta` object representing a whole number of minutes with magnitude less than one day.

**datetime.tzname()**

If `tzinfo` is None, returns None, else returns `self.tzinfo.tzname(self)`, raises an exception if the latter doesn't return None or a string object,

**datetime.timetuple()**

Return a `time.struct_time` such as returned by `time.localtime()`. `d.timetuple()` is equivalent to `time.struct_time((d.year, d.month, d.day, d.hour, d.minute, d.second, d.weekday(), yday, dst))`, where

\[
\text{yday} = \text{d.toordinal()} \land (\text{date(d.year, 1, 1).toordinal()} + 1)
\]

is the day number within the current year starting with 1 for January 1st. The `tm_isdst` flag of the result is set according to the `dst()` method: `tzinfo` is None or `dst()` returns None, `tm_isdst` is set to -1; else if `dst()` returns a non-zero value, `tm_isdst` is set to 1; else `tm_isdst` is set to 0.

**datetime.utctimetuple()**

If `datetime` instance `d` is naive, this is the same as `d.timetuple()` except that `tm_isdst` is forced to 0 regardless of what `d.dst()` returns. DST is never in effect for a UTC time.

If `d` is aware, `d` is normalized to UTC time, by subtracting `d.utcoffset()`, and a `time.struct_time` for the normalized time is returned. `tm_isdst` is forced to 0. Note that an `OverflowError` may be raised if `d.year` was `MINYEAR` or `MAXYEAR` and UTC adjustment spills over a year boundary.
datetime. **toordinal()**

Return the proleptic Gregorian ordinal of the date. The same as `self.date().toordinal()`.

datetime. **timestamp()**

Return POSIX timestamp corresponding to the `datetime` instance. The return value is a `float` similar to that returned by `time.time()`.

Naive `datetime` instances are assumed to represent local time and this method relies on the platform C `mktime()` function to perform the conversion. Since `datetime` supports wider range of values than `mktime()` on many platforms, this method may raise `OverflowError` for times far in the past or far in the future.

For aware `datetime` instances, the return value is computed as:

```
(dt - datetime(1970, 1, 1, tzinfo=timezone.utc)).total_seconds()
```

*New in version 3.3.*

**Note:** There is no method to obtain the POSIX timestamp directly from a naive `datetime` instance representing UTC time. If your application uses this convention and your system timezone is not set to UTC, you can obtain the POSIX timestamp by supplying `tzinfo=timezone.utc`:

```
timestamp = dt.replace(tzinfo=timezone.utc).timestamp()
```

or by calculating the timestamp directly:

```
timestamp = (dt - datetime(1970, 1, 1)) / timedelta
```
datetime. `weekday()`
Return the day of the week as an integer, where Monday is 0 and Sunday is 6. The same as `self.date().weekday()`. See also `isoweekday()`.

datetime. `isoweekday()`
Return the day of the week as an integer, where Monday is 1 and Sunday is 7. The same as `self.date().isoweekday()`. See also `weekday()`, `isocalendar()`.

datetime. `isocalendar()`
Return a 3-tuple, (ISO year, ISO week number, ISO weekday). The same as `self.date().isocalendar()`.

datetime. `isoformat`(`sep='T'`)
Return a string representing the date and time in ISO 8601 format, `YYYY-MM-DDTHH:MM:SS.mmmmmm` or, if `microsecond` is 0, `YYYY-MM-DDTHH:MM:SS`

If `utcoffset()` does not return `None`, a 6-character string is appended, giving the UTC offset in (signed) hours and minutes: `YYYY-MM-DDTHH:MM:SS.mmmmmm+HH:MM` or, if `microsecond` is 0 `YYYY-MM-DDTHH:MM:SS+HH:MM`

The optional argument `sep` (default `'T'`) is a one-character separator, placed between the date and time portions of the result. For example,

```python
>>> from datetime import tzinfo, timedelta, datetime
>>> class TZ(tzinfo):
```
...    def utcoffset(self, dt): return timedelta...

>>> datetime(2002, 12, 25, tzinfo=TZ()).isoformat
'2002-12-25 00:00:00-06:39'

datetime.__str__()
For a datetime instance d, str(d) is equivalent to d.isoformat('').

datetime.ctime()
Return a string representing the date and time, for example
d.ctime() is equivalent to
time.ctime(time.mktime(d.timetuple())) on platforms
where the native C ctime() function (which time.ctime() invokes, but which datetime.ctime() does not invoke)
conforms to the C standard.

datetime.strftime(format)
Return a string representing the date and time, controlled by an
explicit format string. For a complete list of formatting directives,
see strftime() and strptime() Behavior.

datetime.__format__(format)
Same as datetime.strftime(). This makes it possible to
specify format string for a datetime object when using
str.format(). For a complete list of formatting directives, see
strftime() and strptime() Behavior.

Examples of working with datetime objects:

>>> from datetime import datetime, date, time
>>> # Using datetime.combine()
>>> d = date(2005, 7, 14)
>>> t = time(12, 30)
>>> datetime.combine(d, t)
datetime.datetime(2005, 7, 14, 12, 30)
>>> # Using datetime.now() or datetime.utcnow()
>>> datetime.now()
datetime.datetime(2007, 12, 6, 16, 29, 43, 79043)
>>> datetime.utcnow()
datetime.datetime(2007, 12, 6, 15, 29, 43, 79060)
>>> # Using datetime.strptime()
>>> dt = datetime.strptime("21/11/06 16:30", "%d/%m/%y %H:%M")
>>> dt
datetime.datetime(2006, 11, 21, 16, 30)
>>> # Using datetime.timetuple() to get tuple of all attributes
>>> tt = dt.timetuple()
>>> for it in tt:
...     print(it)
... 2006  # year
11  # month
21  # day
16  # hour
30  # minute
0  # second
1  # weekday (0 = Monday)
325  # number of days since 1st January
-1  # dst - method tzinfo.dst() returned None
>>> # Date in ISO format
>>> ic = dt.isocalendar()
>>> for it in ic:
...     print(it)
... 2006  # ISO year
47  # ISO week
2  # ISO weekday
>>> # Formatting datetime
Using datetime with tzinfo:

```python
>>> from datetime import timedelta, datetime, tzinfo
>>> class GMT1(tzinfo):
...     def utcoffset(self, dt):
...         return timedelta(hours=1) + self.dst(dt)
...     def dst(self, dt):
...         # DST starts last Sunday in March
...         d = datetime(dt.year, 4, 1)  # ends last Sunday in October
...         self.dston = d - timedelta(days=d.weekday())
...         self.dstoff = d - timedelta(days=d.weekday())
...         if self.dston <= dt.replace(tzinfo=None):
...             return timedelta(hours=1)
...         else:
...             return timedelta(0)
...     def tzname(self, dt):
...         return "GMT +1"

>>> class GMT2(tzinfo):
...     def utcoffset(self, dt):
...         return timedelta(hours=2) + self.dst(dt)
...     def dst(self, dt):
...         d = datetime(dt.year, 4, 1)
...         self.dston = d - timedelta(days=d.weekday())
...         self.dstoff = d - timedelta(days=d.weekday())
...         if self.dston <= dt.replace(tzinfo=None):
...             return timedelta(hours=1)
...         else:
...             return timedelta(0)
```
...   def tzname(self, dt):
...       return "GMT +2"
...
>>> gmt1 = GMT1()
>>> # Daylight Saving Time
>>> dt1 = datetime(2006, 11, 21, 16, 30, tzinfo=gmt1)
>>> dt1.dst()
datetime.timedelta(0)
>>> dt1.utcoffset()
datetime.timedelta(0, 3600)
>>> dt2 = datetime(2006, 6, 14, 13, 0, tzinfo=gmt1)
>>> dt2.dst()
datetime.timedelta(0, 3600)
>>> dt2.utcoffset()
datetime.timedelta(0, 7200)
>>> # Convert datetime to another time zone
>>> dt3 = dt2.astimezone(GMT2())
>>> dt3
datetime.datetime(2006, 6, 14, 14, 0, tzinfo=<GMT2 object at 0x...>)
>>> dt2
datetime.datetime(2006, 6, 14, 13, 0, tzinfo=<GMT1 object at 0x...>)
>>> dt2.utctimetuple() == dt3.utctimetuple()
True
8.1.5. **time** Objects

A time object represents a (local) time of day, independent of any particular day, and subject to adjustment via a `tzinfo` object.

```python
class datetime.time(hour=0, minute=0, second=0, microsecond=0, tzinfo=None)
```

All arguments are optional. `tzinfo` may be `None`, or an instance of a `tzinfo` subclass. The remaining arguments may be integers, in the following ranges:

- `0 <= hour < 24`
- `0 <= minute < 60`
- `0 <= second < 60`
- `0 <= microsecond < 1000000`

If an argument outside those ranges is given, `ValueError` is raised. All default to 0 except `tzinfo`, which defaults to `None`.

Class attributes:

- **`time.min`**
  
  The earliest representable `time`, `time(0, 0, 0, 0)`.

- **`time.max`**
  
  The latest representable `time`, `time(23, 59, 59, 999999)`.

- **`time.resolution`**
  
  The smallest possible difference between non-equal `time` objects, `timedelta(microseconds=1)`, although note that arithmetic on `time` objects is not supported.
Instance attributes (read-only):

```
 time. **hour**  
        In range(24).
```

```
 time. **minute**  
        In range(60).
```

```
 time. **second**  
        In range(60).
```

```
 time. **microsecond**  
        In range(1000000).
```

```
 time. **tzinfo**  
        The object passed as the tzinfo argument to the time constructor,  
        or None if none was passed.
```

Supported operations:

- comparison of time to time, where a is considered less than b  
  when a precedes b in time. If one comparand is naive and the  
  other is aware, TypeError is raised if an order comparison is  
  attempted. For equality comparisons, naive instances are never  
  equal to aware instances.

If both comparands are aware, and have the same tzinfo attribute, the common tzinfo attribute is ignored and the base  
times are compared. If both comparands are aware and have  
different tzinfo attributes, the comparands are first adjusted by  
subtracting their UTC offsets (obtained from  
self.utcoffset()). In order to stop mixed-type comparisons  
from falling back to the default comparison by object address,
when a `time` object is compared to an object of a different type, `TypeError` is raised unless the comparison is `==` or `!=`. The latter cases return `False` or `True`, respectively.

*Changed in version 3.3:* Equality comparisons between naive and aware `time` instances don’t raise `TypeError`.

- `hash`, use as dict key
- `efficient pickling`
- in Boolean contexts, a `time` object is considered to be true if and only if, after converting it to minutes and subtracting `utcoffset()` (or 0 if that’s `None`), the result is non-zero.

Instance methods:

`time.replace([hour[, minute[, second[, microsecond[, tzinfo]]]]])`

Return a `time` with the same value, except for those attributes given new values by whichever keyword arguments are specified. Note that `tzinfo=None` can be specified to create a naive `time` from an aware `time`, without conversion of the time data.

`time.isoformat()`

Return a string representing the time in ISO 8601 format, `HH:MM:SS.mmmmmm` or, if self.microsecond is 0, `HH:MM:SS` If `utcoffset()` does not return `None`, a 6-character string is appended, giving the UTC offset in (signed) hours and minutes: `HH:MM:SS.mmmmmm+HH:MM` or, if self.microsecond is 0, `HH:MM:SS+HH:MM`

`time.__str__()`

For a time `t`, `str(t)` is equivalent to `t.isoformat()`.
time.strftime(format)

Return a string representing the time, controlled by an explicit format string. For a complete list of formatting directives, see `strftime()` and `strptime() Behavior`.

```
>>> from datetime import time, tzinfo
>>> class GMT1(tzinfo):
```
```python
def utcoffset(self, dt):
    return timedelta(hours=1)
def dst(self, dt):
    return timedelta(0)
def tzname(self, dt):
    return "Europe/Prague"

>>> t = time(12, 10, 30, tzinfo=GMT1())
>>> t
datetime.time(12, 10, 30, tzinfo=<GMT1 object at 0x...
>>> gmt = GMT1()
>>> t.isoformat()
'12:10:30+01:00'
>>> t.dst()
datetime.timedelta(0)
>>> t.tzname()
'Europe/Prague'
>>> t.strftime("%H:%M:%S %Z")
'12:10:30 Europe/Prague'
>>> 'The {} is {:%H:%M}'.format("time", t)
'The time is 12:10.'
```
8.1.6. **tzinfo** Objects

*tzinfo* is an abstract base class, meaning that this class should not be instantiated directly. You need to derive a concrete subclass, and (at least) supply implementations of the standard *tzinfo* methods needed by the *datetime* methods you use. The *datetime* module supplies a simple concrete subclass of *tzinfo timezone* which can represent timezones with fixed offset from UTC such as UTC itself or North American EST and EDT.

An instance of (a concrete subclass of) *tzinfo* can be passed to the constructors for *datetime* and *time* objects. The latter objects view their attributes as being in local time, and the *tzinfo* object supports methods revealing offset of local time from UTC, the name of the time zone, and DST offset, all relative to a date or time object passed to them.

Special requirement for pickling: A *tzinfo* subclass must have an *__init__()* method that can be called with no arguments, else it can be pickled but possibly not unpickled again. This is a technical requirement that may be relaxed in the future.

A concrete subclass of *tzinfo* may need to implement the following methods. Exactly which methods are needed depends on the uses made of aware *datetime* objects. If in doubt, simply implement all of them.

*tzinfo.* **utcoffset**(*dt*)

Return offset of local time from UTC, in minutes east of UTC. If local time is west of UTC, this should be negative. Note that this is intended to be the total offset from UTC; for example, if a *tzinfo*
object represents both time zone and DST adjustments, \texttt{utcoffset()} should return their sum. If the UTC offset isn't known, return \texttt{None}. Else the value returned must be a \texttt{timedelta} object specifying a whole number of minutes in the range -1439 to 1439 inclusive (1440 = 24*60; the magnitude of the offset must be less than one day). Most implementations of \texttt{utcoffset()} will probably look like one of these two:

\begin{verbatim}
return CONSTANT # fixed-offset class
return CONSTANT + self.dst(dt) # daylight-aware
\end{verbatim}

If \texttt{utcoffset()} does not return \texttt{None}, \texttt{dst()} should not return \texttt{None} either.

The default implementation of \texttt{utcoffset()} raises \texttt{NotImplementedError}.

tzinfo.\texttt{dst}(dt)

Return the daylight saving time (DST) adjustment, in minutes east of UTC, or \texttt{None} if DST information isn’t known. Return \texttt{timedelta(0)} if DST is not in effect. If DST is in effect, return the offset as a \texttt{timedelta} object (see \texttt{utcoffset()} for details). Note that DST offset, if applicable, has already been added to the UTC offset returned by \texttt{utcoffset()}, so there’s no need to consult \texttt{dst()} unless you’re interested in obtaining DST info separately. For example, \texttt{datetime.timetuple()} calls its \texttt{tzinfo} attribute’s \texttt{dst()} method to determine how the \texttt{tm_isdst} flag should be set, and \texttt{tzinfo.fromutc()} calls \texttt{dst()} to account for DST changes when crossing time zones.

An instance \texttt{tz} of a \texttt{tzinfo} subclass that models both standard
and daylight times must be consistent in this sense:

\[
tz.utcoffset(dt) - tz.dst(dt)
\]

must return the same result for every `datetime dt` with `dt.tzinfo == tz` For sane `tzinfo` subclasses, this expression yields the time zone’s “standard offset”, which should not depend on the date or the time, but only on geographic location. The implementation of `datetime.astimezone()` relies on this, but cannot detect violations; it’s the programmer’s responsibility to ensure it. If a `tzinfo` subclass cannot guarantee this, it may be able to override the default implementation of `tzinfo.fromutc()` to work correctly with `astimezone()` regardless.

Most implementations of `dst()` will probably look like one of these two:

```python
def dst(self, dt):
    # a fixed-offset class: doesn't account for DST
    return timedelta(0)
```

or

```python
def dst(self, dt):
    # Code to set dston and dstoff to the time zone's DST transition times based on the input dt.year in standard local time. Then
    if dston <= dt.replace(tzinfo=None) < dstoff:
        return timedelta(hours=1)
    else:
        return timedelta(0)
```
The default implementation of \texttt{dst()} raises \texttt{NotImplementedError}.

\texttt{tzinfo.tzname(dt)}

Return the time zone name corresponding to the \texttt{datetime} object \texttt{dt}, as a string. Nothing about string names is defined by the \texttt{datetime} module, and there's no requirement that it mean anything in particular. For example, “GMT”, “UTC”, “-500”, “-5:00”, “EDT”, “US/Eastern”, “America/New York” are all valid replies. Return \texttt{None} if a string name isn’t known. Note that this is a method rather than a fixed string primarily because some \texttt{tzinfo} subclasses will wish to return different names depending on the specific value of \texttt{dt} passed, especially if the \texttt{tzinfo} class is accounting for daylight time.

The default implementation of \texttt{tzname()} raises \texttt{NotImplementedError}.

These methods are called by a \texttt{datetime} or \texttt{time} object, in response to their methods of the same names. A \texttt{datetime} object passes itself as the argument, and a \texttt{time} object passes \texttt{None} as the argument. A \texttt{tzinfo} subclass’s methods should therefore be prepared to accept a \texttt{dt} argument of \texttt{None}, or of class \texttt{datetime}.

When \texttt{None} is passed, it’s up to the class designer to decide the best response. For example, returning \texttt{None} is appropriate if the class wishes to say that time objects don’t participate in the \texttt{tzinfo} protocols. It may be more useful for \texttt{utcoffset(None)} to return the standard UTC offset, as there is no other convention for discovering the standard offset.

When a \texttt{datetime} object is passed in response to a \texttt{datetime}
method, \texttt{dt.tzinfo} is the same object as \texttt{self}. \texttt{tzinfo} methods can rely on this, unless user code calls \texttt{tzinfo} methods directly. The intent is that the \texttt{tzinfo} methods interpret \texttt{dt} as being in local time, and not need worry about objects in other timezones.

There is one more \texttt{tzinfo} method that a subclass may wish to override:

\texttt{tzinfo.fromutc(\texttt{dt})}

This is called from the default \texttt{datetime.astimezone()} implementation. When called from that, \texttt{dt.tzinfo} is \texttt{self}, and \texttt{dt}'s date and time data are to be viewed as expressing a UTC time. The purpose of \texttt{fromutc()} is to adjust the date and time data, returning an equivalent datetime in \texttt{self}'s local time.

Most \texttt{tzinfo} subclasses should be able to inherit the default \texttt{fromutc()} implementation without problems. It's strong enough to handle fixed-offset time zones, and time zones accounting for both standard and daylight time, and the latter even if the DST transition times differ in different years. An example of a time zone the default \texttt{fromutc()} implementation may not handle correctly in all cases is one where the standard offset (from UTC) depends on the specific date and time passed, which can happen for political reasons. The default implementations of \texttt{astimezone()} and \texttt{fromutc()} may not produce the result you want if the result is one of the hours straddling the moment the standard offset changes.

Skipping code for error cases, the default \texttt{fromutc()} implementation acts like:

```python
def fromutc(self, dt):
```
# raise ValueError error if dt.tzinfo is not
dtoff = dt.utcoffset()
dtdst = dt.dst()
# raise ValueError if dtoff is None or dtdst is None
delta = dtoff - dtdst
    # this is self's standard
if delta:
    dt += delta       # convert to standard local
dtdst = dt.dst()
    # raise ValueError if dtdst is None
if dtdst:
    return dt + dtdst
else:
    return dt

Example tzinfo classes:

```python
from datetime import tzinfo, timedelta, datetime

ZERO = timedelta(0)
HOUR = timedelta(hours=1)

# A UTC class.

class UTC(tzinfo):
    """UTC""
    def utcoffset(self, dt):
        return ZERO
    def tzname(self, dt):
        return "UTC"
    def dst(self, dt):
        return ZERO

utc = UTC()
```

# A class building tzinfo objects for fixed-offset time zones.
# Note that FixedOffset(0, "UTC") is a different way to build a UTC tzinfo object.

class FixedOffset(tzinfo):
    """Fixed offset in minutes east from UTC."""

    def __init__(self, offset, name):
        self.__offset = timedelta(minutes=offset)
        self.__name = name

    def utcoffset(self, dt):
        return self.__offset

    def tzname(self, dt):
        return self.__name

    def dst(self, dt):
        return ZERO

# A class capturing the platform's idea of local time.

import time as _time

Eastern = USTimeZone(-5, "Eastern", "EST", "EDT")
Central = USTimeZone(-6, "Central", "CST", "CDT")
Mountain = USTimeZone(-7, "Mountain", "MST", "MDT")
Note that there are unavoidable subtleties twice per year in a \texttt{tzinfo}
subclass accounting for both standard and daylight time, at the DST
transition points. For concreteness, consider US Eastern (UTC -0500),
where EDT begins the minute after 1:59 (EST) on the second Sunday
in March, and ends the minute after 1:59 (EDT) on the first Sunday in
November:

|-----|------|------|------|------|------|------|

When DST starts (the “start” line), the local wall clock leaps from 1:59
to 3:00. A wall time of the form 2:MM doesn’t really make sense on
that day, so \texttt{astimezone(Eastern)} won’t deliver a result with hour
\verb|=|= 2 on the day DST begins. In order for \texttt{astimezone()} to make
this guarantee, the \texttt{tzinfo.dst()} method must consider times in
the “missing hour” (2:MM for Eastern) to be in daylight time.

When DST ends (the “end” line), there’s a potentially worse problem:
there’s an hour that can’t be spelled unambiguously in local wall time:
the last hour of daylight time. In Eastern, that’s times of the form 5:MM
UTC on the day daylight time ends. The local wall clock leaps from
1:59 (daylight time) back to 1:00 (standard time) again. Local times of
the form 1:MM are ambiguous. \texttt{astimezone()} mimics the local
clock’s behavior by mapping two adjacent UTC hours into the same
local hour then. In the Eastern example, UTC times of the form 5:MM
and 6:MM both map to 1:MM when converted to Eastern. In order for `astimezone()` to make this guarantee, the `tzinfo.dst()` method must consider times in the “repeated hour” to be in standard time. This is easily arranged, as in the example, by expressing DST switch times in the time zone’s standard local time.

Applications that can’t bear such ambiguities should avoid using hybrid `tzinfo` subclasses; there are no ambiguities when using `timezone`, or any other fixed-offset `tzinfo` subclass (such as a class representing only EST (fixed offset -5 hours), or only EDT (fixed offset -4 hours)).

See also:

**pytz**

The standard library has no `tzinfo` instances except for UTC, but there exists a third-party library which brings the IANA `timezone database` (also known as the Olson database) to Python: `pytz`.

`pytz` contains up-to-date information and its usage is recommended.

**IANA timezone database**

The Time Zone Database (often called tz or zoneinfo) contains code and data that represent the history of local time for many representative locations around the globe. It is updated periodically to reflect changes made by political bodies to time zone boundaries, UTC offsets, and daylight-saving rules.
8.1.7. timezone Objects

The timezone class is a subclass of tzinfo, each instance of which represents a timezone defined by a fixed offset from UTC. Note that objects of this class cannot be used to represent timezone information in the locations where different offsets are used in different days of the year or where historical changes have been made to civil time.

class datetime.timezone(offset[, name])

The offset argument must be specified as a timedelta object representing the difference between the local time and UTC. It must be strictly between \(-\text{timedelta(hours=24)}\) and \(\text{timedelta(hours=24)}\) and represent a whole number of minutes, otherwise ValueError is raised.

The name argument is optional. If specified it must be a string that is used as the value returned by the tzname(dt) method. Otherwise, tzname(dt) returns a string ‘UTCsHH:MM’, where s is the sign of offset, HH and MM are two digits of offset.hours and offset.minutes respectively.

timezone.utcoffset(dt)

Return the fixed value specified when the timezone instance is constructed. The dt argument is ignored. The return value is a timedelta instance equal to the difference between the local time and UTC.

timezone.tzname(dt)

Return the fixed value specified when the timezone instance is constructed or a string ‘UTCsHH:MM’, where s is the sign of offset,
HH and MM are two digits of offset.hours and offset.minutes respectively.

timezone.\texttt{dst}(dt)
  Always returns \texttt{None}.

timezone.\texttt{fromutc}(dt)
  Return \texttt{dt} + offset. The \texttt{dt} argument must be an aware \texttt{datetime} instance, with \texttt{tzinfo} set to self.

Class attributes:

timezone.\texttt{utc}
  The UTC timezone, \texttt{timezone(timedelta(0))}.
8.18. strftime() and strptime()

Behavior

date, datetime, and time objects all support a strftime(format) method, to create a string representing the time under the control of an explicit format string. Broadly speaking, d.strftime(fmt) acts like the time module's time.strftime(fmt, d.timetuple()) although not all objects support a timetuple() method.

Conversely, the datetime.strptime() class method creates a datetime object from a string representing a date and time and a corresponding format string. datetime.strptime(date_string, format) is equivalent to datetime(* (time.strptime(date_string, format)[0:6])).

For time objects, the format codes for year, month, and day should not be used, as time objects have no such values. If they're used anyway, 1900 is substituted for the year, and 1 for the month and day.

For date objects, the format codes for hours, minutes, seconds, and microseconds should not be used, as date objects have no such values. If they're used anyway, 0 is substituted for them.

The full set of format codes supported varies across platforms, because Python calls the platform C library's strftime() function, and platform variations are common. To see the full set of format codes supported on your platform, consult the strftime(3) documentation.

The following is a list of all the format codes that the C standard (1989
version) requires, and these work on all platforms with a standard C implementation. Note that the 1999 version of the C standard added additional format codes.

</tbody>
</table>

Notes:

1. Because the format depends on the current locale, care should be taken when making assumptions about the output value. Field orderings will vary (for example, “month/day/year” versus “day/month/year”), and the output may contain Unicode
characters encoded using the locale's default encoding (for example, if the current locale is ja_JP, the default encoding could be any one of eucJP, SJIS, or utf-8; use \texttt{locale.getlocale()} to determine the current locale's encoding).

2. The \texttt{strptime()} method can parse years in the full [1, 9999] range, but years < 1000 must be zero-filled to 4-digit width.

\textit{Changed in version 3.2:} In previous versions, \texttt{strftime()} method was restricted to years \( \geq 1900 \).

\textit{Changed in version 3.3:} In version 3.2, \texttt{strftime()} method was restricted to years \( \geq 1000 \).

3. When used with the \texttt{strptime()} method, the \%p directive only affects the output hour field if the \%I directive is used to parse the hour.

4. Unlike the \texttt{time} module, the \texttt{datetime} module does not support leap seconds.

5. When used with the \texttt{strptime()} method, the \%f directive accepts from one to six digits and zero pads on the right. \%f is an extension to the set of format characters in the C standard (but implemented separately in datetime objects, and therefore always available).

6. For a naive object, the \%z and \%Z format codes are replaced by empty strings.

For an aware object:
utcoffset() is transformed into a 5-character string of the form +HHMM or -HHMM, where HH is a 2-digit string giving the number of UTC offset hours, and MM is a 2-digit string giving the number of UTC offset minutes. For example, if utcoffset() returns \texttt{timedelta(hours=-3, minutes=-30)}, \%z is replaced with the string \texttt{'-0330'}.

If \texttt{tzname()} returns None, \%Z is replaced by an empty string. Otherwise \%Z is replaced by the returned value, which must be a string.

\emph{Changed in version 3.2:} When the \%z directive is provided to the strftime() method, an aware \texttt{datetime} object will be produced. The \texttt{tzinfo} of the result will be set to a \texttt{timezone} instance.

7. When used with the strftime() method, \%U and \%W are only used in calculations when the day of the week and the year are specified.

\section*{Footnotes}

\footnote{If, that is, we ignore the effects of Relativity}
8.2. calendar — General calendar-related functions

Source code: Lib/calendar.py

This module allows you to output calendars like the Unix **cal** program, and provides additional useful functions related to the calendar. By default, these calendars have Monday as the first day of the week, and Sunday as the last (the European convention). Use **setfirstweekday()** to set the first day of the week to Sunday (6) or to any other weekday. Parameters that specify dates are given as integers. For related functionality, see also the **datetime** and **time** modules.

Most of these functions and classes rely on the **datetime** module which uses an idealized calendar, the current Gregorian calendar extended in both directions. This matches the definition of the “proleptic Gregorian” calendar in Dershowitz and Reingold’s book “Calendrical Calculations”, where it’s the base calendar for all computations.

```python
class calendar.Calendar(firstweekday=0)
```

Creates a **Calendar** object. **firstweekday** is an integer specifying the first day of the week. 0 is Monday (the default), 6 is Sunday.

A **Calendar** object provides several methods that can be used for preparing the calendar data for formatting. This class doesn’t do any formatting itself. This is the job of subclasses.

**Calendar** instances have the following methods:
iterweekdays()
Return an iterator for the week day numbers that will be used for one week. The first value from the iterator will be the same as the value of the firstweekday property.

itermonthdates(year, month)
Return an iterator for the month month (1-12) in the year year. This iterator will return all days (as datetime.date objects) for the month and all days before the start of the month or after the end of the month that are required to get a complete week.

itermonthdays2(year, month)
Return an iterator for the month month in the year year similar to itermonthdates(). Days returned will be tuples consisting of a day number and a week day number.

itermonthdays(year, month)
Return an iterator for the month month in the year year similar to itermonthdates(). Days returned will simply be day numbers.

monthdatescalendar(year, month)
Return a list of the weeks in the month month of the year as full weeks. Weeks are lists of seven datetime.date objects.

monthdays2calendar(year, month)
Return a list of the weeks in the month month of the year as full weeks. Weeks are lists of seven tuples of day numbers and weekday numbers.

monthdayscalendar(year, month)
Return a list of the weeks in the month month of the year as full
weeks. Weeks are lists of seven day numbers.

**yeardatescalendar**(year, width=3)
Return the data for the specified year ready for formatting. The return value is a list of month rows. Each month row contains up to \(width\) months (defaulting to 3). Each month contains between 4 and 6 weeks and each week contains 1–7 days. Days are `datetime.date` objects.

**yeardays2calendar**(year, width=3)
Return the data for the specified year ready for formatting (similar to `yeardatescalendar()`). Entries in the week lists are tuples of day numbers and weekday numbers. Day numbers outside this month are zero.

**yeardayscalendar**(year, width=3)
Return the data for the specified year ready for formatting (similar to `yeardatescalendar()`). Entries in the week lists are day numbers. Day numbers outside this month are zero.

### class `calendar.TextCalendar`(firstweekday=0)
This class can be used to generate plain text calendars.

`TextCalendar` instances have the following methods:

**formatmonth**(theyear, themonth, w=0, l=0)
Return a month’s calendar in a multi-line string. If \(w\) is provided, it specifies the width of the date columns, which are centered. If \(l\) is given, it specifies the number of lines that each week will use. Depends on the first weekday as specified in the constructor or set by the `setfirstweekday()` method.

**prmonth**(theyear, themonth, w=0, l=0)
Print a month’s calendar as returned by `formatmonth()`.

`formatyear(theyear, w=2, l=1, c=6, m=3)`
Return a \( m \)-column calendar for an entire year as a multi-line string. Optional parameters \( w \), \( l \), and \( c \) are for date column width, lines per week, and number of spaces between month columns, respectively. Depends on the first weekday as specified in the constructor or set by the `setfirstweekday()` method. The earliest year for which a calendar can be generated is platform-dependent.

`pryear(theyear, w=2, l=1, c=6, m=3)`
Print the calendar for an entire year as returned by `formatyear()`.

`class calendar.HTMLCalendar(firstweekday=0)`
This class can be used to generate HTML calendars.

`HTMLCalendar` instances have the following methods:

`formatmonth(theyear, themonth, withyear=True)`
Return a month’s calendar as an HTML table. If \( \text{withyear} \) is true the year will be included in the header, otherwise just the month name will be used.

`formatyear(theyear, width=3)`
Return a year’s calendar as an HTML table. \( \text{width} \) (defaulting to 3) specifies the number of months per row.

`formatyearpage(theyear, width=3, css='calendar.css', encoding=None)`
Return a year’s calendar as a complete HTML page. \( \text{width} \) (defaulting to 3) specifies the number of months per row. \( \text{css} \) is
the name for the cascading style sheet to be used. None can be passed if no style sheet should be used. encoding specifies the encoding to be used for the output (defaulting to the system default encoding).

class calendar..LocaleTextCalendar(firstweekday=0, locale=None)

This subclass of TextCalendar can be passed a locale name in the constructor and will return month and weekday names in the specified locale. If this locale includes an encoding all strings containing month and weekday names will be returned as unicode.

class calendar.(LocaleHTMLCalendar(firstweekday=0, locale=None)

This subclass of HTMLCalendar can be passed a locale name in the constructor and will return month and weekday names in the specified locale. If this locale includes an encoding all strings containing month and weekday names will be returned as unicode.

Note: The formatweekday() and formatmonthname() methods of these two classes temporarily change the current locale to the given locale. Because the current locale is a process-wide setting, they are not thread-safe.

For simple text calendars this module provides the following functions.

calendar.setfirstweekday(weekday)

Sets the weekday (0 is Monday, 6 is Sunday) to start each week. The values MONDAY, TUESDAY, WEDNESDAY, THURSDAY, FRIDAY, SATURDAY, and SUNDAY are provided for convenience. For example, to set the first weekday to Sunday:
import calendar
calendar.setfirstweekday(calendar.SUNDAY)

calendar.firstweekday()
Returns the current setting for the weekday to start each week.

calendar.isleap(year)
Returns True if year is a leap year, otherwise False.

calendar.leapdays(y1, y2)
Returns the number of leap years in the range from y1 to y2 (exclusive), where y1 and y2 are years.

This function works for ranges spanning a century change.

calendar.weekday(year, month, day)
Returns the day of the week (0 is Monday) for year (1970—...), month (1–12), day (1–31).

calendar.weekheader(n)
Return a header containing abbreviated weekday names. n specifies the width in characters for one weekday.

calendar.monthrange(year, month)
Returns weekday of first day of the month and number of days in month, for the specified year and month.

calendar.monthcalendar(year, month)
Returns a matrix representing a month’s calendar. Each row represents a week; days outside of the month a represented by zeros. Each week begins with Monday unless set by setfirstweekday().
calendar. **`prmonth(theyear, themonth, w=0, l=0)`**  
Prints a month’s calendar as returned by `month()`.

calendar. **`month(theyear, themonth, w=0, l=0)`**  
Returns a month’s calendar in a multi-line string using the `formatmonth()` of the `TextCalendar` class.

calendar. **`prcal(year, w=0, l=0, c=6, m=3)`**  
Prints the calendar for an entire year as returned by `calendar()`.

calendar. **`calendar(year, w=2, l=1, c=6, m=3)`**  
Returns a 3-column calendar for an entire year as a multi-line string using the `formatyear()` of the `TextCalendar` class.

calendar. **`timegm(tuple)`**  
An unrelated but handy function that takes a time tuple such as returned by the `gmtime()` function in the `time` module, and returns the corresponding Unix timestamp value, assuming an epoch of 1970, and the POSIX encoding. In fact, `time.gmtime()` and `timegm()` are each others’ inverse.

The **`calendar`** module exports the following data attributes:

calendar. **`day_name`**  
An array that represents the days of the week in the current locale.

calendar. **`day_abbr`**  
An array that represents the abbreviated days of the week in the current locale.

calendar. **`month_name`**  
An array that represents the months of the year in the current locale.
locale. This follows normal convention of January being month number 1, so it has a length of 13 and `month_name[0]` is the empty string.

`calendar.month_abbr`

An array that represents the abbreviated months of the year in the current locale. This follows normal convention of January being month number 1, so it has a length of 13 and `month_abbr[0]` is the empty string.

*Changed in version 3.3:* Moved *Collections Abstract Base Classes* to
the `collections.abc` module. For backwards compatibility, they continue to be visible in this module as well.
8.3.1. **ChainMap objects**

*New in version 3.3.*

A **ChainMap** class is provided for quickly linking a number of mappings so they can be treated as a single unit. It is often much faster than creating a new dictionary and running multiple `update()` calls.

The class can be used to simulate nested scopes and is useful in templating.

```python
class collections.ChainMap(*maps)
```

A **ChainMap** groups multiple dicts or other mappings together to create a single, updateable view. If no `maps` are specified, a single empty dictionary is provided so that a new chain always has at least one mapping.

The underlying mappings are stored in a list. That list is public and can accessed or updated using the `maps` attribute. There is no other state.

Lookups search the underlying mappings successively until a key is found. In contrast, writes, updates, and deletions only operate on the first mapping.

A **ChainMap** incorporates the underlying mappings by reference. So, if one of the underlying mappings gets updated, those changes will be reflected in **ChainMap**.

All of the usual dictionary methods are supported. In addition, there is a `maps` attribute, a method for creating new subcontexts, and a
property for accessing all but the first mapping:

maps

A user updateable list of mappings. The list is ordered from first-searched to last-searched. It is the only stored state and can be modified to change which mappings are searched. The list should always contain at least one mapping.

new_child(m=None)

Returns a new ChainMap containing a new map followed by all of the maps in the current instance. If m is specified, it becomes the new map at the front of the list of mappings; if not specified, an empty dict is used, so that a call to d.new_child() is equivalent to: ChainMap({}, *d.maps). This method is used for creating subcontexts that can be updated without altering values in any of the parent mappings.

Changed in version 3.4: The optional m parameter was added.

parents

Property returning a new ChainMap containing all of the maps in the current instance except the first one. This is useful for skipping the first map in the search. Use cases are similar to those for the nonlocal keyword used in nested scopes. The use cases also parallel those for the built-in super() function. A reference to d.parents is equivalent to: ChainMap(*d.maps[1:]).

See also:

- The MultiContext class in the Enthought CodeTools package has options to support writing to any mapping in the chain.
Django's Context class for templating is a read-only chain of mappings. It also features pushing and popping of contexts similar to the new_child() method and the parents() property.

The Nested Contexts recipe has options to control whether writes and other mutations apply only to the first mapping or to any mapping in the chain.

A greatly simplified read-only version of Chainmap.

8.3.1.1. ChainMap Examples and Recipes

This section shows various approaches to working with chained maps.

Example of simulating Python's internal lookup chain:

```python
import builtins
pylookup = ChainMap(locals(), globals(), vars(builtins))
```

Example of letting user specified command-line arguments take precedence over environment variables which in turn take precedence over default values:

```python
import os, argparse
defaults = {'color': 'red', 'user': 'guest'}

parser = argparse.ArgumentParser()
parser.add_argument('-u', '--user')
parser.add_argument('-c', '--color')
namespace = parser.parse_args()
command_line_args = {k:v for k, v in vars(namespace).items()}
combined = ChainMap(command_line_args, os.environ, defaults)
print(combined['color'])
```
Example patterns for using the `ChainMap` class to simulate nested contexts:

```python
print(combined['user'])
```

The `ChainMap` class only makes updates (writes and deletions) to the first mapping in the chain while lookups will search the full chain. However, if deep writes and deletions are desired, it is easy to make a subclass that updates keys found deeper in the chain:

```python
class DeepChainMap(ChainMap):
    'Variant of ChainMap that allows direct updates

    def __setitem__(self, key, value):
        for mapping in self.maps:
            if key in mapping:
                mapping[key] = value
        return
```
self.maps[0][key] = value

def __delitem__(self, key):
    for mapping in self.maps:
        if key in mapping:
            del mapping[key]
            return
    raise KeyError(key)

>>> d = DeepChainMap({'zebra': 'black'}, {'elephant': 'gray'})
>>> d['lion'] = 'orange'  # update an existing key
>>> d['snake'] = 'red'    # new keys get added to the topmost dict
>>> del d['elephant']    # remove an existing key
DeepChainMap({'zebra': 'black', 'snake': 'red'}, {})
8.3.2. Counter objects

A counter tool is provided to support convenient and rapid tallies. For example:

```python
>>> # Tally occurrences of words in a list
>>> cnt = Counter()
>>> for word in ['red', 'blue', 'red', 'green', 'blue', ...
...     cnt[word] += 1
>>> cnt
Counter({'blue': 3, 'red': 2, 'green': 1})

>>> # Find the ten most common words in Hamlet
>>> import re
>>> words = re.findall(r'\w+', open('hamlet.txt').read())
>>> Counter(words).most_common(10)
[('the', 1143), ('and', 966), ('to', 762), ('of', 662), ('you', 554), ('a', 546), ('my', 514), ('hamlet', 471), ('in', 451)]
```

class collections.Counter([iterable-or-mapping])

A Counter is a dict subclass for counting hashable objects. It is an unordered collection where elements are stored as dictionary keys and their counts are stored as dictionary values. Counts are allowed to be any integer value including zero or negative counts. The Counter class is similar to bags or multisets in other languages.

Elements are counted from an iterable or initialized from another mapping (or counter):

```python
>>> c = Counter()                     # a new, empty counter
>>> c = Counter('gallahad')          # a new counter from an iterable
```
Counter objects have a dictionary interface except that they return a zero count for missing items instead of raising a `KeyError`:

```python
>>> c = Counter({'red': 4, 'blue': 2})  # a new counter from a mapping
>>> c = Counter(cats=4, dogs=8)  # a new counter from keyword args
```

Setting a count to zero does not remove an element from a counter. Use `del` to remove it entirely:

```python
>>> c['sausage'] = 0  # count of a missing element is zero
>>> del c['sausage']  # del actually removes the entry
```

*New in version 3.1.*

Counter objects support three methods beyond those available for all dictionaries:

**elements()**

Return an iterator over elements repeating each as many times as its count. Elements are returned in arbitrary order. If an element's count is less than one, `elements()` will ignore it.

```python
>>> c = Counter(a=4, b=2, c=0, d=-2)
>>> list(c.elements())
['a', 'a', 'a', 'a', 'b', 'b']
```

**most_common([n])**

Return a list of the $n$ most common elements and their counts.
from the most common to the least. If \( n \) is not specified, \texttt{most\_common()} returns \textit{all} elements in the counter. Elements with equal counts are ordered arbitrarily:

\[
>>> \texttt{Counter('abracadabra').most\_common(3)}
[('a', 5), ('r', 2), ('b', 2)]
\]

\texttt{subtract([iterable-or-mapping])}

Elements are subtracted from an \textit{iterable} or from another \textit{mapping} (or counter). Like \texttt{dict.update()} but subtracts counts instead of replacing them. Both inputs and outputs may be zero or negative.

\[
>>> c = \texttt{Counter(a=4, b=2, c=0, d=-2)}
>>> d = \texttt{Counter(a=1, b=2, c=3, d=4)}
>>> c.subtract(d)
>>> c
Counter({'a': 3, 'b': 0, 'c': -3, 'd': -6})
\]

\textit{New in version 3.2.}

The usual dictionary methods are available for \texttt{Counter} objects except for two which work differently for counters.

\texttt{fromkeys(iterable)}

This class method is not implemented for \texttt{Counter} objects.

\texttt{update([iterable-or-mapping])}

Elements are counted from an \textit{iterable} or added-in from another \textit{mapping} (or counter). Like \texttt{dict.update()} but adds counts instead of replacing them. Also, the \textit{iterable} is expected to be a sequence of elements, not a sequence of (key, value) pairs.
Common patterns for working with `Counter` objects:

```
sum(c.values())  # total of all counts
c.clear()       # reset all counts
list(c)         # list unique elements
set(c)          # convert to a set
dict(c)         # convert to a regular dictionary
c.items()       # convert to a list
Counter(dict(list_of_pairs))  # convert from a list

c.most_common()[:n-1:-1]  # n least common elements
+c                         # remove zero and negative counts
```

Several mathematical operations are provided for combining `Counter` objects to produce multisets (counters that have counts greater than zero). Addition and subtraction combine counters by adding or subtracting the counts of corresponding elements. Intersection and union return the minimum and maximum of corresponding counts. Each operation can accept inputs with signed counts, but the output will exclude results with counts of zero or less.

```
>>> c = Counter(a=3, b=1)
>>> d = Counter(a=1, b=2)
>>> c + d                    # add two counters together
Counter({'a': 4, 'b': 3})
>>> c - d                   # subtract (keeping only positive counts)
Counter({'a': 2})
>>> c & d                   # intersection: min
Counter({'a': 1, 'b': 1})
>>> c | d                   # union: max(c[x], d[x])
Counter({'a': 3, 'b': 2})
```

Unary addition and substraction are shortcuts for adding an empty counter or subtracting from an empty counter.
>>> c = Counter(a=2, b=-4)
>>> +c
Counter({'a': 2})
>>> -c
Counter({'b': 4})

New in version 3.3: Added support for unary plus, unary minus, and in-place multiset operations.

**Note:** Counters were primarily designed to work with positive integers to represent running counts; however, care was taken to not unnecessarily preclude use cases needing other types or negative values. To help with those use cases, this section documents the minimum range and type restrictions.

- The `Counter` class itself is a dictionary subclass with no restrictions on its keys and values. The values are intended to be numbers representing counts, but you *could* store anything in the value field.
- The `most_common()` method requires only that the values be orderable.
- For in-place operations such as `c[key] += 1`, the value type need only support addition and subtraction. So fractions, floats, and decimals would work and negative values are supported. The same is also true for `update()` and `subtract()` which allow negative and zero values for both inputs and outputs.
- The multiset methods are designed only for use cases with positive values. The inputs may be negative or zero, but only outputs with positive values are created. There are no type restrictions, but the value type needs to support addition, subtraction, and comparison.
- The `elements()` method requires integer counts. It ignores zero and negative counts.

- For mathematical operations on multisets and their use cases, see Knuth, Donald. *The Art of Computer Programming Volume II, Section 4.6.3, Exercise 19.*
- To enumerate all distinct multisets of a given size over a given set of elements, see `itertools.combinations_with_replacement()`.

```
map(Counter, combinations_with_replacement('ABC', 2)) –
> AA AB AC BB BC CC
```
8.3.3. deque objects

class collections.deque([iterable, maxlen])

Returns a new deque object initialized left-to-right (using append()) with data from iterable. If iterable is not specified, the new deque is empty.

Deques are a generalization of stacks and queues (the name is pronounced “deck” and is short for “double-ended queue”). Deques support thread-safe, memory efficient appends and pops from either side of the deque with approximately the same O(1) performance in either direction.

Though list objects support similar operations, they are optimized for fast fixed-length operations and incur O(n) memory movement costs for pop(0) and insert(0, v) operations which change both the size and position of the underlying data representation.

If maxlen is not specified or is None, deques may grow to an arbitrary length. Otherwise, the deque is bounded to the specified maximum length. Once a bounded length deque is full, when new items are added, a corresponding number of items are discarded from the opposite end. Bounded length deques provide functionality similar to the tail filter in Unix. They are also useful for tracking transactions and other pools of data where only the most recent activity is of interest.

Deque objects support the following methods:

 append(x)
Add $x$ to the right side of the deque.

**appendleft**($x$)
Add $x$ to the left side of the deque.

**clear**()
Remove all elements from the deque leaving it with length 0.

**count**($x$)
Count the number of deque elements equal to $x$.

*New in version 3.2.*

**extend**(*iterable*)
Extend the right side of the deque by appending elements from the iterable argument.

**extendleft**(*iterable*)
Extend the left side of the deque by appending elements from *iterable*. Note, the series of left appends results in reversing the order of elements in the iterable argument.

**pop**()
Remove and return an element from the right side of the deque. If no elements are present, raises an **IndexError**.

**popleft**()
Remove and return an element from the left side of the deque. If no elements are present, raises an **IndexError**.

**remove**(value)
Removed the first occurrence of *value*. If not found, raises a **ValueError**.
**reverse()**
Reverse the elements of the deque in-place and then return None.

*New in version 3.2.*

**rotate(n)**
Rotate the deque *n* steps to the right. If *n* is negative, rotate to the left. Rotating one step to the right is equivalent to:
\[
d\text{.appendleft}(d\text{.pop()}).
\]

Deque objects also provide one read-only attribute:

**maxlen**
Maximum size of a deque or *None* if unbounded.

*New in version 3.1.*

In addition to the above, deques support iteration, pickling, `len(d)`, `reversed(d)`, `copy.copy(d)`, `copy.deepcopy(d)`, membership testing with the `in` operator, and subscript references such as `d[-1]`. Indexed access is O(1) at both ends but slows to O(n) in the middle. For fast random access, use lists instead.

Example:

```python
>>> from collections import deque
>>> d = deque('ghi')  # make a new deque
>>> for elem in d:    # iterate over
...     print(elem.upper())
G
H
I
```
>>> d.append('j') # add a new entry to the right side
>>> d.appendleft('f') # add a new entry to the left side
d
deque([ 'f', 'g', 'h', 'i', 'j' ]) # show the representation of the deque

>>> d.pop() # return and remove the rightmost item
'j'
>>> d.popleft() # return and remove the leftmost item
'f'

>>> list(d) # list the contents of the deque
[ 'g', 'h', 'i' ]

>>> d[0] # peek at leftmost item
'g'
>>> d[-1] # peek at rightmost item
' i'

>>> list(reversed(d)) # list the contents of the deque in reverse
[ 'i', 'h', 'g' ]

>>> 'h' in d # search the deque
True

>>> d.extend('jkl') # add multiple elements at once

>>> d
deque([ 'g', 'h', 'i', 'j', 'k', 'l' ])

>>> d.rotate(1) # right rotation

>>> d
deque([ 'l', 'g', 'h', 'i', 'j', 'k' ])

>>> d.rotate(-1) # left rotation

>>> d
deque([ 'g', 'h', 'i', 'j', 'k', 'l' ])

>>> deque(reversed(d)) # make a new deque in reverse order
deque([ 'l', 'k', 'j', 'i', 'h', 'g' ])

>>> d.clear() # empty the deque

>>> d.pop() # cannot pop from an empty deque
Traceback (most recent call last):
  File "<pyshell#6>", line 1, in -toplevel-
  d.pop()
8.3.3.1. **deque Recipes**

This section shows various approaches to working with deques.

Bounded length deques provide functionality similar to the `tail` filter in Unix:

```python
def tail(filename, n=10):
    'Return the last n lines of a file'
    with open(filename) as f:
        return deque(f, n)
```

Another approach to using deques is to maintain a sequence of recently added elements by appending to the right and popping to the left:

```python
def moving_average(iterable, n=3):
    # moving_average([40, 30, 50, 46, 39, 44]) --> 4
    # http://en.wikipedia.org/wiki/Moving_average
    it = iter(iterable)
    d = deque(itertools.islice(it, n-1))
    d.appendleft(0)
    s = sum(d)
    for elem in it:
        s += elem - d.popleft()
        d.append(elem)
        yield s / n
```

`IndexError: pop from an empty deque`

```python
>>> d.extendleft('abc')  # extendleft()
>>> d
ddeque(['c', 'b', 'a'])
```
The `rotate()` method provides a way to implement deque slicing and deletion. For example, a pure Python implementation of `del d[n]` relies on the `rotate()` method to position elements to be popped:

```python
def delete_nth(d, n):
    d.rotate(-n)
    d.popleft()
    d.rotate(n)
```

To implement deque slicing, use a similar approach applying `rotate()` to bring a target element to the left side of the deque. Remove old entries with `popleft()`, add new entries with `extend()`, and then reverse the rotation. With minor variations on that approach, it is easy to implement Forth style stack manipulations such as `dup`, `drop`, `swap`, `over`, `pick`, `rot`, and `roll`. 
8.3.4. defaultdict objects

class collections.defaultdict([default_factory[, ...]])

Returns a new dictionary-like object. defaultdict is a subclass of the built-in dict class. It overrides one method and adds one writable instance variable. The remaining functionality is the same as for the dict class and is not documented here.

The first argument provides the initial value for the default_factory attribute; it defaults to None. All remaining arguments are treated the same as if they were passed to the dict constructor, including keyword arguments.

defaultdict objects support the following method in addition to the standard dict operations:

__missing__(key)

If the default_factory attribute is None, this raises a KeyError exception with the key as argument.

If default_factory is not None, it is called without arguments to provide a default value for the given key, this value is inserted in the dictionary for the key, and returned.

If calling default_factory raises an exception this exception is propagated unchanged.

This method is called by the __getitem__() method of the dict class when the requested key is not found; whatever it returns or raises is then returned or raised by __getitem__().
Note that __missing__() is not called for any operations besides __getitem__(). This means that get() will, like normal dictionaries, return None as a default rather than using default_factory.

defaultdict objects support the following instance variable:

**default_factory**

This attribute is used by the __missing__() method; it is initialized from the first argument to the constructor, if present, or to None, if absent.

### 8.3.4.1. defaultdict Examples

Using list as the default_factory, it is easy to group a sequence of key-value pairs into a dictionary of lists:

```python
>>> s = [('yellow', 1), ('blue', 2), ('yellow', 3),
>>> d = defaultdict(list)
>>> for k, v in s:
...     d[k].append(v)
... 
>>> list(d.items())
[('blue', [2, 4]), ('red', [1]), ('yellow', [1, 3])]
```

When each key is encountered for the first time, it is not already in the mapping; so an entry is automatically created using the default_factory function which returns an empty list. The list.append() operation then attaches the value to the new list. When keys are encountered again, the look-up proceeds normally (returning the list for that key) and the list.append() operation adds another value to the list. This technique is simpler and faster than
an equivalent technique using `dict.setdefault()`:

```python
>>> d = {}
>>> for k, v in s:
...     d.setdefault(k, []).append(v)
...>>> list(d.items())
[('blue', [2, 4]), ('red', [1]), ('yellow', [1, 3])]
```

Setting the `default_factory` to `int` makes the `defaultdict` useful for counting (like a bag or multiset in other languages):

```python
>>> s = 'mississippi'
>>> d = defaultdict(int)
>>> for k in s:
...     d[k] += 1
...>>> list(d.items())
[['i', 4], ['p', 2], ['s', 4], ['m', 1]]
```

When a letter is first encountered, it is missing from the mapping, so the `default_factory` function calls `int()` to supply a default count of zero. The increment operation then builds up the count for each letter.

The function `int()` which always returns zero is just a special case of constant functions. A faster and more flexible way to create constant functions is to use a lambda function which can supply any constant value (not just zero):

```python
>>> def constant_factory(value):
...     return lambda: value
>>> d = defaultdict(constant_factory('<missing>'))
>>> d.update(name='John', action='ran')
```
Setting the `default_factory` to `set` makes the `defaultdict` useful for building a dictionary of sets:

```python
>>> s = [('red', 1), ('blue', 2), ('red', 3), ('blue', 4), ('red', 3), ('blue', 4)]
>>> d = defaultdict(set)
>>> for k, v in s:
...    d[k].add(v)
...  
>>> list(d.items())
[('blue', {2, 4}), ('red', {1, 3})]
```
8.3.5. **namedtuple()** Factory Function for Tuples with Named Fields

Named tuples assign meaning to each position in a tuple and allow for more readable, self-documenting code. They can be used wherever regular tuples are used, and they add the ability to access fields by name instead of position index.

```python
collections.namedtuple(typename, field_names, verbose=False, rename=False)
```

Returns a new tuple subclass named `typename`. The new subclass is used to create tuple-like objects that have fields accessible by attribute lookup as well as being indexable and iterable. Instances of the subclass also have a helpful docstring (with typename and field_names) and a helpful `__repr__()` method which lists the tuple contents in a `name=value` format.

The `field_names` are a single string with each fieldname separated by whitespace and/or commas, for example `'x, y'` or `'x, y'`. Alternatively, `field_names` can be a sequence of strings such as `['x', 'y']`.

Any valid Python identifier may be used for a fieldname except for names starting with an underscore. Valid identifiers consist of letters, digits, and underscores but do not start with a digit or underscore and cannot be a keyword such as `class`, `for`, `return`, `global`, `pass`, or `raise`.

If `rename` is true, invalid fieldnames are automatically replaced with positional names. For example, `['abc', 'def', 'ghi', 'abc']` is converted to `['abc', '_1', 'ghi', '_3']`,
eliminating the keyword `def` and the duplicate fieldname `abc`.

If `verbose` is true, the class definition is printed after it is built. This option is outdated; instead, it is simpler to print the `_source` attribute.

Named tuple instances do not have per-instance dictionaries, so they are lightweight and require no more memory than regular tuples.

*Changed in version 3.1*: Added support for `rename`.

```python
>>> # Basic example
>>> Point = namedtuple('Point', ['x', 'y'])
>>> p = Point(11, y=22)  # instantiate with positional arguments
>>> p[0] + p[1]  # indexable like the plain tuple (11, 22)
33
>>> x, y = p  # unpack like a regular tuple
>>> x, y
(11, 22)
>>> p.x + p.y  # fields also accessible by name
33
>>> p  # readable __repr__ with named fields
Point(x=11, y=22)
```

Named tuples are especially useful for assigning field names to result tuples returned by the `csv` or `sqlite3` modules:

```python
EmployeeRecord = namedtuple('EmployeeRecord', 'name, age, title, department, paygrade')
import csv
for emp in map(EmployeeRecord._make, csv.reader(open('data.csv'))):
    print(emp.name, emp.title)
import sqlite3
```
conn = sqlite3.connect('/companydata')
cursor = conn.cursor()
cursor.execute('SELECT name, age, title, department,
for emp in map(EmployeeRecord._make, cursor.fetchall()
print(emp.name, emp.title)

In addition to the methods inherited from tuples, named tuples support
three additional methods and two attributes. To prevent conflicts with
field names, the method and attribute names start with an underscore.

classmethod somenamedtuple._make(iterable)

Class method that makes a new instance from an existing
sequence or iterable.

```>>> t = [11, 22]
>>> Point._make(t)
Point(x=11, y=22)
```

somenamedtuple._asdict()

Return a new OrderedDict which maps field names to their
_corresponding values. Note, this method is no longer needed now
that the same effect can be achieved by using the built-in vars() function:

```>>> vars(p)
OrderedDict([('x', 11), ('y', 22)])
```

*Changed in version 3.1:* Returns an OrderedDict instead of a
regular dict.

somenamedtuple._replace(kwars)

Return a new instance of the named tuple replacing specified fields
with new values:
somenamedtuple._source
A string with the pure Python source code used to create the named tuple class. The source makes the named tuple self-documenting. It can be printed, executed using `exec()`, or saved to a file and imported.

*New in version 3.3.*

somenamedtuple._fields
Tuple of strings listing the field names. Useful for introspection and for creating new named tuple types from existing named tuples.

To retrieve a field whose name is stored in a string, use the `getattr()` function:
To convert a dictionary to a named tuple, use the double-star-operator (as described in *Unpacking Argument Lists*):

```python
defining dictionary
>>> d = {'x': 11, 'y': 22}
defining named tuple
>>> Point(**d)
Point(x=11, y=22)
```

Since a named tuple is a regular Python class, it is easy to add or change functionality with a subclass. Here is how to add a calculated field and a fixed-width print format:

```python
>>>
```class Point(namedtuple('Point', 'x y')):
    __slots__ = ()
    @property
def hypot(self):
        return (self.x ** 2 + self.y ** 2) ** 0.5
def __str__(self):
        return 'Point: x=%6.3f  y=%6.3f  hypot=%6.3f'
```

```python
>>> for p in Point(3, 4), Point(14, 5/7):
    print(p)
Point:  x= 3.000  y= 4.000  hypot= 5.000
Point:  x=14.000  y=  0.714  hypot=14.018
```  

The subclass shown above sets `__slots__` to an empty tuple. This helps keep memory requirements low by preventing the creation of instance dictionaries.

Subclassing is not useful for adding new, stored fields. Instead, simply create a new named tuple type from the `_fields` attribute:

```python
>>> Point3D = namedtuple('Point3D', Point._fields +
```
Default values can be implemented by using \_replace() to customize a prototype instance:

```python
>>> Account = namedtuple('Account', 'owner balance transaction_count', default=None)
>>> default_account = Account('<owner name>', 0.0, 0)
>>> johns_account = default_account._replace(owner='John', balance=100.0)
>>> janews_account = default_account._replace(owner='Jane', balance=50.0)
```

Enumerated constants can be implemented with named tuples, but it is simpler and more efficient to use a simple class declaration:

```python
>>> Status = namedtuple('Status', 'open pending closed', default=(0, 1, 2))
>>> Status.open, Status.pending, Status.closed = range(3)

>>> class Status:
    open, pending, closed = range(3)
```

- Recipe for named tuple abstract base class with a metaclass mix-in by Jan Kaliszewski. Besides providing an abstract base class for named tuples, it also supports an alternate metaclass-based constructor that is convenient for use cases where named tuples are being subclassed.
8.3.6. **OrderedDict** objects

Ordered dictionaries are just like regular dictionaries but they remember the order that items were inserted. When iterating over an ordered dictionary, the items are returned in the order their keys were first added.

```python
class collections.OrderedDict([items])
```

Return an instance of a dict subclass, supporting the usual `dict` methods. An `OrderedDict` is a dict that remembers the order that keys were first inserted. If a new entry overwrites an existing entry, the original insertion position is left unchanged. Deleting an entry and reinserting it will move it to the end.

*New in version 3.1.*

**popitem**(last=True)

The `popitem()` method for ordered dictionaries returns and removes a (key, value) pair. The pairs are returned in LIFO order if `last` is true or FIFO order if false.

**move_to_end**(key, last=True)

Move an existing key to either end of an ordered dictionary. The item is moved to the right end if `last` is true (the default) or to the beginning if `last` is false. Raises `KeyError` if the key does not exist:

```python
>>> d = OrderedDict.fromkeys('abcde')
>>> d.move_to_end('b')
>>> ''.join(d.keys())
'acdeb'
>>> d.move_to_end('b', last=False)
```
In addition to the usual mapping methods, ordered dictionaries also support reverse iteration using `reversed()`.

Equality tests between `OrderedDict` objects are order-sensitive and are implemented as `list(od1.items())==list(od2.items())`. Equality tests between `OrderedDict` objects and other `Mapping` objects are order-insensitive like regular dictionaries. This allows `OrderedDict` objects to be substituted anywhere a regular dictionary is used.

The `OrderedDict` constructor and `update()` method both accept keyword arguments, but their order is lost because Python's function call semantics pass-in keyword arguments using a regular unordered dictionary.

### 8.3.6.1. `OrderedDict` Examples and Recipes

Since an ordered dictionary remembers its insertion order, it can be used in conjunction with sorting to make a sorted dictionary:

```python
>>> # regular unsorted dictionary
>>> d = {'banana': 3, 'apple': 4, 'pear': 1, 'orange': 2}

>>> # dictionary sorted by key
>>> OrderedDict(sorted(d.items(), key=lambda t: t[0]))
OrderedDict([('apple', 4), ('banana', 3), ('orange', 2)])

>>> # dictionary sorted by value
>>> OrderedDict(sorted(d.items(), key=lambda t: t[1]))
OrderedDict([('orange', 2), ('apple', 4), ('banana', 3), ('pear', 1)])
```
OrderedDict([('pear', 1), ('orange', 2), ('banana', 3), ('apple', 4)])

>>> # dictionary sorted by length of the key string
>>> OrderedDict(sorted(d.items(), key=lambda t: len(t[0])))
OrderedDict([('pear', 1), ('apple', 4), ('orange', 2), ('banana', 3)])

The new sorted dictionaries maintain their sort order when entries are deleted. But when new keys are added, the keys are appended to the end and the sort is not maintained.

It is also straight-forward to create an ordered dictionary variant that remembers the order the keys were last inserted. If a new entry overwrites an existing entry, the original insertion position is changed and moved to the end:

class LastUpdatedOrderedDict(OrderedDict):
    'Store items in the order the keys were last added'

    def __setitem__(self, key, value):
        if key in self:
            del self[key]
        OrderedDict.__setitem__(self, key, value)

An ordered dictionary can be combined with the Counter class so that the counter remembers the order elements are first encountered:

class OrderedCounter(Counter, OrderedDict):
    'Counter that remembers the order elements are first encountered'

    def __repr__(self):
        return '%s(%r) % (self.__class__.__name__,

    def __reduce__(self):
        return self.__class__, (OrderedDict(self),)
8.3.7. UserDict objects

The class, UserDict acts as a wrapper around dictionary objects. The need for this class has been partially supplanted by the ability to subclass directly from dict; however, this class can be easier to work with because the underlying dictionary is accessible as an attribute.

class collections.UserDict([initialdata])

Class that simulates a dictionary. The instance’s contents are kept in a regular dictionary, which is accessible via the data attribute of UserDict instances. If initialdata is provided, data is initialized with its contents; note that a reference to initialdata will not be kept, allowing it be used for other purposes.

In addition to supporting the methods and operations of mappings, UserDict instances provide the following attribute:

data

A real dictionary used to store the contents of the UserDict class.
8.3.8. **UserList** objects

This class acts as a wrapper around list objects. It is a useful base class for your own list-like classes which can inherit from them and override existing methods or add new ones. In this way, one can add new behaviors to lists.

The need for this class has been partially supplanted by the ability to subclass directly from `list`; however, this class can be easier to work with because the underlying list is accessible as an attribute.

```python
class collections.UserList([list])
```

Class that simulates a list. The instance's contents are kept in a regular list, which is accessible via the `data` attribute of `UserList` instances. The instance's contents are initially set to a copy of `list`, defaulting to the empty list `[]`. `list` can be any iterable, for example a real Python list or a `UserList` object.

In addition to supporting the methods and operations of mutable sequences, `UserList` instances provide the following attribute:

```python
data
```

A real `list` object used to store the contents of the `UserList` class.

**Subclassing requirements:** Subclasses of `UserList` are expected to offer a constructor which can be called with either no arguments or one argument. List operations which return a new sequence attempt to create an instance of the actual implementation class. To do so, it assumes that the constructor can be called with a single parameter, which is a sequence object used as a data source.
If a derived class does not wish to comply with this requirement, all of the special methods supported by this class will need to be overridden; please consult the sources for information about the methods which need to be provided in that case.
8.3.9. **UserString** objects

The class, **UserString** acts as a wrapper around string objects. The need for this class has been partially supplanted by the ability to subclass directly from **str**; however, this class can be easier to work with because the underlying string is accessible as an attribute.

```python
class collections.UserString([sequence])

Class that simulates a string or a Unicode string object. The instance's content is kept in a regular string object, which is accessible via the data attribute of **UserString** instances. The instance's contents are initially set to a copy of `sequence`. The `sequence` can be an instance of `bytes`, `str`, **UserString** (or a subclass) or an arbitrary sequence which can be converted into a string using the built-in `str()` function.
```
8.4. **collections.abc** — Abstract Base Classes for Containers

*New in version 3.3:* Formerly, this module was part of the `collections` module.

**Source code:** `Lib/_collections_abc.py`

This module provides *abstract base classes* that can be used to test whether a class provides a particular interface; for example, whether it is hashable or whether it is a mapping.
# 8.4.1. Collections Abstract Base Classes

The collections module offers the following *ABCs*:

<table>
<thead>
<tr>
<th>ABC</th>
<th>Inherits from</th>
<th>Abstract Methods</th>
<th>Mixin Methods</th>
</tr>
</thead>
<tbody>
<tr>
<td>Container</td>
<td></td>
<td><code>_contains_</code></td>

</tbody>
</table>
class collections.abc.Container
class collections.abc.Hashable
class collections.abc.Sized
class collections.abc.Callable
    ABCs for classes that provide respectively the methods __contains__(), __hash__(), __len__(), and __call__().

class collections.abc.Iterable
    ABC for classes that provide the __iter__() method. See also the definition of iterable.

class collections.abc.Iterator
    ABC for classes that provide the __iter__() and __next__() methods. See also the definition of iterator.

class collections.abc.Sequence
class collections.abc.MutableSequence
    ABCs for read-only and mutable sequences.

class collections.abc.Set
class collections.abc.MutableSet
    ABCs for read-only and mutable sets.

class collections.abc.Mapping
class collections.abc.MutableMapping
    ABCs for read-only and mutable mappings.

class collections.abc.MappingView
class collections.abc.ItemsView
class collections.abc.KeysView
class collections.abc.ValuesView
    ABCs for mapping, items, keys, and values views.
These ABCs allow us to ask classes or instances if they provide particular functionality, for example:

```python
size = None
if isinstance(myvar, collections.abc.Sized):
    size = len(myvar)
```

Several of the ABCs are also useful as mixins that make it easier to develop classes supporting container APIs. For example, to write a class supporting the full `Set` API, it only necessary to supply the three underlying abstract methods: `__contains__()`, `__iter__()`, and `__len__()`. The ABC supplies the remaining methods such as `__and__()` and `isdisjoint()`:

```python
class ListBasedSet(collections.abc.Set):
    '''Alternate set implementation favoring space and not requiring the set elements to be hashable.'''
    def __init__(self, iterable):
        self.elements = lst = []
        for value in iterable:
            if value not in lst:
                lst.append(value)
    def __iter__(self):
        return iter(self.elements)
    def __contains__(self, value):
        return value in self.elements
    def __len__(self):
        return len(self.elements)

s1 = ListBasedSet('abcdef')
s2 = ListBasedSet('defghi')
overlap = s1 & s2  # The __and__() method
```

Notes on using `Set` and `MutableSet` as a mixin:
1. Since some set operations create new sets, the default mixin methods need a way to create new instances from an iterable. The class constructor is assumed to have a signature in the form `ClassName(iterable)`. That assumption is factored-out to an internal classmethod called `__from_iterable()` which calls `cls(iterable)` to produce a new set. If the `Set` mixin is being used in a class with a different constructor signature, you will need to override `__from_iterable()` with a classmethod that can construct new instances from an iterable argument.

2. To override the comparisons (presumably for speed, as the semantics are fixed), redefine `__le__()` and then the other operations will automatically follow suit.

3. The `Set` mixin provides a `_hash()` method to compute a hash value for the set; however, `__hash__()` is not defined because not all sets are hashable or immutable. To add set hashability using mixins, inherit from both `Set()` and `Hashable()`, then define `__hash__ = Set._hash`.

**See also:**

- [OrderedSet recipe](#) for an example built on `MutableSet`.
- For more about ABCs, see the `abc` module and [PEP 3119](#).

Last updated on Mar 16, 2014. Found a bug?  
Created using Sphinx 1.2.
This module provides an implementation of the heap queue algorithm, also known as the priority queue algorithm.

Heaps are binary trees for which every parent node has a value less than or equal to any of its children. This implementation uses arrays for which $heap[k] \leq heap[2*k+1]$ and $heap[k] \leq heap[2*k+2]$ for all $k$, counting elements from zero. For the sake of comparison, non-existing elements are considered to be infinite. The interesting property of a heap is that its smallest element is always the root, $heap[0]$.

The API below differs from textbook heap algorithms in two aspects: (a) We use zero-based indexing. This makes the relationship between the index for a node and the indexes for its children slightly less obvious, but is more suitable since Python uses zero-based indexing. (b) Our pop method returns the smallest item, not the largest (called a “min heap” in textbooks; a “max heap” is more common in texts because of its suitability for in-place sorting).

These two make it possible to view the heap as a regular Python list without surprises: $heap[0]$ is the smallest item, and $heap.sort()$ maintains the heap invariant!

To create a heap, use a list initialized to [], or you can transform a populated list into a heap via function heapify().
The following functions are provided:

heapq. **heappush**(heap, item)

Push the value *item* onto the *heap*, maintaining the heap invariant.

heapq. **heappop**(heap)

Pop and return the smallest item from the *heap*, maintaining the heap invariant. If the heap is empty, *IndexError* is raised.

heapq. **heappushpop**(heap, item)

Push *item* on the heap, then pop and return the smallest item from the *heap*. The combined action runs more efficiently than **heappush()** followed by a separate call to **heappop()**.

heapq. **heapify**(x)

Transform list *x* into a heap, in-place, in linear time.

heapq. **heappopreplace**(heap, item)

Pop and return the smallest item from the *heap*, and also push the new *item*. The heap size doesn’t change. If the heap is empty, *IndexError* is raised.

This one step operation is more efficient than a **heappop()** followed by **heappush()** and can be more appropriate when using a fixed-size heap. The pop/push combination always returns an element from the heap and replaces it with *item*.

The value returned may be larger than the *item* added. If that isn’t desired, consider using **heappushpop()** instead. Its push/pop combination returns the smaller of the two values, leaving the larger value on the heap.

The module also offers three general purpose functions based on
heaps.

heapq. **merge**(*iterables*)

Merge multiple sorted inputs into a single sorted output (for example, merge timestamped entries from multiple log files). Returns an *iterator* over the sorted values.

Similar to `sorted(itertools.chain(*iterables))` but returns an iterable, does not pull the data into memory all at once, and assumes that each of the input streams is already sorted (smallest to largest).

heapq. **nlargest**(*n, iterable, key=None*)

Return a list with the *n* largest elements from the dataset defined by *iterable*. *key*, if provided, specifies a function of one argument that is used to extract a comparison key from each element in the iterable: `key=str.lower` Equivalent to: `sorted(iterable, key=key, reverse=True)[:n]

heapq. **nsmallest**(*n, iterable, key=None*)

Return a list with the *n* smallest elements from the dataset defined by *iterable*. *key*, if provided, specifies a function of one argument that is used to extract a comparison key from each element in the iterable: `key=str.lower` Equivalent to: `sorted(iterable, key=key)[:n]

The latter two functions perform best for smaller values of *n*. For larger values, it is more efficient to use the `sorted()` function. Also, when *n*=1, it is more efficient to use the built-in `min()` and `max()` functions.
8.5.1. Basic Examples

A heapsort can be implemented by pushing all values onto a heap and then popping off the smallest values one at a time:

```python
>>> def heapsort(iterable):
...     'Equivalent to sorted(iterable)'
...     h = []
...     for value in iterable:
...         heappush(h, value)
...     return [heappop(h) for i in range(len(h))]
...
>>> heapsort([1, 3, 5, 7, 9, 2, 4, 6, 8, 0])
[0, 1, 2, 3, 4, 5, 6, 7, 8, 9]
```

Heap elements can be tuples. This is useful for assigning comparison values (such as task priorities) alongside the main record being tracked:

```python
>>> h = []
>>> heappush(h, (5, 'write code'))
>>> heappush(h, (7, 'release product'))
>>> heappush(h, (1, 'write spec'))
>>> heappush(h, (3, 'create tests'))
>>> heappop(h)
(1, 'write spec')
```
8.5.2. Priority Queue Implementation

Notes

A priority queue is common use for a heap, and it presents several implementation challenges:

- Sort stability: how do you get two tasks with equal priorities to be returned in the order they were originally added?
- Tuple comparison breaks for (priority, task) pairs if the priorities are equal and the tasks do not have a default comparison order.
- If the priority of a task changes, how do you move it to a new position in the heap?
- Or if a pending task needs to be deleted, how do you find it and remove it from the queue?

A solution to the first two challenges is to store entries as 3-element list including the priority, an entry count, and the task. The entry count serves as a tie-breaker so that two tasks with the same priority are returned in the order they were added. And since no two entry counts are the same, the tuple comparison will never attempt to directly compare two tasks.

The remaining challenges revolve around finding a pending task and making changes to its priority or removing it entirely. Finding a task can be done with a dictionary pointing to an entry in the queue.

Removing the entry or changing its priority is more difficult because it would break the heap structure invariants. So, a possible solution is to mark the entry as removed and add a new entry with the revised priority:

```python
pq = []  # list of entries arranged in a heap
entry_finder = {}  # mapping of tasks to entries
```
REMOVED = '<removed-task>'        # placeholder for a
counter = itertools.count()        # unique sequence co

def add_task(task, priority=0):
    'Add a new task or update the priority of an exi
    if task in entry_finder:
        remove_task(task)
    count = next(counter)
    entry = [priority, count, task]
    entry_finder[task] = entry
    heappush(pq, entry)

def remove_task(task):
    'Mark an existing task as REMOVED. Raise KeyError
    entry = entry_finder.pop(task)
    entry[-1] = REMOVED

def pop_task():
    'Remove and return the lowest priority task. Rai
    while pq:
        priority, count, task = heappop(pq)
        if task is not REMOVED:
            del entry_finder[task]
            return task
    raise KeyError('pop from an empty priority queue')
8.5.3. Theory

Heaps are arrays for which $a[k] \leq a[2*k+1]$ and $a[k] \leq a[2*k+2]$ for all $k$, counting elements from 0. For the sake of comparison, non-existing elements are considered to be infinite. The interesting property of a heap is that $a[0]$ is always its smallest element.

The strange invariant above is meant to be an efficient memory representation for a tournament. The numbers below are $k$, not $a[k]$:

```
   0
  /  \
 1   2
 / \ / \n3  4 5
/ \ / \ / \n7  8  9 10 11 12 13 14 15 16 17 18 19 20 21 22 23 24 25 26 27 28
```

In the tree above, each cell $k$ is topping $2*k+1$ and $2*k+2$. In an usual binary tournament we see in sports, each cell is the winner over the two cells it tops, and we can trace the winner down the tree to see all opponents s/he had. However, in many computer applications of such tournaments, we do not need to trace the history of a winner. To be more memory efficient, when a winner is promoted, we try to replace it by something else at a lower level, and the rule becomes that a cell and the two cells it tops contain three different items, but the top cell “wins” over the two topped cells.

If this heap invariant is protected at all time, index 0 is clearly the
overall winner. The simplest algorithmic way to remove it and find the “next” winner is to move some loser (let’s say cell 30 in the diagram above) into the 0 position, and then percolate this new 0 down the tree, exchanging values, until the invariant is re-established. This is clearly logarithmic on the total number of items in the tree. By iterating over all items, you get an $O(n \log n)$ sort.

A nice feature of this sort is that you can efficiently insert new items while the sort is going on, provided that the inserted items are not “better” than the last 0’th element you extracted. This is especially useful in simulation contexts, where the tree holds all incoming events, and the “win” condition means the smallest scheduled time. When an event schedules other events for execution, they are scheduled into the future, so they can easily go into the heap. So, a heap is a good structure for implementing schedulers (this is what I used for my MIDI sequencer :-).

Various structures for implementing schedulers have been extensively studied, and heaps are good for this, as they are reasonably speedy, the speed is almost constant, and the worst case is not much different than the average case. However, there are other representations which are more efficient overall, yet the worst cases might be terrible.

Heaps are also very useful in big disk sorts. You most probably all know that a big sort implies producing “runs” (which are pre-sorted sequences, which size is usually related to the amount of CPU memory), followed by a merging passes for these runs, which merging is often very cleverly organised [1]. It is very important that the initial sort produces the longest runs possible. Tournaments are a good way to that. If, using all the memory available to hold a tournament, you replace and percolate items that happen to fit the current run, you’ll produce runs which are twice the size of the memory for random input, and much better for input fuzzily ordered.
Moreover, if you output the 0'th item on disk and get an input which may not fit in the current tournament (because the value “wins” over the last output value), it cannot fit in the heap, so the size of the heap decreases. The freed memory could be cleverly reused immediately for progressively building a second heap, which grows at exactly the same rate the first heap is melting. When the first heap completely vanishes, you switch heaps and start a new run. Clever and quite effective!

In a word, heaps are useful memory structures to know. I use them in a few applications, and I think it is good to keep a ‘heap’ module around. :-)  

**Footnotes**

The disk balancing algorithms which are current, nowadays, are more annoying than clever, and this is a consequence of the seeking capabilities of the disks. On devices which cannot seek, like big tape drives, the story was quite different, and one had to be very clever to ensure (far in advance) that each tape movement will be the most effective possible (that is, will best participate at “progressing” the merge). Some tapes were even able to read backwards, and this was also used to avoid the rewinding time. Believe me, real good tape sorts were quite spectacular to watch! From all times, sorting has always been a Great Art! :-)

[1]
8.6. **bisect** — Array bisection algorithm

**Source code:** Lib/bisect.py

This module provides support for maintaining a list in sorted order without having to sort the list after each insertion. For long lists of items with expensive comparison operations, this can be an improvement over the more common approach. The module is called **bisect** because it uses a basic bisection algorithm to do its work. The source code may be most useful as a working example of the algorithm (the boundary conditions are already right!).

The following functions are provided:

**bisect.**bisect_left**(a, x, lo=0, hi=len(a))**

Locate the insertion point for \( x \) in \( a \) to maintain sorted order. The parameters \( lo \) and \( hi \) may be used to specify a subset of the list which should be considered; by default the entire list is used. If \( x \) is already present in \( a \), the insertion point will be before (to the left of) any existing entries. The return value is suitable for use as the first parameter to `list.insert()` assuming that \( a \) is already sorted.

The returned insertion point \( i \) partitions the array \( a \) into two halves so that `all(val < x for val in a[lo:i])` for the left side and `all(val >= x for val in a[i:hi])` for the right side.

**bisect.**bisect_right**(a, x, lo=0, hi=len(a))**

**bisect.**bisect**(a, x, lo=0, hi=len(a))**

Similar to `bisect_left()`, but returns an insertion point which
comes after (to the right of) any existing entries of $x$ in $a$.

The returned insertion point $i$ partitions the array $a$ into two halves
so that all($val \leq x$ for $val$ in $a[lo:i]$) for the left side
and all($val > x$ for $val$ in $a[i:hi]$) for the right side.

`bisect.insort_left(a, x, lo=0, hi=len(a))`

Insert $x$ in $a$ in sorted order. This is equivalent to
$a$.insert(bisect.bisect_left(a, x, lo, hi), x)
assuming that $a$ is already sorted. Keep in mind that the $O(\log n)$
search is dominated by the slow $O(n)$ insertion step.

`bisect.insort_right(a, x, lo=0, hi=len(a))`
`bisect.insort(a, x, lo=0, hi=len(a))`

Similar to `insort_left()`, but inserting $x$ in $a$ after any existing
entries of $x$.

**See also:** SortedCollection recipe that uses bisect to build a full-
featured collection class with straightforward search methods and
support for a key-function. The keys are precomputed to save
unnecessary calls to the key function during searches.
8.6.1. Searching Sorted Lists

The above `bisect()` functions are useful for finding insertion points but can be tricky or awkward to use for common searching tasks. The following five functions show how to transform them into the standard lookups for sorted lists:

```python
def index(a, x):
    # Locate the leftmost value exactly equal to x'
    i = bisect_left(a, x)
    if i != len(a) and a[i] == x:
        return i
    raise ValueError

def find_lt(a, x):
    # Find rightmost value less than x'
    i = bisect_left(a, x)
    if i:
        return a[i-1]
    raise ValueError

def find_le(a, x):
    # Find rightmost value less than or equal to x'
    i = bisect_right(a, x)
    if i:
        return a[i-1]
    raise ValueError

def find_gt(a, x):
    # Find leftmost value greater than x'
    i = bisect_right(a, x)
    if i != len(a):
        return a[i]
    raise ValueError
```
def find_ge(a, x):
    'Find leftmost item greater than or equal to x'
    i = bisect_left(a, x)
    if i != len(a):
        return a[i]
    raise ValueError
8.6.2. Other Examples

The `bisect()` function can be useful for numeric table lookups. This example uses `bisect()` to look up a letter grade for an exam score (say) based on a set of ordered numeric breakpoints: 90 and up is an ‘A’, 80 to 89 is a ‘B’, and so on:

```python
>>> def grade(score, breakpoints=[60, 70, 80, 90], grades=['F', 'D', 'C', 'B', 'A']):
...     i = bisect(breakpoints, score)
...     return grades[i]
... >>> [grade(score) for score in [33, 99, 77, 70, 89, 'F', 'A', 'C', 'C', 'B', 'A', 'A']]
['F', 'A', 'C', 'C', 'B', 'A', 'A']
```

Unlike the `sorted()` function, it does not make sense for the `bisect()` functions to have `key` or `reversed` arguments because that would lead to an inefficient design (successive calls to bisect functions would not “remember” all of the previous key lookups).

Instead, it is better to search a list of precomputed keys to find the index of the record in question:

```python
>>> data = [('red', 5), ('blue', 1), ('yellow', 8), ('green', 2), ('purple', 3)]
>>> data.sort(key=lambda r: r[1])
>>> keys = [r[1] for r in data]
# precompute
>>> data[bisect_left(keys, 0)]
('black', 0)
>>> data[bisect_left(keys, 1)]
('blue', 1)
>>> data[bisect_left(keys, 5)]
('red', 5)
>>> data[bisect_left(keys, 8)]
('yellow', 8)
```
8.7. **array** — Efficient arrays of numeric values

This module defines an object type which can compactly represent an array of basic values: characters, integers, floating point numbers. Arrays are sequence types and behave very much like lists, except that the type of objects stored in them is constrained. The type is specified at object creation time by using a *type code*, which is a single character. The following type codes are defined:

<table>
<thead>
<tr>
<th>Type code</th>
<th>C Type</th>
<th>Python Type</th>
<th>Minimum size in bytes</th>
<th>Notes</th>
</tr>
</thead>
<tbody>
<tr>
<td>'b'</td>
<td>signed char</td>
<td>int</td>
<td>1</td>
<td></td>
</tr>
<tr>
<td>'B'</td>
<td>unsigned char</td>
<td>int</td>
<td>1</td>
<td></td>
</tr>
<tr>
<td>'u'</td>
<td>Py_UNICODE</td>
<td>Unicode character</td>
<td>2</td>
<td>(1)</td>
</tr>
<tr>
<td>'h'</td>
<td>signed short</td>
<td>int</td>
<td>2</td>
<td></td>
</tr>
<tr>
<td>'H'</td>
<td>unsigned short</td>
<td>int</td>
<td>2</td>
<td></td>
</tr>
<tr>
<td>'i'</td>
<td>signed int</td>
<td>int</td>
<td>2</td>
<td></td>
</tr>
<tr>
<td>'I'</td>
<td>unsigned int</td>
<td>int</td>
<td>2</td>
<td></td>
</tr>
<tr>
<td>'l'</td>
<td>signed long</td>
<td>int</td>
<td>4</td>
<td></td>
</tr>
<tr>
<td>'L'</td>
<td>unsigned long</td>
<td>int</td>
<td>4</td>
<td></td>
</tr>
<tr>
<td>'q'</td>
<td>signed long long</td>
<td>int</td>
<td>8</td>
<td>(2)</td>
</tr>
<tr>
<td>'Q'</td>
<td>unsigned long long</td>
<td>int</td>
<td>8</td>
<td>(2)</td>
</tr>
<tr>
<td>'f'</td>
<td>float</td>
<td>float</td>
<td>4</td>
<td></td>
</tr>
<tr>
<td>'d'</td>
<td>double</td>
<td>float</td>
<td>8</td>
<td></td>
</tr>
</tbody>
</table>

Notes:

1. The `u` type code corresponds to Python’s obsolete unicode character (Py_UNICODE which is wchar_t). Depending on the platform, it can be 16 bits or 32 bits.

   `u` will be removed together with the rest of the Py_UNICODE API.

   **Deprecated since version 3.3, will be removed in version 4.0.**

2. The `q` and `Q` type codes are available only if the platform C compiler used to build Python supports C long long, or, on Windows, __int64.

   **New in version 3.3.**

The actual representation of values is determined by the machine architecture (strictly speaking, by the C implementation). The actual size can be accessed through the itemsize attribute.

The module defines the following type:

```ruby
class array.array(typecode[, initializer])
```

A new array whose items are restricted by typecode, and initialized from the optional initializer value, which must be a list, a bytes-like object, or iterable over elements of the appropriate type.

If given a list or string, the initializer is passed to the new array's fromlist(), frombytes(), or fromunicode() method (see below) to add initial items to the array. Otherwise, the iterable
initializer is passed to the `extend()` method.

```
array.typecodes
```

A string with all available type codes.

Array objects support the ordinary sequence operations of indexing, slicing, concatenation, and multiplication. When using slice assignment, the assigned value must be an array object with the same type code; in all other cases, `TypeError` is raised. Array objects also implement the buffer interface, and may be used wherever `bytes-like objects` are supported.

The following data items and methods are also supported:

```
array.typecode
```

The typecode character used to create the array.

```
array.itemsize
```

The length in bytes of one array item in the internal representation.

```
array.append(x)
```

Append a new item with value `x` to the end of the array.

```
array.buffer_info()
```

Return a tuple `(address, length)` giving the current memory address and the length in elements of the buffer used to hold array's contents. The size of the memory buffer in bytes can be computed as `array.buffer_info()[1] * array.itemsize`. This is occasionally useful when working with low-level (and inherently unsafe) I/O interfaces that require memory addresses, such as certain `ioctl()` operations. The returned numbers are valid as long as the array exists and no length-changing operations are applied to it.
Note: When using array objects from code written in C or C++ (the only way to effectively make use of this information), it makes more sense to use the buffer interface supported by array objects. This method is maintained for backward compatibility and should be avoided in new code. The buffer interface is documented in *Buffer Protocol*.

array. **byteswap()**

"Byteswap" all items of the array. This is only supported for values which are 1, 2, 4, or 8 bytes in size; for other types of values, *RuntimeError* is raised. It is useful when reading data from a file written on a machine with a different byte order.

array. **count(x)**

Return the number of occurrences of *x* in the array.

array. **extend(iterable)**

Append items from *iterable* to the end of the array. If *iterable* is another array, it must have exactly the same type code; if not, *TypeError* will be raised. If *iterable* is not an array, it must be iterable and its elements must be the right type to be appended to the array.

array. **frombytes(s)**

Appends items from the string, interpreting the string as an array of machine values (as if it had been read from a file using the *fromfile()* method).

*New in version 3.2:* *fromstring()* is renamed to *frombytes()* for clarity.

array. **fromfile(f, n)**
Read $n$ items (as machine values) from the *file object* $f$ and append them to the end of the array. If less than $n$ items are available, *EOFError* is raised, but the items that were available are still inserted into the array. $f$ must be a real built-in file object; something else with a read() method won’t do.

array.*fromlist*(list)

Append items from the list. This is equivalent to

```
for x in list:
a.append(x)
```

except that if there is a type error, the array is unchanged.

array.*fromstring*()

Deprecated alias for *frombytes()*.

array.*fromunicode*(s)

Extends this array with data from the given unicode string. The array must be a type `u` array; otherwise a *ValueError* is raised.

Use

```
array.frombytes(unicodestring.encode(enc))
```

to append Unicode data to an array of some other type.

array.*index*(x)

Return the smallest $i$ such that $i$ is the index of the first occurrence of $x$ in the array.

array.*insert*(i, x)

Insert a new item with value $x$ in the array before position $i$. Negative values are treated as being relative to the end of the array.

array.*pop*([i])

Removes the item with the index $i$ from the array and returns it.
The optional argument defaults to -1, so that by default the last item is removed and returned.

array.remove(x)
Remove the first occurrence of x from the array.

array.reverse()
Reverse the order of the items in the array.

array.tobynes()
Convert the array to an array of machine values and return the bytes representation (the same sequence of bytes that would be written to a file by the tofile() method.)

*New in version 3.2: tostring() is renamed to tobytes() for clarity.*

array.tofile(f)
Write all items (as machine values) to the file object f.

array.tolist()
Convert the array to an ordinary list with the same items.

array.tostring()
Deprecated alias for tobytes().

array.totunicaode()
Convert the array to a unicode string. The array must be a type 'u' array; otherwise a ValueError is raised. Use array.tobynes().decode(enc) to obtain a unicode string from an array of some other type.

When an array object is printed or converted to a string, it is
represented as `array(typecode, initializer)`. The `initializer` is omitted if the array is empty, otherwise it is a string if the `typecode` is 'u', otherwise it is a list of numbers. The string is guaranteed to be able to be converted back to an array with the same type and value using `eval()`, so long as the `array()` function has been imported using `from array import array`. Examples:

```
array('l')
array('u', 'hello ♁')
array('l', [1, 2, 3, 4, 5])
array('d', [1.0, 2.0, 3.14])
```

**Module xdrlib**

Packing and unpacking of External Data Representation (XDR) data as used in some remote procedure call systems.

**The Numerical Python Documentation**

8.8. `weakref` — Weak references

Source code: `Lib/weakref.py`

The `weakref` module allows the Python programmer to create weak references to objects.

In the following, the term *referent* means the object which is referred to by a weak reference.

A weak reference to an object is not enough to keep the object alive: when the only remaining references to a referent are weak references, *garbage collection* is free to destroy the referent and reuse its memory for something else. However, until the object is actually destroyed the weak reference may return the object even if there are no strong references to it.

A primary use for weak references is to implement caches or mappings holding large objects, where it’s desired that a large object not be kept alive solely because it appears in a cache or mapping.

For example, if you have a number of large binary image objects, you may wish to associate a name with each. If you used a Python dictionary to map names to images, or images to names, the image objects would remain alive just because they appeared as values or keys in the dictionaries. The `WeakKeyDictionary` and `WeakValueDictionary` classes supplied by the `weakref` module are an alternative, using weak references to construct mappings that don’t keep objects alive solely because they appear in the mapping objects. If, for example, an image object is a value in a `WeakValueDictionary`, then when the last remaining references to
that image object are the weak references held by weak mappings, garbage collection can reclaim the object, and its corresponding entries in weak mappings are simply deleted.

**WeakKeyDictionary** and **WeakValueDictionary** use weak references in their implementation, setting up callback functions on the weak references that notify the weak dictionaries when a key or value has been reclaimed by garbage collection. **WeakSet** implements the **set** interface, but keeps weak references to its elements, just like a **WeakKeyDictionary** does.

**finalize** provides a straightforward way to register a cleanup function to be called when an object is garbage collected. This is simpler to use than setting up a callback function on a raw weak reference, since the module automatically ensures that the finalizer remains alive until the object is collected.

Most programs should find that using one of these weak container types or **finalize** is all they need – it’s not usually necessary to create your own weak references directly. The low-level machinery is exposed by the **weakref** module for the benefit of advanced uses.

Not all objects can be weakly referenced; those objects which can include class instances, functions written in Python (but not in C), instance methods, sets, frozensets, some **file objects**, **generators**, type objects, sockets, arrays, deques, regular expression pattern objects, and code objects.

*Changed in version 3.2:* Added support for thread.lock, threading.Lock, and code objects.

Several built-in types such as **list** and **dict** do not directly support weak references but can add support through subclassing:
```python
class Dict(dict):
    pass

obj = Dict(red=1, green=2, blue=3)  # this object is weak referenceable
```

Other built-in types such as `tuple` and `int` do not support weak references even when subclassed (This is an implementation detail and may be different across various Python implementations.).

Extension types can easily be made to support weak references; see `Weak Reference Support`.

```python
class weakref.ref(object[, callback])
```

Return a weak reference to `object`. The original object can be retrieved by calling the reference object if the referent is still alive; if the referent is no longer alive, calling the reference object will cause `None` to be returned. If `callback` is provided and not `None`, and the returned weakref object is still alive, the callback will be called when the object is about to be finalized; the weak reference object will be passed as the only parameter to the callback; the referent will no longer be available.

It is allowable for many weak references to be constructed for the same object. Callbacks registered for each weak reference will be called from the most recently registered callback to the oldest registered callback.

Exceptions raised by the callback will be noted on the standard error output, but cannot be propagated; they are handled in exactly the same way as exceptions raised from an object's `__del__()` method.
Weak references are *hashable* if the *object* is hashable. They will maintain their hash value even after the *object* was deleted. If *hash()* is called the first time only after the *object* was deleted, the call will raise *TypeError*.

Weak references support tests for equality, but not ordering. If the referents are still alive, two references have the same equality relationship as their referents (regardless of the *callback*). If either referent has been deleted, the references are equal only if the reference objects are the same object.

This is a subclassable type rather than a factory function.

**__callback__**

This read-only attribute returns the callback currently associated to the weakref. If there is no callback or if the referent of the weakref is no longer alive then this attribute will have value *None*.

*Changed in version 3.4:* Added the **__callback__** attribute.

`weakref.proxy(object[, callback])`

Return a proxy to *object* which uses a weak reference. This supports use of the proxy in most contexts instead of requiring the explicit dereferencing used with weak reference objects. The returned object will have a type of either `ProxyType` or `CallableProxyType`, depending on whether *object* is callable. Proxy objects are not *hashable* regardless of the referent; this avoids a number of problems related to their fundamentally mutable nature, and prevent their use as dictionary keys. *callback* is the same as the parameter of the same name to the *ref()* function.
weakref.getweakrefcount(object)

Return the number of weak references and proxies which refer to object.

weakref.getweakrefs(object)

Return a list of all weak reference and proxy objects which refer to object.

class weakref.WeakKeyDictionary([dict])

Mapping class that references keys weakly. Entries in the dictionary will be discarded when there is no longer a strong reference to the key. This can be used to associate additional data with an object owned by other parts of an application without adding attributes to those objects. This can be especially useful with objects that override attribute accesses.

Note: Caution: Because a WeakKeyDictionary is built on top of a Python dictionary, it must not change size when iterating over it. This can be difficult to ensure for a WeakKeyDictionary because actions performed by the program during iteration may cause items in the dictionary to vanish “by magic” (as a side effect of garbage collection).

WeakKeyDictionary objects have the following additional methods. These expose the internal references directly. The references are not guaranteed to be “live” at the time they are used, so the result of calling the references needs to be checked before being used. This can be used to avoid creating references that will cause the garbage collector to keep the keys around longer than needed.

WeakKeyDictionary.keyrefs()

Return an iterable of the weak references to the keys.
class weakref.WeakValueDictionary(dict)

Mapping class that references values weakly. Entries in the dictionary will be discarded when no strong reference to the value exists any more.

**Note:** Caution: Because a WeakValueDictionary is built on top of a Python dictionary, it must not change size when iterating over it. This can be difficult to ensure for a WeakValueDictionary because actions performed by the program during iteration may cause items in the dictionary to vanish “by magic” (as a side effect of garbage collection).

WeakValueDictionary objects have the following additional methods. These method have the same issues as the and keyrefs() method of WeakKeyDictionary objects.

WeakValueDictionary.valuerefs()

Return an iterable of the weak references to the values.

class weakref.WeakSet([elements])

Set class that keeps weak references to its elements. An element will be discarded when no strong reference to it exists any more.

class weakref.WeakMethod(method)

A custom ref subclass which simulates a weak reference to a bound method (i.e., a method defined on a class and looked up on an instance). Since a bound method is ephemeral, a standard weak reference cannot keep hold of it. WeakMethod has special code to recreate the bound method until either the object or the original function dies:
```python
>>> class C:
...     def method(self):
...         print("method called!")
...     
>>> c = C()
>>> r = weakref.ref(c.method)
>>> r()
>>> r = weakref.WeakMethod(c.method)
>>> r()
<bound method C method of <__main__.C object at 0x7fc859830220>>
>>> r()() method called!
>>> del c
>>> gc.collect() 0
>>> r()
```

New in version 3.4.

```python
class weakref.**finalize**(obj, func, *args, **kwargs)
```

Return a callable finalizer object which will be called when `obj` is garbage collected. Unlike an ordinary weak reference, a finalizer will always survive until the reference object is collected, greatly simplifying lifecycle management.

A finalizer is considered *alive* until it is called (either explicitly or at garbage collection), and after that it is *dead*. Calling a live finalizer returns the result of evaluating `func(*arg, **kwargs)`, whereas calling a dead finalizer returns `None`.

Exceptions raised by finalizer callbacks during garbage collection will be shown on the standard error output, but cannot be propagated. They are handled in the same way as exceptions
raised from an object’s __del__() method or a weak reference’s callback.

When the program exits, each remaining live finalizer is called unless its `atexit` attribute has been set to false. They are called in reverse order of creation.

A finalizer will never invoke its callback during the later part of the interpreter shutdown when module globals are liable to have been replaced by `None`.

__call__()
If `self` is alive then mark it as dead and return the result of calling `func(*args, **kwargs)`. If `self` is dead then return `None`.

detach()
If `self` is alive then mark it as dead and return the tuple `(obj, func, args, kwargs)`. If `self` is dead then return `None`.

peek()
If `self` is alive then return the tuple `(obj, func, args, kwargs)`. If `self` is dead then return `None`.

alive
Property which is true if the finalizer is alive, false otherwise.

atexit
A writable boolean property which by default is true. When the program exits, it calls all remaining live finalizers for which `atexit` is true. They are called in reverse order of creation.
Note: It is important to ensure that `func`, `args` and `kwargs` do not own any references to `obj`, either directly or indirectly, since otherwise `obj` will never be garbage collected. In particular, `func` should not be a bound method of `obj`.

New in version 3.4.

`weakref.ReferenceType`

The type object for weak references objects.

`weakref.ProxyType`

The type object for proxies of objects which are not callable.

`weakref.CallableProxyType`

The type object for proxies of callable objects.

`weakref.ProxyTypes`

Sequence containing all the type objects for proxies. This can make it simpler to test if an object is a proxy without being dependent on naming both proxy types.

`exception weakref.ReferenceError`

Exception raised when a proxy object is used but the underlying object has been collected. This is the same as the standard `ReferenceError` exception.

See also:

PEP 0205 - Weak References

The proposal and rationale for this feature, including links to earlier implementations and information about similar features in other languages.
8.8.1. Weak Reference Objects

Weak reference objects have no methods and no attributes besides `ref.__callback__`. A weak reference object allows the referent to be obtained, if it still exists, by calling it:

```python
>>> import weakref
>>> class Object:
    ...
    pass
...
>>> o = Object()
>>> r = weakref.ref(o)
>>> o2 = r()
>>> o is o2
True
```

If the referent no longer exists, calling the reference object returns `None`:

```python
>>> del o, o2
>>> print(r())
None
```

Testing that a weak reference object is still live should be done using the expression `ref() is not None`. Normally, application code that needs to use a reference object should follow this pattern:

```python
# r is a weak reference object
o = r()
if o is None:
    # referent has been garbage collected
    print("Object has been deallocated; can't frobn"
else:
    print("Object is still live!")
```
Using a separate test for “liveness” creates race conditions in threaded applications; another thread can cause a weak reference to become invalidated before the weak reference is called; the idiom shown above is safe in threaded applications as well as single-threaded applications.

Specialized versions of `ref` objects can be created through subclassing. This is used in the implementation of the `WeakValueDictionary` to reduce the memory overhead for each entry in the mapping. This may be most useful to associate additional information with a reference, but could also be used to insert additional processing on calls to retrieve the referent.

This example shows how a subclass of `ref` can be used to store additional information about an object and affect the value that’s returned when the referent is accessed:

```python
import weakref

class ExtendedRef(weakref.ref):
    def __init__(self, ob, callback=None, **annotations):
        super(ExtendedRef, self).__init__(ob, callback)
        self.__counter = 0
        for k, v in annotations.items():
            setattr(self, k, v)

    def __call__(self):
        """Return a pair containing the referent and the number of times the reference has been called."
        ob = super(ExtendedRef, self).__call__()
        if ob is not None:
            return ob, self.__counter
```

```bash
o.do_something_useful()
```
self.__counter += 1
ob = (ob, self.__counter)
return ob
8.8.2. Example

This simple example shows how an application can use objects IDs to retrieve objects that it has seen before. The IDs of the objects can then be used in other data structures without forcing the objects to remain alive, but the objects can still be retrieved by ID if they do.

```python
import weakref

_id2obj_dict = weakref.WeakValueDictionary()

def remember(obj):
    oid = id(obj)
    _id2obj_dict[oid] = obj
    return oid

def id2obj(oid):
    return _id2obj_dict[oid]
```
8.8.3. Finalizer Objects

The main benefit of using `finalize` is that it makes it simple to register a callback without needing to preserve the returned finalizer object. For instance

```python
>>> import weakref
>>> class Object:
...     pass
...
>>> kenny = Object()
>>> weakref.finalize(kenny, print, "You killed Kenny")
<finalize object at ...; for 'Object' at ...>
>>> del kenny
You killed Kenny!
```

The finalizer can be called directly as well. However the finalizer will invoke the callback at most once.

```python
>>> def callback(x, y, z):
...     print("CALLBACK")
...     return x + y + z
...
>>> obj = Object()
>>> f = weakref.finalize(obj, callback, 1, 2, z=3)
>>> assert f.alive
>>> assert f() == 6
CALLBACK
>>> assert not f.alive
>>> f() # callback not called be
>>> del obj # callback not called be
```

You can unregister a finalizer using its `detach()` method. This kills
the finalizer and returns the arguments passed to the constructor when it was created.

```python
>>> obj = Object()
>>> f = weakref.finalize(obj, callback, 1, 2, z=3)
>>> f.detach()
(<__main__.Object object ...>, <function callback ...>, (1, 2), {'z': 3})
>>> assert not f.alive
>>> assert newobj is obj
>>> assert func(*args, **kwargs) == 6
```

Unless you set the `atexit` attribute to `False`, a finalizer will be called when the program exits if it is still alive. For instance

```python
>>> obj = Object()
>>> weakref.finalize(obj, print, "obj dead or exiting")
<finalize object at ...; for 'Object' at ...>
>>> exit()
obj dead or exiting
```
8.8.4. Comparing finalizers with `__del__( )` methods

Suppose we want to create a class whose instances represent temporary directories. The directories should be deleted with their contents when the first of the following events occurs:

- the object is garbage collected,
- the object's `remove()` method is called, or
- the program exits.

We might try to implement the class using a `__del__( )` method as follows:

```python
class TempDir:
    def __init__(self):
        self.name = tempfile.mkdtemp()

    def remove(self):
        if self.name is not None:
            shutil.rmtree(self.name)
        self.name = None

@property
def removed(self):
    return self.name is None

def __del__(self):
    self.remove()
```

Starting with Python 3.4, `__del__( )` methods no longer prevent reference cycles from being garbage collected, and module globals are no longer forced to `None` during interpreter shutdown. So this
code should work without any issues on CPython.

However, handling of `__del__() methods is notoriously implementation specific, since it depends on internal details of the interpreter’s garbage collector implementation.

A more robust alternative can be to define a finalizer which only references the specific functions and objects that it needs, rather than having access to the full state of the object:

```python
class TempDir:
    def __init__(self):
        self.name = tempfile.mkdtemp()
        self._finalizer = weakref.finalize(self, shutil.rmtree)

    def remove(self):
        self._finalizer()

@property
def removed(self):
    return not self._finalizer.alive
```

Defined like this, our finalizer only receives a reference to the details it needs to clean up the directory appropriately. If the object never gets garbage collected the finalizer will still be called at exit.

The other advantage of weakref based finalizers is that they can be used to register finalizers for classes where the definition is controlled by a third party, such as running code when a module is unloaded:

```python
import weakref, sys
def unloading_module():
    # implicit reference to the module globals from
    weakref.finalize(sys.modules[__name__], unloading_module)
```
**Note:** If you create a finalizer object in a daemonic thread just as
the program exits then there is the possibility that the finalizer
does not get called at exit. However, in a daemonic thread
`atexit.register()`, `try: ... finally: ...` and `with:`...
do not guarantee that cleanup occurs either.
8.9. **types** — Dynamic type creation and names for built-in types

**Source code:** Lib/types.py

This module defines utility function to assist in dynamic creation of new types.

It also defines names for some object types that are used by the standard Python interpreter, but not exposed as builtins like `int` or `str` are.

Finally, it provides some additional type-related utility classes and functions that are not fundamental enough to be builtins.
8.9.1. Dynamic Type Creation

```python
types.new_class(name, bases=(), kwds=None, exec_body=None)
```

Creates a class object dynamically using the appropriate metaclass.

The first three arguments are the components that make up a class definition header: the class name, the base classes (in order), the keyword arguments (such as metaclass).

The `exec_body` argument is a callback that is used to populate the freshly created class namespace. It should accept the class namespace as its sole argument and update the namespace directly with the class contents. If no callback is provided, it has the same effect as passing in `lambda ns: ns`.

*New in version 3.3.*

```python
types.prepare_class(name, bases=(), kwds=None)
```

Calculates the appropriate metaclass and creates the class namespace.

The arguments are the components that make up a class definition header: the class name, the base classes (in order) and the keyword arguments (such as `metaclass`).

The return value is a 3-tuple: `metaclass`, `namespace`, `kwds`

`metaclass` is the appropriate metaclass, `namespace` is the prepared class namespace and `kwds` is an updated copy of the passed in `kwds` argument with any 'metaclass' entry removed.
If no `kwds` argument is passed in, this will be an empty dict.

*New in version 3.3.*

**See also:**

*Customizing class creation*

Full details of the class creation process supported by these functions

**PEP 3115 - Metaclasses in Python 3000**

Introduced the `__prepare__` namespace hook
8.9.2. Standard Interpreter Types

This module provides names for many of the types that are required to implement a Python interpreter. It deliberately avoids including some of the types that arise only incidentally during processing such as the listiterator type.

Typical use of these names is for `isinstance()` or `issubclass()` checks.

Standard names are defined for the following types:

- **FunctionType**
- **LambdaType**
  - The type of user-defined functions and functions created by `lambda` expressions.
- **GeneratorType**
  - The type of `generator`-iterator objects, produced by calling a generator function.
- **CodeType**
  - The type for code objects such as returned by `compile()`.
- **MethodType**
  - The type of methods of user-defined class instances.
- **BuiltinFunctionType**
- **BuiltinMethodType**
  - The type of built-in functions like `len()` or `sys.exit()`, and methods of built-in classes. (Here, the term “built-in” means “written in C”.)
class types. **ModuleType**(name, doc=None)

The type of *modules*. Constructor takes the name of the module to be created and optionally its *docstring*.

**__doc__**

The *docstring* of the module. Defaults to None.

**__loader__**

The *loader* which loaded the module. Defaults to None.

*Changed in version 3.4:* Defaults to None. Previously the attribute was optional.

**__name__**

The name of the module.

**__package__**

Which *package* a module belongs to. If the module is top-level (i.e. not a part of any specific package) then the attribute should be set to `'` , else it should be set to the name of the package (which can be **__name__** if the module is a package itself). Defaults to None.

*Changed in version 3.4:* Defaults to None. Previously the attribute was optional.

types. **TracebackType**

The type of traceback objects such as found in `sys.exc_info()` [2].

types. **FrameType**

The type of frame objects such as found in `tb.tb_frame` if `tb` is a traceback object.
**types.** **GetSetDescriptorType**

The type of objects defined in extension modules with `PyGetSetDef`, such as `FrameType.f_locals` or `array.array.typecode`. This type is used as descriptor for object attributes; it has the same purpose as the `property` type, but for classes defined in extension modules.

**types.** **MemberDescriptorType**

The type of objects defined in extension modules with `PyMemberDef`, such as `datetime.timedelta.days`. This type is used as descriptor for simple C data members which use standard conversion functions; it has the same purpose as the `property` type, but for classes defined in extension modules.

**CPython implementation detail:** In other implementations of Python, this type may be identical to `GetSetDescriptorType`.

**class** **types.** **MappingProxyType**(mapping)

Read-only proxy of a mapping. It provides a dynamic view on the mapping’s entries, which means that when the mapping changes, the view reflects these changes.

*New in version 3.3.*

**key in proxy**

Return `True` if the underlying mapping has a key `key`, else `False`.

**proxy[key]**

Return the item of the underlying mapping with key `key`. Raises a `KeyError` if `key` is not in the underlying mapping.
iter(proxy)

Return an iterator over the keys of the underlying mapping. This is a shortcut for `iter(proxy.keys())`.

len(proxy)

Return the number of items in the underlying mapping.

copy()

Return a shallow copy of the underlying mapping.

get(key[, default])

Return the value for `key` if `key` is in the underlying mapping, else `default`. If `default` is not given, it defaults to `None`, so that this method never raises a `KeyError`.

items()

Return a new view of the underlying mapping’s items `((key, value) pairs)`.

keys()

Return a new view of the underlying mapping’s keys.

values()

Return a new view of the underlying mapping’s values.
8.9.3. Additional Utility Classes and Functions

class types.SimpleNamespace

A simple object subclass that provides attribute access to its namespace, as well as a meaningful repr.

Unlike object, with SimpleNamespace you can add and remove attributes. If a SimpleNamespace object is initialized with keyword arguments, those are directly added to the underlying namespace.

The type is roughly equivalent to the following code:

```python
class SimpleNamespace:
    def __init__(self, **kwargs):
        self.__dict__.update(kwargs)
    def __repr__(self):
        keys = sorted(self.__dict__)
        items = ("{}={!r}".format(k, self.__dict__ for k in keys)
        return "{}({})".format(type(self).__name__, dict(items))
    def __eq__(self, other):
        return self.__dict__ == other.__dict__
```

SimpleNamespace may be useful as a replacement for class NS: pass. However, for a structured record type use namedtuple() instead.

New in version 3.3.

types.DynamicClassAttribute(fget=None, fset=None, fdel=None, doc=None)
Route attribute access on a class to __getattr__.

This is a descriptor, used to define attributes that act differently when accessed through an instance and through a class. Instance access remains normal, but access to an attribute through a class will be routed to the class's __getattr__ method; this is done by raising AttributeError.

This allows one to have properties active on an instance, and have virtual attributes on the class with the same name (see Enum for an example).

*New in version 3.4.*
8.10. copy — Shallow and deep copy operations

Assignment statements in Python do not copy objects, they create bindings between a target and an object. For collections that are mutable or contain mutable items, a copy is sometimes needed so one can change one copy without changing the other. This module provides generic shallow and deep copy operations (explained below).

Interface summary:

- **copy.copy(x)**
  - Return a shallow copy of x.

- **copy.deepcopy(x)**
  - Return a deep copy of x.

- **exception copy.error**
  - Raised for module specific errors.

The difference between shallow and deep copying is only relevant for compound objects (objects that contain other objects, like lists or class instances):

- A *shallow copy* constructs a new compound object and then (to the extent possible) inserts *references* into it to the objects found in the original.
- A *deep copy* constructs a new compound object and then, recursively, inserts *copies* into it of the objects found in the original.

Two problems often exist with deep copy operations that don’t exist
with shallow copy operations:

- Recursive objects (compound objects that, directly or indirectly, contain a reference to themselves) may cause a recursive loop.
- Because deep copy copies *everything* it may copy too much, e.g., administrative data structures that should be shared even between copies.

The `deepcopy()` function avoids these problems by:

- keeping a “memo” dictionary of objects already copied during the current copying pass; and
- letting user-defined classes override the copying operation or the set of components copied.

This module does not copy types like module, method, stack trace, stack frame, file, socket, window, array, or any similar types. It does “copy” functions and classes (shallow and deeply), by returning the original object unchanged; this is compatible with the way these are treated by the `pickle` module.

Shallow copies of dictionaries can be made using `dict.copy()` and of lists by assigning a slice of the entire list, for example, `copied_list = original_list[:]`.

Classes can use the same interfaces to control copying that they use to control pickling. See the description of module `pickle` for information on these methods. In fact, `copy` module uses the registered pickle functions from `copyreg` module.

In order for a class to define its own copy implementation, it can define special methods `__copy__()` and `__deepcopy__()`. The former is called to implement the shallow copy operation; no additional arguments are passed. The latter is called to implement the deep copy
operation; it is passed one argument, the memo dictionary. If the `__deepcopy__()` implementation needs to make a deep copy of a component, it should call the `deepcopy()` function with the component as first argument and the memo dictionary as second argument.

See also:

**Module pickle**

Discussion of the special methods used to support object state retrieval and restoration.
8.11. pprint — Data pretty printer

**Source code:** Lib/pprint.py

The **pprint** module provides a capability to “pretty-print” arbitrary Python data structures in a form which can be used as input to the interpreter. If the formatted structures include objects which are not fundamental Python types, the representation may not be loadable. This may be the case if objects such as files, sockets or classes are included, as well as many other objects which are not representable as Python literals.

The formatted representation keeps objects on a single line if it can, and breaks them onto multiple lines if they don’t fit within the allowed width. Construct **PrettyPrinter** objects explicitly if you need to adjust the width constraint.

Dictionaries are sorted by key before the display is computed.

The **pprint** module defines one class:

```python
class pprint.PrettyPrinter(indent=1, width=80, depth=None, stream=None, *, compact=False)
```

Construct a **PrettyPrinter** instance. This constructor understands several keyword parameters. An output stream may be set using the `stream` keyword; the only method used on the stream object is the file protocol's `write()` method. If not specified, the **PrettyPrinter** adopts `sys.stdout`. The amount of indentation added for each recursive level is specified by `indent`; the default is one. Other values can cause output to look a little
odd, but can make nesting easier to spot. The number of levels which may be printed is controlled by \textit{depth}; if the data structure being printed is too deep, the next contained level is replaced by \textit{...}. By default, there is no constraint on the depth of the objects being formatted. The desired output width is constrained using the \textit{width} parameter; the default is 80 characters. If a structure cannot be formatted within the constrained width, a best effort will be made. If \textit{compact} is false (the default) each item of a long sequence will be formatted on a separate line. If \textit{compact} is true, as many items as will fit within the \textit{width} will be formatted on each output line.

\textit{Changed in version 3.4: Added the \textit{compact} parameter.}

```
>>> import pprint
>>> stuff = ['spam', 'eggs', 'lumberjack', 'knights', 'ni
spam',
  eggs,
  lumberjack,
  knights,
  ni]
>>> pp = pprint.PrettyPrinter(indent=4)
>>> pp.pprint(stuff)
[['spam', 'eggs', 'lumberjack', 'knights', 'ni
spam',
  eggs,
  lumberjack,
  knights,
  ni']
>>> pp = pprint.PrettyPrinter(width=41, compact=True)
>>> pp.pprint(stuff)
[['spam', 'eggs', 'lumberjack',
  knights', 'ni'],
['spam', 'eggs', 'lumberjack', 'knights',
'ni']
>>> tup = ('spam', ('eggs', ('lumberjack', ('knig
... ('parrot', ('fresh fruit',))))))))
>>> pp = pprint.PrettyPrinter(depth=6)
>>> pp.pprint(tup)
```
The `pprint` module also provides several shortcut functions:

```python
def pprint.pformat(object, indent=1, width=80, depth=None, *, compact=False):
    Return the formatted representation of `object` as a string. `indent`, `width`, `depth` and `compact` will be passed to the `PrettyPrinter` constructor as formatting parameters.
```

*Changed in version 3.4:* Added the `compact` parameter.

```python
def pprint.pprint(object, stream=None, indent=1, width=80, depth=None, *, compact=False):
    Prints the formatted representation of `object` on `stream`, followed by a newline. If `stream` is `None`, `sys.stdout` is used. This may be used in the interactive interpreter instead of the `print()` function for inspecting values (you can even reassign `print = pprint.pprint` for use within a scope). `indent`, `width`, `depth` and `compact` will be passed to the `PrettyPrinter` constructor as formatting parameters.
```

*Changed in version 3.4:* Added the `compact` parameter.

```python
>>> import pprint
>>> stuff = ['spam', 'eggs', 'lumberjack', 'knights',
>>> stuff.insert(0, stuff)
>>> pprint.pprint(stuff)
[<Recursion on list with id=...>,
 'spam',
 'eggs',
 'lumberjack',
 'knights',
]```
pprint.\texttt{isreadable}(\texttt{object})

Determine if the formatted representation of \texttt{object} is “readable,” or can be used to reconstruct the value using \texttt{eval()}. This always returns \texttt{False} for recursive objects.

\begin{verbatim}
>>> pprint.isreadable(stuff)
False
\end{verbatim}

pprint.\texttt{isrecursive}(\texttt{object})

Determine if \texttt{object} requires a recursive representation.

One more support function is also defined:

pprint.\texttt{saferepr}(\texttt{object})

Return a string representation of \texttt{object}, protected against recursive data structures. If the representation of \texttt{object} exposes a recursive entry, the recursive reference will be represented as \texttt{<Recursion on typename with id=number>}. The representation is not otherwise formatted.

\begin{verbatim}
>>> pprint.saferepr(stuff)
"[<Recursion on list with id=...>, 'spam', 'eggs', 'lumberjack', 'knights', 'ni']"
\end{verbatim}
8.11.1. PrettyPrinter Objects

`PrettyPrinter` instances have the following methods:

`PrettyPrinter.pformat(object)`

Return the formatted representation of `object`. This takes into account the options passed to the `PrettyPrinter` constructor.

`PrettyPrinter.pprint(object)`

Print the formatted representation of `object` on the configured stream, followed by a newline.

The following methods provide the implementations for the corresponding functions of the same names. Using these methods on an instance is slightly more efficient since new `PrettyPrinter` objects don’t need to be created.

`PrettyPrinter.isreadable(object)`

Determine if the formatted representation of the object is “readable,” or can be used to reconstruct the value using `eval()`. Note that this returns `False` for recursive objects. If the `depth` parameter of the `PrettyPrinter` is set and the object is deeper than allowed, this returns `False`.

`PrettyPrinter.isrecursive(object)`

Determine if the object requires a recursive representation.

This method is provided as a hook to allow subclasses to modify the way objects are converted to strings. The default implementation uses the internals of the `saferepr()` implementation.

`PrettyPrinter.format(object, context, maxlevels, level)`
Returns three values: the formatted version of object as a string, a flag indicating whether the result is readable, and a flag indicating whether recursion was detected. The first argument is the object to be presented. The second is a dictionary which contains the id() of objects that are part of the current presentation context (direct and indirect containers for object that are affecting the presentation) as the keys; if an object needs to be presented which is already represented in context, the third return value should be True. Recursive calls to the format() method should add additional entries for containers to this dictionary. The third argument, maxlevels, gives the requested limit to recursion; this will be 0 if there is no requested limit. This argument should be passed unmodified to recursive calls. The fourth argument, level, gives the current level; recursive calls should be passed a value less than that of the current call.
8.11.2. Example

To demonstrate several uses of the `pprint()` function and its parameters, let's fetch information about a project from PyPI:

```python
>>> import json
>>> import pprint
>>> from urllib.request import urlopen
>>> with urlopen('http://pypi.python.org/pypi/Twisted/json') as url:
    ...   http_info = url.info()
    ...   raw_data = url.read().decode(http_info.get_content_charset())
>>> project_info = json.loads(raw_data)
```

In its basic form, `pprint()` shows the whole object:

```python
>>> pprint.pprint(project_info)
{'info': {'_pypi_hidden': False,
         '_pypi_ordering': 125,
         'author': 'Glyph Lefkowitz',
         'author_email': 'glyph@twistedmatrix.com',
         'bugtrack_url': '',
         'cheesecake_code_kwalitee_id': None,
         'cheesecake_documentation_id': None,
         'cheesecake_installability_id': None,
         'classifiers': ['Programming Language :: Python :: 2.6',
                         'Programming Language :: Python :: 2.7',
                         'Programming Language :: Python :: 2 :: Only'],
         'description': 'An extensible framework for
            with special focus\n            on event-based network pro
            multiprotocol integration.

            'docs_url': '',
            'download_url': 'UNKNOWN',
            'home_page': 'http://twistedmatrix.com/'},
```
The result can be limited to a certain depth (ellipsis is used for deeper contents):
Additionally, maximum character width can be suggested. If a long object cannot be split, the specified width will be exceeded:

```python
>>> pprint.pprint(project_info, depth=2, width=50)
{'info': {'_pypi_hidden': False,
  '_pypi_ordering': 125,
  'author': 'Glyph Lefkowitz',
  'author_email': 'glyph@twistedmatrix.com',
  'bugtrack_url': '',

8.12. reprlib — Alternate repr() implementation

Source code: Lib/reprlib.py

The reprlib module provides a means for producing object representations with limits on the size of the resulting strings. This is used in the Python debugger and may be useful in other contexts as well.

This module provides a class, an instance, and a function:

class reprlib.Repr
    Class which provides formatting services useful in implementing functions similar to the built-in repr(); size limits for different object types are added to avoid the generation of representations which are excessively long.

reprlib.aRepr
    This is an instance of Repr which is used to provide the repr() function described below. Changing the attributes of this object will affect the size limits used by repr() and the Python debugger.

reprlib.repr(obj)
    This is the repr() method of aRepr. It returns a string similar to that returned by the built-in function of the same name, but with limits on most sizes.

In addition to size-limiting tools, the module also provides a decorator for detecting recursive calls to __repr__() and substituting a
@reprlib.recursive_repr(fillvalue="...")

Decorator for __repr__() methods to detect recursive calls within the same thread. If a recursive call is made, the fillvalue is returned, otherwise, the usual __repr__() call is made. For example:

```python
>>> class MyList(list):
...     @recursive_repr()
...     def __repr__(self):
...         return '<' + '|'.join(map(repr, self))
...

>>> m = MyList('abc')
>>> m.append(m)
>>> m.append('x')
>>> print(m)
<a'|'b'|'c'|...'|'x'>
```

New in version 3.2.
8.12.1. Repr Objects

Repr instances provide several attributes which can be used to provide size limits for the representations of different object types, and methods which format specific object types.

Repr. **maxlevel**
Depth limit on the creation of recursive representations. The default is 6.

Repr. **maxdict**
Repr. **maxlist**
Repr. **maxtuple**
Repr. **maxset**
Repr. **maxfrozenset**
Repr. **maxdeque**
Repr. **maxarray**
Limits on the number of entries represented for the named object type. The default is 4 for `maxdict`, 5 for `maxarray`, and 6 for the others.

Repr. **maxlong**
Maximum number of characters in the representation for an integer. Digits are dropped from the middle. The default is 40.

Repr. **maxstring**
Limit on the number of characters in the representation of the string. Note that the “normal” representation of the string is used as the character source: if escape sequences are needed in the representation, these may be mangled when the representation is shortened. The default is 30.
Repr. **maxother**

This limit is used to control the size of object types for which no specific formatting method is available on the **Repr** object. It is applied in a similar manner as **maxstring**. The default is 20.

Repr. **repr**(obj)

The equivalent to the built-in **repr()** that uses the formatting imposed by the instance.

Repr. **repr1**(obj, level)

Recursive implementation used by **repr()**. This uses the type of **obj** to determine which formatting method to call, passing it **obj** and **level**. The type-specific methods should call **repr1()** to perform recursive formatting, with **level - 1** for the value of **level** in the recursive call.

Repr. **repr_TYPE**(obj, level)

Formatting methods for specific types are implemented as methods with a name based on the type name. In the method name, **TYPE** is replaced by `string.join(string.split(type(obj).__name__, '$_'))`. Dispatch to these methods is handled by **repr1()**. Type-specific methods which need to recursively format a value should call **self.repr1**(subobj, level - 1).
8.12.2. Subclassing Repr Objects

The use of dynamic dispatching by `Repr.repr1()` allows subclasses of `Repr` to add support for additional built-in object types or to modify the handling of types already supported. This example shows how special support for file objects could be added:

```python
import reprlib
import sys

class MyRepr(reprlib.Repr):
    def repr_file(self, obj, level):
        if obj.name in ['<stdin>', '<stdout>', '<stderr>']:
            return obj.name
        else:
            return repr(obj)

aRepr = MyRepr()
print(aRepr.repr(sys.stdin))  # prints '<stdin>'
```

8.13. `enum` — Support for enumerations

New in version 3.4.

Source code: [Lib/enum.py](Lib/enum.py)

An enumeration is a set of symbolic names (members) bound to unique, constant values. Within an enumeration, the members can be compared by identity, and the enumeration itself can be iterated over.
8.13.1. Module Contents

This module defines two enumeration classes that can be used to define unique sets of names and values: `Enum` and `IntEnum`. It also defines one decorator, `unique()`.

```python
class enum.Enum
    Base class for creating enumerated constants. See section Functional API for an alternate construction syntax.
```

```python
class enum.IntEnum
    Base class for creating enumerated constants that are also subclasses of `int`.
```

```python
enum.unique()
    Enum class decorator that ensures only one name is bound to any one value.
```
8.13.2. Creating an Enum

Enumerations are created using the `class` syntax, which makes them easy to read and write. An alternative creation method is described in Functional API. To define an enumeration, subclass `Enum` as follows:

```python
>>> from enum import Enum
>>> class Color(Enum):
...     red = 1
...     green = 2
...     blue = 3
...
```

**Note:** Nomenclature

- The class `Color` is an *enumeration* (or *enum*)
- The attributes `Color.red`, `Color.green`, etc., are *enumeration members* (or *enum members*).
- The enum members have *names* and *values* (the name of `Color.red` is red, the value of `Color.blue` is 3, etc.)

**Note:** Even though we use the `class` syntax to create Enums, Enums are not normal Python classes. See How are Enums different? for more details.

Enumeration members have human readable string representations:

```python
>>> print(Color.red)
Color.red
```

...while their `repr` has more information:
```python
>>> print(repr(Color.red))
<Color.red: 1>

The type of an enumeration member is the enumeration it belongs to:
```n
```python
>>> type(Color.red)
<enum 'Color'>
>>> isinstance(Color.green, Color)
True
```n
Enum members also have a property that contains just their item name:
```python
>>> print(Color.red.name)
red
```n
Enumerations support iteration, in definition order:
```python
>>> class Shake(Enum):
...    vanilla = 7
...    chocolate = 4
...    cookies = 9
...    mint = 3
...
>>> for shake in Shake:
...    print(shake)
...Shake.vanilla
Shake.chocolate
Shake.cookies
Shake.mint
```n
Enumeration members are hashable, so they can be used in dictionaries and sets:
>>> apples = {}
>>> apples[Color.red] = 'red delicious'
>>> apples[Color.green] = 'granny smith'
>>> apples == {Color.red: 'red delicious', Color.green: 'granny smith'}
True
8.13.3. Programmatic access to enumeration members and their attributes

Sometimes it's useful to access members in enumerations programmatically (i.e. situations where `Color.red` won't do because the exact color is not known at program-writing time). `Enum` allows such access:

```
>>> Color(1)
<Color.red: 1>
>>> Color(3)
<Color.blue: 3>
```

If you want to access enum members by `name`, use item access:

```
>>> Color['red']
<Color.red: 1>
>>> Color['green']
<Color.green: 2>
```

If you have an enum member and need its name or value:

```
>>> member = Color.red
>>> member.name
'red'
>>> member.value
1
```
8.13.4. Duplicating enum members and values

Having two enum members with the same name is invalid:

```python
>>> class Shape(Enum):
...      square = 2
...      square = 3
...
Traceback (most recent call last):
...  TypeError: Attempted to reuse key: 'square'
```

However, two enum members are allowed to have the same value. Given two members A and B with the same value (and A defined first), B is an alias to A. By-value lookup of the value of A and B will return A. By-name lookup of B will also return A:

```python
>>> class Shape(Enum):
...      square = 2
...      diamond = 1
...      circle = 3
...      alias_for_square = 2
...
>>> Shape.square
<Shape.square: 2>
>>> Shape.alias_for_square
<Shape.square: 2>
>>> Shape(2)
<Shape.square: 2>
```

**Note:** Attempting to create a member with the same name as an already defined attribute (another member, a method, etc.) or
attempting to create an attribute with the same name as a member is not allowed.
8.13.5. Ensuring unique enumeration values

By default, enumerations allow multiple names as aliases for the same value. When this behavior isn’t desired, the following decorator can be used to ensure each value is used only once in the enumeration:

```python
@enum.unique
```

A class decorator specifically for enumerations. It searches an enumeration’s `__members__` gathering any aliases it finds; if any are found `ValueError` is raised with the details:

```python
>>> from enum import Enum, unique
>>> @unique
... class Mistake(Enum):
...     one = 1
...     two = 2
...     three = 3
...     four = 3
...
Traceback (most recent call last):
...
ValueError: duplicate values found in <enum 'Mistake'>:
```
8.13.6. Iteration

Iterating over the members of an enum does not provide the aliases:

```python
>>> list(Shape)
[<Shape.square: 2>, <Shape.diamond: 1>, <Shape.circle: 3>]
```

The special attribute `__members__` is an ordered dictionary mapping names to members. It includes all names defined in the enumeration, including the aliases:

```python
>>> for name, member in Shape.__members__.items():
...     name, member
...
('square', <Shape.square: 2>)
('diamond', <Shape.diamond: 1>)
('circle', <Shape.circle: 3>)
('alias_for_square', <Shape.square: 2>)
```

The `__members__` attribute can be used for detailed programmatic access to the enumeration members. For example, finding all the aliases:

```python
>>> [name for name, member in Shape.__members__.items() if name == 'alias_for_square']
['alias_for_square']
```
8.13.7. Comparisons

Enumeration members are compared by identity:

```python
>>> Color.red == Color.red
True
>>> Color.red == Color.blue
False
>>> Color.red != Color.blue
True
```

Ordered comparisons between enumeration values are not supported. Enum members are not integers (but see `IntEnum` below):

```python
>>> Color.red < Color.blue
Traceback (most recent call last):
  File "<stdin>", line 1, in <module>
TypeError: unorderable types: Color() < Color()
```

Equality comparisons are defined though:

```python
>>> Color.blue == Color.red
False
>>> Color.blue != Color.red
True
>>> Color.blue == Color.blue
True
```

Comparisons against non-enumeration values will always compare not equal (again, `IntEnum` was explicitly designed to behave differently, see below):

```python
>>> Color.blue == 2
False
```
8.13.8. Allowed members and attributes of enumerations

The examples above use integers for enumeration values. Using integers is short and handy (and provided by default by the Functional API), but not strictly enforced. In the vast majority of use-cases, one doesn’t care what the actual value of an enumeration is. But if the value is important, enumerations can have arbitrary values.

Enumerations are Python classes, and can have methods and special methods as usual. If we have this enumeration:

```python
>>> class Mood(Enum):
...     funky = 1
...     happy = 3
...     def describe(self):
...         # self is the member here
...         return self.name, self.value
...     def __str__(self):
...         return 'my custom str! {0}'.format(self)

>>> @classmethod
...     def favorite_mood(cls):
...         # cls here is the enumeration
...         return cls.happy

Then:

>>> Mood.favorite_mood()
<Mood.happy: 3>```
The rules for what is allowed are as follows: _sunder_ names (starting and ending with a single underscore) are reserved by enum and cannot be used; all other attributes defined within an enumeration will become members of this enumeration, with the exception of __dunder__ names and descriptors (methods are also descriptors).

Note: if your enumeration defines __new__() and/or __init__() then whatever value(s) were given to the enum member will be passed into those methods. See Planet for an example.
8.13.9. Restricted subclassing of enumerations

Subclassing an enumeration is allowed only if the enumeration does not define any members. So this is forbidden:

```python
>>> class MoreColor(Color):
...     pink = 17
...
Traceback (most recent call last):
...  TypeError: Cannot extend enumerations
```

But this is allowed:

```python
>>> class Foo(Enum):
...     def some_behavior(self):
...         pass
...
>>> class Bar(Foo):
...     happy = 1
...     sad = 2
...
```

Allowing subclassing of enums that define members would lead to a violation of some important invariants of types and instances. On the other hand, it makes sense to allow sharing some common behavior between a group of enumerations. (See OrderedEnum for an example.)
8.13.10. Pickling

Enumerations can be pickled and unpickled:

```python
>>> from test.test_enum import Fruit
>>> from pickle import dumps, loads
>>> Fruit.tomato is loads(dumps(Fruit.tomato))
True
```

The usual restrictions for pickling apply: picklable enums must be defined in the top level of a module, since unpickling requires them to be importable from that module.

**Note:** With pickle protocol version 4 it is possible to easily pickle enums nested in other classes.

It is possible to modify how Enum members are pickled/unpickled by defining `__reduce_ex__()` in the enumeration class.
8.13.11. Functional API

The `Enum` class is callable, providing the following functional API:

```python
>>> Animal = Enum('Animal', 'ant bee cat dog')
>>> Animal
<enum 'Animal'>
>>> Animal.ant
<Animal.ant: 1>
>>> Animal.ant.value
1
>>> list(Animal)
```

The semantics of this API resemble `namedtuple`. The first argument of the call to `Enum` is the name of the enumeration.

The second argument is the source of enumeration member names. It can be a whitespace-separated string of names, a sequence of names, a sequence of 2-tuples with key/value pairs, or a mapping (e.g. dictionary) of names to values. The last two options enable assigning arbitrary values to enumerations; the others auto-assign increasing integers starting with 1. A new class derived from `Enum` is returned. In other words, the above assignment to `Animal` is equivalent to:

```python
>>> class Animals(Enum):
    ...    ant = 1
    ...    bee = 2
    ...    cat = 3
    ...    dog = 4
```
The reason for defaulting to 1 as the starting number and not 0 is that 0 is False in a boolean sense, but enum members all evaluate to True.

Pickling enums created with the functional API can be tricky as frame stack implementation details are used to try and figure out which module the enumeration is being created in (e.g. it will fail if you use a utility function in separate module, and also may not work on IronPython or Jython). The solution is to specify the module name explicitly as follows:

```python
>>> Animals = Enum('Animals', 'ant bee cat dog', module=
```

**Warning:** If module is not supplied, and Enum cannot determine what it is, the new Enum members will not be unpicklable; to keep errors closer to the source, pickling will be disabled.

The new pickle protocol 4 also, in some circumstances, relies on `__qualname__` being set to the location where pickle will be able to find the class. For example, if the class was made available in class SomeData in the global scope:

```python
>>> Animals = Enum('Animals', 'ant bee cat dog', qua
```

The complete signature is:

```
Enum(value='NewEnumName', names=<...>, *, module='...')
```

**value:** What the new Enum class will record as its name.

The Enum members. This can be a whitespace or comma-separated string.
<table>
<thead>
<tr>
<th>type:</th>
<th>module:</th>
<th>names:</th>
</tr>
</thead>
<tbody>
<tr>
<td>type to mix in to new Enum class</td>
<td>name of module where new Enum class can be found</td>
<td>(values will start at 1):</td>
</tr>
<tr>
<td>tqualname:</td>
<td>module:</td>
<td></td>
</tr>
<tr>
<td>name of module where new Enum class can be found</td>
<td>[{'chartruese': 7, 'sea-green': 11, 'rosemary'</td>
<td></td>
</tr>
<tr>
<td></td>
<td></td>
<td>'red,green,blue'}</td>
</tr>
</tbody>
</table>
8.13.12. Derived Enumerations

8.13.12.1. IntEnum

A variation of `Enum` is provided which is also a subclass of `int`. Members of an `IntEnum` can be compared to integers; by extension, integer enumerations of different types can also be compared to each other:

```python
>>> from enum import IntEnum
>>> class Shape(IntEnum):
...     circle = 1
...     square = 2
... 
>>> class Request(IntEnum):
...     post = 1
...     get = 2
... 
>>> Shape == 1
False
>>> Shape.circle == 1
True
>>> Shape.circle == Request.post
True
```

However, they still can’t be compared to standard `Enum` enumerations:

```python
>>> class Shape(IntEnum):
...     circle = 1
...     square = 2
... 
>>> class Color(Enum):
...     red = 1
...     green = 2
```
\[ \text{...} \]

```python
>>> Shape.circle == Color.red
False
```

\textit{IntEnum} values behave like integers in other ways you’d expect:

```python
>>> int(Shape.circle)
1
>>> ['a', 'b', 'c'][Shape.circle]
'b'
>>> [i for i in range(Shape.square)]
[0, 1]
```

For the vast majority of code, \textit{Enum} is strongly recommended, since \textit{IntEnum} breaks some semantic promises of an enumeration (by being comparable to integers, and thus by transitivity to other unrelated enumerations). It should be used only in special cases where there’s no other choice; for example, when integer constants are replaced with enumerations and backwards compatibility is required with code that still expects integers.

\section*{8.13.12.2. Others}

While \textit{IntEnum} is part of the \textit{enum} module, it would be very simple to implement independently:

```python
class IntEnum(int, Enum):
    pass
```

This demonstrates how similar derived enumerations can be defined; for example a \texttt{StrEnum} that mixes in \texttt{str} instead of \texttt{int}.

Some rules:
1. When subclassing `Enum`, mix-in types must appear before `Enum` itself in the sequence of bases, as in the `IntEnum` example above.

2. While `Enum` can have members of any type, once you mix in an additional type, all the members must have values of that type, e.g. `int` above. This restriction does not apply to mix-ins which only add methods and don’t specify another data type such as `int` or `str`.

3. When another data type is mixed in, the value attribute is not the same as the enum member itself, although it is equivalent and will compare equal.

4. %-style formatting: `%s` and `%r` call `Enum`'s `__str__()` and `__repr__()` respectively; other codes (such as `%i` or `%h` for `IntEnum`) treat the enum member as its mixed-in type.

5. `str.__format__()` (or `format()`) will use the mixed-in type's `__format__()`. If the `Enum`'s `str()` or `repr()` is desired use the `!s` or `!r str` format codes.
8.13.13. Interesting examples

While `Enum` and `IntEnum` are expected to cover the majority of use-cases, they cannot cover them all. Here are recipes for some different types of enumerations that can be used directly, or as examples for creating one’s own.

8.13.13.1. AutoNumber

Avoids having to specify the value for each enumeration member:

```python
>>> class AutoNumber(Enum):
...     def __new__(cls):
...         value = len(cls.__members__) + 1
...         obj = object.__new__(cls)
...         obj._value_ = value
...         return obj
...
>>> class Color(AutoNumber):
...     red = ()
...     green = ()
...     blue = ()
...
>>> Color.green.value == 2
True
```

**Note:** The `__new__()` method, if defined, is used during creation of the Enum members; it is then replaced by Enum’s `__new__()`, which is used after class creation for lookup of existing members. Due to the way Enums are supposed to behave, there is no way to customize Enum’s `__new__()`.
8.13.13.2. OrderedEnum

An ordered enumeration that is not based on `IntEnum` and so maintains the normal `Enum` invariants (such as not being comparable to other enumerations):

```python
>>> class OrderedEnum(Enum):
    ...
    def __ge__(self, other):
        ...
        if self.__class__ is other.__class__:
            ...
            return self.value >= other.value
        ...
        return NotImplemented
    ...
    def __gt__(self, other):
        ...
        if self.__class__ is other.__class__:
            ...
            return self.value > other.value
        ...
        return NotImplemented
    ...
    def __le__(self, other):
        ...
        if self.__class__ is other.__class__:
            ...
            return self.value <= other.value
        ...
        return NotImplemented
    ...
    def __lt__(self, other):
        ...
        if self.__class__ is other.__class__:
            ...
            return self.value < other.value
        ...
        return NotImplemented
    ...

>>> class Grade(OrderedEnum):
    ...
    A = 5
    B = 4
    C = 3
    D = 2
    F = 1
    ...

>>> Grade.C < Grade.A
True
```

8.13.13.3. DuplicateFreeEnum
Raises an error if a duplicate member name is found instead of creating an alias:

```python
>>> class DuplicateFreeEnum(Enum):
...     def __init__(self, *args):
...         cls = self.__class__
...         if any(self.value == e.value for e in cls):
...             a = self.name
...             e = cls(self.value).name
...             raise ValueError(
...                 "aliases not allowed in DuplicateFreeEnum:
...                 % (a, e))
...
>>> class Color(DuplicateFreeEnum):
...     red = 1
...     green = 2
...     blue = 3
...     grene = 2
...
Traceback (most recent call last):
...
ValueError: aliases not allowed in DuplicateFreeEnum
```

**Note:** This is a useful example for subclassing `Enum` to add or change other behaviors as well as disallowing aliases. If the only desired change is disallowing aliases, the `unique()` decorator can be used instead.

### 8.13.13.4. Planet

If `__new__()` or `__init__()` is defined the value of the enum member will be passed to those methods:
```python
>>> class Planet(Enum):
...     MERCURY = (3.303e+23, 2.4397e6)
...     VENUS = (4.869e+24, 6.0518e6)
...     EARTH = (5.976e+24, 6.37814e6)
...     MARS = (6.421e+23, 3.3972e6)
...     JUPITER = (1.9e+27, 7.1492e7)
...     SATURN = (5.688e+26, 6.0268e7)
...     URANUS = (8.686e+25, 2.5559e7)
...     NEPTUNE = (1.024e+26, 2.4746e7)
...     def __init__(self, mass, radius):
...         self.mass = mass # in kilograms
...         self.radius = radius # in meters
...     @property
...     def surface_gravity(self):
...         # universal gravitational constant (m3 kg^-1 s^-2)
...         G = 6.67300E-11
...         return G * self.mass / (self.radius * self.radius)

>>> Planet.EARTH.value
(5.976e+24, 6378140.0)
>>> Planet.EARTH.surface_gravity
9.80265274337129
```
8.13.14. How are Enums different?

Enums have a custom metaclass that affects many aspects of both derived Enum classes and their instances (members).

The EnumMeta metaclass is responsible for providing the \_\_contains\_\_(), \_\_dir\_\_(), \_\_iter\_\_() and other methods that allow one to do things with an Enum class that fail on a typical class, such as list(Color) or some\_var in Color. EnumMeta is responsible for ensuring that various other methods on the final Enum class are correct (such as \_\_new\_\_(), \_\_getnewargs\_\_(), \_\_str\_\_() and \_\_repr\_\_())

8.13.14.2. Enum Members (aka instances)

The most interesting thing about Enum members is that they are singletons. EnumMeta creates them all while it is creating the Enum class itself, and then puts a custom \_\_new\_\_() in place to ensure that no new ones are ever instantiated by returning only the existing member instances.

8.13.14.3. Finer Points

Enum members are instances of an Enum class, and even though they are accessible as EnumClass.member, they are not accessible directly from the member:

```python
>>> Color.red
```
Likewise, the __members__ is only available on the class.

If you give your Enum subclass extra methods, like the Planet class above, those methods will show up in a dir() of the member, but not of the class:

```python
>>> dir(Planet)
['EARTH', 'JUPITER', 'MARS', 'MERCURY', 'NEPTUNE', 'SATURN', 'URANUS', 'VENUS', '__class__', '__doc__', '__members__', '__module__']
>>> dir(Planet.EARTH)
['__class__', '__doc__', '__module__', 'name', 'surface_gravity', 'value']
```

A __new__() method will only be used for the creation of the Enum members – after that it is replaced. This means if you wish to change how Enum members are looked up you either have to write a helper function or a classmethod().
9. Numeric and Mathematical Modules

The modules described in this chapter provide numeric and math-related functions and data types. The numbers module defines an abstract hierarchy of numeric types. The math and cmath modules contain various mathematical functions for floating-point and complex numbers. The decimal module supports exact representations of decimal numbers, using arbitrary precision arithmetic.

The following modules are documented in this chapter:

- **9.1. numbers — Numeric abstract base classes**
  - 9.1.1. The numeric tower
  - 9.1.2. Notes for type implementors
    - 9.1.2.1. Adding More Numeric ABCs
    - 9.1.2.2. Implementing the arithmetic operations
- **9.2. math — Mathematical functions**
  - 9.2.1. Number-theoretic and representation functions
  - 9.2.2. Power and logarithmic functions
  - 9.2.3. Trigonometric functions
  - 9.2.4. Angular conversion
  - 9.2.5. Hyperbolic functions
  - 9.2.6. Special functions
  - 9.2.7. Constants
- **9.3. cmath — Mathematical functions for complex numbers**
  - 9.3.1. Conversions to and from polar coordinates
  - 9.3.2. Power and logarithmic functions
  - 9.3.3. Trigonometric functions
  - 9.3.4. Hyperbolic functions
  - 9.3.5. Classification functions
• 9.3.6. Constants

• 9.4. decimal — Decimal fixed point and floating point arithmetic
  • 9.4.1. Quick-start Tutorial
  • 9.4.2. Decimal objects
    • 9.4.2.1. Logical operands
  • 9.4.3. Context objects
  • 9.4.4. Constants
  • 9.4.5. Rounding modes
  • 9.4.6. Signals
  • 9.4.7. Floating Point Notes
    • 9.4.7.1. Mitigating round-off error with increased precision
    • 9.4.7.2. Special values
  • 9.4.8. Working with threads
  • 9.4.9. Recipes
  • 9.4.10. Decimal FAQ

• 9.5. fractions — Rational numbers

• 9.6. random — Generate pseudo-random numbers
  • 9.6.1. Notes on Reproducibility
  • 9.6.2. Examples and Recipes

• 9.7. statistics — Mathematical statistics functions
  • 9.7.1. Averages and measures of central location
  • 9.7.2. Measures of spread
  • 9.7.3. Function details
  • 9.7.4. Exceptions
9.1. numbers — Numeric abstract base classes

The numbers module (PEP 3141) defines a hierarchy of numeric abstract base classes which progressively define more operations. None of the types defined in this module can be instantiated.

```
class numbers.Number
    The root of the numeric hierarchy. If you just want to check if an argument \( x \) is a number, without caring what kind, use `isinstance(x, Number)`.```
9.1.1. The numeric tower

class numbers. Complex
    Subclasses of this type describe complex numbers and include the operations that work on the built-in complex type. These are: conversions to complex and bool, real, imag, +, -, *, /, abs(), conjugate(), ==, and !=. All except - and != are abstract.

real
    Abstract. Retrieves the real component of this number.

imag
    Abstract. Retrieves the imaginary component of this number.

conjugate()
    Abstract. Returns the complex conjugate. For example, (1+3j).conjugate() == (1-3j).

class numbers. Real
    To Complex, Real adds the operations that work on real numbers.

    In short, those are: a conversion to float, math.trunc(), round(), math.floor(), math.ceil(), divmod(), //, %, <, <=, >, and >=.

    Real also provides defaults for complex(), real, imag, and conjugate().

class numbers. Rational
    Subtypes Real and adds numerator and denominator
properties, which should be in lowest terms. With these, it provides a default for `float()`.

**numerator**
Abstract.

**denominator**
Abstract.

class numbers. **Integral**
Subtypes **Rational** and adds a conversion to `int`. Provides defaults for `float()`, **numerator**, and **denominator**. Adds abstract methods for `**` and bit-string operations: `<<, >>, &, ^, |, ~`.
9.1.2. Notes for type implementors

Implementors should be careful to make equal numbers equal and hash them to the same values. This may be subtle if there are two different extensions of the real numbers. For example, `fractions.Fraction` implements `hash()` as follows:

```python
def __hash__(self):
    if self.denominator == 1:
        # Get integers right.
        return hash(self.numerator)
    # Expensive check, but definitely correct.
    if self == float(self):
        return hash(float(self))
    else:
        # Use tuple's hash to avoid a high collision rate on
        # simple fractions.
        return hash((self.numerator, self.denominator))
```

9.1.2.1. Adding More Numeric ABCs

There are, of course, more possible ABCs for numbers, and this would be a poor hierarchy if it precluded the possibility of adding those. You can add `MyFoo` between `Complex` and `Real` with:

```python
class MyFoo(Complex): ...
MyFoo.register(Real)
```

9.1.2.2. Implementing the arithmetic operations

We want to implement the arithmetic operations so that mixed-mode
operations either call an implementation whose author knew about the
types of both arguments, or convert both to the nearest built in type
and do the operation there. For subtypes of \texttt{Integral}, this means
that \texttt{__add__()} and \texttt{__radd__()} should be defined as:

```python
class MyIntegral(Integral):
    def __add__(self, other):
        if isinstance(other, MyIntegral):
            return do_my_adding_stuff(self, other)
        elif isinstance(other, OtherTypeIKnowAbout):
            return do_my_other_adding_stuff(self, other)
        else:
            return NotImplemented
    def __radd__(self, other):
        if isinstance(other, MyIntegral):
            return do_my_adding_stuff(other, self)
        elif isinstance(other, OtherTypeIKnowAbout):
            return do_my_other_adding_stuff(other, self)
        elif isinstance(other, Integral):
            return int(other) + int(self)
        elif isinstance(other, Real):
            return float(other) + float(self)
        elif isinstance(other, Complex):
            return complex(other) + complex(self)
        else:
            return NotImplemented
```

There are 5 different cases for a mixed-type operation on subclasses
of \texttt{Complex}. I'll refer to all of the above code that doesn't refer to
\texttt{MyIntegral} and \texttt{OtherTypeIKnowAbout} as “boilerplate”. \texttt{a}
will be an instance of \texttt{A}, which is a subtype of \texttt{Complex} \texttt{(a : A <= Complex)}, and \texttt{b : B <= Complex}. I'll consider \texttt{a + b}:
1. If \( A \) defines an \code{__add__()} which accepts \code{b}, all is well.
2. If \( A \) falls back to the boilerplate code, and it were to return a value from \code{__add__()}, we’d miss the possibility that \( B \) defines a more intelligent \code{__radd__()}, so the boilerplate should return \code{NotImplemented} from \code{__add__()}. (Or \( A \) may not implement \code{__add__()} at all.)
3. Then \( B \)'s \code{__radd__()} gets a chance. If it accepts \code{a}, all is well.
4. If it falls back to the boilerplate, there are no more possible methods to try, so this is where the default implementation should live.
5. If \( B <: A \), Python tries \( B.__radd__ \) before \( A.__add__ \). This is ok, because it was implemented with knowledge of \( A \), so it can handle those instances before delegating to \code{Complex}.

If \( A <: \text{Complex} \) and \( B <: \text{Real} \) without sharing any other knowledge, then the appropriate shared operation is the one involving the built in \code{complex}, and both \code{__radd__()} s land there, so \( a+b == b+a \).

Because most of the operations on any given type will be very similar, it can be useful to define a helper function which generates the forward and reverse instances of any given operator. For example, \code{fractions.Fraction} uses:

```python
def _operator_fallbacks(monomorphic_operator, fallback_operator):
    def forward(a, b):
        if isinstance(b, (int, Fraction)):
            return monomorphic_operator(a, b)
        elif isinstance(b, float):
            return fallback_operator(float(a), b)
        elif isinstance(b, complex):
            return fallback_operator(complex(a), b)
```
else:
    return NotImplemented
forward.__name__ = '__' + fallback_operator.__name__
forward.__doc__ = monomorphic_operator.__doc__

def reverse(b, a):
    if isinstance(a, Rational):
        # Includes ints.
        return monomorphic_operator(a, b)
    elif isinstance(a, numbers.Real):
        return fallback_operator(float(a), float(b))
    elif isinstance(a, numbers.Complex):
        return fallback_operator(complex(a), complex(b))
    else:
        return NotImplemented
reverse.__name__ = '__r' + fallback_operator.__name__
reverse.__doc__ = monomorphic_operator.__doc__

return forward, reverse
def __add__(a, b):
    """a + b""
    return Fraction(a.numerator * b.denominator +
                      b.numerator * a.denominator,
                      a.denominator * b.denominator)
__add__, __radd__ = _operator_fallbacks(__add__, operator)

# ...
9.2. math — Mathematical functions

This module is always available. It provides access to the mathematical functions defined by the C standard.

These functions cannot be used with complex numbers; use the functions of the same name from the cmath module if you require support for complex numbers. The distinction between functions which support complex numbers and those which don’t is made since most users do not want to learn quite as much mathematics as required to understand complex numbers. Receiving an exception instead of a complex result allows earlier detection of the unexpected complex number used as a parameter, so that the programmer can determine how and why it was generated in the first place.

The following functions are provided by this module. Except when explicitly noted otherwise, all return values are floats.
9.2.1. Number-theoretic and representation functions

**math.ceil(x)**

Return the ceiling of x, the smallest integer greater than or equal to x. If x is not a float, delegates to x.__ceil__(), which should return an **Integral** value.

**math.copysign(x, y)**

Return a float with the magnitude (absolute value) of x but the sign of y. On platforms that support signed zeros, copysign(1.0, -0.0) returns -1.0.

**math.fabs(x)**

Return the absolute value of x.

**math.factorial(x)**

Return x factorial. Raises **ValueError** if x is not integral or is negative.

**math.floor(x)**

Return the floor of x, the largest integer less than or equal to x. If x is not a float, delegates to x.__floor__(), which should return an **Integral** value.

**math.fmod(x, y)**

Return fmod(x, y), as defined by the platform C library. Note that the Python expression x % y may not return the same result. The intent of the C standard is that fmod(x, y) be exactly (mathematically; to infinite precision) equal to x - n\*y for some
integer $n$ such that the result has the same sign as $x$ and magnitude less than $\text{abs}(y)$. Python’s $x \% y$ returns a result with the sign of $y$ instead, and may not be exactly computable for float arguments. For example, $\text{fmod}(-1e-100, 1e100)$ is $-1e-100$, but the result of Python’s $-1e-100 \% 1e100$ is $1e100-1e-100$, which cannot be represented exactly as a float, and rounds to the surprising $1e100$. For this reason, function $\text{fmod}()$ is generally preferred when working with floats, while Python’s $x \% y$ is preferred when working with integers.

**math.** $\text{frexp}(x)$

Return the mantissa and exponent of $x$ as the pair $(m, e)$. $m$ is a float and $e$ is an integer such that $x == m * 2**e$ exactly. If $x$ is zero, returns $(0.0, 0)$, otherwise $0.5 <= \text{abs}(m) < 1$. This is used to “pick apart” the internal representation of a float in a portable way.

**math.** $\text{fsum}(\text{iterable})$

Return an accurate floating point sum of values in the iterable. Avoids loss of precision by tracking multiple intermediate partial sums:

```python
>>> sum([.1, .1, .1, .1, .1, .1, .1, .1, .1])
0.9999999999999999
>>> fsum([.1, .1, .1, .1, .1, .1, .1, .1, .1])
1.0
```

The algorithm’s accuracy depends on IEEE-754 arithmetic guarantees and the typical case where the rounding mode is half-even. On some non-Windows builds, the underlying C library uses extended precision addition and may occasionally double-round an intermediate sum causing it to be off in its least significant bit.
For further discussion and two alternative approaches, see the ASPN cookbook recipes for accurate floating point summation.

```
math.isfinite(x)
```

Return `True` if `x` is neither an infinity nor a NaN, and `False` otherwise. (Note that `0.0` is considered finite.)

*New in version 3.2.*

```
math.isinf(x)
```

Return `True` if `x` is a positive or negative infinity, and `False` otherwise.

```
math.isnan(x)
```

Return `True` if `x` is a NaN (not a number), and `False` otherwise.

```
math.ldexp(x, i)
```

Return `x * (2**i)`. This is essentially the inverse of function `frexp()`.

```
math.modf(x)
```

Return the fractional and integer parts of `x`. Both results carry the sign of `x` and are floats.

```
math.trunc(x)
```

Return the `Real` value `x` truncated to an `Integral` (usually an integer). Delegates to `x.__trunc__()`. Note that `frexp()` and `modf()` have a different call/return pattern than their C equivalents: they take a single argument and return a pair of values, rather than returning their second return value through an ‘output parameter’ (there is no such thing in Python).
For the `ceil()`, `floor()`, and `modf()` functions, note that all floating-point numbers of sufficiently large magnitude are exact integers. Python floats typically carry no more than 53 bits of precision (the same as the platform C double type), in which case any float $x$ with $\text{abs}(x) \geq 2^{52}$ necessarily has no fractional bits.
9.2.2. Power and logarithmic functions

**math.** `exp(x)`

Return $e^{x}$.

**math.** `expm1(x)`

Return $e^{x} - 1$. For small floats $x$, the subtraction in $\exp(x) - 1$ can result in a significant loss of precision; the `expm1()` function provides a way to compute this quantity to full precision:

```python
>>> from math import exp, expm1
>>> exp(1e-5) - 1  # gives result accurate to 11 places
1.000005000069649e-05
>>> expm1(1e-5)  # result accurate to full precision
1.0000050000166668e-05
```

*New in version 3.2.*

**math.** `log(x[, base])`

With one argument, return the natural logarithm of $x$ (to base $e$).

With two arguments, return the logarithm of $x$ to the given $base$, calculated as $\log(x) / \log(base)$.

**math.** `log1p(x)`

Return the natural logarithm of $1+x$ (base $e$). The result is calculated in a way which is accurate for $x$ near zero.

**math.** `log2(x)`

Return the base-2 logarithm of $x$. This is usually more accurate than $\log(x, 2)$. 
New in version 3.3.

See also: `int.bit_length()` returns the number of bits necessary to represent an integer in binary, excluding the sign and leading zeros.

```
math.log10(x)
```
Return the base-10 logarithm of x. This is usually more accurate than `log(x, 10)`.

```
math.pow(x, y)
```
Return x raised to the power y. Exceptional cases follow Annex ‘F’ of the C99 standard as far as possible. In particular, `pow(1.0, x)` and `pow(x, 0.0)` always return 1.0, even when x is a zero or a NaN. If both x and y are finite, x is negative, and y is not an integer then `pow(x, y)` is undefined, and raises `ValueError`.

Unlike the built-in ** operator, `math.pow()` converts both its arguments to type `float`. Use ** or the built-in `pow()` function for computing exact integer powers.

```
math.sqrt(x)
```
Return the square root of x.
9.2.3. Trigonometric functions

math.\texttt{acos}(x)
  Return the arc cosine of $x$, in radians.

math.\texttt{asin}(x)
  Return the arc sine of $x$, in radians.

math.\texttt{atan}(x)
  Return the arc tangent of $x$, in radians.

math.\texttt{atan2}(y, x)
  Return $\text{atan}(y / x)$, in radians. The result is between -$\pi$ and $\pi$. The vector in the plane from the origin to point $(x, y)$ makes this angle with the positive X axis. The point of $\text{atan2}()$ is that the signs of both inputs are known to it, so it can compute the correct quadrant for the angle. For example, $\text{atan}(1)$ and $\text{atan2}(1, 1)$ are both $\pi/4$, but $\text{atan2}(-1, -1)$ is $-3\pi/4$.

math.\texttt{cos}(x)
  Return the cosine of $x$ radians.

math.\texttt{hypot}(x, y)
  Return the Euclidean norm, $\sqrt{x^2 + y^2}$. This is the length of the vector from the origin to point $(x, y)$.

math.\texttt{sin}(x)
  Return the sine of $x$ radians.

math.\texttt{tan}(x)
  Return the tangent of $x$ radians.
9.2.4. Angular conversion

math. **degrees**$(x)$

Converts angle $x$ from radians to degrees.

math. **radians**$(x)$

Converts angle $x$ from degrees to radians.
9.2.5. Hyperbolic functions

Hyperbolic functions are analogs of trigonometric functions that are based on hyperbolas instead of circles.

\texttt{math.acosh(x)}

    Return the inverse hyperbolic cosine of \( x \).

\texttt{math.asinh(x)}

    Return the inverse hyperbolic sine of \( x \).

\texttt{math.atanh(x)}

    Return the inverse hyperbolic tangent of \( x \).

\texttt{math.cosh(x)}

    Return the hyperbolic cosine of \( x \).

\texttt{math.sinh(x)}

    Return the hyperbolic sine of \( x \).

\texttt{math.tanh(x)}

    Return the hyperbolic tangent of \( x \).
9.2.6. Special functions

math.\texttt{erf}(x)

Return the \texttt{error function} at $x$.

The \texttt{erf()} function can be used to compute traditional statistical functions such as the \texttt{cumulative standard normal distribution}:

\begin{verbatim}
def phi(x):
    'Cumulative distribution function for the standard normal distribution'
    return (1.0 + erf(x / sqrt(2.0))) / 2.0
\end{verbatim}

\textit{New in version 3.2.}

math.\texttt{erfc}(x)

Return the complementary error function at $x$. The \texttt{complementary error function} is defined as $1.0 - \texttt{erf}(x)$. It is used for large values of $x$ where a subtraction from one would cause a loss of significance.

\textit{New in version 3.2.}

math.\texttt{gamma}(x)

Return the \texttt{Gamma function} at $x$.

\textit{New in version 3.2.}

math.\texttt{lgamma}(x)

Return the natural logarithm of the absolute value of the Gamma function at $x$.

\textit{New in version 3.2.}
9.2.7. Constants

**math.pi**

The mathematical constant $\pi = 3.141592...$, to available precision.

**math.e**

The mathematical constant $e = 2.718281...$, to available precision.

**CPython implementation detail:** The `math` module consists mostly of thin wrappers around the platform C math library functions. Behavior in exceptional cases follows Annex F of the C99 standard where appropriate. The current implementation will raise `ValueError` for invalid operations like `sqrt(-1.0)` or `log(0.0)` (where C99 Annex F recommends signaling invalid operation or divide-by-zero), and `OverflowError` for results that overflow (for example, `exp(1000.0)`). A NaN will not be returned from any of the functions above unless one or more of the input arguments was a NaN; in that case, most functions will return a NaN, but (again following C99 Annex F) there are some exceptions to this rule, for example `pow(float('nan'), 0.0)` or `hypot(float('nan'), float('inf'))`.

Note that Python makes no effort to distinguish signaling NaNs from quiet NaNs, and behavior for signaling NaNs remains unspecified. Typical behavior is to treat all NaNs as though they were quiet.

**See also:**

**Module cmath**

Complex number versions of many of these functions.
9.3. `cmath` — Mathematical functions for complex numbers

This module is always available. It provides access to mathematical functions for complex numbers. The functions in this module accept integers, floating-point numbers or complex numbers as arguments. They will also accept any Python object that has either a `__complex__()` or a `__float__()` method: these methods are used to convert the object to a complex or floating-point number, respectively, and the function is then applied to the result of the conversion.

**Note:** On platforms with hardware and system-level support for signed zeros, functions involving branch cuts are continuous on both sides of the branch cut: the sign of the zero distinguishes one side of the branch cut from the other. On platforms that do not support signed zeros the continuity is as specified below.
9.3.1. Conversions to and from polar coordinates

A Python complex number `z` is stored internally using *rectangular* or *Cartesian* coordinates. It is completely determined by its *real part* `z.real` and its *imaginary part* `z.imag`. In other words:

\[
z = z.real + z.imag*1j
\]

*Polar coordinates* give an alternative way to represent a complex number. In polar coordinates, a complex number `z` is defined by the *modulus* `r` and the *phase angle* `phi`. The modulus `r` is the distance from `z` to the origin, while the phase `phi` is the counterclockwise angle, measured in radians, from the positive x-axis to the line segment that joins the origin to `z`.

The following functions can be used to convert from the native rectangular coordinates to polar coordinates and back.

`cmath.phase(x)`

Return the phase of `x` (also known as the *argument* of `x`), as a float. `phase(x)` is equivalent to `math.atan2(x.imag, x.real)`. The result lies in the range \([-\pi, \pi]\), and the branch cut for this operation lies along the negative real axis, continuous from above. On systems with support for signed zeros (which includes most systems in current use), this means that the sign of the result is the same as the sign of `x.imag`, even when `x.imag` is zero:

```python
>>> phase(complex(-1.0, 0.0))
3.141592653589793
>>> phase(complex(-1.0, -0.0))
-3.141592653589793
```
Note: The modulus (absolute value) of a complex number \(x\) can be computed using the built-in \(\texttt{abs()}\) function. There is no separate \texttt{cmath} module function for this operation.

\texttt{cmath.polar}(x)

Return the representation of \(x\) in polar coordinates. Returns a pair \((r, \phi)\) where \(r\) is the modulus of \(x\) and \(\phi\) is the phase of \(x\). \(\texttt{polar(x)}\) is equivalent to \((\texttt{abs(x)}, \texttt{phase(x)})\).

\texttt{cmath.rect}(r, phi)

Return the complex number \(x\) with polar coordinates \(r\) and \(\phi\). Equivalent to \(r * (\texttt{math.cos(phi)} + \texttt{math.sin(phi)}*\texttt{1j})\).
9.3.2. Power and logarithmic functions

\texttt{cmath.exp}(x)

Return the exponential value \( e^{**x} \).

\texttt{cmath.log}(x[, base])

Returns the logarithm of \( x \) to the given \( \text{base} \). If the \( \text{base} \) is not specified, returns the natural logarithm of \( x \). There is one branch cut, from 0 along the negative real axis to \(-\infty\), continuous from above.

\texttt{cmath.log10}(x)

Return the base-10 logarithm of \( x \). This has the same branch cut as \texttt{log()}.

\texttt{cmath.sqrt}(x)

Return the square root of \( x \). This has the same branch cut as \texttt{log()}. 
9.3.3. Trigonometric functions

cmath.\texttt{acos}(x)
Return the arc cosine of \( x \). There are two branch cuts: One extends right from 1 along the real axis to \( \infty \), continuous from below. The other extends left from \(-1\) along the real axis to \(-\infty\), continuous from above.

cmath.\texttt{asin}(x)
Return the arc sine of \( x \). This has the same branch cuts as \texttt{acos()}.

cmath.\texttt{atan}(x)
Return the arc tangent of \( x \). There are two branch cuts: One extends from \( 1j \) along the imaginary axis to \( \infty j \), continuous from the right. The other extends from \(-1j\) along the imaginary axis to \(-\infty j\), continuous from the left.

cmath.\texttt{cos}(x)
Return the cosine of \( x \).

cmath.\texttt{sin}(x)
Return the sine of \( x \).

cmath.\texttt{tan}(x)
Return the tangent of \( x \).
9.3.4. Hyperbolic functions

cmath.\texttt{acosh}(x)
Return the hyperbolic arc cosine of \( x \). There is one branch cut, extending left from 1 along the real axis to \(-\infty\), continuous from above.

cmath.\texttt{asinh}(x)
Return the hyperbolic arc sine of \( x \). There are two branch cuts: One extends from \( 1j \) along the imaginary axis to \( \infty j \), continuous from the right. The other extends from \(-1j\) along the imaginary axis to \(-\infty j\), continuous from the left.

cmath.\texttt{atanh}(x)
Return the hyperbolic arc tangent of \( x \). There are two branch cuts: One extends from 1 along the real axis to \( \infty \), continuous from below. The other extends from -1 along the real axis to \(-\infty\), continuous from above.

cmath.\texttt{cosh}(x)
Return the hyperbolic cosine of \( x \).

cmath.\texttt{sinh}(x)
Return the hyperbolic sine of \( x \).

cmath.\texttt{tanh}(x)
Return the hyperbolic tangent of \( x \).
9.3.5. Classification functions

cmath.\texttt{isfinite}(x)
   
   Return \texttt{True} if both the real and imaginary parts of \( x \) are finite, and \texttt{False} otherwise.

   \textit{New in version 3.2.}

cmath.\texttt{isinf}(x)
   
   Return \texttt{True} if either the real or the imaginary part of \( x \) is an infinity, and \texttt{False} otherwise.

cmath.\texttt{isnan}(x)
   
   Return \texttt{True} if either the real or the imaginary part of \( x \) is a NaN, and \texttt{False} otherwise.
9.3.6. Constants

**cmath.pi**

The mathematical constant \( \pi \), as a float.

**cmath.e**

The mathematical constant \( e \), as a float.

Note that the selection of functions is similar, but not identical, to that in module `math`. The reason for having two modules is that some users aren’t interested in complex numbers, and perhaps don’t even know what they are. They would rather have `math.sqrt(-1)` raise an exception than return a complex number. Also note that the functions defined in `cmath` always return a complex number, even if the answer can be expressed as a real number (in which case the complex number has an imaginary part of zero).

A note on branch cuts: They are curves along which the given function fails to be continuous. They are a necessary feature of many complex functions. It is assumed that if you need to compute with complex functions, you will understand about branch cuts. Consult almost any (not too elementary) book on complex variables for enlightenment. For information of the proper choice of branch cuts for numerical purposes, a good reference should be the following:

9.4. **decimal** — Decimal fixed point and floating point arithmetic

The **decimal** module provides support for fast correctly-rounded decimal floating point arithmetic. It offers several advantages over the **float** datatype:

- Decimal “is based on a floating-point model which was designed with people in mind, and necessarily has a paramount guiding principle – computers must provide an arithmetic that works in the same way as the arithmetic that people learn at school.” – excerpt from the decimal arithmetic specification.

- Decimal numbers can be represented exactly. In contrast, numbers like 1.1 and 2.2 do not have exact representations in binary floating point. End users typically would not expect $1.1 + 2.2$ to display as $3.3000000000000003$ as it does with binary floating point.

- The exactness carries over into arithmetic. In decimal floating point, $0.1 + 0.1 + 0.1 - 0.3$ is exactly equal to zero. In binary floating point, the result is $5.5511151231257827e-017$. While near to zero, the differences prevent reliable equality testing and differences can accumulate. For this reason, decimal is preferred in accounting applications which have strict equality invariants.

- The decimal module incorporates a notion of significant places so that $1.30 + 1.20$ is $2.50$. The trailing zero is kept to indicate significance. This is the customary presentation for monetary
applications. For multiplication, the “schoolbook” approach uses all the figures in the multiplicands. For instance, $1.3 \times 1.2$ gives 1.56 while $1.30 \times 1.20$ gives 1.5600.

- Unlike hardware based binary floating point, the decimal module has a user alterable precision (defaulting to 28 places) which can be as large as needed for a given problem:

```python
>>> from decimal import *
>>> getcontext().prec = 6
>>> Decimal(1) / Decimal(7)
Decimal('0.142857')
>>> getcontext().prec = 28
>>> Decimal(1) / Decimal(7)
Decimal('0.1428571428571428571428571429')
```

- Both binary and decimal floating point are implemented in terms of published standards. While the built-in float type exposes only a modest portion of its capabilities, the decimal module exposes all required parts of the standard. When needed, the programmer has full control over rounding and signal handling. This includes an option to enforce exact arithmetic by using exceptions to block any inexact operations.

- The decimal module was designed to support “without prejudice, both exact unrounded decimal arithmetic (sometimes called fixed-point arithmetic) and rounded floating-point arithmetic.” – excerpt from the decimal arithmetic specification.

The module design is centered around three concepts: the decimal number, the context for arithmetic, and signals.

A decimal number is immutable. It has a sign, coefficient digits, and an exponent. To preserve significance, the coefficient digits do not
truncate trailing zeros. Decimals also include special values such as Infinity, -Infinity, and NaN. The standard also differentiates -0 from +0.

The context for arithmetic is an environment specifying precision, rounding rules, limits on exponents, flags indicating the results of operations, and trap enablers which determine whether signals are treated as exceptions. Rounding options include ROUND_CEILING, ROUND_DOWN, ROUND_FLOOR, ROUND_HALF_DOWN, ROUND_HALF_EVEN, ROUND_HALF_UP, ROUND_UP, and ROUND_05UP.

Signals are groups of exceptional conditions arising during the course of computation. Depending on the needs of the application, signals may be ignored, considered as informational, or treated as exceptions. The signals in the decimal module are: Clamped, InvalidOperation, DivisionByZero, Inexact, Rounded, Subnormal, Overflow, Underflow and FloatOperation.

For each signal there is a flag and a trap enabler. When a signal is encountered, its flag is set to one, then, if the trap enabler is set to one, an exception is raised. Flags are sticky, so the user needs to reset them before monitoring a calculation.

See also:

9.4.1. Quick-start Tutorial

The usual start to using decimals is importing the module, viewing the current context with `getcontext()` and, if necessary, setting new values for precision, rounding, or enabled traps:

```python
>>> from decimal import *
>>> getcontext()
Context(prec=28, rounding=ROUND_HALF_EVEN, Emin=-999999, Emax=999999,
capitals=1, clamp=0, flags=[], traps=[Overflow, InvalidOperation])
```

```python
>>> getcontext().prec = 7  # Set a new precision
```

Decimal instances can be constructed from integers, strings, floats, or tuples. Construction from an integer or a float performs an exact conversion of the value of that integer or float. Decimal numbers include special values such as NaN which stands for “Not a number”, positive and negative Infinity, and -0:

```python
>>> getcontext().prec = 28
>>> Decimal(10)
Decimal('10')
>>> Decimal('3.14')
Decimal('3.14')
>>> Decimal(3.14)
Decimal('3.140000000000000124344978758017532527446748141640625')
>>> Decimal((0, (3, 1, 4), -2))
Decimal('3.14')
>>> Decimal(str(2.0 ** 0.5))
Decimal('1.4142135623730951')
>>> Decimal(2) ** Decimal('0.5')
Decimal('1.41421356237095048801688724')
```
If the `FloatOperation` signal is trapped, accidental mixing of decimals and floats in constructors or ordering comparisons raises an exception:

```python
>>> c = getcontext()
>>> c.traps[FloatOperation] = True
>>> Decimal(3.14)
Traceback (most recent call last):
  File "<stdin>", line 1, in <module>
decimal.FloatOperation: [<class 'decimal.FloatOperation'>
>>> Decimal('3.5') < 3.7
Traceback (most recent call last):
  File "<stdin>", line 1, in <module>
decimal.FloatOperation: [<class 'decimal.FloatOperation'>
>>> Decimal('3.5') == 3.5
True
```

New in version 3.3.

The significance of a new Decimal is determined solely by the number of digits input. Context precision and rounding only come into play during arithmetic operations.

```python
>>> getcontext().prec = 6
>>> Decimal('3.0')
Decimal('3.0')
>>> Decimal('3.1415926535')
Decimal('3.1415926535')
>>> Decimal('3.1415926535') + Decimal('2.7182818285')
```

```python
Decimal('5.8598744815')
```
Decimal('5.85987')
>>> getcontext().rounding = ROUND_UP
>>> Decimal('3.1415926535') + Decimal('2.7182818285')
Decimal('5.85988')

If the internal limits of the C version are exceeded, constructing a decimal raises `InvalidOperation`:

```python
>>> Decimal("1e9999999999999999999")
Traceback (most recent call last):
  File "<stdin>", line 1, in <module>
decimal.InvalidOperation: [<class 'decimal.InvalidOperation'>]
```

*Changed in version 3.3.*

Decimals interact well with much of the rest of Python. Here is a small decimal floating point flying circus:

```python
>>> data = list(map(Decimal, '1.34 1.87 3.45 2.35 1.00 0.03 9.25'))
>>> max(data)
Decimal('9.25')
>>> min(data)
Decimal('0.03')
>>> sorted(data)
[Decimal('0.03'), Decimal('1.00'), Decimal('1.34'), Decimal('1.87'), Decimal('2.35'), Decimal('3.45'), Decimal('9.25')]
>>> sum(data)
Decimal('19.29')
>>> a,b,c = data[:3]
>>> str(a)
'1.34'
>>> float(a)
1.34
>>> round(a, 1)
Decimal('1.3')
```

And some mathematical functions are also available to Decimal:

```python
>>> getcontext().prec = 28
>>> Decimal(2).sqrt()
Decimal('1.414213562373095048801688724')
>>> Decimal(1).exp()
Decimal('2.718281828459045235360287471')
>>> Decimal('10').ln()
Decimal('2.302585092994045684017991455')
>>> Decimal('10').log10()
Decimal('1')
```

The `quantize()` method rounds a number to a fixed exponent. This method is useful for monetary applications that often round results to a fixed number of places:

```python
>>> Decimal('7.325').quantize(Decimal('.01'), rounding=ROUND_HALF_UP)
Decimal('7.32')
>>> Decimal('7.325').quantize(Decimal('1.'), rounding=ROUND_HALF_UP)
Decimal('8')
```

As shown above, the `getcontext()` function accesses the current context and allows the settings to be changed. This approach meets the needs of most applications.
For more advanced work, it may be useful to create alternate contexts using the `Context()` constructor. To make an alternate active, use the `setcontext()` function.

In accordance with the standard, the `Decimal` module provides two ready to use standard contexts, `BasicContext` and `ExtendedContext`. The former is especially useful for debugging because many of the traps are enabled:

```python
>>> myothercontext = Context(prec=60, rounding=ROUND_HALF_DOWN)
>>> setcontext(myothercontext)
>>> Decimal(1) / Decimal(7)
Decimal('0.142857142857142857142857142857142857142857142857142857142857')

>>> ExtendedContext
Context(prec=9, rounding=ROUND_HALF_EVEN, Emin=-999999, Emax=999999,
capitals=1, clamp=0, flags=[], traps=[])  
>>> setcontext(ExtendedContext)
>>> Decimal(1) / Decimal(7)
Decimal('0.142857143')
>>> Decimal(42) / Decimal(0)
Decimal('Infinity')

>>> setcontext(BasicContext)
>>> Decimal(42) / Decimal(0)
Traceback (most recent call last):
  File "<pyshell#143>", line 1, in -toplevel-
    Decimal(42) / Decimal(0)
DivisionByZero: x / 0
```

Contexts also have signal flags for monitoring exceptional conditions encountered during computations. The flags remain set until explicitly cleared, so it is best to clear the flags before each set of monitored computations by using the `clear_flags()` method.
The `flags` entry shows that the rational approximation to Pi was rounded (digits beyond the context precision were thrown away) and that the result is inexact (some of the discarded digits were non-zero).

Individual traps are set using the dictionary in the `traps` field of a context:

Most programs adjust the current context only once, at the beginning of the program. And, in many applications, data is converted to `Decimal` with a single cast inside a loop. With context set and decimals created, the bulk of the program manipulates the data no differently than with other Python numeric types.
9.4.2. Decimal objects

class decimal. **Decimal**(value="0", context=None)
Construct a new Decimal object based from value.

value can be an integer, string, tuple, float, or another Decimal object. If no value is given, returns Decimal('0'). If value is a string, it should conform to the decimal numeric string syntax after leading and trailing whitespace characters are removed:

```
sign ::=  '+' | '-'
digit ::=  '0' | '1' | '2' | '3' | '4' | '5' | '6' | '7' | '8' | '9'
digits ::= digit [digit]...
decimal-part ::= digits '.' [digits] | ['.'] digits
exponent-part ::= indicator [sign] digits
infinity ::= 'Infinity' | 'Inf'
nan ::= 'NaN' [digits] | 'sNaN' [digits]
numeric-value ::= decimal-part [exponent-part]
numeric-string ::= [sign] numeric-value | [sign]
```

Other Unicode decimal digits are also permitted where digit appears above. These include decimal digits from various other alphabets (for example, Arabic-Indic and Devanāgarī digits) along with the fullwidth digits '\uff10' through '\uff19'.

If value is a tuple, it should have three components, a sign (0 for positive or 1 for negative), a tuple of digits, and an integer exponent. For example, Decimal(((0, (1, 4, 1, 4), -3)) returns Decimal('1.414')

If value is a float, the binary floating point value is losslessly
converted to its exact decimal equivalent. This conversion can often require 53 or more digits of precision. For example, `Decimal(float('1.1'))` converts to `Decimal('1.100000000000000088817841970012523233890533447265625')`

The context precision does not affect how many digits are stored. That is determined exclusively by the number of digits in `value`. For example, `Decimal('3.00000')` records all five zeros even if the context precision is only three.

The purpose of the context argument is determining what to do if `value` is a malformed string. If the context traps `InvalidOperation`, an exception is raised; otherwise, the constructor returns a new Decimal with the value of NaN.

Once constructed, `Decimal` objects are immutable.

*Changed in version 3.2:* The argument to the constructor is now permitted to be a `float` instance.

*Changed in version 3.3:* `float` arguments raise an exception if the `FloatOperation` trap is set. By default the trap is off.

Decimal floating point objects share many properties with the other built-in numeric types such as `float` and `int`. All of the usual math operations and special methods apply. Likewise, decimal objects can be copied, pickled, printed, used as dictionary keys, used as set elements, compared, sorted, and coerced to another type (such as `float` or `int`).

There are some small differences between arithmetic on Decimal objects and arithmetic on integers and floats. When the remainder operator `%` is applied to Decimal objects, the sign of the result is
the sign of the *dividend* rather than the sign of the divisor:

```python
>>> (-7) % 4
1
>>> Decimal(-7) % Decimal(4)
Decimal('-3')
```

The integer division operator `/` behaves analogously, returning the integer part of the true quotient (truncating towards zero) rather than its floor, so as to preserve the usual identity `x == (x // y) * y + x % y`:

```python
>>> -7 // 4
-2
>>> Decimal(-7) // Decimal(4)
Decimal('-1')
```

The `%` and `//` operators implement the *remainder* and *divide-integer* operations (respectively) as described in the specification.

Decimal objects cannot generally be combined with floats or instances of `fractions.Fraction` in arithmetic operations: an attempt to add a `Decimal` to a `float`, for example, will raise a `TypeError`. However, it is possible to use Python's comparison operators to compare a `Decimal` instance `x` with another number `y`. This avoids confusing results when doing equality comparisons between numbers of different types.

*Changed in version 3.2:* Mixed-type comparisons between `Decimal` instances and other numeric types are now fully supported.
In addition to the standard numeric properties, decimal floating point objects also have a number of specialized methods:

**adjusted()**
Return the adjusted exponent after shifting out the coefficient's rightmost digits until only the lead digit remains: `Decimal('321e+5').adjusted()` returns seven. Used for determining the position of the most significant digit with respect to the decimal point.

**as_tuple()**
Return a *named tuple* representation of the number: `DecimalTuple(sign, digits, exponent)`.

**canonical()**
Return the canonical encoding of the argument. Currently, the encoding of a `Decimal` instance is always canonical, so this operation returns its argument unchanged.

**compare(other, context=None)**
Compare the values of two Decimal instances. `compare()` returns a Decimal instance, and if either operand is a NaN then the result is a NaN:

- `a or b is a NaN` ➞ `Decimal('NaN')`
- `a < b` ➞ `Decimal('-1')`
- `a == b` ➞ `Decimal('0')`
- `a > b` ➞ `Decimal('1')`

**compare_signal(other, context=None)**
This operation is identical to the `compare()` method, except that all NaNs signal. That is, if neither operand is a signaling
NaN then any quiet NaN operand is treated as though it were a signaling NaN.

**compare_total**(other, context=None)

Compare two operands using their abstract representation rather than their numerical value. Similar to the compare() method, but the result gives a total ordering on Decimal instances. Two Decimal instances with the same numeric value but different representations compare unequal in this ordering:

```python
>>> Decimal('12.0').compare_total(Decimal('12'))
Decimal('-1')
```

Quiet and signaling NaNs are also included in the total ordering. The result of this function is Decimal('0') if both operands have the same representation, Decimal('-1') if the first operand is lower in the total order than the second, and Decimal('1') if the first operand is higher in the total order than the second operand. See the specification for details of the total order.

This operation is unaffected by context and is quiet: no flags are changed and no rounding is performed. As an exception, the C version may raise InvalidOperation if the second operand cannot be converted exactly.

**compare_total_mag**(other, context=None)

Compare two operands using their abstract representation rather than their value as in compare_total(), but ignoring the sign of each operand. `x.compare_total_mag(y)` is equivalent to
x.copy_abs().compare_total(y.copy_abs()).

This operation is unaffected by context and is quiet: no flags are changed and no rounding is performed. As an exception, the C version may raise InvalidOperation if the second operand cannot be converted exactly.

**conjugate()**

Just returns self, this method is only to comply with the Decimal Specification.

**copy_abs()**

Return the absolute value of the argument. This operation is unaffected by the context and is quiet: no flags are changed and no rounding is performed.

**copy_negate()**

Return the negation of the argument. This operation is unaffected by the context and is quiet: no flags are changed and no rounding is performed.

**copy_sign(other, context=None)**

Return a copy of the first operand with the sign set to be the same as the sign of the second operand. For example:

```python
>>> Decimal('2.3').copy_sign(Decimal('-1.5'))
Decimal('-2.3')
```

This operation is unaffected by context and is quiet: no flags are changed and no rounding is performed. As an exception, the C version may raise InvalidOperation if the second operand cannot be converted exactly.
**exp**(context=None)

Return the value of the (natural) exponential function $e^{**x}$ at the given number. The result is correctly rounded using the **ROUND_HALF_EVEN** rounding mode.

```python
>>> Decimal(1).exp()
Decimal('2.718281828459045235360287471')
>>> Decimal(321).exp()
Decimal('2.561702493119680037517373933E+139')
```

**from_float**(f)

Classmethod that converts a float to a decimal number, exactly.

Note **Decimal.from_float(0.1)** is not the same as **Decimal('0.1')**. Since 0.1 is not exactly representable in binary floating point, the value is stored as the nearest representable value which is $0x1.9999999999999ap-4$. That equivalent value in decimal is $0.10000000000000000555111512312578270211815834045410$

**Note:** From Python 3.2 onwards, a **Decimal** instance can also be constructed directly from a **float**.

```python
>>> Decimal.from_float(0.1)
Decimal('0.10000000000000000555111512312578270211815834045410')
>>> Decimal.from_float(float('nan'))
Decimal('NaN')
>>> Decimal.from_float(float('inf'))
Decimal('Infinity')
>>> Decimal.from_float(float('-inf'))
Decimal('-Infinity')
```

*New in version 3.1.*
**fma**(other, third, context=None)

Fused multiply-add. Return self*other+third with no rounding of the intermediate product self*other.

```python
>>> Decimal(2).fma(3, 5)
Decimal('11')
```

**is_canonical()**

Return `True` if the argument is canonical and `False` otherwise. Currently, a `Decimal` instance is always canonical, so this operation always returns `True`.

**is_finite()**

Return `True` if the argument is a finite number, and `False` if the argument is an infinity or a NaN.

**is_infinite()**

Return `True` if the argument is either positive or negative infinity and `False` otherwise.

**is_nan()**

Return `True` if the argument is a (quiet or signaling) NaN and `False` otherwise.

**is_normal**(context=None)

Return `True` if the argument is a *normal* finite number. Return `False` if the argument is zero, subnormal, infinite or a NaN.

**is_qnan()**

Return `True` if the argument is a quiet NaN, and `False` otherwise.
**is_signed()**
Return `True` if the argument has a negative sign and `False` otherwise. Note that zeros and NaNs can both carry signs.

**is_snan()**
Return `True` if the argument is a signaling NaN and `False` otherwise.

**is_subnormal** *(context=None)*
Return `True` if the argument is subnormal, and `False` otherwise.

**is_zero()**
Return `True` if the argument is a (positive or negative) zero and `False` otherwise.

**ln** *(context=None)*
Return the natural (base e) logarithm of the operand. The result is correctly rounded using the `ROUND_HALF_EVEN` rounding mode.

**log10** *(context=None)*
Return the base ten logarithm of the operand. The result is correctly rounded using the `ROUND_HALF_EVEN` rounding mode.

**logb** *(context=None)*
For a nonzero number, return the adjusted exponent of its operand as a `Decimal` instance. If the operand is a zero then `Decimal('-Infinity')` is returned and the `DivisionByZero` flag is raised. If the operand is an infinity then `Decimal('Infinity')` is returned.
**logical_and**(other, context=None)

*logical_and()* is a logical operation which takes two *logical operands* (see *Logical operands*). The result is the digit-wise and of the two operands.

**logical_invert**(context=None)

*logical_invert()* is a logical operation. The result is the digit-wise inversion of the operand.

**logical_or**(other, context=None)

*logical_or()* is a logical operation which takes two *logical operands* (see *Logical operands*). The result is the digit-wise or of the two operands.

**logical_xor**(other, context=None)

*logical_xor()* is a logical operation which takes two *logical operands* (see *Logical operands*). The result is the digit-wise exclusive or of the two operands.

**max**(other, context=None)

Like *max(self, other)* except that the context rounding rule is applied before returning and that NaN values are either signaled or ignored (depending on the context and whether they are signaling or quiet).

**max_mag**(other, context=None)

Similar to the *max()* method, but the comparison is done using the absolute values of the operands.

**min**(other, context=None)

Like *min(self, other)* except that the context rounding rule is applied before returning and that NaN values are either
signaled or ignored (depending on the context and whether they are signaling or quiet).

`min_mag(other, context=None)`

Similar to the `min()` method, but the comparison is done using the absolute values of the operands.

`next_minus(context=None)`

Return the largest number representable in the given context (or in the current thread's context if no context is given) that is smaller than the given operand.

`next_plus(context=None)`

Return the smallest number representable in the given context (or in the current thread's context if no context is given) that is larger than the given operand.

`next_toward(other, context=None)`

If the two operands are unequal, return the number closest to the first operand in the direction of the second operand. If both operands are numerically equal, return a copy of the first operand with the sign set to be the same as the sign of the second operand.

`normalize(context=None)`

Normalize the number by stripping the rightmost trailing zeros and converting any result equal to Decimal('0') to Decimal('0e0'). Used for producing canonical values for attributes of an equivalence class. For example, Decimal('32.100') and Decimal('0.321000e+2') both normalize to the equivalent value Decimal('32.1').
**number_class**(context=None)

Return a string describing the class of the operand. The returned value is one of the following ten strings.

- "-Infinity", indicating that the operand is negative infinity.
- "-Normal", indicating that the operand is a negative normal number.
- "-Subnormal", indicating that the operand is negative and subnormal.
- "-Zero", indicating that the operand is a negative zero.
- "+Zero", indicating that the operand is a positive zero.
- "+Subnormal", indicating that the operand is positive and subnormal.
- "+Normal", indicating that the operand is a positive normal number.
- "+Infinity", indicating that the operand is positive infinity.
- "NaN", indicating that the operand is a quiet NaN (Not a Number).
- "sNaN", indicating that the operand is a signaling NaN.

**quantize**(exp, rounding=None, context=None, watchexp=True)

Return a value equal to the first operand after rounding and having the exponent of the second operand.

```python
>>> Decimal('1.41421356').quantize(Decimal('1.000'))
Decimal('1.414')
```

Unlike other operations, if the length of the coefficient after the quantize operation would be greater than precision, then an **InvalidOperation** is signaled. This guarantees that, unless
there is an error condition, the quantized exponent is always equal to that of the right-hand operand.

Also unlike other operations, quantize never signals Underflow, even if the result is subnormal and inexact.

If the exponent of the second operand is larger than that of the first then rounding may be necessary. In this case, the rounding mode is determined by the `rounding` argument if given, else by the given `context` argument; if neither argument is given the rounding mode of the current thread’s context is used.

If `watchexp` is set (default), then an error is returned whenever the resulting exponent is greater than Emax or less than Etiny.

```markdown
Deprecated since version 3.3: watchexp is an implementation detail from the pure Python version and is not present in the C version. It will be removed in version 3.4, where it defaults to True.
```

**radix()**

Return `Decimal(10)`, the radix (base) in which the `Decimal` class does all its arithmetic. Included for compatibility with the specification.

**remainder_near(other, context=None)**

Return the remainder from dividing `self` by `other`. This differs from `self % other` in that the sign of the remainder is chosen so as to minimize its absolute value. More precisely, the return value is `self - n * other` where `n` is the integer nearest to the exact value of `self / other`, and if two

```markdown
```
integers are equally near then the even one is chosen.

If the result is zero then its sign will be the sign of self.

```python
>>> Decimal(18).remainder_near(Decimal(10))
Decimal('-2')
>>> Decimal(25).remainder_near(Decimal(10))
Decimal('5')
>>> Decimal(35).remainder_near(Decimal(10))
Decimal('-5')
```

**rotate**(other, context=None)

Return the result of rotating the digits of the first operand by an amount specified by the second operand. The second operand must be an integer in the range -precision through precision. The absolute value of the second operand gives the number of places to rotate. If the second operand is positive then rotation is to the left; otherwise rotation is to the right. The coefficient of the first operand is padded on the left with zeros to length precision if necessary. The sign and exponent of the first operand are unchanged.

**same_quantum**(other, context=None)

Test whether self and other have the same exponent or whether both are NaN.

This operation is unaffected by context and is quiet: no flags are changed and no rounding is performed. As an exception, the C version may raise InvalidOperation if the second operand cannot be converted exactly.

**scaleb**(other, context=None)

Return the first operand with exponent adjusted by the second.
Equivalently, return the first operand multiplied by $10^{**other}$. The second operand must be an integer.

**shift**(other, context=None)
Return the result of shifting the digits of the first operand by an amount specified by the second operand. The second operand must be an integer in the range -precision through precision. The absolute value of the second operand gives the number of places to shift. If the second operand is positive then the shift is to the left; otherwise the shift is to the right. Digits shifted into the coefficient are zeros. The sign and exponent of the first operand are unchanged.

**sqrt**(context=None)
Return the square root of the argument to full precision.

**to_eng_string**(context=None)
Convert to an engineering-type string.

Engineering notation has an exponent which is a multiple of 3, so there are up to 3 digits left of the decimal place. For example, converts `Decimal('123E+1')` to `Decimal('1.23E+3')`

**to_integral**(rounding=None, context=None)
Identical to the **to_integral_value()** method. The **to_integral** name has been kept for compatibility with older versions.

**to_integral_exact**(rounding=None, context=None)
Round to the nearest integer, signaling **Inexact** or **Rounded** as appropriate if rounding occurs. The rounding mode is
determined by the `rounding` parameter if given, else by the given `context`. If neither parameter is given then the rounding mode of the current context is used.

**to_integral_value**(rounding=None, context=None)
Round to the nearest integer without signaling *Inexact* or *Rounded*. If given, applies `rounding`; otherwise, uses the rounding method in either the supplied `context` or the current context.

### 9.4.2.1. Logical operands

The `logical_and()`, `logical_invert()`, `logical_or()`, and `logical_xor()` methods expect their arguments to be *logical operands*. A *logical operand* is a `Decimal` instance whose exponent and sign are both zero, and whose digits are all either 0 or 1.
9.4.3. Context objects

Contexts are environments for arithmetic operations. They govern precision, set rules for rounding, determine which signals are treated as exceptions, and limit the range for exponents.

Each thread has its own current context which is accessed or changed using the `getcontext()` and `setcontext()` functions:

```python
decimal.getcontext()
    Return the current context for the active thread.

decimal.setcontext(c)
    Set the current context for the active thread to c.
```

You can also use the `with` statement and the `localcontext()` function to temporarily change the active context.

```python
decimal.localcontext(ctx=None)
    Return a context manager that will set the current context for the active thread to a copy of ctx on entry to the with-statement and restore the previous context when exiting the with-statement. If no context is specified, a copy of the current context is used.
```

For example, the following code sets the current decimal precision to 42 places, performs a calculation, and then automatically restores the previous context:

```python
from decimal import localcontext

with localcontext() as ctx:
    ctx.prec = 42  # Perform a high precision calculation
    s = calculate_something()
```
New contexts can also be created using the `Context` constructor described below. In addition, the module provides three pre-made contexts:

`class decimal.BasicContext`

This is a standard context defined by the General Decimal Arithmetic Specification. Precision is set to nine. Rounding is set to `ROUND_HALF_UP`. All flags are cleared. All traps are enabled (treated as exceptions) except `Inexact`, `Rounded`, and `Subnormal`.

Because many of the traps are enabled, this context is useful for debugging.

`class decimal.ExtendedContext`

This is a standard context defined by the General Decimal Arithmetic Specification. Precision is set to nine. Rounding is set to `ROUND_HALF_EVEN`. All flags are cleared. No traps are enabled (so that exceptions are not raised during computations).

Because the traps are disabled, this context is useful for applications that prefer to have result value of NaN or Infinity instead of raising exceptions. This allows an application to complete a run in the presence of conditions that would otherwise halt the program.

`class decimal.DefaultContext`

This context is used by the `Context` constructor as a prototype for new contexts. Changing a field (such a precision) has the effect of changing the default for new contexts created by the `Context`
This context is most useful in multi-threaded environments. Changing one of the fields before threads are started has the effect of setting system-wide defaults. Changing the fields after threads have started is not recommended as it would require thread synchronization to prevent race conditions.

In single threaded environments, it is preferable to not use this context at all. Instead, simply create contexts explicitly as described below.

The default values are \( \text{prec}=28 \), \( \text{rounding}=	ext{ROUND_HALF_EVEN} \), and enabled traps for \text{Overflow}, \text{InvalidOperation}, and \text{DivisionByZero}.

In addition to the three supplied contexts, new contexts can be created with the \texttt{Context} constructor.

```python
class decimal.Context(prec=None, rounding=None, Emin=None, Emax=None, capitals=None, clamp=None, flags=None, traps=None)
```

Creates a new context. If a field is not specified or is \texttt{None}, the default values are copied from the \texttt{DefaultContext}. If the \texttt{flags} field is not specified or is \texttt{None}, all flags are cleared.

\( \text{prec} \) is an integer in the range \([1, \text{MAX_PREC}]\) that sets the precision for arithmetic operations in the context.

The \textit{rounding} option is one of the constants listed in the section \textit{Rounding Modes}.

The \textit{traps} and \textit{flags} fields list any signals to be set. Generally, new contexts should only set traps and leave the flags clear.
The $E_{\text{min}}$ and $E_{\text{max}}$ fields are integers specifying the outer limits allowable for exponents. $E_{\text{min}}$ must be in the range $[\text{MIN}_E{\text{MIN}}, 0]$, $E_{\text{max}}$ in the range $[0, \text{MAX}_E{\text{MAX}}]$.

The $\text{capital}$s field is either 0 or 1 (the default). If set to 1, exponents are printed with a capital E; otherwise, a lowercase e is used: $\text{Decimal('6.02e+23')}$.

The $\text{clamp}$ field is either 0 (the default) or 1. If set to 1, the exponent $e$ of a $\text{Decimal}$ instance representable in this context is strictly limited to the range $E_{\text{min}} - \text{prec} + 1 \leq e \leq E_{\text{max}} - \text{prec} + 1$. If $\text{clamp}$ is 0 then a weaker condition holds: the adjusted exponent of the $\text{Decimal}$ instance is at most $E_{\text{max}}$. When $\text{clamp}$ is 1, a large normal number will, where possible, have its exponent reduced and a corresponding number of zeros added to its coefficient, in order to fit the exponent constraints; this preserves the value of the number but loses information about significant trailing zeros. For example:

```python
>>> Context(prec=6, Emax=999, clamp=1).create_decimal('1.23000E+999')
```

A $\text{clamp}$ value of 1 allows compatibility with the fixed-width decimal interchange formats specified in IEEE 754.

The $\text{Context}$ class defines several general purpose methods as well as a large number of methods for doing arithmetic directly in a given context. In addition, for each of the $\text{Decimal}$ methods described above (with the exception of the $\text{adjusted()}$ and $\text{as\_tuple()}$ methods) there is a corresponding $\text{Context}$ method. For example, for a $\text{Context}$ instance $C$ and $\text{Decimal}$
instance $x$, $C.exp(x)$ is equivalent to $x.exp(context=C)$. Each \texttt{Context} method accepts a Python integer (an instance of \texttt{int}) anywhere that a Decimal instance is accepted.

\begin{itemize}
  \item \textbf{clear\_flags()}
    \begin{itemize}
      \item Resets all of the flags to 0.
    \end{itemize}
  \item \textbf{clear\_traps()}
    \begin{itemize}
      \item Resets all of the traps to 0.
    \end{itemize}
    \textit{New in version 3.3.}
  \item \textbf{copy()}
    \begin{itemize}
      \item Return a duplicate of the context.
    \end{itemize}
  \item \textbf{copy\_decimal(num)}
    \begin{itemize}
      \item Return a copy of the Decimal instance \texttt{num}.
    \end{itemize}
  \item \textbf{create\_decimal(num)}
    \begin{itemize}
      \item Creates a new Decimal instance from \texttt{num} but using \texttt{self} as context. Unlike the \texttt{Decimal} constructor, the context precision, rounding method, flags, and traps are applied to the conversion.
    \end{itemize}
    This is useful because constants are often given to a greater precision than is needed by the application. Another benefit is that rounding immediately eliminates unintended effects from digits beyond the current precision. In the following example, using unrounded inputs means that adding zero to a sum can change the result:
    \begin{verbatim}
>>> getcontext().prec = 3
>>> Decimal('3.4445') + Decimal('1.0023')
Decimal('4.45')
    \end{verbatim}
\end{itemize}
This method implements the to-number operation of the IBM specification. If the argument is a string, no leading or trailing whitespace is permitted.

**create_decimal_from_float(f)**

Creates a new Decimal instance from a float f but rounding using `self` as the context. Unlike the `Decimal.from_float()` class method, the context precision, rounding method, flags, and traps are applied to the conversion.

```python
>>> context = Context(prec=5, rounding=ROUND_DOWN)
>>> context.create_decimal_from_float(math.pi)
Decimal('3.1415')
>>> context = Context(prec=5, traps=[Inexact])
>>> context.create_decimal_from_float(math.pi)
Traceback (most recent call last):
  ...  
decimal.Inexact: None
```

*New in version 3.1.*

**Etiny()**

Returns a value equal to \( E_{\text{min}} - \text{prec} + 1 \) which is the minimum exponent value for subnormal results. When underflow occurs, the exponent is set to Etiny.

**Etop()**

Returns a value equal to \( E_{\text{max}} - \text{prec} + 1 \).

The usual approach to working with decimals is to create `Decimal`
instances and then apply arithmetic operations which take place within the current context for the active thread. An alternative approach is to use context methods for calculating within a specific context. The methods are similar to those for the `Decimal` class and are only briefly recounted here.

**abs**(x)
Returns the absolute value of x.

**add**(x, y)
Return the sum of x and y.

**canonical**(x)
Returns the same Decimal object x.

**compare**(x, y)
Compares x and y numerically.

**compare_signal**(x, y)
Compares the values of the two operands numerically.

**compare_total**(x, y)
Compares two operands using their abstract representation.

**compare_total_mag**(x, y)
Compares two operands using their abstract representation, ignoring sign.

**copy_abs**(x)
Returns a copy of x with the sign set to 0.

**copy_negate**(x)
Returns a copy of x with the sign inverted.
copy_sign(x, y)
    Copies the sign from y to x.

divide(x, y)
    Return x divided by y.

divide_int(x, y)
    Return x divided by y, truncated to an integer.

divmod(x, y)
    Divides two numbers and returns the integer part of the result.

exp(x)
    Returns e ** x.

fma(x, y, z)
    Returns x multiplied by y, plus z.

is_canonical(x)
    Returns True if x is canonical; otherwise returns False.

is_finite(x)
    Returns True if x is finite; otherwise returns False.

is_infinite(x)
    Returns True if x is infinite; otherwise returns False.

is_nan(x)
    Returns True if x is a qNaN or sNaN; otherwise returns False.

is_normal(x)
    Returns True if x is a normal number; otherwise returns
is_qnan(x)
Returns True if x is a quiet NaN; otherwise returns False.

is_signed(x)
Returns True if x is negative; otherwise returns False.

is_snan(x)
Returns True if x is a signaling NaN; otherwise returns False.

is_subnormal(x)
Returns True if x is subnormal; otherwise returns False.

is_zero(x)
Returns True if x is a zero; otherwise returns False.

ln(x)
Returns the natural (base e) logarithm of x.

log10(x)
Returns the base 10 logarithm of x.

logb(x)
Returns the exponent of the magnitude of the operand's MSD.

logical_and(x, y)
Applies the logical operation and between each operand's digits.

logical_invert(x)
Invert all the digits in x.
logical_or($x, y$
Applies the logical operation or between each operand's digits.

logical_xor($x, y$
Applies the logical operation xor between each operand's digits.

max($x, y$
Compares two values numerically and returns the maximum.

max_mag($x, y$
Compares the values numerically with their sign ignored.

min($x, y$
Compares two values numerically and returns the minimum.

min_mag($x, y$
Compares the values numerically with their sign ignored.

minus($x$
Minus corresponds to the unary prefix minus operator in Python.

multiply($x, y$
Return the product of $x$ and $y$.

next_minus($x$
Returns the largest representable number smaller than $x$.

next_plus($x$
Returns the smallest representable number larger than $x$.

next_toward($x, y$
Returns the number closest to $x$, in direction towards $y$. 
**normalize**(x)

Reduces x to its simplest form.

**number_class**(x)

Returns an indication of the class of x.

**plus**(x)

Plus corresponds to the unary prefix plus operator in Python. This operation applies the context precision and rounding, so it is *not* an identity operation.

**power**(x, y, modulo=None)

Return x to the power of y, reduced modulo modulo if given.

With two arguments, compute \(x^y\). If x is negative then y must be integral. The result will be inexact unless y is integral and the result is finite and can be expressed exactly in ‘precision’ digits. The rounding mode of the context is used. Results are always correctly-rounded in the Python version.

*Changed in version 3.3:* The C module computes \(\text{power}()\) in terms of the correctly-rounded \(\text{exp}()\) and \(\text{ln}()\) functions. The result is well-defined but only “almost always correctly-rounded”.

With three arguments, compute \((x^y) \mod \text{modulo}\). For the three argument form, the following restrictions on the arguments hold:

- all three arguments must be integral
- y must be nonnegative
- at least one of x or y must be nonzero
- modulo must be nonzero and have at most ‘precision’
The value resulting from `Context.power(x, y, modulo)` is equal to the value that would be obtained by computing \((x**y) \% \text{modulo}\) with unbounded precision, but is computed more efficiently. The exponent of the result is zero, regardless of the exponents of \(x, y\) and \(\text{modulo}\). The result is always exact.

**quantize\((x, y)\)**

Returns a value equal to \(x\) (rounded), having the exponent of \(y\).

**radix\()**

Just returns 10, as this is Decimal, :)  

**remainder\((x, y)\)**

Returns the remainder from integer division.

The sign of the result, if non-zero, is the same as that of the original dividend.

**remainder\_near\((x, y)\)**

Returns \(x - y * n\), where \(n\) is the integer nearest the exact value of \(x / y\) (if the result is 0 then its sign will be the sign of \(x\)).

**rotate\((x, y)\)**

Returns a rotated copy of \(x, y\) times.

**same\_quantum\((x, y)\)**

Returns True if the two operands have the same exponent.
Returns the first operand after adding the second value its exp.

\texttt{shift}(x, y)
Returns a shifted copy of \(x\), \(y\) times.

\texttt{sqrt}(x)
Square root of a non-negative number to context precision.

\texttt{subtract}(x, y)
Return the difference between \(x\) and \(y\).

\texttt{to\_eng\_string}(x)
Converts a number to a string, using scientific notation.

\texttt{to\_integral\_exact}(x)
Rounds to an integer.

\texttt{to\_sci\_string}(x)
Converts a number to a string using scientific notation.
9.4.4. Constants

The constants in this section are only relevant for the C module. They are also included in the pure Python version for compatibility.

<table>
<thead>
<tr>
<th></th>
<th>32-bit</th>
<th>64-bit</th>
</tr>
</thead>
<tbody>
<tr>

<td>-199999999999999999</td>
</tr>
</tbody>
</table>

**decimal.HAVE_THREADS**

The default value is **True**. If Python is compiled without threads, the C version automatically disables the expensive thread local context machinery. In this case, the value is **False**.
9.4.5. Rounding modes

decimal. **ROUND_CEILING**
   Round towards Infinity.

decimal. **ROUND_DOWN**
   Round towards zero.

decimal. **ROUND_FLOOR**
   Round towards -Infinity.

decimal. **ROUND_HALF_DOWN**
   Round to nearest with ties going towards zero.

decimal. **ROUND_HALF_EVEN**
   Round to nearest with ties going to nearest even integer.

decimal. **ROUND_HALF_UP**
   Round to nearest with ties going away from zero.

decimal. **ROUND_UP**
   Round away from zero.

decimal. **ROUND_05UP**
   Round away from zero if last digit after rounding towards zero would have been 0 or 5; otherwise round towards zero.
9.4.6. Signals

Signals represent conditions that arise during computation. Each corresponds to one context flag and one context trap enabler.

The context flag is set whenever the condition is encountered. After the computation, flags may be checked for informational purposes (for instance, to determine whether a computation was exact). After checking the flags, be sure to clear all flags before starting the next computation.

If the context's trap enabler is set for the signal, then the condition causes a Python exception to be raised. For example, if the DivisionByZero trap is set, then a DivisionByZero exception is raised upon encountering the condition.

class decimal.Clamped

Altered an exponent to fit representation constraints.

Typically, clamping occurs when an exponent falls outside the context's Emin and Emax limits. If possible, the exponent is reduced to fit by adding zeros to the coefficient.

class decimal.DecimalException

Base class for other signals and a subclass of ArithmeticError.

class decimal.DivisionByZero

Signals the division of a non-infinite number by zero.

Can occur with division, modulo division, or when raising a number to a negative power. If this signal is not trapped, returns Infinity
or -Infinity with the sign determined by the inputs to the calculation.

**class decimal. Inexact**

Indicates that rounding occurred and the result is not exact.

Signals when non-zero digits were discarded during rounding. The rounded result is returned. The signal flag or trap is used to detect when results are inexact.

**class decimal. InvalidOperation**

An invalid operation was performed.

Indicates that an operation was requested that does not make sense. If not trapped, returns NaN. Possible causes include:

```
Infinity - Infinity
0 * Infinity
Infinity / Infinity
x % 0
Infinity % x
sqrt(-x) and x > 0
0 ** 0
x ** (non-integer)
x ** Infinity
```

**class decimal. Overflow**

Numerical overflow.

Indicates the exponent is larger than Emax after rounding has occurred. If not trapped, the result depends on the rounding mode, either pulling inward to the largest representable finite number or rounding outward to Infinity. In either case, Inexact and Rounded are also signaled.
class decimal. **Rounded**
Rounding occurred though possibly no information was lost.

Signaled whenever rounding discards digits; even if those digits are zero (such as rounding 5.00 to 5.0). If not trapped, returns the result unchanged. This signal is used to detect loss of significant digits.

class decimal. **Subnormal**
Exponent was lower than Emin prior to rounding.

Occurs when an operation result is subnormal (the exponent is too small). If not trapped, returns the result unchanged.

class decimal. **Underflow**
Numerical underflow with result rounded to zero.

Occurs when a subnormal result is pushed to zero by rounding. **Inexact** and **Subnormal** are also signaled.

class decimal. **FloatOperation**
Enable stricter semantics for mixing floats and Decimals.

If the signal is not trapped (default), mixing floats and Decimals is permitted in the **Decimal** constructor, **create_decimal()** and all comparison operators. Both conversion and comparisons are exact. Any occurrence of a mixed operation is silently recorded by setting **FloatOperation** in the context flags. Explicit conversions with **from_float()** or **create_decimal_from_float()** do not set the flag.

Otherwise (the signal is trapped), only equality comparisons and explicit conversions are silent. All other mixed operations raise
**FloatOperation.**

The following table summarizes the hierarchy of signals:

```plaintext
exceptions.ArithmeticError(exceptions.Exception)
  DecimalException
    Clamped
  DivisionByZero(DecimalException, exceptions.Exception)
    Inexact
      Overflow(Inexact, Rounded)
      Underflow(Inexact, Rounded, Subnormal)
    InvalidOperation
    Rounded
    Subnormal
  FloatOperation(DecimalException, exceptions.Exception)
```
9.4.7. Floating Point Notes

9.4.7.1. Mitigating round-off error with increased precision

The use of decimal floating point eliminates decimal representation error (making it possible to represent 0.1 exactly); however, some operations can still incur round-off error when non-zero digits exceed the fixed precision.

The effects of round-off error can be amplified by the addition or subtraction of nearly offsetting quantities resulting in loss of significance. Knuth provides two instructive examples where rounded floating point arithmetic with insufficient precision causes the breakdown of the associative and distributive properties of addition:

```python
# Examples from Seminumerical Algorithms, Section 4.
>>> from decimal import Decimal, getcontext
>>> getcontext().prec = 8

>>> u, v, w = Decimal('1111113'), Decimal('-1111111'),
>>> (u + v) + w
Decimal('9.5111111')
>>> u + (v + w)
Decimal('10')

>>> u, v, w = Decimal(20000), Decimal(-6), Decimal('6.0000003')
>>> (u*v) + (u*w)
Decimal('0.01')
>>> u * (v+w)
Decimal('0.0060000')
```

The `decimal` module makes it possible to restore the identities by
expanding the precision sufficiently to avoid loss of significance:

```python
>>> getcontext().prec = 20
>>> u, v, w = Decimal('11111113'), Decimal('-11111111'),
>>> (u + v) + w
Decimal('9.51111111')
>>> u + (v + w)
Decimal('9.51111111')

>>> u, v, w = Decimal('20000'), Decimal('-6'), Decimal('6.0000003')
>>> (u*v) + (u*w)
Decimal('0.0060000')
>>> u * (v+w)
Decimal('0.0060000')
```

9.4.7.2. Special values

The number system for the `decimal` module provides special values including NaN, sNaN, -Infinity, Infinity, and two zeros, +0 and -0.

Infinities can be constructed directly with: `Decimal('Infinity')`. Also, they can arise from dividing by zero when the `DivisionByZero` signal is not trapped. Likewise, when the `Overflow` signal is not trapped, infinity can result from rounding beyond the limits of the largest representable number.

The infinities are signed (affine) and can be used in arithmetic operations where they get treated as very large, indeterminate numbers. For instance, adding a constant to infinity gives another infinite result.

Some operations are indeterminate and return NaN, or if the
InvalidOperation signal is trapped, raise an exception. For example, \(0/0\) returns NaN which means “not a number”. This variety of NaN is quiet and, once created, will flow through other computations always resulting in another NaN. This behavior can be useful for a series of computations that occasionally have missing inputs — it allows the calculation to proceed while flagging specific results as invalid.

A variant is sNaN which signals rather than remaining quiet after every operation. This is a useful return value when an invalid result needs to interrupt a calculation for special handling.

The behavior of Python’s comparison operators can be a little surprising where a NaN is involved. A test for equality where one of the operands is a quiet or signaling NaN always returns False (even when doing Decimal('NaN')==Decimal('NaN')), while a test for inequality always returns True. An attempt to compare two Decimals using any of the \(<, \leq, >\) or \(\geq\) operators will raise the InvalidOperation signal if either operand is a NaN, and return False if this signal is not trapped. Note that the General Decimal Arithmetic specification does not specify the behavior of direct comparisons; these rules for comparisons involving a NaN were taken from the IEEE 854 standard (see Table 3 in section 5.7). To ensure strict standards-compliance, use the compare() and compare-signal() methods instead.

The signed zeros can result from calculations that underflow. They keep the sign that would have resulted if the calculation had been carried out to greater precision. Since their magnitude is zero, both positive and negative zeros are treated as equal and their sign is informational.
In addition to the two signed zeros which are distinct yet equal, there are various representations of zero with differing precisions yet equivalent in value. This takes a bit of getting used to. For an eye accustomed to normalized floating point representations, it is not immediately obvious that the following calculation returns a value equal to zero:

```python
>>> 1 / Decimal('Infinity')
Decimal('0E-10000026')
```
9.4.8. Working with threads

The `getcontext()` function accesses a different `Context` object for each thread. Having separate thread contexts means that threads may make changes (such as `getcontext().prec=10`) without interfering with other threads.

Likewise, the `setcontext()` function automatically assigns its target to the current thread.

If `setcontext()` has not been called before `getcontext()`, then `getcontext()` will automatically create a new context for use in the current thread.

The new context is copied from a prototype context called `DefaultContext`. To control the defaults so that each thread will use the same values throughout the application, directly modify the `DefaultContext` object. This should be done before any threads are started so that there won’t be a race condition between threads calling `getcontext()`. For example:

```
# Set applicationwide defaults for all threads about to be launched
DefaultContext.prec = 12
DefaultContext.rounding = ROUND_DOWN
DefaultContext.traps = ExtendedContext.traps.copy()
DefaultContext.traps[InvalidOperation] = 1
setcontext(DefaultContext)

# Afterwards, the threads can be started
t1.start()
t2.start()
t3.start()
...
```
9.4.9. Recipes

Here are a few recipes that serve as utility functions and that demonstrate ways to work with the `Decimal` class:

```python
def moneyfmt(value, places=2, curr='', sep=',', dp='.', pos='', neg='-', trailneg=''):  
    """Convert Decimal to a money formatted string.
    
    places:  required number of places after the decimal point
    curr:   optional currency symbol before the sign
    sep:    optional grouping separator (comma, period, space, or blank)
    dp:     decimal point indicator (comma or period)
            only specify as blank when places is zero
    pos:    optional sign for positive numbers: '+'
    neg:    optional sign for negative numbers: '-'
    trailneg:optional trailing minus indicator: '-'
    """

    q = Decimal(10) ** -places  
    sign, digits, exp = value.quantize(q).as_tuple()  
    result = []
    digits = list(map(str, digits))  
```
build, next = result.append, digits.pop
if sign:
    build(trailneg)
for i in range(places):
    build(next() if digits else '0')
if places:
    build(dp)
if not digits:
    build('0')
i = 0
while digits:
    build(next())
    i += 1
    if i == 3 and digits:
        i = 0
        build(sep)
build(curr)
build(neg if sign else pos)
return ''.join(reversed(result))

def pi():
    """Compute Pi to the current precision."

9.4.10. Decimal FAQ

Q. It is cumbersome to type `decimal.Decimal('1234.5')`. Is there a way to minimize typing when using the interactive interpreter?

A. Some users abbreviate the constructor to just a single letter:

```
>>> D = decimal.Decimal
>>> D('1.23') + D('3.45')
Decimal('4.68')
```

Q. In a fixed-point application with two decimal places, some inputs have many places and need to be rounded. Others are not supposed to have excess digits and need to be validated. What methods should be used?

A. The quantize() method rounds to a fixed number of decimal places. If the `Inexact` trap is set, it is also useful for validation:

```
>>> TWOPLACES = Decimal(10) ** -2  # same as Decimal('0.01')

>>> # Round to two places
>>> Decimal('3.214').quantize(TWOPLACES)
Decimal('3.21')

>>> # Validate that a number does not exceed two places
>>> Decimal('3.21').quantize(TWOPLACES, context=Context)
Decimal('3.21')
```

```
>>> Decimal('3.214').quantize(TWOPLACES, context=Context)
Traceback (most recent call last):
...
Q. Once I have valid two place inputs, how do I maintain that invariant throughout an application?

A. Some operations like addition, subtraction, and multiplication by an integer will automatically preserve fixed point. Others operations, like division and non-integer multiplication, will change the number of decimal places and need to be followed-up with a quantize() step:

>>> a = Decimal('102.72')  # Initial fixed-point values
>>> b = Decimal('3.17')
>>> a + b  # Addition preserves fixed-point
Decimal('105.89')
>>> a - b
Decimal('99.55')
>>> a * 42  # So does integer multiplication
Decimal('4314.24')
>>> (a * b).quantize(TWOPLACES)  # Must quantize non-integer multiplication
Decimal('325.62')
>>> (b / a).quantize(TWOPLACES)  # And quantize division
Decimal('0.03')

In developing fixed-point applications, it is convenient to define functions to handle the quantize() step:

>>> def mul(x, y, fp=TWOPLACES):
...     return (x * y).quantize(fp)
>>> mul(a, b)  # Automatically preserves fixed-point
Decimal('325.62')
>>> def div(x, y, fp=TWOPLACES):
...     return (x / y).quantize(fp)
>>> div(b, a)
Q. There are many ways to express the same value. The numbers 200, 200.000, 2E2, and 02E+4 all have the same value at various precisions. Is there a way to transform them to a single recognizable canonical value?

A. The `normalize()` method maps all equivalent values to a single representative:

```python
>>> values = map(Decimal, '200 200.000 2E2 .02E+4'.split)
>>> [v.normalize() for v in values]
[Decimal('2E+2'), Decimal('2E+2'), Decimal('2E+2'), Decimal('2E+2')]
```

Q. Some decimal values always print with exponential notation. Is there a way to get a non-exponential representation?

A. For some values, exponential notation is the only way to express the number of significant places in the coefficient. For example, expressing 5.0E+3 as 5000 keeps the value constant but cannot show the original’s two-place significance.

If an application does not care about tracking significance, it is easy to remove the exponent and trailing zeroes, losing significance, but keeping the value unchanged:

```python
>>> def remove_exponent(d):
...     return d.quantize(Decimal(1)) if d == d.to_integral

>>> remove_exponent(Decimal('5E+3'))
Decimal('5000')
```
Q. Is there a way to convert a regular float to a Decimal?

A. Yes, any binary floating point number can be exactly expressed as a Decimal though an exact conversion may take more precision than intuition would suggest:

```python
>>> Decimal(math.pi)
Decimal('3.141592653589793115997963468544185161590576171875')
```

Q. Within a complex calculation, how can I make sure that I haven't gotten a spurious result because of insufficient precision or rounding anomalies.

A. The decimal module makes it easy to test results. A best practice is to re-run calculations using greater precision and with various rounding modes. Widely differing results indicate insufficient precision, rounding mode issues, ill-conditioned inputs, or a numerically unstable algorithm.

Q. I noticed that context precision is applied to the results of operations but not to the inputs. Is there anything to watch out for when mixing values of different precisions?

A. Yes. The principle is that all values are considered to be exact and so is the arithmetic on those values. Only the results are rounded. The advantage for inputs is that “what you type is what you get”. A disadvantage is that the results can look odd if you forget that the inputs haven’t been rounded:

```python
>>> getcontext().prec = 3
>>> Decimal('3.104') + Decimal('2.104')
Decimal('5.21')
>>> Decimal('3.104') + Decimal('0.000') + Decimal('2')
Decimal('3.104')
```
The solution is either to increase precision or to force rounding of inputs using the unary plus operation:

```
>>> getcontext().prec = 3
>>> +Decimal('1.23456789')  # unary plus triggers rounding
Decimal('1.23')
```

Alternatively, inputs can be rounded upon creation using the `Context.create_decimal()` method:

```
>>> Context(prec=5, rounding=ROUND_DOWN).create_decimal('1.2345')
Decimal('1.2345')
```
9.5. fractions — Rational numbers

Source code: Lib/fractions.py

The fractions module provides support for rational number arithmetic.

A Fraction instance can be constructed from a pair of integers, from another rational number, or from a string.

class fractions.Fraction(numerator=0, denominator=1)
class fractions.Fraction(other_fraction)
class fractions.Fraction(float)
class fractions.Fraction(decimal)
class fractions.Fraction(string)

The first version requires that numerator and denominator are instances of numbers.Rational and returns a new Fraction instance with value numerator/denominator. If denominator is 0, it raises a ZeroDivisionError. The second version requires that other_fraction is an instance of numbers.Rational and returns a Fraction instance with the same value. The next two versions accept either a float or a decimal.Decimal instance, and return a Fraction instance with exactly the same value. Note that due to the usual issues with binary floating-point (see Floating Point Arithmetic: Issues and Limitations), the argument to Fraction(1.1) is not exactly equal to 11/10, and so Fraction(1.1) does not return Fraction(11, 10) as one might expect. (But see the documentation for the
limit_denominator() method below.) The last version of the constructor expects a string or unicode instance. The usual form for this instance is:

```
[sign] numerator ['/' denominator]
```

where the optional sign may be either ‘+’ or ‘-’ and numerator and denominator (if present) are strings of decimal digits. In addition, any string that represents a finite value and is accepted by the float constructor is also accepted by the Fraction constructor. In either form the input string may also have leading and/or trailing whitespace. Here are some examples:

```
>>> from fractions import Fraction
>>> Fraction(16, -10)
Fraction(-8, 5)
>>> Fraction(123)
Fraction(123, 1)
>>> Fraction()
Fraction(0, 1)
>>> Fraction('3/7')
Fraction(3, 7)
>>> Fraction(' -3/7 ')
Fraction(-3, 7)
>>> Fraction('1.414213 \t\n')
Fraction(1414213, 1000000)
>>> Fraction('- .125')
Fraction(-1, 8)
>>> Fraction('7e-6')
Fraction(7, 10000000)
>>> Fraction(2.25)
Fraction(9, 4)
>>> Fraction(1.1)
Fraction(2476979795053773, 2251799813685248)
>>> from decimal import Decimal
```
The `Fraction` class inherits from the abstract base class `numbers.Rational`, and implements all of the methods and operations from that class. `Fraction` instances are hashable, and should be treated as immutable. In addition, `Fraction` has the following properties and methods:

*Changed in version 3.2*: The `Fraction` constructor now accepts `float` and `decimal.Decimal` instances.

**numerator**

Numerator of the Fraction in lowest term.

**denominator**

Denominator of the Fraction in lowest term.

**from_float**(flt)

This class method constructs a `Fraction` representing the exact value of `flt`, which must be a `float`. Beware that `Fraction.from_float(0.3)` is not the same value as `Fraction(3, 10)`

**from_decimal**(dec)

This class method constructs a `Fraction` representing the exact value of `dec`, which must be a `decimal.Decimal` instance.
**Note:** From Python 3.2 onwards, you can also construct a `Fraction` instance directly from a `decimal.Decimal` instance.

**limit_denominator**(max_denominator=1000000)

Finds and returns the closest `Fraction` to `self` that has denominator at most `max_denominator`. This method is useful for finding rational approximations to a given floating-point number:

```python
>>> from fractions import Fraction
>>> Fraction('3.1415926535897932').limit_denominator()
Fraction(355, 113)
```

or for recovering a rational number that's represented as a float:

```python
>>> from math import pi, cos
>>> Fraction(cos(pi/3))
Fraction(4503599627370497, 9007199254740992)
>>> Fraction(cos(pi/3)).limit_denominator()
Fraction(1, 2)
>>> Fraction(1.1).limit_denominator()
Fraction(11, 10)
```

**__floor__()**

Returns the greatest `int <= self`. This method can also be accessed through the `math.floor()` function:

```python
>>> from math import floor
>>> floor(Fraction(355, 113))
3
```

**__ceil__()**
Returns the least \texttt{int} \texttt{>= self}. This method can also be accessed through the \texttt{math.ceil()} function.

\begin{verbatim}
__round__()
__round__(ndigits)
\end{verbatim}

The first version returns the nearest \texttt{int} to \texttt{self}, rounding half to even. The second version rounds \texttt{self} to the nearest multiple of \texttt{Fraction(1, 10**ndigits)} (logically, if \texttt{ndigits} is negative), again rounding half toward even. This method can also be accessed through the \texttt{round()} function.

\begin{verbatim}
fractions.gcd(a, b)
\end{verbatim}

Return the greatest common divisor of the integers \texttt{a} and \texttt{b}. If either \texttt{a} or \texttt{b} is nonzero, then the absolute value of \texttt{gcd(a, b)} is the largest integer that divides both \texttt{a} and \texttt{b}. \texttt{gcd(a, b)} has the same sign as \texttt{b} if \texttt{b} is nonzero; otherwise it takes the sign of \texttt{a}. \texttt{gcd(0, 0)} returns 0.

\underline{Module \texttt{numbers}}

The abstract base classes making up the numeric tower.
9.6. random — Generate pseudo-random numbers

Source code: Lib/random.py

This module implements pseudo-random number generators for various distributions.

For integers, there is uniform selection from a range. For sequences, there is uniform selection of a random element, a function to generate a random permutation of a list in-place, and a function for random sampling without replacement.

On the real line, there are functions to compute uniform, normal (Gaussian), lognormal, negative exponential, gamma, and beta distributions. For generating distributions of angles, the von Mises distribution is available.

Almost all module functions depend on the basic function random(), which generates a random float uniformly in the semi-open range [0.0, 1.0). Python uses the Mersenne Twister as the core generator. It produces 53-bit precision floats and has a period of 2**19937-1. The underlying implementation in C is both fast and threadsafe. The Mersenne Twister is one of the most extensively tested random number generators in existence. However, being completely deterministic, it is not suitable for all purposes, and is completely unsuitable for cryptographic purposes.

The functions supplied by this module are actually bound methods of a hidden instance of the random.Random class. You can instantiate
your own instances of Random to get generators that don’t share state.

Class Random can also be subclassed if you want to use a different basic generator of your own devising: in that case, override the random(), seed(), getstate(), and setstate() methods. Optionally, a new generator can supply a getrandbits() method — this allows randrange() to produce selections over an arbitrarily large range.

The random module also provides the SystemRandom class which uses the system function os.urandom() to generate random numbers from sources provided by the operating system.

**Warning:** The pseudo-random generators of this module should not be used for security purposes. Use os.urandom() or SystemRandom if you require a cryptographically secure pseudo-random number generator.

Bookkeeping functions:

random.seed(a=None, version=2)

Initialize the random number generator.

If a is omitted or None, the current system time is used. If randomness sources are provided by the operating system, they are used instead of the system time (see the os.urandom() function for details on availability).

If a is an int, it is used directly.

With version 2 (the default), a str, bytes, or bytearray object
gets converted to an `int` and all of its bits are used. With version 1, the `hash()` of a is used instead.

*Changed in version 3.2:* Moved to the version 2 scheme which uses all of the bits in a string seed.

**random.getstate()**

Return an object capturing the current internal state of the generator. This object can be passed to `setstate()` to restore the state.

**random.setstate(state)**

`state` should have been obtained from a previous call to `getstate()`, and `setstate()` restores the internal state of the generator to what it was at the time `getstate()` was called.

**random.getrandbits(k)**

Returns a Python integer with `k` random bits. This method is supplied with the MersenneTwister generator and some other generators may also provide it as an optional part of the API. When available, `getrandbits()` enables `randrange()` to handle arbitrarily large ranges.

Functions for integers:

**random.randrange(stop)**

**random.randrange(start, stop[, step])**

Return a randomly selected element from `range(start, stop, step)`. This is equivalent to `choice(range(start, stop, step))`, but doesn’t actually build a range object.

The positional argument pattern matches that of `range()`.
Keyword arguments should not be used because the function may use them in unexpected ways.

*Changed in version 3.2:* `randrange()` is more sophisticated about producing equally distributed values. Formerly it used a style like `int(random() * n)` which could produce slightly uneven distributions.

```python
random.randint(a, b)
```

Return a random integer $N$ such that $a \leq N \leq b$. Alias for `randrange(a, b+1)`.

Functions for sequences:

```python
random.choice(seq)
```

Return a random element from the non-empty sequence `seq`. If `seq` is empty, raises `IndexError`.

```python
random.shuffle(x[, random])
```

Shuffle the sequence `x` in place. The optional argument `random` is a 0-argument function returning a random float in $[0.0, 1.0)$; by default, this is the function `random()`.

Note that for even rather small `len(x)`, the total number of permutations of `x` is larger than the period of most random number generators; this implies that most permutations of a long sequence can never be generated.

```python
random.sample(population, k)
```

Return a $k$ length list of unique elements chosen from the population sequence or set. Used for random sampling without replacement.
Returns a new list containing elements from the population while leaving the original population unchanged. The resulting list is in selection order so that all sub-slices will also be valid random samples. This allows raffle winners (the sample) to be partitioned into grand prize and second place winners (the subslices).

Members of the population need not be hashable or unique. If the population contains repeats, then each occurrence is a possible selection in the sample.

To choose a sample from a range of integers, use an range() object as an argument. This is especially fast and space efficient for sampling from a large population:
```
sample(range(10000000), 60).
```

If the sample size is larger than the population size, a ValueError is raised.

The following functions generate specific real-valued distributions. Function parameters are named after the corresponding variables in the distribution’s equation, as used in common mathematical practice; most of these equations can be found in any statistics text.

**random.random()**
Return the next random floating point number in the range [0.0, 1.0).

**random.uniform(a, b)**
Return a random floating point number N such that a <= N <= b for a <= b and b <= N <= a for b < a.

The end-point value b may or may not be included in the range depending on floating-point rounding in the equation a + (b-a)
random.triangular(low, high, mode)

Return a random floating point number $N$ such that $\text{low} \leq N \leq \text{high}$ and with the specified $\text{mode}$ between those bounds. The $\text{low}$ and $\text{high}$ bounds default to zero and one. The $\text{mode}$ argument defaults to the midpoint between the bounds, giving a symmetric distribution.

random.betavariate(alpha, beta)

Beta distribution. Conditions on the parameters are $\alpha > 0$ and $\beta > 0$. Returned values range between 0 and 1.

random.expovariate(lambd)

Exponential distribution. $\text{lambd}$ is 1.0 divided by the desired mean. It should be nonzero. (The parameter would be called “lambda”, but that is a reserved word in Python.) Returned values range from 0 to positive infinity if $\text{lambd}$ is positive, and from negative infinity to 0 if $\text{lambd}$ is negative.

random.gammavariate(alpha, beta)

Gamma distribution. (Not the gamma function!) Conditions on the parameters are $\alpha > 0$ and $\beta > 0$.

The probability distribution function is:

$$
\text{pdf}(x) = \frac{x^{(\alpha - 1)} \exp(-x / \beta)}{\text{math.gamma}(\alpha) \times \beta^{\alpha}}
$$

random.gauss(mu, sigma)

Gaussian distribution. $\mu$ is the mean, and $\sigma$ is the standard
deviation. This is slightly faster than the `{normalvariate()}` function defined below.

```
random.lognormvariate(mu, sigma)
```
Log normal distribution. If you take the natural logarithm of this distribution, you’ll get a normal distribution with mean `mu` and standard deviation `sigma`. `mu` can have any value, and `sigma` must be greater than zero.

```
random.normalvariate(mu, sigma)
```
Normal distribution. `mu` is the mean, and `sigma` is the standard deviation.

```
random.vonmisesvariate(mu, kappa)
```
`mu` is the mean angle, expressed in radians between 0 and 2*pi, and `kappa` is the concentration parameter, which must be greater than or equal to zero. If `kappa` is equal to zero, this distribution reduces to a uniform random angle over the range 0 to 2*pi.

```
random.paretovariate(alpha)
```
Pareto distribution. `alpha` is the shape parameter.

```
random.weibullvariate(alpha, beta)
```
Weibull distribution. `alpha` is the scale parameter and `beta` is the shape parameter.

Alternative Generator:

```
class random.SystemRandom([seed])
```
Class that uses the `{os.urandom()}` function for generating random numbers from sources provided by the operating system. Not available on all systems. Does not rely on software state, and
sequences are not reproducible. Accordingly, the `seed()` method has no effect and is ignored. The `getstate()` and `setstate()` methods raise `NotImplementedError` if called.

**See also:** M. Matsumoto and T. Nishimura, “Mersenne Twister: A 623-dimensionally equidistributed uniform pseudorandom number generator”, ACM Transactions on Modeling and Computer Simulation Vol. 8, No. 1, January pp.3-30 1998.

Complementary-Multiply-with-Carry recipe for a compatible alternative random number generator with a long period and comparatively simple update operations.
9.6.1. Notes on Reproducibility

Sometimes it is useful to be able to reproduce the sequences given by a pseudo random number generator. By re-using a seed value, the same sequence should be reproducible from run to run as long as multiple threads are not running.

Most of the random module's algorithms and seeding functions are subject to change across Python versions, but two aspects are guaranteed not to change:

- If a new seeding method is added, then a backward compatible seeder will be offered.
- The generator’s random() method will continue to produce the same sequence when the compatible seeder is given the same seed.
9.6.2. Examples and Recipes

Basic usage:

```python
generator(random.random)  # Random floating point
0.3744887175646646

(generator(random.uniform(1, 10))  # Random floating point
1.1800146073117523

generator(random.randint(10))  # Integer from 0 to 9
7

(generator(random.randint(0, 101, 2))  # Even integer from 0 to 100
26

(generator(random.choice('abcdefghij'))  # Single random element
'c'

generator(items = [1, 2, 3, 4, 5, 6, 7])
gerandrange(items)
[7, 3, 2, 5, 6, 4, 1]

generator(random.sample([1, 2, 3, 4, 5], 3))  # Three samples without replacement
[4, 1, 5]
```

A common task is to make a `random.choice()` with weighted probabilities.

If the weights are small integer ratios, a simple technique is to build a sample population with repeats:

```python
>>> weighted_choices = [("Red", 3), ("Blue", 2), ("Yellow", 5)]
```
A more general approach is to arrange the weights in a cumulative distribution with `itertools.accumulate()`, and then locate the random value with `bisect.bisect()`:

```python
>>> choices, weights = zip(*weighted_choices)
>>> cumdist = list(itertools.accumulate(weights))
>>> x = random.random() * cumdist[-1]
>>> choices[bisect.bisect(cumdist, x)]
'Blue'
```
9.7. statistics — Mathematical statistics functions

New in version 3.4.

Source code: Lib/statistics.py

This module provides functions for calculating mathematical statistics of numeric (Real-valued) data.

**Note:** Unless explicitly noted otherwise, these functions support `int`, `float`, `decimal.Decimal` and `fractions.Fraction`. Behaviour with other types (whether in the numeric tower or not) is currently unsupported. Mixed types are also undefined and implementation-dependent. If your input data consists of mixed types, you may be able to use `map()` to ensure a consistent result, e.g. `map(float, input_data).`
9.7.1. Averages and measures of central location

These functions calculate an average or typical value from a population or sample.

<table>
<thead>
<tr>
<th>Function</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>mean()</td>
<td>Arithmetic mean (“average”) of data.</td>
</tr>
<tr>
<td>median()</td>
<td>Median (middle value) of data.</td>
</tr>
<tr>
<td>median_low()</td>
<td>Low median of data.</td>
</tr>
<tr>
<td>median_high()</td>
<td>High median of data.</td>
</tr>
<tr>
<td>median_grouped()</td>
<td>Median, or 50th percentile, of grouped data.</td>
</tr>
<tr>
<td>mode()</td>
<td>Mode (most common value) of discrete data.</td>
</tr>
</tbody>
</table>
9.7.2. Measures of spread

These functions calculate a measure of how much the population or sample tends to deviate from the typical or average values.

<table>
<thead>
<tr>
<th>Function</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>pstdev()</td>
<td>Population standard deviation of data.</td>
</tr>
<tr>
<td>pvariance()</td>
<td>Population variance of data.</td>
</tr>
<tr>
<td>stdev()</td>
<td>Sample standard deviation of data.</td>
</tr>
<tr>
<td>variance()</td>
<td>Sample variance of data.</td>
</tr>
</tbody>
</table>
9.7.3. Function details

Note: The functions do not require the data given to them to be sorted. However, for reading convenience, most of the examples show sorted sequences.

**statistics.mean(data)**

Return the sample arithmetic mean of *data*, a sequence or iterator of real-valued numbers.

The arithmetic mean is the sum of the data divided by the number of data points. It is commonly called “the average”, although it is only one of many different mathematical averages. It is a measure of the central location of the data.

If *data* is empty, *StatisticsError* will be raised.

Some examples of use:

```python
>>> mean([1, 2, 3, 4, 4])
2.8
>>> mean([-1.0, 2.5, 3.25, 5.75])
2.625

>>> from fractions import Fraction as F
>>> mean([F(3, 7), F(1, 21), F(5, 3), F(1, 3)])
Fraction(13, 21)

>>> from decimal import Decimal as D
>>> mean([D('0.5'), D('0.75'), D('0.625'), D('0.3')])
Decimal('0.5625')
```

*Note:* The mean is strongly affected by outliers and is not a
robust estimator for central location: the mean is not necessarily a typical example of the data points. For more robust, although less efficient, measures of central location, see \texttt{median()} and \texttt{mode()}. (In this case, “efficient” refers to statistical efficiency rather than computational efficiency.)

The sample mean gives an unbiased estimate of the true population mean, which means that, taken on average over all the possible samples, \( \text{mean(sample)} \) converges on the true mean of the entire population. If \( \text{data} \) represents the entire population rather than a sample, then \( \text{mean(data)} \) is equivalent to calculating the true population mean \( \mu \).

\begin{verbatim}
statistics.median(data)
\end{verbatim}

Return the median (middle value) of numeric data, using the common “mean of middle two” method. If \( \text{data} \) is empty, \texttt{StatisticsError} is raised.

The median is a robust measure of central location, and is less affected by the presence of outliers in your data. When the number of data points is odd, the middle data point is returned:

\begin{verbatim}
>>> median([1, 3, 5])
3
\end{verbatim}

When the number of data points is even, the median is interpolated by taking the average of the two middle values:

\begin{verbatim}
>>> median([1, 3, 5, 7])
4.0
\end{verbatim}

This is suited for when your data is discrete, and you don’t mind that the median may not be an actual data point.
See also: median_low(), median_high(), median_grouped()

**statistics.median_low(data)**

Return the low median of numeric data. If `data` is empty, `StatisticsError` is raised.

The low median is always a member of the data set. When the number of data points is odd, the middle value is returned. When it is even, the smaller of the two middle values is returned.

```
>>> median_low([1, 3, 5])
3
>>> median_low([1, 3, 5, 7])
3
```

Use the low median when your data are discrete and you prefer the median to be an actual data point rather than interpolated.

**statistics.median_high(data)**

Return the high median of data. If `data` is empty, `StatisticsError` is raised.

The high median is always a member of the data set. When the number of data points is odd, the middle value is returned. When it is even, the larger of the two middle values is returned.

```
>>> median_high([1, 3, 5])
3
>>> median_high([1, 3, 5, 7])
5
```

Use the high median when your data are discrete and you prefer
the median to be an actual data point rather than interpolated.

\begin{verbatim}
statistics.median_grouped(data, interval=1)
\end{verbatim}

Return the median of grouped continuous data, calculated as the 50th percentile, using interpolation. If data is empty, \texttt{StatisticsError} is raised.

\begin{verbatim}
>>> median_grouped([52, 52, 53, 54])
52.5
\end{verbatim}

In the following example, the data are rounded, so that each value represents the midpoint of data classes, e.g. 1 is the midpoint of the class 0.5-1.5, 2 is the midpoint of 1.5-2.5, 3 is the midpoint of 2.5-3.5, etc. With the data given, the middle value falls somewhere in the class 3.5-4.5, and interpolation is used to estimate it:

\begin{verbatim}
>>> median_grouped([1, 2, 2, 3, 4, 4, 4, 4, 5])
3.7
\end{verbatim}

Optional argument \texttt{interval} represents the class interval, and defaults to 1. Changing the class interval naturally will change the interpolation:

\begin{verbatim}
>>> median_grouped([1, 3, 3, 5, 7], interval=1)
3.25
>>> median_grouped([1, 3, 3, 5, 7], interval=2)
3.5
\end{verbatim}

This function does not check whether the data points are at least \texttt{interval} apart.

\textbf{CPython implementation detail:} Under some circumstances, \texttt{median_grouped()} may coerce data points to floats. This
behaviour is likely to change in the future.

**See also:**
- Calculating the median.
- The `SSMEDIAN` function in the Gnome Gnumeric spreadsheet, including this discussion.

**statistics.mode(data)**

Return the most common data point from discrete or nominal `data`. The mode (when it exists) is the most typical value, and is a robust measure of central location.

If `data` is empty, or if there is not exactly one most common value, `StatisticsError` is raised.

`mode` assumes discrete data, and returns a single value. This is the standard treatment of the mode as commonly taught in schools:

```python
>>> mode([1, 1, 2, 3, 3, 3, 3, 4])
3
```

The mode is unique in that it is the only statistic which also applies to nominal (non-numeric) data:

```python
>>> mode(['red', 'blue', 'blue', 'red', 'green', 'red', 'red'])
'red'
```

**statistics.pstdev(data, mu=None)**

Return the population standard deviation (the square root of the
population variance). See `pvariance()` for arguments and other details.

```python
>>> pstdev([1.5, 2.5, 2.5, 2.75, 3.25, 4.75])
0.986893273527251
```

```
statistics.pvariance(data, mu=None)
```

Return the population variance of `data`, a non-empty iterable of real-valued numbers. Variance, or second moment about the mean, is a measure of the variability (spread or dispersion) of data. A large variance indicates that the data is spread out; a small variance indicates it is clustered closely around the mean.

If the optional second argument `mu` is given, it should be the mean of `data`. If it is missing or `None` (the default), the mean is automatically calculated.

Use this function to calculate the variance from the entire population. To estimate the variance from a sample, the `variance()` function is usually a better choice.

Raises `StatisticsError` if `data` is empty.

Examples:

```python
>>> data = [0.0, 0.25, 0.25, 1.25, 1.5, 1.75, 2.7
>>> pvariance(data)
1.25
```

If you have already calculated the mean of your data, you can pass it as the optional second argument `mu` to avoid recalculation:

```python
>>> mu = mean(data)
```
This function does not attempt to verify that you have passed the actual mean as \( \mu \). Using arbitrary values for \( \mu \) may lead to invalid or impossible results.

Decimals and Fractions are supported:

```
>>> from decimal import Decimal as D
>>> pvariance([D("27.5"), D("30.25"), D("30.25"),
               Decimal('24.815')])
1.25
```

```
>>> from fractions import Fraction as F
>>> pvariance([F(1, 4), F(5, 4), F(1, 2)])
Fraction(13, 72)
```

**Note:** When called with the entire population, this gives the population variance \( \sigma^2 \). When called on a sample instead, this is the biased sample variance \( s^2 \), also known as variance with \( N \) degrees of freedom. If you somehow know the true population mean \( \mu \), you may use this function to calculate the variance of a sample, giving the known population mean as the second argument. Provided the data points are representative (e.g. independent and identically distributed), the result will be an unbiased estimate of the population variance.

```
statistics.stdev(data, xbar=None)
```

Return the sample standard deviation (the square root of the sample variance). See \( \text{variance()} \) for arguments and other details.
statistics.\texttt{variance}(data, xbar=None)

Return the sample variance of \textit{data}, an iterable of at least two real-valued numbers. Variance, or second moment about the mean, is a measure of the variability (spread or dispersion) of data. A large variance indicates that the data is spread out; a small variance indicates it is clustered closely around the mean.

If the optional second argument \textit{xbar} is given, it should be the mean of \textit{data}. If it is missing or \texttt{None} (the default), the mean is automatically calculated.

Use this function when your data is a sample from a population. To calculate the variance from the entire population, see \texttt{pvariance()}. 

Raises \texttt{StatisticsError} if \textit{data} has fewer than two values.

Examples:

\begin{verbatim}
>>> data = [2.75, 1.75, 1.25, 0.25, 0.5, 1.25, 3.
>>> variance(data)
1.3720238095238095
\end{verbatim}

If you have already calculated the mean of your data, you can pass it as the optional second argument \textit{xbar} to avoid recalculation:

\begin{verbatim}
>>> m = mean(data)
>>> variance(data, m)
1.3720238095238095
\end{verbatim}
This function does not attempt to verify that you have passed the actual mean as \( xbar \). Using arbitrary values for \( xbar \) can lead to invalid or impossible results.

Decimal and Fraction values are supported:

```python
given: >>> from decimal import Decimal as D >>> variance([D("27.5"), D("30.25"), D("30.25"), Decimal('31.01875')]
Fraction(67, 108)
```

Note: This is the sample variance \( s^2 \) with Bessel's correction, also known as variance with N-1 degrees of freedom. Provided that the data points are representative (e.g. independent and identically distributed), the result should be an unbiased estimate of the true population variance.

If you somehow know the actual population mean \( \mu \) you should pass it to the `pvariance()` function as the \( mu \) parameter to get the variance of a sample.
9.7.4. Exceptions

A single exception is defined:

```
exception statistics.StatisticsError
```

Subclass of `ValueError` for statistics-related exceptions.
10. Functional Programming Modules

The modules described in this chapter provide functions and classes that support a functional programming style, and general operations on callables.

The following modules are documented in this chapter:

- **10.1. itertools** — Functions creating iterators for efficient looping
  - 10.1.1. Itertool functions
  - 10.1.2. Itertools Recipes
- **10.2. functools** — Higher-order functions and operations on callable objects
  - 10.2.1. partial Objects
- **10.3. operator** — Standard operators as functions
  - 10.3.1. Mapping Operators to Functions
  - 10.3.2. Inplace Operators
10.1. **itertools** — Functions creating iterators for efficient looping

This module implements a number of *iterator* building blocks inspired by constructs from APL, Haskell, and SML. Each has been recast in a form suitable for Python.

The module standardizes a core set of fast, memory efficient tools that are useful by themselves or in combination. Together, they form an “iterator algebra” making it possible to construct specialized tools succinctly and efficiently in pure Python.

For instance, SML provides a tabulation tool: `tabulate(f)` which produces a sequence `f(0), f(1), ...`. The same effect can be achieved in Python by combining `map()` and `count()` to form `map(f, count())`.

These tools and their built-in counterparts also work well with the high-speed functions in the *operator* module. For example, the multiplication operator can be mapped across two vectors to form an efficient dot-product: `sum(map(operator.mul, vector1, vector2))`.

### Infinite Iterators:

<table>
<thead>

10.1.1. Itertool functions

The following module functions all construct and return iterators. Some provide streams of infinite length, so they should only be accessed by functions or loops that truncate the stream.

```
10.1.1.4 Itertool functions

The following module functions all construct and return iterators. Some provide streams of infinite length, so they should only be accessed by functions or loops that truncate the stream.

```

**itertools.accumulate(iterable[, func])**

Make an iterator that returns accumulated sums. Elements may be any addable type including Decimal or Fraction. If the optional func argument is supplied, it should be a function of two arguments and it will be used instead of addition.

Equivalent to:

```python
def accumulate(iterable, func=operator.add):
    'Return running totals'
    it = iter(iterable)
    total = next(it)
    yield total
    for element in it:
        total = func(total, element)
        yield total
```

There are a number of uses for the func argument. It can be set to min() for a running minimum, max() for a running maximum, or operator.mul() for a running product. Amortization tables can be built by accumulating interest and applying payments. First-order recurrence relations can be modeled by supplying the initial value in the iterable and using only the accumulated total in func argument:
```python
>>> data = [3, 4, 6, 2, 1, 9, 0, 7, 5, 8]
>>> list(accumulate(data, operator.mul))   # running product
[3, 12, 72, 144, 144, 1296, 0, 0, 0, 0]
>>> list(accumulate(data, max))             # running maximum
[3, 4, 6, 6, 9, 9, 9, 9, 9, 9]

# Amortize a 5% loan of 1000 with 4 annual payments
>>> cashflows = [1000, -90, -90, -90, -90]
>>> list(accumulate(cashflows, lambda bal, pmt: bal + pmt))
[1000, 960.0, 918.0, 873.9000000000001, 827.5950000000001]

# Chaotic recurrence relation http://en.wikipedia.org/wiki/Logistic_map
>>> logistic_map = lambda x, _: r * x * (1 - x)
>>> r = 3.8
>>> x0 = 0.4
>>> inputs = repeat(x0, 36)       # only the initial value is used
>>> [format(x, '.2f') for x in accumulate(inputs, logistic_map)]
['0.40', '0.91', '0.30', '0.81', '0.60', '0.92', '0.88', '0.39', '0.90', '0.33', '0.84', '0.52', '0.93', '0.25', '0.71', '0.79', '0.63', '0.88', '0.83', '0.54', '0.95', '0.20', '0.60', '0.91',

See `functools.reduce()` for a similar function that returns only the final accumulated value.

New in version 3.2.

Changed in version 3.3: Added the optional `func` parameter.

`itertools.chain(*iterables)`

Make an iterator that returns elements from the first iterable until it is exhausted, then proceeds to the next iterable, until all of the iterables are exhausted. Used for treating consecutive sequences as a single sequence. Equivalent to:
```python
def chain(*iterables):
    # chain('ABC', 'DEF') --> A B C D E F
    for it in iterables:
        for element in it:
            yield element

classmethod chain.from_iterable(iterable)
Alternate constructor for chain(). Gets chained inputs from a single iterable argument that is evaluated lazily. Roughly equivalent to:
```
The code for `combinations()` can be also expressed as a subsequence of `permutations()` after filtering entries where the elements are not in sorted order (according to their position in the input pool):

```python
def combinations(iterable, r):
    pool = tuple(iterable)
    n = len(pool)
    for indices in permutations(range(n), r):
        if sorted(indices) == list(indices):
            yield tuple(pool[i] for i in indices)
```

The number of items returned is $\frac{n!}{r! \cdot (n-r)!}$ when $0 \leq r \leq n$ or zero when $r > n$.

`itertools.combinations_with_replacement(iterable, r)`

Return $r$ length subsequences of elements from the input `iterable` allowing individual elements to be repeated more than once.
Combinations are emitted in lexicographic sort order. So, if the input iterable is sorted, the combination tuples will be produced in sorted order.

Elements are treated as unique based on their position, not on their value. So if the input elements are unique, the generated combinations will also be unique.

Equivalent to:

```python
def combinations_with Replacement(iterable, r):
    # combinations_with_replacement('ABC', 2) --> AA AB AC BB BC CC
    pool = tuple(iterable)
n = len(pool)
    if not n and r:
        return
    indices = [0] * r
    yield tuple(pool[i] for i in indices)
while True:
    for i in reversed(range(r)):
        if indices[i] != n - 1:
            break
    else:
        return
    indices[i:] = [indices[i] + 1] * (r - i)
    yield tuple(pool[i] for i in indices)
```

The code for combinations_with_replacement() can be also expressed as a subsequence of product() after filtering entries where the elements are not in sorted order (according to their position in the input pool):

```python
def combinations_with_replacement(iterable, r):
    pool = tuple(iterable)
```
\[ n = \text{len}(\text{pool}) \]
\[
\text{for } \text{indices} \text{ in } \text{product}(\text{range}(n), \text{repeat}=r): \]
\[
\text{if } \text{sorted}(\text{indices}) == \text{list}(\text{indices}): \]
\[
\text{yield } \text{tuple}(\text{pool}[i] \text{ for } i \text{ in } \text{indices})
\]

The number of items returned is \((n+r-1)! / r! / (n-1)!\) when \(n > 0\).

*New in version 3.1.*

**itertools.``compress``(data, selectors)**

Make an iterator that filters elements from `data` returning only those that have a corresponding element in `selectors` that evaluates to True. Stops when either the `data` or `selectors` iterables has been exhausted. Equivalent to:

```python
def compress(data, selectors):
    # compress('ABCDEF', [1,0,1,0,1,1]) --> A C E
    return (d for d, s in zip(data, selectors) if
```

*New in version 3.1.*

**itertools.``count``(start=0, step=1)**

Make an iterator that returns evenly spaced values starting with number `start`. Often used as an argument to `map()` to generate consecutive data points. Also, used with `zip()` to add sequence numbers. Equivalent to:

```python
def count(start=0, step=1):
    # count(10) --> 10 11 12 13 14 ...
    # count(2.5, 0.5) --> 2.5 3.0 3.5 ...
    n = start
    while True:
```
When counting with floating point numbers, better accuracy can sometimes be achieved by substituting multiplicative code such as: 

```
(start + step * i for i in count()).
```

*Changed in version 3.1: Added step argument and allowed non-integer arguments.*

**itertools.cyle(iterable)**

Make an iterator returning elements from the iterable and saving a copy of each. When the iterable is exhausted, return elements from the saved copy. Repeats indefinitely. Equivalent to:

```python
def cycle(iterable):  
    # cycle('ABCD') -> A B C D A B C D A B C D ...
    saved = []
    for element in iterable:
        yield element
        saved.append(element)
    while saved:
        for element in saved:
            yield element
```

Note, this member of the toolkit may require significant auxiliary storage (depending on the length of the iterable).

**itertools.dropwhile(predicate, iterable)**

Make an iterator that drops elements from the iterable as long as the predicate is true; afterwards, returns every element. Note, the iterator does not produce *any* output until the predicate first becomes false, so it may have a lengthy start-up time. Equivalent
def dropwhile(predicate, iterable):
    # dropwhile(lambda x: x<5, [1,4,6,4,1]) --> 6
    iterable = iter(iterable)
    for x in iterable:
        if not predicate(x):
            yield x
            break
    for x in iterable:
        yield x

itertools.filterfalse(predicate, iterable)

Make an iterator that filters elements from iterable returning only those for which the predicate is False. If predicate is None, return the items that are false. Equivalent to:

def filterfalse(predicate, iterable):
    # filterfalse(lambda x: x%2, range(10)) --> 0
    if predicate is None:
        predicate = bool
    for x in iterable:
        if not predicate(x):
            yield x

itertools.groupby(iterable, key=None)

Make an iterator that returns consecutive keys and groups from the iterable. The key is a function computing a key value for each element. If not specified or is None, key defaults to an identity function and returns the element unchanged. Generally, the iterable needs to already be sorted on the same key function.

The operation of groupby() is similar to the uniq filter in Unix. It
generates a break or new group every time the value of the key function changes (which is why it is usually necessary to have sorted the data using the same key function). That behavior differs from SQL’s GROUP BY which aggregates common elements regardless of their input order.

The returned group is itself an iterator that shares the underlying iterable with `groupby()`. Because the source is shared, when the `groupby()` object is advanced, the previous group is no longer visible. So, if that data is needed later, it should be stored as a list:

```python
groups = []
uniquekeys = []
data = sorted(data, key=keyfunc)
for k, g in groupby(data, keyfunc):
    groups.append(list(g))  # Store group iterator as a list
    uniquekeys.append(k)
```

`groupby()` is equivalent to:

```python
class groupby:
    # [k for k, g in groupby('AAAAABBBCCDAAABBB')]  # [list(g) for k, g in groupby('AAAAABBBCCD')]
    def __init__(self, iterable, key=None):
        if key is None:
            key = lambda x: x
        self.keyfunc = key
        self.it = iter(iterable)
        self.tgtkey = self.currkey = self.currval
    def __iter__(self):
        return self
    def __next__(self):
        while self.currkey == self.tgtkey:
            self.currvalue = next(self.it)  # End
```python
self.currkey = self.keyfunc(self.currvalue)
self.tgtkey = self.currkey
return (self.currkey, self._grouper(self, tgtkey))
def _grouper(self, tgtkey):
    while self.currkey == tgtkey:
        yield self.currvalue
        self.currvalue = next(self.it)  # E
self.currkey = self.keyfunc(self.currvalue)
```

`itertools.islice(iterable, start, stop)`

`itertools.islice(iterable, start, stop[, step])`

Make an iterator that returns selected elements from the iterable. If `start` is non-zero, then elements from the iterable are skipped until start is reached. Afterward, elements are returned consecutively unless `step` is set higher than one which results in items being skipped. If `stop` is `None`, then iteration continues until the iterator is exhausted, if at all; otherwise, it stops at the specified position. Unlike regular slicing, `islice()` does not support negative values for `start`, `stop`, or `step`. Can be used to extract related fields from data where the internal structure has been flattened (for example, a multi-line report may list a name field on every third line). Equivalent to:

```python
def islice(iterable, *args):
    # islice('ABCDEFG', 2) --> A B
    # islice('ABCDEFG', 2, 4) --> C D
    # islice('ABCDEFG', 2, None) --> C D E F G
    # islice('ABCDEFG', 0, None, 2) --> A C E G
    s = slice(*args)
    it = iter(range(s.start or 0, s.stop or sys.maxsize))
    nexti = next(it)
    for i, element in enumerate(iterable):
        if i == nexti:
```
If \texttt{start} is \texttt{None}, then iteration starts at zero. If \texttt{step} is \texttt{None}, then the step defaults to one.

\begin{Verbatim}
\texttt{yield} \quad \texttt{element}
\texttt{nexti} = \texttt{next(it)}
\end{Verbatim}

\textbf{itertools.\texttt{permutations}(iterable, r=None)}

Return successive \textit{r} length permutations of elements in the \textit{iterable}.

If \textit{r} is not specified or is \texttt{None}, then \textit{r} defaults to the length of the \textit{iterable} and all possible full-length permutations are generated.

Permutations are emitted in lexicographic sort order. So, if the input \textit{iterable} is sorted, the permutation tuples will be produced in sorted order.

Elements are treated as unique based on their position, not on their value. So if the input elements are unique, there will be no repeat values in each permutation.

Equivalent to:

\begin{Verbatim}
def \texttt{permutations}(iterable, r=\texttt{None}):
    # \texttt{permutations('ABCD', 2)} \rightarrow AB AC AD BA BC
    # \texttt{permutations(range(3))} \rightarrow 012 021 102 120 201 210
    pool = \texttt{tuple}(iterable)
n = \texttt{len}(pool)
r = n \texttt{if} r \texttt{is} \texttt{None} \texttt{else} \texttt{r}
if r > n:
    \texttt{return}
indices = \texttt{list}(\texttt{range}(n))
cycles = \texttt{list}(\texttt{range}(n, n-r, -1))
\texttt{yield} \quad \texttt{tuple}(\texttt{pool}[i] \texttt{for} \ i \ \texttt{in} \ \texttt{indices}[\texttt{r}])
\end{Verbatim}
while n:
    for i in reversed(range(r)):
        cycles[i] -= 1
        if cycles[i] == 0:
            indices[i:] = indices[i+1:] + indices[:i]
            cycles[i] = n - i
        else:
            j = cycles[i]
            indices[i], indices[-j] = indices[-j], indices[i]
            yield tuple(pool[i] for i in indices)
    else:
        break
else:
    return

The code for permutations() can be also expressed as a subsequence of product(), filtered to exclude entries with repeated elements (those from the same position in the input pool):

def permutations(iterable, r=None):
    pool = tuple(iterable)
    n = len(pool)
    r = n if r is None else r
    for indices in product(range(n), repeat=r):
        if len(set(indices)) == r:
            yield tuple(pool[i] for i in indices)

The number of items returned is \( \frac{n!}{(n-r)!} \) when \( 0 \leq r \leq n \) or zero when \( r > n \).

Itertools.product(*iterables, repeat=1)

Cartesian product of input iterables.

Equivalent to nested for-loops in a generator expression. For example, product(A, B) returns the same as ((x,y) for x in A for y in B).
in A for y in B).

The nested loops cycle like an odometer with the rightmost element advancing on every iteration. This pattern creates a lexicographic ordering so that if the input's iterables are sorted, the product tuples are emitted in sorted order.

To compute the product of an iterable with itself, specify the number of repetitions with the optional repeat keyword argument. For example, product(A, repeat=4) means the same as product(A, A, A, A).

This function is equivalent to the following code, except that the actual implementation does not build up intermediate results in memory:

```python
def product(*args, repeat=1):
    # product('ABCD', 'xy') --> Ax Ay Bx By Cx Cy
    # product(range(2), repeat=3) --> 000 001 010
    pools = [tuple(pool) for pool in args] * repeat
    result = [[]]
    for pool in pools:
        result = [x+y for x in result for y in pool]
    for prod in result:
        yield tuple(prod)
```

`itertools.repeat(object[, times])`

Make an iterator that returns object over and over again. Runs indefinitely unless the times argument is specified. Used as argument to map() for invariant parameters to the called function. Also used with zip() to create an invariant part of a tuple record. Equivalent to:
def repeat(object, times=None):
    # repeat(10, 3) --> 10 10 10
    if times is None:
        while True:
            yield object
    else:
        for i in range(times):
            yield object

A common use for repeat is to supply a stream of constant values to map or zip:

>>> list(map(pow, range(10), repeat(2)))
[0, 1, 4, 9, 16, 25, 36, 49, 64, 81]

itertools.starmap(function, iterable)
Make an iterator that computes the function using arguments obtained from the iterable. Used instead of map() when argument parameters are already grouped in tuples from a single iterable (the data has been “pre-zipped”). The difference between map() and starmap() parallels the distinction between function(a,b) and function(*c). Equivalent to:

def starmap(function, iterable):
    # starmap(pow, [(2,5), (3,2), (10,3)]) --> 32
    for args in iterable:
        yield function(*args)

itertools.takewhile(predicate, iterable)
Make an iterator that returns elements from the iterable as long as the predicate is true. Equivalent to:

def takewhile(predicate, iterable):
```python
# takewhile(lambda x: x<5, [1,4,6,4,1]) --> 1
for x in iterable:
    if predicate(x):
        yield x
else:
    break
```

**itertools.tee(iterable, n=2)**

Return \(n\) independent iterators from a single iterable. Equivalent to:

```python
def tee(iterable, n=2):
    it = iter(iterable)
    deques = [collections.deque() for i in range(n)]
    def gen(mydeque):
        while True:
            if not mydeque:  # when the local deque is empty
                newval = next(it)  # fetch a new value
            for d in deques:
                # load it to all the deques
                d.append(newval)
            yield mydeque.popleft()
    return tuple(gen(d) for d in deques)
```

Once `tee()` has made a split, the original `iterable` should not be used anywhere else; otherwise, the `iterable` could get advanced without the `tee` objects being informed.

This itertool may require significant auxiliary storage (depending on how much temporary data needs to be stored). In general, if one iterator uses most or all of the data before another iterator starts, it is faster to use `list()` instead of `tee()`.

**itertools.zip_longest(*iterables, fillvalue=None)**

Make an iterator that aggregates elements from each of the
iterables. If the iterables are of uneven length, missing values are filled-in with `fillvalue`. Iteration continues until the longest iterable is exhausted. Equivalent to:

```python
class ZipExhausted(Exception):
    pass

def zip_longest(*args, **kwds):
    # zip_longest('ABCD', 'xy', fillvalue='-') --> Ax By C- D-
    fillvalue = kwds.get('fillvalue')
    counter = len(args) - 1
    def sentinel():
        nonlocal counter
        if not counter:
            raise ZipExhausted
        counter -= 1
        yield fillvalue
    fillers = repeat(fillvalue)
    iterators = [chain(it, sentinel(), fillers) for it in args]
    try:
        while iterators:
            yield tuple(map(next, iterators))
    except ZipExhausted:
        pass
```

If one of the iterables is potentially infinite, then the `zip_longest()` function should be wrapped with something that limits the number of calls (for example `islice()` or `takewhile()`). If not specified, `fillvalue` defaults to `None`. 
10.1.2. Itertools Recipes

This section shows recipes for creating an extended toolset using the existing itertools as building blocks.

The extended tools offer the same high performance as the underlying toolset. The superior memory performance is kept by processing elements one at a time rather than bringing the whole iterable into memory all at once. Code volume is kept small by linking the tools together in a functional style which helps eliminate temporary variables. High speed is retained by preferring “vectorized” building blocks over the use of for-loops and *generators* which incur interpreter overhead.

```python
def take(n, iterable):
    """Return first n items of the iterable as a list""
    return list(islice(iterable, n))

def tabulate(function, start=0):
    """Return function(0), function(1), ..."
    return map(function, count(start))

def consume(iterator, n):
    """Advance the iterator n-steps ahead. If n is non
    # Use functions that consume iterators at C speed
    if n is None:
        # feed the entire iterator into a zero-length
collections.deque(iterator, maxlen=0)
    else:
        # advance to the empty slice starting at pos
next(islice(iterator, n, n), None)

def nth(iterable, n, default=\None):
    """Returns the nth item or a default value"
```
```python
return next(islice(iterable, n, None), default)

def quantify(iterable, pred=bool):
    """Count how many times the predicate is true""
    return sum(map(pred, iterable))

def padnone(iterable):
    """Returns the sequence elements and then returns None indefinitely. Useful for emulating the behavior of the built-in map() function."
    return chain(iterable, repeat(None))

def ncycles(iterable, n):
    """Returns the sequence elements n times""
    return chain.from_iterable(repeat(tuple(iterable), n))

def dotproduct(vec1, vec2):
    return sum(map(operator.mul, vec1, vec2))

def flatten(listOfLists):
    """Flatten one level of nesting""
    return chain.from_iterable(listOfLists)

def repeatfunc(func, times=None, *args):
    """Repeat calls to func with specified arguments""
    Example: repeatfunc(random.random)
    """
    if times is None:
        return starmap(func, repeat(args))
    return starmap(func, repeat(args, times))

def pairwise(iterable):
    """s -> (s0,s1), (s1,s2), (s2, s3), ...""
    a, b = tee(iterable)
    next(b, None)
```
return zip(a, b)

def grouper(iterable, n, fillvalue=None):
    "Collect data into fixed-length chunks or blocks"
    # grouper('ABCDEFG', 3, 'x') --> ABC DEF Gxx"
    args = [iter(iterable)] * n
    return zip_longest(*args, fillvalue=fillvalue)

def roundrobin(*iterables):
    "roundrobin('ABC', 'D', 'EF') --> A D E B F C"
    # Recipe credited to George Sakkis
    pending = len(iterables)
    nexts = cycle(iter(it).__next__ for it in iterables)
    while pending:
        try:
            for next in nexts:
                yield next()
        except StopIteration:
            pending -= 1
            nexts = cycle(islice(nexts, pending))

def partition(pred, iterable):
    'Use a predicate to partition entries into false and true entries'
    # partition(is_odd, range(10)) --> 0 2 4 6 8 1 3 5 7 9
    t1, t2 = tee(iterable)
    return filterfalse(pred, t1), filter(pred, t2)

def powerset(iterable):
    "powerset([1,2,3]) --> ( ) (1) (2) (3) (1,2) (1,3) (2,3) (1,2,3)"
    s = list(iterable)
    return chain.from_iterable(combinations(s, r) for r in range(len(s) + 1))

def unique_everseen(iterable, key=None):
    "List unique elements, preserving order. Remember all elements ever seen."
    # unique_everseen('AAAABBBCCDAABBB') --> A B C D
    # unique_everseen('ABBCcAD', str.lower) --> A B C D
    seen = set()
seen_add = seen.add
if key is None:
    for element in filterfalse(seen.__contains__, seen_add(element)):
        yield element
else:
    for element in iterable:
        k = key(element)
        if k not in seen:
            seen_add(k)
            yield element

def unique_justseen(iterable, key=None):
    "List unique elements, preserving order. Remember only the element just seen."
    # unique_justseen('AAAABBBCCDAABBB')  -->  A B C D
    # unique_justseen('ABBCcAD', str.lower)  -->  A B C A D
    return map(next, map(itemgetter(1), groupby(iterable, key=key)))

def iter_except(func, exception, first=None):
    """Call a function repeatedly until an exception is raised."

    Converts a call-until-exception interface to an iterator interface.
    Like builtins.iter(func, sentinel) but uses an exception instead of a sentinel to end the loop.

    Examples:
        iter_except(functools.partial(heappop, h), IndexError)
        # priority queue iterator
        iter_except(d.popitem, KeyError)
        # non-blocking dict iterator
        iter_except(d.popleft, IndexError)
        # non-blocking deque iterator
        iter_except(q.get_nowait, Queue.Empty)
        # loop over a producer Queue
        iter_except(s.pop, KeyError)

    """
    try:
        if first is not None:
            yield first()  # For database
    while 1:
```python
yield func()
extcept exception:
    pass

def random_product(*args, repeat=1):
    "Random selection from itertools.product(*args, repeat=1):
    pools = [tuple(pool) for pool in args] * repeat
    return tuple(random.choice(pool) for pool in pools)

def random_permutation(iterable, r=None):
    "Random selection from itertools.permutations(iterable, r=None):
    pool = tuple(iterable)
    r = len(pool) if r is None else r
    return tuple(random.sample(pool, r))

def random_combination(iterable, r):
    "Random selection from itertools.combinations(iterable, r):
    pool = tuple(iterable)
    n = len(pool)
    indices = sorted(random.sample(range(n), r))
    return tuple(pool[i] for i in indices)

def random_combination_with_replacement(iterable, r):
    "Random selection from itertools.combinations_with_replacement(iterable, r):
    pool = tuple(iterable)
    n = len(pool)
    indices = sorted(random.randrange(n) for i in range(r))
    return tuple(pool[i] for i in indices)
```

Note, many of the above recipes can be optimized by replacing global lookups with local variables defined as default values. For example, the `dotproduct` recipe can be written as:

```python
def dotproduct(vec1, vec2, sum=sum, map=map, mul=operator.mul):
    return sum(map(mul, vec1, vec2))
```
10.2. **functools** — Higher-order functions and operations on callable objects

**Source code:** Lib/functools.py

The **functools** module is for higher-order functions: functions that act on or return other functions. In general, any callable object can be treated as a function for the purposes of this module.

The **functools** module defines the following functions:

```python
functools.cmp_to_key(func)
```

Transform an old-style comparison function to a key function. Used with tools that accept key functions (such as `sorted()`, `min()`, `max()`, `heapq.nlargest()`, `heapq.nsmallest()`, `itertools.groupby()`). This function is primarily used as a transition tool for programs being converted from Python 2 which supported the use of comparison functions.

A comparison function is any callable that accept two arguments, compares them, and returns a negative number for less-than, zero for equality, or a positive number for greater-than. A key function is a callable that accepts one argument and returns another value indicating the position in the desired collation sequence.

Example:

```python
sorted(iterable, key=cmp_to_key(locale.strcoll))
```
New in version 3.2.

@functools.lru_cache(maxsize=128, typed=False)

Decorator to wrap a function with a memoizing callable that saves up to the maxsize most recent calls. It can save time when an expensive or I/O bound function is periodically called with the same arguments.

Since a dictionary is used to cache results, the positional and keyword arguments to the function must be hashable.

If maxsize is set to None, the LRU feature is disabled and the cache can grow without bound. The LRU feature performs best when maxsize is a power-of-two.

If typed is set to True, function arguments of different types will be cached separately. For example, \( f(3) \) and \( f(3.0) \) will be treated as distinct calls with distinct results.

To help measure the effectiveness of the cache and tune the maxsize parameter, the wrapped function is instrumented with a cache_info() function that returns a named tuple showing hits, misses, maxsize and currsize. In a multi-threaded environment, the hits and misses are approximate.

The decorator also provides a cache_clear() function for clearing or invalidating the cache.

The original underlying function is accessible through the __wrapped__ attribute. This is useful for introspection, for bypassing the cache, or for rewrapping the function with a different cache.
An **LRU (least recently used) cache** works best when the most recent calls are the best predictors of upcoming calls (for example, the most popular articles on a news server tend to change each day). The cache’s size limit assures that the cache does not grow without bound on long-running processes such as web servers.

Example of an LRU cache for static web content:

```python
@lru_cache(maxsize=32)
def get_pep(num):
    'Retrieve text of a Python Enhancement Proposal'
    resource = 'http://www.python.org/dev/peps/pep-%04d/'
    try:
        with urllib.request.urlopen(resource) as s:
            return s.read()
    except urllib.error.HTTPError:
        return 'Not Found'

>>> for n in 8, 290, 308, 320, 8, 218, 320, 279, ...
    ...    pep = get_pep(n)
    ...    print(n, len(pep))
```

```bash
CacheInfo(hits=3, misses=8, maxsize=32, currsize=8)
```

Example of efficiently computing **Fibonacci numbers** using a cache to implement a **dynamic programming** technique:

```python
@lru_cache(maxsize=None)
def fib(n):
    if n < 2:
        return n
    return fib(n-1) + fib(n-2)

>>> [fib(n) for n in range(16)]
```
New in version 3.2.

Changed in version 3.3: Added the typed option.

@functools.total_ordering

Given a class defining one or more rich comparison ordering methods, this class decorator supplies the rest. This simplifies the effort involved in specifying all of the possible rich comparison operations:

The class must define one of __lt__(), __le__(), __gt__(), or __ge__() method. In addition, the class should supply an __eq__() method.

For example:

```python
@total_ordering
class Student:
    def _is_valid_operand(self, other):
        return (hasattr(other, "lastname") and
                hasattr(other, "firstname"))
    def __eq__(self, other):
        if not self._is_valid_operand(other):
            return NotImplemented
        return ((self.lastname.lower(), self.firstname),
                other.lastname.lower(), other.firstname)
    def __lt__(self, other):
        if not self._is_valid_operand(other):
            return NotImplemented
        return ((self.lastname.lower(), self.firstname),
                other.lastname.lower(), other.firstname)
```
Note: While this decorator makes it easy to create well behaved totally ordered types, it does come at the cost of slower execution and more complex stack traces for the derived comparison methods. If performance benchmarking indicates this is a bottleneck for a given application, implementing all six rich comparison methods instead is likely to provide an easy speed boost.

New in version 3.2.

Changed in version 3.4: Returning NotImplemented from the underlying comparison function for unrecognised types is now supported.

`functools.partial(func, *args, **keywords)`

Return a new `partial` object which when called will behave like `func` called with the positional arguments `args` and keyword arguments `keywords`. If more arguments are supplied to the call, they are appended to `args`. If additional keyword arguments are supplied, they extend and override `keywords`. Roughly equivalent to:

```python
def partial(func, *args, **keywords):
    def newfunc(*fargs, **fkeywords):
        newkeywords = keywords.copy()
        newkeywords.update(fkeywords)
        return func(*(args + fargs), **newkeywords)
    newfunc.func = func
    newfunc.args = args
    newfunc.keywords = keywords
    return newfunc
```
The `partial()` is used for partial function application which “freezes” some portion of a function's arguments and/or keywords resulting in a new object with a simplified signature. For example, `partial()` can be used to create a callable that behaves like the `int()` function where the `base` argument defaults to two:

```python
defint = partial(int, base=2)
defint('10010')  # returns 18
```

```python
classfunctools.partialmethod(func, *args, **keywords)
Return a new `partialmethod` descriptor which behaves like `partial` except that it is designed to be used as a method definition rather than being directly callable.

`func` must be a `descriptor` or a callable (objects which are both, like normal functions, are handled as descriptors).

When `func` is a descriptor (such as a normal Python function, `classmethod()`, `staticmethod()`, `abstractmethod()` or another instance of `partialmethod`), calls to `__get__` are delegated to the underlying descriptor, and an appropriate `partial` object returned as the result.

When `func` is a non-descriptor callable, an appropriate bound method is created dynamically. This behaves like a normal Python function when used as a method: the `self` argument will be inserted as the first positional argument, even before the `args` and `keywords` supplied to the `partialmethod` constructor.
Example:

```python
>>> class Cell(object):
...     @property
...     def alive(self):
...         return self._alive
...     def set_state(self, state):
...         self._alive = bool(state)
...     set_alive = partialmethod(set_state, True)
...     set_dead = partialmethod(set_state, False)
...
>>> c = Cell()
>>> c.alive
False
>>> c.set_alive()
>>> c.alive
True
```

*New in version 3.4.*

```python
import functools

functools.reduce(function, iterable[, initializer])
```

Apply `function` of two arguments cumulatively to the items of `sequence`, from left to right, so as to reduce the sequence to a single value. For example, `reduce(lambda x, y: x+y, [1, 2, 3, 4, 5])` calculates `((((1+2)+3)+4)+5)`. The left argument, `x`, is the accumulated value and the right argument, `y`, is the update value from the `sequence`. If the optional `initializer` is present, it is placed before the items of the sequence in the calculation, and serves as a default when the sequence is empty. If `initializer` is not given and `sequence` contains only one item, the first item is returned.

Equivalent to:
```python
def reduce(function, iterable, initializer=None):
    it = iter(iterable)
    if initializer is None:
        value = next(it)
    else:
        value = initializer
    for element in it:
        value = function(value, element)
    return value
```

```python
@functools.singledispatch(default)
Transforms a function into a single-dispatch generic function.

To define a generic function, decorate it with the @singledispatch decorator. Note that the dispatch happens on the type of the first argument, create your function accordingly:

```python
>>> from functools import singledispatch
>>> @singledispatch
... def fun(arg, verbose=False):
...     if verbose:
...         print("Let me just say,", end=" ")
...     print(arg)

To add overloaded implementations to the function, use the register() attribute of the generic function. It is a decorator, taking a type parameter and decorating a function implementing the operation for that type:

```python
>>> @fun.register(int)
... def _(arg, verbose=False):
...     if verbose:
...         print("Strength in numbers, eh?", end=")
...     print(arg)```
To enable registering lambdas and pre-existing functions, the register() attribute can be used in a functional form:

```python
>>> @fun.register(type(None), nothing)

>>> def nothing(arg, verbose=False):
...     print("Nothing.")

>>> fun.register(type(None), nothing)
```

The register() attribute returns the undecorated function which enables decorator stacking, pickling, as well as creating unit tests for each variant independently:

```python
>>> @fun.register(float)
... @fun.register(Decimal)
... def fun_num(arg, verbose=False):
...     if verbose:
...         print("Half of your number:", end=" ")
...         print(arg / 2)

>>> fun_num is fun
False
```

When called, the generic function dispatches on the type of the first argument:

```python
>>> fun("Hello, world.")
```
Hello, world.

```python
>>> fun("test.", verbose=True)
Let me just say, test.
```

```python
>>> fun(42, verbose=True)
Strength in numbers, eh? 42
```

```python
>>> fun(['spam', 'spam', 'eggs', 'spam'], verbose=True)
Enumerate this:
0 spam
1 spam
2 eggs
3 spam
```

```python
>>> fun(None)
Nothing.
```

```python
>>> fun(1.23)
0.615
```

Where there is no registered implementation for a specific type, its method resolution order is used to find a more generic implementation. The original function decorated with `@singledispatch` is registered for the base `object` type, which means it is used if no better implementation is found.

To check which implementation will the generic function choose for a given type, use the `dispatch()` attribute:

```python
>>> fun.dispatch(float)
<function fun_num at 0x1035a2840>
```

```python
>>> fun.dispatch(dict)  # note: default implementation
<function fun at 0x103fe0000>
```

To access all registered implementations, use the read-only `registry` attribute:

```python
>>> fun.registry.keys()
```
fun registry[float]
<function fun_num at 0x1035a2840>

fun registry[object]
<function fun at 0x103fe0000>

New in version 3.4.

functools.update_wrapper(wrapper, wrapped, assigned=WRAPPER_ASSIGNMENTS, updated=WRAPPER_UPDATES)

Update a wrapper function to look like the wrapped function. The optional arguments are tuples to specify which attributes of the original function are assigned directly to the matching attributes on the wrapper function and which attributes of the wrapper function are updated with the corresponding attributes from the original function. The default values for these arguments are the module level constants WRAPPER_ASSIGNMENTS (which assigns to the wrapper function’s __name__, __module__, __annotations__ and __doc__, the documentation string) and WRAPPER_UPDATES (which updates the wrapper function’s __dict__, i.e. the instance dictionary).

To allow access to the original function for introspection and other purposes (e.g. bypassing a caching decorator such as lru_cache()), this function automatically adds a __wrapped__ attribute to the wrapper that refers to the function being wrapped.

The main intended use for this function is in decorator functions which wrap the decorated function and return the wrapper. If the wrapper function is not updated, the metadata of the returned
function will reflect the wrapper definition rather than the original function definition, which is typically less than helpful.

`update_wrapper()` may be used with callables other than functions. Any attributes named in `assigned` or `updated` that are missing from the object being wrapped are ignored (i.e. this function will not attempt to set them on the wrapper function). `AttributeError` is still raised if the wrapper function itself is missing any attributes named in `updated`.

*New in version 3.2:* Automatic addition of the `__wrapped__` attribute.

*New in version 3.2:* Copying of the `__annotations__` attribute by default.

*Changed in version 3.2:* Missing attributes no longer trigger an `AttributeError`.

*Changed in version 3.4:* The `__wrapped__` attribute now always refers to the wrapped function, even if that function defined a `__wrapped__` attribute. (see issue 17482)

@functools.wraps(wrapped, assigned=WRAPPER_ASSIGNMENTS, updated=WRAPPER_UPDATES)
This is a convenience function for invoking
`partial(update_wrapper, wrapped=wrapped, assigned=assigned, updated=updated)` as a function decorator when defining a wrapper function. For example:

```python
>>> from functools import wraps
>>> def my_decorator(f):
```
Without the use of this decorator factory, the name of the example function would have been 'wrapper', and the docstring of the original example() would have been lost.
10.2.1. **partial** Objects

`partial` objects are callable objects created by `partial()`. They have three read-only attributes:

**partial.func**

A callable object or function. Calls to the `partial` object will be forwarded to `func` with new arguments and keywords.

**partial.args**

The leftmost positional arguments that will be prepended to the positional arguments provided to a `partial` object call.

**partial.keywords**

The keyword arguments that will be supplied when the `partial` object is called.

`partial` objects are like function objects in that they are callable, weak referencable, and can have attributes. There are some important differences. For instance, the `__name__` and `__doc__` attributes are not created automatically. Also, `partial` objects defined in classes behave like static methods and do not transform into bound methods during instance attribute look-up.
The `operator` module exports a set of efficient functions corresponding to the intrinsic operators of Python. For example, `operator.add(x, y)` is equivalent to the expression `x+y`. The function names are those used for special class methods; variants without leading and trailing `__` are also provided for convenience.

The functions fall into categories that perform object comparisons, logical operations, mathematical operations and sequence operations.

The object comparison functions are useful for all objects, and are named after the rich comparison operators they support:

```python
operator.lt(a, b)
operator.le(a, b)
operator.eq(a, b)
operator.ne(a, b)
operator.ge(a, b)
operator.gt(a, b)
operator.__lt__(a, b)
operator.__le__(a, b)
operator.__eq__(a, b)
operator.__ne__(a, b)
operator.__ge__(a, b)
operator.__gt__(a, b)
```
Perform “rich comparisons” between $a$ and $b$. Specifically, $\text{lt}(a, b)$ is equivalent to $a < b$, $\text{le}(a, b)$ is equivalent to $a \leq b$, $\text{eq}(a, b)$ is equivalent to $a == b$, $\text{ne}(a, b)$ is equivalent to $a \neq b$, $\text{gt}(a, b)$ is equivalent to $a > b$ and $\text{ge}(a, b)$ is equivalent to $a \geq b$. Note that these functions can return any value, which may or may not be interpretable as a Boolean value. See *Comparisons* for more information about rich comparisons.

The logical operations are also generally applicable to all objects, and support truth tests, identity tests, and boolean operations:

operator.\textbf{not}(_\text{obj})

operator.\textbf{__not__}(\text{obj})

Return the outcome of \textbf{not} \text{obj}. (Note that there is no \textbf{__not__}() method for object instances; only the interpreter core defines this operation. The result is affected by the \textbf{__bool__}() and \textbf{__len__}() methods.)

operator.\textbf{truth}(\text{obj})

Return \textbf{True} if \text{obj} is true, and \textbf{False} otherwise. This is equivalent to using the \textbf{bool} constructor.

operator.\textbf{is}(_a, b)

Return \texttt{a is b}. Tests object identity.

operator.\textbf{is\_not}(_a, b)

Return \texttt{a is not b}. Tests object identity.

The mathematical and bitwise operations are the most numerous:

operator.\textbf{abs}(\text{obj})

operator.\textbf{__abs__}(\text{obj})
Return the absolute value of `obj`.

```python
operator.add(a, b)
operator.__add__(a, b)
    Return `a + b`, for `a` and `b` numbers.
```

```python
operator.and_(a, b)
operator.__and__(a, b)
    Return the bitwise and of `a` and `b`.
```

```python
operator.floordiv(a, b)
operator.__floordiv__(a, b)
    Return `a // b`.
```

```python
operator.index(a)
operator.__index__(a)
    Return `a` converted to an integer. Equivalent to `a.__index__()`.
```

```python
operator.inv(obj)
operator.invert(obj)
operator.__inv__(obj)
operator.__invert__(obj)
    Return the bitwise inverse of the number `obj`. This is equivalent to `~obj`.
```

```python
operator.lshift(a, b)
operator.__lshift__(a, b)
    Return `a` shifted left by `b`.
```

```python
operator.mod(a, b)
operator.__mod__(a, b)
    Return `a % b`.
```
operator. **mul***(a, b)*
operator. **_mul_***(a, b)*
    Return \( a \times b \), for \( a \) and \( b \) numbers.

operator. **neg***(obj)*
operator. **_neg_***(obj)*
    Return \( -obj \).

operator. **or_**(a, b)
operator. **_or_***(a, b)
    Return the bitwise or of \( a \) and \( b \).

operator. **pos**(obj)
operator. **_pos_**(obj)
    Return \( +obj \).

operator. **pow**(a, b)
operator. **_pow_***(a, b)
    Return \( a \^ b \), for \( a \) and \( b \) numbers.

operator. **rshift**(a, b)
operator. **_rshift_***(a, b)
    Return \( a \) shifted right by \( b \).

operator. **sub**(a, b)
operator. **_sub_***(a, b)
    Return \( a - b \).

operator. **truediv**(a, b)
operator. **_truediv_***(a, b)
    Return \( a / b \) where \( 2/3 \) is .66 rather than 0. This is also known as “true” division.
operator. **xor**\((a, b)\)
operator. **__xor__**\((a, b)\)

Return the bitwise exclusive or of \(a\) and \(b\).

Operations which work with sequences (some of them with mappings too) include:

operator. **concat**\((a, b)\)
operator. **__concat__**\((a, b)\)

Return \(a + b\) for \(a\) and \(b\) sequences.

operator. **contains**\((a, b)\)
operator. **__contains__**\((a, b)\)

Return the outcome of the test \(b\ in\ a\). Note the reversed operands.

operator. **countOf**\((a, b)\)

Return the number of occurrences of \(b\) in \(a\).

operator. **delitem**\((a, b)\)
operator. **__delitem__**\((a, b)\)

Remove the value of \(a\) at index \(b\).

operator. **getitem**\((a, b)\)
operator. **__getitem__**\((a, b)\)

Return the value of \(a\) at index \(b\).

operator. **indexOf**\((a, b)\)

Return the index of the first of occurrence of \(b\) in \(a\).

operator. **setitem**\((a, b, c)\)
operator. **__setitem__**\((a, b, c)\)
Set the value of $a$ at index $b$ to $c$.

Example: Build a dictionary that maps the ordinals from 0 to 255 to their character equivalents.

```python
d = {}
keys = range(256)
vals = map(chr, keys)
map(operator.setitem, [d]*len(keys), keys, vals)
```

**operator.** `length_hint(obj, default=0)`

Return an estimated length for the object $o$. First try to return its actual length, then an estimate using `object.__length_hint__()`, and finally return the default value.

*New in version 3.4.*

The `operator` module also defines tools for generalized attribute and item lookups. These are useful for making fast field extractors as arguments for `map()`, `sorted()`, `itertools.groupby()`, or other functions that expect a function argument.

**operator.attrgetter(attr)**

**operator.attrgetter(*attrs)**

Return a callable object that fetches $attr$ from its operand. If more than one attribute is requested, returns a tuple of attributes. The attribute names can also contain dots. For example:

- After $f = \text{attrgetter('name')}$, the call $f(b)$ returns $b.name$.
- After $f = \text{attrgetter('name', 'date')}$, the call $f(b)$ returns $(b.name, b.date)$.
After \( f = \text{attrgetter('name.first', 'name.last')} \), the call \( f(b) \) returns \((b.name.first, b.name.last)\).

Equivalent to:

```python
def attrgetter(*items):
    if any(not isinstance(item, str) for item in items):
        raise TypeError('attribute name must be a string')
    if len(items) == 1:
        attr = items[0]
        def g(obj):
            return resolve_attr(obj, attr)
    else:
        def g(obj):
            return tuple(resolve_attr(obj, attr) for attr in items)
        return g

def resolve_attr(obj, attr):
    for name in attr.split('.'):  
        obj = getattr(obj, name)
    return obj
```

operator.\texttt{itemgetter(item)}
operator.\texttt{itemgetter(*items)}

Return a callable object that fetches \textit{item} from its operand using the operand's \texttt{__getitem__()} method. If multiple items are specified, returns a tuple of lookup values. For example:

- After \( f = \text{itemgetter(2)} \), the call \( f(r) \) returns \( r[2] \).
- After \( g = \text{itemgetter(2, 5, 3)} \), the call \( g(r) \) returns \((r[2], r[5], r[3])\).

Equivalent to:

```python
def itemgetter(*items):
```
```python
if len(items) == 1:
    item = items[0]
    def g(obj):
        return obj[item]
else:
    def g(obj):
        return tuple(obj[item] for item in it
return g
```

The items can be any type accepted by the operand's `__getitem__()` method. Dictionaries accept any hashable value. Lists, tuples, and strings accept an index or a slice:

```python
>>> itemgetter(1)('ABCDEFG')
'B'
>>> itemgetter(1,3,5)('ABCDEFG')
('B', 'D', 'F')
>>> itemgetter(slice(2,None))('ABCDEFG')
'CDEFG'
```

Example of using `itemgetter()` to retrieve specific fields from a tuple record:

```python
>>> inventory = [('apple', 3), ('banana', 2), ('pear', 1)]
>>> getcount = itemgetter(1)
>>> list(map(getcount, inventory))
[3, 2, 5, 1]
>>> sorted(inventory, key=getcount)
[('orange', 1), ('banana', 2), ('apple', 3), ('pear', 5)]
```

operator. **methodcaller**(name[, args...])

Return a callable object that calls the method `name` on its operand. If additional arguments and/or keyword arguments are given, they
will be given to the method as well. For example:

- After `f = methodcaller('name')`, the call `f(b)` returns `b.name()`.
- After `f = methodcaller('name', 'foo', bar=1)`, the call `f(b)` returns `b.name('foo', bar=1)

Equivalent to:

```python

def methodcaller(name, *args, **kwargs):
    def caller(obj):
        return getattr(obj, name)(*args, **kwargs)
    return caller
```
10.3.1. Mapping Operators to Functions

This table shows how abstract operations correspond to operator symbols in the Python syntax and the functions in the `operator` module.

<table>
<thead>
<tr>
<th>Operation</th>

</tbody>
</table>
10.3.2. Inplace Operators

Many operations have an “in-place” version. Listed below are functions providing a more primitive access to in-place operators than the usual syntax does; for example, the statement \( x += y \) is equivalent to \( x = \text{operator.iadd}(x, y) \). Another way to put it is to say that \( z = \text{operator.iadd}(x, y) \) is equivalent to the compound statement \( z = x; z += y \).

In those examples, note that when an in-place method is called, the computation and assignment are performed in two separate steps. The in-place functions listed below only do the first step, calling the in-place method. The second step, assignment, is not handled.

For immutable targets such as strings, numbers, and tuples, the updated value is computed, but not assigned back to the input variable:

```python
>>> a = 'hello'
>>> iadd(a, 'world')
'hello world'
>>> a
'hello'
```

For mutable targets such as lists and dictionaries, the inplace method will perform the update, so no subsequent assignment is necessary:

```python
>>> s = ['h', 'e', 'l', 'l', 'o']
>>> iadd(s, [' ', 'w', 'o', 'r', 'l', 'd'])
['h', 'e', 'l', 'l', 'o', ' ', 'w', 'o', 'r', 'l', 'd']
>>> s
['h', 'e', 'l', 'l', 'o', ' ', 'w', 'o', 'r', 'l', 'd']
```
operator. **iadd**(a, b)
operator. **__iadd__**(a, b)
    a = iadd(a, b) is equivalent to a += b.

operator. **iand**(a, b)
operator. **__iand__**(a, b)
    a = iand(a, b) is equivalent to a &= b.

operator. **iconcat**(a, b)
operator. **__iconcat__**(a, b)
    a = iconcat(a, b) is equivalent to a += b for a and b sequences.

operator. **ifloordiv**(a, b)
operator. **__ifloordiv__**(a, b)
    a = ifloordiv(a, b) is equivalent to a //= b.

operator. **ilshift**(a, b)
operator. **__ilshift__**(a, b)
    a = ilshift(a, b) is equivalent to a <<= b.

operator. **imod**(a, b)
operator. **__imod__**(a, b)
    a = imod(a, b) is equivalent to a %= b.

operator. **imul**(a, b)
operator. **__imul__**(a, b)
    a = imul(a, b) is equivalent to a *= b.

operator. **ior**(a, b)
operator. **__ior__**(a, b)
    a = ior(a, b) is equivalent to a |= b.
operator. `ipow(a, b)`
operator. `__ipow__(a, b)`
    a = ipow(a, b) is equivalent to a **= b.

operator. `irshift(a, b)`
operator. `__irshift__(a, b)`
    a = irshift(a, b) is equivalent to a >>= b.

operator. `isub(a, b)`
operator. `__isub__(a, b)`
    a = isub(a, b) is equivalent to a -= b.

operator. `itruediv(a, b)`
operator. `__itruediv__(a, b)`
    a = itruediv(a, b) is equivalent to a /= b.

operator. `ixor(a, b)`
operator. `__ixor__(a, b)`
    a = ixor(a, b) is equivalent to a ^= b.
11. File and Directory Access

The modules described in this chapter deal with disk files and directories. For example, there are modules for reading the properties of files, manipulating paths in a portable way, and creating temporary files. The full list of modules in this chapter is:

- **11.1. pathlib — Object-oriented filesystem paths**
  - 11.1.1. Basic use
  - 11.1.2. Pure paths
    - 11.1.2.1. General properties
    - 11.1.2.2. Operators
    - 11.1.2.3. Accessing individual parts
    - 11.1.2.4. Methods and properties
  - 11.1.3. Concrete paths
    - 11.1.3.1. Methods
- **11.2. os.path — Common pathname manipulations**
- **11.3. fileinput — Iterate over lines from multiple input streams**
- **11.4. stat — Interpreting stat() results**
- **11.5. filecmp — File and Directory Comparisons**
  - 11.5.1. The dircmp class
- **11.6. tempfile — Generate temporary files and directories**
  - 11.6.1. Examples
- **11.7. glob — Unix style pathname pattern expansion**
- **11.8. fnmatch — Unix filename pattern matching**
- **11.9. linecache — Random access to text lines**
- **11.10. shutil — High-level file operations**
  - 11.10.1. Directory and files operations
    - 11.10.1.1. copytree example
  - 11.10.2. Archiving operations
    - 11.10.2.1. Archiving example
  - 11.10.3. Querying the size of the output terminal
11.11. macpath — Mac OS 9 path manipulation functions

See also:

Module os

Operating system interfaces, including functions to work with files at a lower level than Python file objects.

Module io

Python's built-in I/O library, including both abstract classes and some concrete classes such as file I/O.

Built-in function open()

The standard way to open files for reading and writing with Python.
11.1. *pathlib* — Object-oriented filesystem paths

_New in version 3.4._

This module offers classes representing filesystem paths with semantics appropriate for different operating systems. Path classes are divided between _pure paths_, which provide purely computational operations without I/O, and _concrete paths_, which inherit from pure paths but also provide I/O operations.

If you've never used this module before or just aren't sure which class
is right for your task, **Path** is most likely what you need. It instantiates a *concrete path* for the platform the code is running on.

Pure paths are useful in some special cases; for example:

1. If you want to manipulate Windows paths on a Unix machine (or vice versa). You cannot instantiate a **WindowsPath** when running on Unix, but you can instantiate **PureWindowsPath**.
2. You want to make sure that your code only manipulates paths without actually accessing the OS. In this case, instantiating one of the pure classes may be useful since those simply don’t have any OS-accessing operations.

**Note:** This module has been included in the standard library on a *provisional basis*. Backwards incompatible changes (up to and including removal of the package) may occur if deemed necessary by the core developers.

**See also:** [PEP 428](pep428): The pathlib module – object-oriented filesystem paths.

**See also:** For low-level path manipulation on strings, you can also use the **os.path** module.
11.1.1. Basic use

Importing the main class:

```python
>>> from pathlib import Path
```

Listing subdirectories:

```python
>>> p = Path('.
>>> [x for x in p.iterdir() if x.is_dir()]
[PosixPath('.hg'), PosixPath('docs'), PosixPath('dist'),
 PosixPath('__pycache__'), PosixPath('build')]
```

Listing Python source files in this directory tree:

```python
>>> list(p.glob('**/*.py'))
[PosixPath('test_pathlib.py'), PosixPath('setup.py'),
 PosixPath('pathlib.py'), PosixPath('docs/conf.py'),
 PosixPath('build/lib/pathlib.py')]
```

Navigating inside a directory tree:

```python
>>> p = Path('/etc')
>>> q = p / 'init.d' / 'reboot'
>>> q
PosixPath('/etc/init.d/reboot')
>>> q.resolve()
PosixPath('/etc/rc.d/init.d/halt')
```

Querying path properties:

```python
>>> q.exists()
True
```
Opening a file:

```python
>>> with q.open() as f: f.readline()
... '#!/bin/bash
'
11.1.2. Pure paths

Pure path objects provide path-handling operations which don't actually access a filesystem. There are three ways to access these classes, which we also call *flavours*:

```python
class pathlib.PurePath(*pathsegments)
```

A generic class that represents the system's path flavour (instantiating it creates either a `PurePosixPath` or a `PureWindowsPath`):

```python
>>> PurePath('setup.py')  # Running on a Unix
PurePosixPath('setup.py')
```

Each element of `pathsegments` can be either a string or bytes object representing a path segment; it can also be another path object:

```python
>>> PurePath('foo', 'some/path', 'bar')
PurePosixPath('foo/some/path/bar')
>>> PurePath(Path('foo'), Path('bar'))
PurePosixPath('foo/bar')
```

When `pathsegments` is empty, the current directory is assumed:

```python
>>> PurePath()
PurePosixPath('..')
```

When several absolute paths are given, the last is taken as an anchor (mimicking `os.path.join()`'s behaviour):

```python
>>> PurePath('/etc', '/usr', 'lib64')
```
However, in a Windows path, changing the local root doesn't discard the previous drive setting:

```python
g>>> PureWindowsPath('c:/Windows', '/Program Files')
gPureWindowsPath('c:/Program Files')
```

Spurious slashes and single dots are collapsed, but double dots (`'..'`) are not, since this would change the meaning of a path in the face of symbolic links:

```python
g>>> PurePath('foo//bar')
gPurePosixPath('foo/bar')
g>>> PurePath('foo./bar')
gPurePosixPath('foo/bar')
g>>> PurePath('foo../bar')
gPurePosixPath('foo/../bar')
```

(a naïve approach would make
PurePosixPath('foo/../bar') equivalent to
PurePosixPath('bar'), which is wrong if foo is a symbolic link to another directory)

```python
class pathlib.PurePosixPath(*pathsegments)
cA subclass of PurePath, this path flavour represents non-Windows filesystem paths:
```
*pathsegments* is specified similarly to **PurePath**.

```python
class pathlib.PureWindowsPath(*pathsegments)
```

A subclass of **PurePath**, this path flavour represents Windows filesystem paths:

```python
>>> PureWindowsPath('c:/Program Files/')
PureWindowsPath('c:/Program Files')
```

*pathsegments* is specified similarly to **PurePath**.

Regardless of the system you’re running on, you can instantiate all of these classes, since they don’t provide any operation that does system calls.

### 11.1.2.1. General properties

Paths are immutable and hashable. Paths of a same flavour are comparable and orderable. These properties respect the flavour’s case-folding semantics:

```python
>>> PurePosixPath('foo') == PurePosixPath('FOO')
False
>>> PureWindowsPath('foo') == PureWindowsPath('FOO')
True
>>> PureWindowsPath('FOO') in { PureWindowsPath('foo') }
True
>>> PureWindowsPath('C:') < PureWindowsPath('d:')
True
```

Paths of a different flavour compare unequal and cannot be ordered:

```python
>>> PureWindowsPath('foo') == PurePosixPath('foo')
```
11.1.2.2. Operators

The slash operator helps create child paths, similarly to `os.path.join()`:

```python
>>> p = PurePath('/etc')
>>> p
PurePosixPath('/etc')
>>> p / 'init.d' / 'apache2'
PurePosixPath('/etc/init.d/apache2')
>>> q = PurePath('bin')
>>> '/usr' / q
PurePosixPath('/usr/bin')
```

The string representation of a path is the raw filesystem path itself (in native form, e.g. with backslashes under Windows), which you can pass to any function taking a file path as a string:

```python
>>> p = PurePath('/etc')
>>> str(p)
'/etc'
>>> p = PureWindowsPath('c:/Program Files')
>>> str(p)
'c:\Program Files'
```

Similarly, calling `bytes` on a path gives the raw filesystem path as a bytes object, as encoded by `os.fsencode()`:
11.1.2.3. Accessing individual parts

To access the individual “parts” (components) of a path, use the following property:

```
PurePath.parts
```

A tuple giving access to the path’s various components:

```
>>> p = PurePath('/usr/bin/python3')
>>> p.parts
('/', 'usr', 'bin', 'python3')

>>> p = PureWindowsPath('c:/Program Files/PSF')
>>> p.parts
('c:\', 'Program Files', 'PSF')
```

(note how the drive and local root are regrouped in a single part)

11.1.2.4. Methods and properties

Pure paths provide the following methods and properties:

```
PurePath.drive
```

A string representing the drive letter or name, if any:

```
>>> PureWindowsPath('c:/Program Files/').drive
```
UNC shares are also considered drives:

```python
>>> PureWindowsPath('/etc').drive
'c:'
>>> PureWindowsPath('//host/share/foo.txt').drive
'\\\host\\share'
```

**PurePath. root**

A string representing the (local or global) root, if any:

```python
>>> PureWindowsPath('c:/Program Files/').root
'\'
>>> PureWindowsPath('c:Program Files/').root
'\'
>>> PurePosixPath('/etc').root
'/'
```

UNC shares always have a root:

```python
>>> PureWindowsPath('//host/share').root
'\\\host\\share'
```

**PurePath. anchor**

The concatenation of the drive and root:

```python
>>> PureWindowsPath('c:/Program Files/').anchor
'c:\'
>>> PureWindowsPath('c:Program Files/').anchor
'c:\'
>>> PurePosixPath('/etc').anchor
'/'
```
PurePath. **parents**

An immutable sequence providing access to the logical ancestors of the path:

```python
>>> p = PureWindowsPath('c:/foo/bar/setup.py')
>>> p.parents[0]
PureWindowsPath('c:/foo/bar')
>>> p.parents[1]
PureWindowsPath('c:/foo')
>>> p.parents[2]
PureWindowsPath('c:/')
```

PurePath. **parent**

The logical parent of the path:

```python
>>> p = PurePosixPath('/a/b/c/d')
>>> p.parent
PurePosixPath('/a/b/c')
```

You cannot go past an anchor, or empty path:

```python
>>> p = PurePosixPath('/')
>>> p.parent
PurePosixPath('/')
>>> p = PurePosixPath('.')
>>> p.parent
PurePosixPath('.')
```

**Note:** This is a purely lexical operation, hence the following behaviour:

```python
>>> p = PurePosixPath('foo/..')
```
If you want to walk an arbitrary filesystem path upwards, it is recommended to first call `Path.resolve()` so as to resolve symlinks and eliminate ".." components.

**PurePath. name**

A string representing the final path component, excluding the drive and root, if any:

```python
>>> PurePosixPath('my/library/setup.py').name
'setup.py'
```

UNC drive names are not considered:

```python
>>> PureWindowsPath('//some/share/setup.py').name
'setup.py'
>>> PureWindowsPath('//some/share').name
''
```

**PurePath. suffix**

The file extension of the final component, if any:

```python
>>> PurePosixPath('my/library/setup.py').suffix
'.py'
>>> PurePosixPath('my/library.tar.gz').suffix
'.gz'
>>> PurePosixPath('my/library').suffix
''
```

**PurePath. suffixes**

A list of the path's file extensions:
PurePosixPath('my/library.tar.gar').suffixes
['.tar', '.gar']

PurePosixPath('my/library.tar.gz').suffixes
['.tar', '.gz']

PurePosixPath('my/library').suffixes
[]

PurePath.stem
The final path component, without its suffix:

PurePosixPath('my/library.tar.gz').stem
'library.tar'

PurePosixPath('my/library.tar').stem
'library'

PurePosixPath('my/library').stem
'library'

PurePath.as_posix()
Return a string representation of the path with forward slashes (/):

PurePosixPath('my/library.tar.gz').stem
'library.tar'

PurePosixPath('my/library.tar').stem
'library'

PurePosixPath('my/library').stem
'library'

p = PureWindowsPath('c:\windows')
str(p)
'c:\windows'
p.as_posix()
'c:/windows'

PurePath.as_uri()
Represent the path as a file URI. ValueError is raised if the path isn't absolute.

p = PurePosixPath('/etc/passwd')
p.as_uri()
'file:///etc/passwd'
p = PureWindowsPath('c:/Windows')
p.as_uri()
PurePath. **is_absolute()**

Return whether the path is absolute or not. A path is considered absolute if it has both a root and (if the flavour allows) a drive:

```python
>>> PurePosixPath('/a/b').is_absolute()
True
>>> PurePosixPath('a/b').is_absolute()
False
```

```python
>>> PureWindowsPath('c:/a/b').is_absolute()
True
>>> PureWindowsPath('/a/b').is_absolute()
False
>>> PureWindowsPath('c:').is_absolute()
False
>>> PureWindowsPath('//some/share').is_absolute()
True
```

PurePath. **is_reserved()**

With *PureWindowsPath*, return `True` if the path is considered reserved under Windows, `False` otherwise. With *PurePosixPath*, `False` is always returned.

```python
>>> PureWindowsPath('nul').is_reserved()
True
>>> PurePosixPath('nul').is_reserved()
False
```

File system calls on reserved paths can fail mysteriously or have unintended effects.

PurePath. **joinpath(**other)**
Calling this method is equivalent to combining the path with each of the other arguments in turn:

```python
>>> PurePosixPath('/etc').joinpath('passwd')
PurePosixPath('/etc/passwd')
>>> PurePosixPath('/etc').joinpath(PurePosixPath('/etc/passwd'))
>>> PurePosixPath('/etc').joinpath('init.d', 'apache2')
PurePosixPath('/etc/init.d/apache2')
>>> PureWindowsPath('c:').joinpath('/Program Files')
PureWindowsPath('c:/Program Files')
```

**PurePath.match(pattern)**

Match this path against the provided glob-style pattern. Return True if matching is successful, False otherwise.

If pattern is relative, the path can be either relative or absolute, and matching is done from the right:

```python
>>> PurePath('a/b.py').match('*.py')
True
>>> PurePath('/a/b/c.py').match('b/*.*')
True
>>> PurePath('/a/b/c.py').match('a/*.*')
False
```

If pattern is absolute, the path must be absolute, and the whole path must match:

```python
>>> PurePath('/a.py').match('/.*.*')
True
>>> PurePath('a/b.py').match('/.*.*')
False
```
As with other methods, case-sensitivity is observed:

```python
>>> PureWindowsPath('b.py').match('*.PY')
True
```

**PurePath. `relative_to`(*other)**

Compute a version of this path relative to the path represented by `other`. If it’s impossible, `ValueError` is raised:

```python
>>> p = PurePosixPath('/etc/passwd')
>>> p.relative_to('/')
PurePosixPath('etc/passwd')
>>> p.relative_to('/etc')
PurePosixPath('passwd')
>>> p.relative_to('/usr')
Traceback (most recent call last):
  File "<stdin>", line 1, in <module>
  File "pathlib.py", line 694, in relative_to
    .format(str(self), str(formatted)))
ValueError: '/etc/passwd' does not start with '/usr'
```

**PurePath. `with_name`(*name)**

Return a new path with the `name` changed. If the original path doesn’t have a name, `ValueError` is raised:

```python
>>> p = PureWindowsPath('c:/Downloads/pathlib.tar.gz')
>>> p.with_name('setup.py')
PureWindowsPath('c:/Downloads/setup.py')
>>> p = PureWindowsPath('c:/')
>>> p.with_name('setup.py')
Traceback (most recent call last):
  File "<stdin>", line 1, in <module>
  File "/home/antoine/cpython/default/Lib/pathlib.py", line 658, in with_name
    raise ValueError("%r has an empty name" % (self
```
ValueError: PureWindowsPath('c:/') has an empty name.

PurePath. `with_suffix(suffix)`

Return a new path with the `suffix` changed. If the original path doesn’t have a suffix, the new `suffix` is appended instead:

```python
>>> p = PureWindowsPath('c:/Downloads/pathlib.tar.gz')
>>> p.with_suffix('.bz2')
PureWindowsPath('c:/Downloads/pathlib.tar.bz2')
>>> p = PureWindowsPath('README')
>>> p.with_suffix('.txt')
PureWindowsPath('README.txt')
```
11.1.3. Concrete paths

Concrete paths are subclasses of the pure path classes. In addition to operations provided by the latter, they also provide methods to do system calls on path objects. There are three ways to instantiate concrete paths:

*class* *pathlib.*\ **Path(** \*pathsegments\ **)**

A subclass of *PurePath*, this class represents concrete paths of the system's path flavour (instantiating it creates either a *PosixPath* or a *WindowsPath*):

```python
>>> Path('setup.py')
PosixPath('setup.py')
```

*pathsegments* is specified similarly to *PurePath*.

*class* *pathlib.*\ **PosixPath(** \*pathsegments\ **)**

A subclass of *Path* and *PurePosixPath*, this class represents concrete non-Windows filesystem paths:

```python
>>> PosixPath('/etc')
PosixPath('/etc')
```

*pathsegments* is specified similarly to *PurePath*.

*class* *pathlib.*\ **WindowsPath(** \*pathsegments\ **)**

A subclass of *Path* and *PureWindowsPath*, this class represents concrete Windows filesystem paths:

```python
>>> WindowsPath('c:/Program Files/')
WindowsPath('c:/Program Files')
```
*pathsegments* is specified similarly to *PurePath*.

You can only instantiate the class flavour that corresponds to your system (allowing system calls on non-compatible path flavours could lead to bugs or failures in your application):

```python
>>> import os
>>> os.name
'posix'
>>> Path('setup.py')
PosixPath('setup.py')
>>> PosixPath('setup.py')
PosixPath('setup.py')
>>> WindowsPath('setup.py')
Traceback (most recent call last):
  File "<stdin>", line 1, in <module>
  File "pathlib.py", line 798, in __new__
    % (cls.__name__,))
NotImplementedError: cannot instantiate 'WindowsPath'
```

### 11.1.3.1. Methods

Concrete paths provide the following methods in addition to pure paths methods. Many of these methods can raise an *OSError* if a system call fails (for example because the path doesn't exist):

**classmethod** *Path.cwd()*

Return a new path object representing the current directory (as returned by *os.getcwd()*):

```python
>>> Path.cwd()
PosixPath('/home/antoine/pathlib')
```
Path. **stat()**
Return information about this path (similarly to os.stat()). The result is looked up at each call to this method.

```python
>>> p = Path('setup.py')
>>> p.stat().st_size
956
>>> p.stat().st_mtime
1327883547.852554
```

Path. **chmod(mode)**
Change the file mode and permissions, like os.chmod():

```python
>>> p = Path('setup.py')
>>> p.stat().st_mode
33277
>>> p.chmod(0o444)
>>> p.stat().st_mode
33060
```

Path. **exists()**
Whether the path points to an existing file or directory:

```python
c>> Path('.').exists()
True
c>> Path('setup.py').exists()
True
c>> Path('/etc').exists()
True
c>> Path('nonexistentfile').exists()
False
```

**Note:** If the path points to a symlink, exists() returns whether the symlink points to an existing file or directory.
Path. **glob**(*pattern*)

Glob the given *pattern* in the directory represented by this path, yielding all matching files (of any kind):

```python
>>> sorted(Path('.').glob('*.py'))
[PosixPath('pathlib.py'), PosixPath('setup.py'),
>>> sorted(Path('.').glob('*/*.py'))
[PosixPath('docs/conf.py')]
```

The "**" pattern means “this directory and all subdirectories, recursively”. In other words, it enables recursive globbing:

```python
>>> sorted(Path('.').glob('*//*.py'))
[PosixPath('build/lib/pathlib.py'),
 PosixPath('docs/conf.py'),
 PosixPath('pathlib.py'),
 PosixPath('setup.py'),
 PosixPath('test_pathlib.py')]
```

**Note:** Using the "**" pattern in large directory trees may consume an inordinate amount of time.

Path. **group**()

Return the name of the group owning the file. **KeyError** is raised if the file's gid isn't found in the system database.

Path. **is_dir**()

Return `True` if the path points to a directory (or a symbolic link pointing to a directory), `False` if it points to another kind of file.

`False` is also returned if the path doesn't exist or is a broken symlink; other errors (such as permission errors) are propagated.
Path. `is_file()`
Return `True` if the path points to a regular file (or a symbolic link pointing to a regular file), `False` if it points to another kind of file.

`False` is also returned if the path doesn’t exist or is a broken symlink; other errors (such as permission errors) are propagated.

Path. `is_symlink()`
Return `True` if the path points to a symbolic link, `False` otherwise.

`False` is also returned if the path doesn’t exist; other errors (such as permission errors) are propagated.

Path. `is_socket()`
Return `True` if the path points to a Unix socket (or a symbolic link pointing to a Unix socket), `False` if it points to another kind of file.

`False` is also returned if the path doesn’t exist or is a broken symlink; other errors (such as permission errors) are propagated.

Path. `is_fifo()`
Return `True` if the path points to a FIFO (or a symbolic link pointing to a FIFO), `False` if it points to another kind of file.

`False` is also returned if the path doesn’t exist or is a broken symlink; other errors (such as permission errors) are propagated.

Path. `is_block_device()`
Return `True` if the path points to a block device (or a symbolic link pointing to a block device), `False` if it points to another kind of file.

`False` is also returned if the path doesn’t exist or is a broken symlink; other errors (such as permission errors) are propagated.
Path. **is_char_device()**

Return `True` if the path points to a character device (or a symbolic link pointing to a character device), `False` if it points to another kind of file.

`False` is also returned if the path doesn't exist or is a broken symlink; other errors (such as permission errors) are propagated.

Path. **iterdir()**

When the path points to a directory, yield path objects of the directory contents:

```python
>>> p = Path('docs')
>>> for child in p.iterdir(): child
...
PosixPath('docs/conf.py')
PosixPath('docs/_templates')
PosixPath('docs/make.bat')
PosixPath('docs/index.rst')
PosixPath('docs/_build')
PosixPath('docs/_static')
PosixPath('docs/Makefile')
```

Path. **lchmod(mode)**

Like `Path.chmod()` but, if the path points to a symbolic link, the symbolic link's mode is changed rather than its target's.

Path. **lstat()**

Like `Path.stat()` but, if the path points to a symbolic link, return the symbolic link's information rather than its target's.

Path. **mkdir(mode=0o777, parents=False)**

Create a new directory at this given path. If `mode` is given, it is
combined with the process' `umask` value to determine the file mode and access flags. If the path already exists, `FileExistsError` is raised.

If `parents` is true, any missing parents of this path are created as needed; they are created with the default permissions without taking `mode` into account (mimicking the POSIX `mkdir -p` command).

If `parents` is false (the default), a missing parent raises `FileNotFoundError`.

Path. `open(mode='r', buffering=-1, encoding=None, errors=None, newline=None)`

Open the file pointed to by the path, like the built-in `open()` function does:

```python
>>> p = Path('setup.py')
>>> with p.open() as f:
...     f.readline()
... '#!/usr/bin/env python3
```

Path. `owner()`

Return the name of the user owning the file. `KeyError` is raised if the file's uid isn't found in the system database.

Path. `rename(target)`

Rename this file or directory to the given `target`. `target` can be either a string or another path object:

```python
>>> p = Path('foo')
>>> p.open('w').write('some text')
```
>>> target = Path('bar')
>>> p.rename(target)
>>> target.open().read()
'some text'

Path. **replace**(*target*)

Rename this file or directory to the given *target*. If *target* points to an existing file or directory, it will be unconditionally replaced.

Path. **resolve**()

Make the path absolute, resolving any symlinks. A new path object is returned:

```python
>>> p = Path()
>>> p
PosixPath('.
')
>>> p.resolve()
PosixPath('/home/antoine/pathlib')
```

".." components are also eliminated (this is the only method to do so):

```python
>>> p = Path('docs/../setup.py')
>>> p.resolve()
PosixPath('/home/antoine/pathlib/setup.py')
```

If the path doesn't exist, **FileNotFoundError** is raised. If an infinite loop is encountered along the resolution path, **RuntimeError** is raised.

Path. **rglob**(pattern)

This is like calling **glob()** with "**" added in front of the given pattern:
```python
g++ -std=c++11 -Wall -I pathlib -o build/opathlib.py build/opathlib.py
```

```
[PosixPath('build/lib/pathlib.py'),
 PosixPath('docs/conf.py'),
 PosixPath('pathlib.py'),
 PosixPath('setup.py'),
 PosixPath('test_pathlib.py')]
```

Path. `rmdir()`
Remove this directory. The directory must be empty.

Path. `symlink_to(target, target_is_directory=False)`
Make this path a symbolic link to `target`. Under Windows, `target_is_directory` must be true (default False) if the link’s target is a directory. Under POSIX, `target_is_directory`'s value is ignored.

```python
>>> p = Path('mylink')
>>> p.symlink_to('setup.py')
>>> p.resolve()  
PosixPath('/home/antoine/pathlib/setup.py')
>>> p.stat().st_size
956
>>> p.lstat().st_size
8
```

**Note:** The order of arguments (link, target) is the reverse of `os.symlink()`'s.

Path. `touch(mode=0o777, exist_ok=True)`
Create a file at this given path. If `mode` is given, it is combined with the process’ `umask` value to determine the file mode and access flags. If the file already exists, the function succeeds if `exist_ok` is true (and its modification time is updated to the current time), otherwise `FileExistsError` is raised.
Path.**unlink()**

Remove this file or symbolic link. If the path points to a directory, use **Path.rmdir()** instead.
11.2. **os.path** — Common pathname manipulations

This module implements some useful functions on pathnames. To read or write files see `open()`, and for accessing the filesystem see the `os` module. The path parameters can be passed as either strings, or bytes. Applications are encouraged to represent file names as (Unicode) character strings. Unfortunately, some file names may not be representable as strings on Unix, so applications that need to support arbitrary file names on Unix should use bytes objects to represent path names. Vice versa, using bytes objects cannot represent all file names on Windows (in the standard mbcs encoding), hence Windows applications should use string objects to access all files.

Unlike a unix shell, Python does not do any automatic path expansions. Functions such as `expanduser()` and `expandvars()` can be invoked explicitly when an application desires shell-like path expansion. (See also the `glob` module.)

**See also:** The `pathlib` module offers high-level path objects.

**Note:** All of these functions accept either only bytes or only string objects as their parameters. The result is an object of the same type, if a path or file name is returned.

**Note:** Since different operating systems have different path name conventions, there are several versions of this module in the standard library. The `os.path` module is always the path module suitable for the operating system Python is running on, and therefore...
usable for local paths. However, you can also import and use the individual modules if you want to manipulate a path that is always in one of the different formats. They all have the same interface:

- **posixpath** for UNIX-style paths
- **ntpath** for Windows paths
- **macpath** for old-style MacOS paths

**os.path.abspath**(*path*)

Return a normalized absolutized version of the pathname *path*. On most platforms, this is equivalent to calling the function `normpath()` as follows: `normpath(join(os.getcwd(), path))`.

**os.path.basename**(*path*)

Return the base name of pathname *path*. This is the second element of the pair returned by passing *path* to the function `split()`. Note that the result of this function is different from the Unix `basename` program; where `basename` for `/foo/bar/` returns `bar`, the `basename()` function returns an empty string (`''`).

**os.path.commonprefix**(*list*)

Return the longest path prefix (taken character-by-character) that is a prefix of all paths in *list*. If *list* is empty, return the empty string (`''`). Note that this may return invalid paths because it works a character at a time.

**os.path.dirname**(*path*)

Return the directory name of pathname *path*. This is the first element of the pair returned by passing *path* to the function
split().

**os.path.exists(path)**

Return True if *path* refers to an existing path or an open file descriptor. Returns False for broken symbolic links. On some platforms, this function may return False if permission is not granted to execute `os.stat()` on the requested file, even if the *path* physically exists.

*Changed in version 3.3:* *path* can now be an integer: True is returned if it is an open file descriptor, False otherwise.

**os.path.lexists(path)**

Return True if *path* refers to an existing path. Returns True for broken symbolic links. Equivalent to `exists()` on platforms lacking `os.lstat()`.

**os.path.expanduser(path)**

On Unix and Windows, return the argument with an initial component of ~ or ~user replaced by that user’s home directory.

On Unix, an initial ~ is replaced by the environment variable HOME if it is set; otherwise the current user’s home directory is looked up in the password directory through the built-in module `pwd`. An initial ~user is looked up directly in the password directory.

On Windows, HOME and USERPROFILE will be used if set, otherwise a combination of HOMEPATH and HOMEDRIVE will be used. An initial ~user is handled by stripping the last directory component from the created user path derived above.

If the expansion fails or if the path does not begin with a tilde, the
path is returned unchanged.

**os.path.expandvars(path)**

Return the argument with environment variables expanded. Substrings of the form $\text{name}$ or ${\text{name}}$ are replaced by the value of environment variable \text{name}. Malformed variable names and references to non-existing variables are left unchanged.

On Windows, \%name\% expansions are supported in addition to $\text{name}$ and ${\text{name}}$.

**os.path.getatime(path)**

Return the time of last access of \text{path}. The return value is a number giving the number of seconds since the epoch (see the \text{time} module). Raise \text{OSError} if the file does not exist or is inaccessible.

If \text{os.stat_float_times()} returns \text{True}, the result is a floating point number.

**os.path.getmtime(path)**

Return the time of last modification of \text{path}. The return value is a number giving the number of seconds since the epoch (see the \text{time} module). Raise \text{OSError} if the file does not exist or is inaccessible.

If \text{os.stat_float_times()} returns \text{True}, the result is a floating point number.

**os.path.getctime(path)**

Return the system's ctime which, on some systems (like Unix) is the time of the last metadata change, and, on others (like Windows), is the creation time for \text{path}. The return value is a
number giving the number of seconds since the epoch (see the `time` module). Raise `OSError` if the file does not exist or is inaccessible.

```python
os.path.getsize(path)
```
Return the size, in bytes, of `path`. Raise `OSError` if the file does not exist or is inaccessible.

```python
os.path.isabs(path)
```
Return `True` if `path` is an absolute pathname. On Unix, that means it begins with a slash, on Windows that it begins with a (back)slash after chopping off a potential drive letter.

```python
os.path.isfile(path)
```
Return `True` if `path` is an existing regular file. This follows symbolic links, so both `islink()` and `isfile()` can be true for the same path.

```python
os.path.isdir(path)
```
Return `True` if `path` is an existing directory. This follows symbolic links, so both `islink()` and `isdir()` can be true for the same path.

```python
os.path.islink(path)
```
Return `True` if `path` refers to a directory entry that is a symbolic link. Always `False` if symbolic links are not supported.

```python
os.path.ismount(path)
```
Return `True` if pathname `path` is a mount point: a point in a file system where a different file system has been mounted. On POSIX, the function checks whether `path`'s parent, `path/..`, is on a different device than `path`, or whether `path/..` and `path` point to
the same i-node on the same device — this should detect mount points for all Unix and POSIX variants. On Windows, a drive letter root and a share UNC are always mount points, and for any other path `GetVolumePathName` is called to see if it is different from the input path.

*New in version 3.4:* Support for detecting non-root mount points on Windows.

```python
os.path.join(path1[, path2[, ...]])
```

Join one or more path components intelligently. If any component is an absolute path, all previous components (on Windows, including the previous drive letter, if there was one) are thrown away, and joining continues. The return value is the concatenation of `path1`, and optionally `path2`, etc., with exactly one directory separator (`os.sep`) following each non-empty part except the last. (This means that an empty last part will result in a path that ends with a separator.) Note that on Windows, since there is a current directory for each drive, `os.path.join("c:", "foo")` represents a path relative to the current directory on drive C: (`c:foo`), not `c:\foo`.

```python
os.path.normcase(path)
```

Normalize the case of a pathname. On Unix and Mac OS X, this returns the path unchanged; on case-insensitive filesystems, it converts the path to lowercase. On Windows, it also converts forward slashes to backward slashes. Raise a `TypeError` if the type of `path` is not `str` or `bytes`.

```python
os.path.normpath(path)
```

Normalize a pathname by collapsing redundant separators and up-level references so that `A///B`, `A/B/`, `A/..B` and `A/foo/././/B` all become `A/B`. This string manipulation may change the meaning of
a path that contains symbolic links. On Windows, it converts forward slashes to backward slashes. To normalize case, use `normcase()`.

**os.path.realpath(path)**

Return the canonical path of the specified filename, eliminating any symbolic links encountered in the path (if they are supported by the operating system).

**os.path.relpath(path, start=None)**

Return a relative filepath to `path` either from the current directory or from an optional `start` directory. This is a path computation: the filesystem is not accessed to confirm the existence or nature of `path` or `start`.

`start` defaults to `os.curdir`.

Availability: Unix, Windows.

**os.path.samefile(path1, path2)**

Return `True` if both pathname arguments refer to the same file or directory. This is determined by the device number and i-node number and raises an exception if a `os.stat()` call on either pathname fails.

Availability: Unix, Windows.

*Changed in version 3.2:* Added Windows support.

*Changed in version 3.4:* Windows now uses the same implementation as all other platforms.

**os.path.sameopenfile(fp1, fp2)**
Return \texttt{True} if the file descriptors \texttt{fp1} and \texttt{fp2} refer to the same file.

Availability: Unix, Windows.

\textit{Changed in version 3.2: Added Windows support.}

\texttt{os.path\texttt{.\ samestat(stat1, stat2)}}

Return \texttt{True} if the stat tuples \texttt{stat1} and \texttt{stat2} refer to the same file. These structures may have been returned by \texttt{os.fstat()}, \texttt{os.lstat()}, or \texttt{os.stat()}. This function implements the underlying comparison used by \texttt{samefile()} and \texttt{sameopenfile()}.

Availability: Unix, Windows.

\textit{Changed in version 3.4: Added Windows support.}

\texttt{os.path\texttt{.\ split(path)}}

Split the pathname \texttt{path} into a pair, (\texttt{head}, \texttt{tail}) where \texttt{tail} is the last pathname component and \texttt{head} is everything leading up to that. The \texttt{tail} part will never contain a slash; if \texttt{path} ends in a slash, \texttt{tail} will be empty. If there is no slash in \texttt{path}, \texttt{head} will be empty. If \texttt{path} is empty, both \texttt{head} and \texttt{tail} are empty. Trailing slashes are stripped from \texttt{head} unless it is the root (one or more slashes only). In all cases, \texttt{join(head, tail)} returns a path to the same location as \texttt{path} (but the strings may differ). Also see the functions \texttt{dirname()} and \texttt{basename()}.

\texttt{os.path\texttt{.\ splitdrive(path)}}

Split the pathname \texttt{path} into a pair (\texttt{drive}, \texttt{tail}) where \texttt{drive} is either a mount point or the empty string. On systems which do not use drive specifications, \texttt{drive} will always be the empty string.
In all cases, drive + tail will be the same as path.

On Windows, splits a pathname into drive/UNC sharepoint and relative path.

If the path contains a drive letter, drive will contain everything up to and including the colon. e.g. splitdrive("c:/dir") returns ("c:", "/dir")

If the path contains a UNC path, drive will contain the host name and share, up to but not including the fourth separator. e.g. splitdrive("//host/computer/dir") returns ("//host/computer", "/dir")

os.path.splitext(path)
Split the pathname path into a pair (root, ext) such that root + ext == path, and ext is empty or begins with a period and contains at most one period. Leading periods on the basename are ignored; splitext('.cshrc') returns ('.cshrc', '')

os.path.splitunc(path)
*Deprecated since version 3.1: Use splitdrive instead.*
Split the pathname path into a pair (unc, rest) so that unc is the UNC mount point (such as r'\host\mount'), if present, and rest the rest of the path (such as r'\path\file.ext'). For paths containing drive letters, unc will always be the empty string.

Availability: Windows.

os.path.supports_unicode_filenames
True if arbitrary Unicode strings can be used as file names (within limitations imposed by the file system).
11.3. **fileinput** — Iterate over lines from multiple input streams

**Source code:** Lib/fileinput.py

This module implements a helper class and functions to quickly write a loop over standard input or a list of files. If you just want to read or write one file see `open()`.

The typical use is:

```python
import fileinput
for line in fileinput.input():
    process(line)
```

This iterates over the lines of all files listed in `sys.argv[1:]`, defaulting to `sys.stdin` if the list is empty. If a filename is `'-'`, it is also replaced by `sys.stdin`. To specify an alternative list of filenames, pass it as the first argument to `input()`. A single file name is also allowed.

All files are opened in text mode by default, but you can override this by specifying the `mode` parameter in the call to `input()` or `FileInput`. If an I/O error occurs during opening or reading a file, `OSError` is raised.

*Changed in version 3.3:* `IOError` used to be raised; it is now an alias of `OSError`.

If `sys.stdin` is used more than once, the second and further use will
return no lines, except perhaps for interactive use, or if it has been explicitly reset (e.g. using `sys.stdin.seek(0)`).

Empty files are opened and immediately closed; the only time their presence in the list of filenames is noticeable at all is when the last file opened is empty.

Lines are returned with any newlines intact, which means that the last line in a file may not have one.

You can control how files are opened by providing an opening hook via the `openhook` parameter to `fileinput.input()` or `FileInput()`. The hook must be a function that takes two arguments, `filename` and `mode`, and returns an accordingly opened file-like object. Two useful hooks are already provided by this module.

The following function is the primary interface of this module:

```python
fileinput.input(files=None, inplace=False, backup='', bufsize=0, mode='r', openhook=None)
```

Create an instance of the `FileInput` class. The instance will be used as global state for the functions of this module, and is also returned to use during iteration. The parameters to this function will be passed along to the constructor of the `FileInput` class.

The `FileInput` instance can be used as a context manager in the `with` statement. In this example, `input` is closed after the `with` statement is exited, even if an exception occurs:
Changed in version 3.2: Can be used as a context manager.

The following functions use the global state created by `fileinput.input()`; if there is no active state, `RuntimeError` is raised.

`fileinput.filename()`
Return the name of the file currently being read. Before the first line has been read, returns `None`.

`fileinput.fileno()`
Return the integer “file descriptor” for the current file. When no file is opened (before the first line and between files), returns `-1`.

`fileinput.lineno()`
Return the cumulative line number of the line that has just been read. Before the first line has been read, returns `0`. After the last line of the last file has been read, returns the line number of that line.

`fileinput.filelineno()`
Return the line number in the current file. Before the first line has been read, returns `0`. After the last line of the last file has been read, returns the line number of that line within the file.

`fileinput.isfirstline()`
Returns true if the line just read is the first line of its file, otherwise returns false.

`fileinput.isstdin()`
Returns true if the last line was read from `sys.stdin`, otherwise returns false.
fileinput.nextfile()

Close the current file so that the next iteration will read the first line from the next file (if any); lines not read from the file will not count towards the cumulative line count. The filename is not changed until after the first line of the next file has been read. Before the first line has been read, this function has no effect; it cannot be used to skip the first file. After the last line of the last file has been read, this function has no effect.

fileinput.close()

Close the sequence.

The class which implements the sequence behavior provided by the module is available for subclassing as well:

class fileinput.FileInput(files=None, inplace=False, backup='', bufsize=0, mode='r', openhook=None)

Class FileInput is the implementation; its methods filename(), fileno(), lineno(), filelineno(), isfirstline(), isstdin(), nextfile() and close() correspond to the functions of the same name in the module. In addition it has a readline() method which returns the next input line, and a __getitem__() method which implements the sequence behavior. The sequence must be accessed in strictly sequential order; random access and readline() cannot be mixed.

With mode you can specify which file mode will be passed to open(). It must be one of 'r', 'rU', 'U' and 'rb'.

The openhook, when given, must be a function that takes two arguments, filename and mode, and returns an accordingly opened
file-like object. You cannot use `inplace` and `openhook` together.

A `FileInput` instance can be used as a context manager in the `with` statement. In this example, `input` is closed after the `with` statement is exited, even if an exception occurs:

```python
with FileInput(files=('spam.txt', 'eggs.txt')) as process(input)
```

*Changed in version 3.2:* Can be used as a context manager.

*Deprecated since version 3.4:* The `rU` and `U` modes.

**Optional in-place filtering:** if the keyword argument `inplace=True` is passed to `fileinput.input()` or to the `FileInput` constructor, the file is moved to a backup file and standard output is directed to the input file (if a file of the same name as the backup file already exists, it will be replaced silently). This makes it possible to write a filter that rewrites its input file in place. If the `backup` parameter is given (typically as `backup='.<some extension>'`), it specifies the extension for the backup file, and the backup file remains around; by default, the extension is `'.bak'` and it is deleted when the output file is closed. In-place filtering is disabled when standard input is read.

The two following opening hooks are provided by this module:

```python
fileinput.hook_compressed(filename, mode)
```

  Transparently opens files compressed with gzip and bzip2 (recognized by the extensions `'.gz'` and `'.bz2'`) using the `gzip` and `bz2` modules. If the filename extension is not `'.gz'` or `'.bz2'`, the file is opened normally (ie, using `open()` without any decompression).
Usage example: `fi = fileinput.FileInput(openhook=fileinput.hook_compressed)`

`fileinput.hook_encoded(encoding)`

Returns a hook which opens each file with `codecs.open()`, using the given `encoding` to read the file.

Usage example: `fi = fileinput.FileInput(openhook=fileinput.hook_encoded('iso-8859-1'))`
11.4. `stat` — Interpreting `stat()` results

**Source code:** Modules/_stat.c
Lib/stat.py

The `stat` module defines constants and functions for interpreting the results of `os.stat()`, `os.fstat()` and `os.lstat()` (if they exist). For complete details about the `stat()`, `fstat()` and `lstat()` calls, consult the documentation for your system.

*Changed in version 3.4:* The stat module is backed by a C implementation.

The `stat` module defines the following functions to test for specific file types:

- `stat.S_ISDIR(mode)`
  Return non-zero if the mode is from a directory.

- `stat.S_ISCHR(mode)`
  Return non-zero if the mode is from a character special device file.

- `stat.S_ISBLK(mode)`
  Return non-zero if the mode is from a block special device file.

- `stat.S_ISREG(mode)`
  Return non-zero if the mode is from a regular file.

- `stat.S_ISFIFO(mode)`
Return non-zero if the mode is from a FIFO (named pipe).

\texttt{stat.S_ISLNK(mode)}

Return non-zero if the mode is from a symbolic link.

\texttt{stat.S_ISSOCK(mode)}

Return non-zero if the mode is from a socket.

\texttt{stat.S_ISDOOR(mode)}

Return non-zero if the mode is from a door.

\textit{New in version 3.4.}

\texttt{stat.S_ISPORT(mode)}

Return non-zero if the mode is from an event port.

\textit{New in version 3.4.}

\texttt{stat.S_ISWHT(mode)}

Return non-zero if the mode is from a whiteout.

\textit{New in version 3.4.}

Two additional functions are defined for more general manipulation of the file's mode:

\texttt{stat.S_IMODE(mode)}

Return the portion of the file's mode that can be set by \texttt{os.chmod()}—that is, the file's permission bits, plus the sticky bit, set-group-id, and set-user-id bits (on systems that support them).

\texttt{stat.S_IFMT(mode)}

Return the portion of the file's mode that describes the file type (used by the \texttt{S_IS*()} functions above).
Normally, you would use the `os.path.is*()` functions for testing the type of a file; the functions here are useful when you are doing multiple tests of the same file and wish to avoid the overhead of the `stat()` system call for each test. These are also useful when checking for information about a file that isn’t handled by `os.path`, like the tests for block and character devices.

Example:

```python
import os, sys
from stat import *

def walktree(top, callback):
    '''recursively descend the directory tree rooted at top, calling the callback function for each regular file.'''
    for f in os.listdir(top):
        pathname = os.path.join(top, f)
        mode = os.stat(pathname).st_mode
        if S_ISDIR(mode):
            # It's a directory, recurse into it
            walktree(pathname, callback)
        elif S_ISREG(mode):
            # It's a file, call the callback function
            callback(pathname)
        else:
            # Unknown file type, print a message
            print('Skipping %s' % pathname)

def visitfile(file):
    print('visiting', file)

if __name__ == '__main__':
    walktree(sys.argv[1], visitfile)
```
An additional utility function is provided to convert a file's mode in a human readable string:

```python
stat.filemode(mode)
```

Convert a file's mode to a string of the form `-rwxrwxrwx'.

*New in version 3.3.*

*Changed in version 3.4:* The function supports `S_IFDOOR`, `S_IFPORT` and `S_IFWHT`.

All the variables below are simply symbolic indexes into the 10-tuple returned by `os.stat()`, `os.fstat()` or `os.lstat()`.

```python
stat.ST_MODE
```

Inode protection mode.

```python
stat.ST_INO
```

Inode number.

```python
stat.ST_DEV
```

Device inode resides on.

```python
stat.ST_NLINK
```

Number of links to the inode.

```python
stat.ST_UID
```

User id of the owner.

```python
stat.ST_GID
```

Group id of the owner.

```python
stat.ST_SIZE
```

Size in bytes of a plain file; amount of data waiting on some special
files.

stat.ST_ATIME
   Time of last access.

stat.ST_MTIME
   Time of last modification.

stat.ST_CTIME
   The “ctime” as reported by the operating system. On some systems (like Unix) is the time of the last metadata change, and, on others (like Windows), is the creation time (see platform documentation for details).

The interpretation of “file size” changes according to the file type. For plain files this is the size of the file in bytes. For FIFOs and sockets under most flavors of Unix (including Linux in particular), the “size” is the number of bytes waiting to be read at the time of the call to os.stat(), os.fstat(), or os.lstat(); this can sometimes be useful, especially for polling one of these special files after a non-blocking open. The meaning of the size field for other character and block devices varies more, depending on the implementation of the underlying system call.

The variables below define the flags used in the ST_MODE field.

Use of the functions above is more portable than use of the first set of flags:

stat.S_IFSOCK
   Socket.

stat.S_IFLNK
Symbolic link.

stat.\texttt{S\_IFREG}
Regular file.

stat.\texttt{S\_IFBLK}
Block device.

stat.\texttt{S\_IFDIR}
Directory.

stat.\texttt{S\_IFCHR}
Character device.

stat.\texttt{S\_IFIFO}
FIFO.

stat.\texttt{S\_IFDOOR}
Door.

\textit{New in version 3.4.}

stat.\texttt{S\_IFPORT}
Event port.

\textit{New in version 3.4.}

stat.\texttt{S\_IFWHT}
Whiteout.

\textit{New in version 3.4.}

\textbf{Note:} \texttt{S\_IFDOOR}, \texttt{S\_IFPORT} or \texttt{S\_IFWHT} are defined as 0 when the platform does not have support for the file types.
The following flags can also be used in the *mode* argument of `os.chmod()`:

```c
stat.S_ISUID
    Set UID bit.

stat.S_ISGID
    Set-group-ID bit. This bit has several special uses. For a directory it indicates that BSD semantics is to be used for that directory: files created there inherit their group ID from the directory, not from the effective group ID of the creating process, and directories created there will also get the S_ISGID bit set. For a file that does not have the group execution bit (S_IXGRP) set, the set-group-ID bit indicates mandatory file/record locking (see also S_ENFMT).

stat.S_ISVTX
    Sticky bit. When this bit is set on a directory it means that a file in that directory can be renamed or deleted only by the owner of the file, by the owner of the directory, or by a privileged process.

stat.S_IRWXU
    Mask for file owner permissions.

stat.S_IRUSR
    Owner has read permission.

stat.S_IWUSR
    Owner has write permission.

stat.S_IXUSR
    Owner has execute permission.

stat.S_IRWXG
```
Mask for group permissions.

```
stat.S_IRGRP
Group has read permission.
```

```
stat.S_IWGRP
Group has write permission.
```

```
stat.S_IXGRP
Group has execute permission.
```

```
stat.S_IRWXO
Mask for permissions for others (not in group).
```

```
stat.S_IROTH
Others have read permission.
```

```
stat.S_IWOTH
Others have write permission.
```

```
stat.S_IXOTH
Others have execute permission.
```

```
stat.S_ENFMT
System V file locking enforcement. This flag is shared with S_ISGID: file/record locking is enforced on files that do not have the group execution bit (S_IXGRP) set.
```

```
stat.S_IREAD
Unix V7 synonym for S_IRUSR.
```

```
stat.S_IWRITE
Unix V7 synonym for S_IWUSR.
```
**stat. S_IEXEC**
Unix V7 synonym for `S_IXUSR`.

The following flags can be used in the **flags** argument of `os.chflags()`:

**stat. UF_NODUMP**
Do not dump the file.

**stat. UF_IMMUTABLE**
The file may not be changed.

**stat. UF_APPEND**
The file may only be appended to.

**stat. UF_OPAQUE**
The directory is opaque when viewed through a union stack.

**stat. UF_NOUNLINK**
The file may not be renamed or deleted.

**stat. UF_COMPRESSED**
The file is stored compressed (Mac OS X 10.6+).

**stat. UF_HIDDEN**
The file should not be displayed in a GUI (Mac OS X 10.5+).

**stat. SF_ARCHIVED**
The file may be archived.

**stat. SF_IMMUTABLE**
The file may not be changed.

**stat. SF_APPEND**
The file may only be appended to.

```
stat.SF_NOUNLINK
```

The file may not be renamed or deleted.

```
stat.SF_SNAPSHOT
```

The file is a snapshot file.

See the *BSD or Mac OS systems man page `chflags(2)` for more information.
11.5. `filecmp` — File and Directory Comparisons

Source code: `Lib/filecmp.py`

The `filecmp` module defines functions to compare files and directories, with various optional time/correctness trade-offs. For comparing files, see also the `difflib` module.

The `filecmp` module defines the following functions:

`filecmp.cmp(f1, f2, shallow=True)`

Compare the files named `f1` and `f2`, returning `True` if they seem equal, `False` otherwise.

If `shallow` is true, files with identical `os.stat()` signatures are taken to be equal. Otherwise, the contents of the files are compared.

Note that no external programs are called from this function, giving it portability and efficiency.

This function uses a cache for past comparisons and the results, with cache entries invalidated if the `os.stat()` information for the file changes. The entire cache may be cleared using `clear_cache()`.

`filecmp.cmpfiles(dir1, dir2, common, shallow=True)`

Compare the files in the two directories `dir1` and `dir2` whose names are given by `common`. 
Returns three lists of file names: `match`, `mismatch`, `errors`. `match` contains the list of files that match, `mismatch` contains the names of those that don't, and `errors` lists the names of files which could not be compared. Files are listed in `errors` if they don't exist in one of the directories, the user lacks permission to read them or if the comparison could not be done for some other reason.

The `shallow` parameter has the same meaning and default value as for `filecmp.cmp()`.

For example, `cmpfiles('a', 'b', ['c', 'd/e'])` will compare `a/c` with `b/c` and `a/d/e` with `b/d/e`. 'c' and 'd/e' will each be in one of the three returned lists.

`filecmp.clear_cache()`

Clear the filecmp cache. This may be useful if a file is compared so quickly after it is modified that it is within the mtime resolution of the underlying filesystem.

*New in version 3.4.*
11.5.1. The \texttt{dircmp} class

\texttt{class filecmp.dircmp(a, b, ignore=None, hide=None)}

Construct a new directory comparison object, to compare the directories \(a\) and \(b\). \textit{ignore} is a list of names to ignore, and defaults to \texttt{filecmp.DEFAULT_IGNORES}. \textit{hide} is a list of names to hide, and defaults to [\texttt{os.curdir}, \texttt{os.pardir}].

The \texttt{dircmp} class compares files by doing \textit{shallow} comparisons as described for \texttt{filecmp.cmp()}.

The \texttt{dircmp} class provides the following methods:

\texttt{report()}

Print (to \texttt{sys.stdout}) a comparison between \(a\) and \(b\).

\texttt{report_partial_closure()}

Print a comparison between \(a\) and \(b\) and common immediate subdirectories.

\texttt{report_full_closure()}

Print a comparison between \(a\) and \(b\) and common subdirectories (recursively).

The \texttt{dircmp} class offers a number of interesting attributes that may be used to get various bits of information about the directory trees being compared.

Note that via \texttt{__getattr__()} hooks, all attributes are computed lazily, so there is no speed penalty if only those attributes which are lightweight to compute are used.
left
The directory a.

right
The directory b.

left_list
Files and subdirectories in a, filtered by *hide* and *ignore*.

right_list
Files and subdirectories in b, filtered by *hide* and *ignore*.

common
Files and subdirectories in both a and b.

left_only
Files and subdirectories only in a.

right_only
Files and subdirectories only in b.

common_dirs
Subdirectories in both a and b.

common_files
Files in both a and b.

common_funny
Names in both a and b, such that the type differs between the directories, or names for which *os.stat()* reports an error.

same_files
Files which are identical in both a and b, using the class’s file comparison operator.
**diff_files**
Files which are in both a and b, whose contents differ according to the class's file comparison operator.

**funny_files**
Files which are in both a and b, but could not be compared.

**subdirs**
A dictionary mapping names in `common_dirs` to `dircmp` objects.

```
>>> from filecmp import dircmp
>>> def print_diff_files(dcmp):
...    for name in dcmp.diff_files:
...        print("diff_file %s found in %s and %s" %
...               (name, dcmp.left, dcmp.right))
...    for sub_dcmp in dcmp.subdirs.values():
...        print_diff_files(sub_dcmp)
...    
>>> dcmp = dircmp('dir1', 'dir2')
>>> print_diff_files(dcmp)
```

Last updated on Mar 16, 2014. Found a bug?

Created using Sphinx 1.2.
11.6. **tempfile** — Generate temporary files and directories

**Source code:** Lib/tempfile.py

This module generates temporary files and directories. It works on all supported platforms. It provides three new functions, `NamedTemporaryFile()`, `mkstemp()`, and `mkdtemp()`, which should eliminate all remaining need to use the insecure `mktemp()` function. Temporary file names created by this module no longer contain the process ID; instead a string of six random characters is used.

Also, all the user-callable functions now take additional arguments which allow direct control over the location and name of temporary files. It is no longer necessary to use the global `tempdir` variable. To maintain backward compatibility, the argument order is somewhat odd; it is recommended to use keyword arguments for clarity.

The module defines the following user-callable items:

```python
tempfile.TemporaryFile(mode='w+b', buffering=None, encoding=None, newline=None, suffix='', prefix='tmp', dir=None)
```

Return a *file-like object* that can be used as a temporary storage area. The file is created using `mkstemp()`. It will be destroyed as soon as it is closed (including an implicit close when the object is garbage collected). Under Unix, the directory entry for the file is removed immediately after the file is created. Other platforms do not support this; your code should not rely on a temporary file created using this function having or not having a visible name in
the file system.

The `mode` parameter defaults to `'w+b'` so that the file created can be read and written without being closed. Binary mode is used so that it behaves consistently on all platforms without regard for the data that is stored. `buffering`, `encoding` and `newline` are interpreted as for `open()`.

The `dir`, `prefix` and `suffix` parameters are passed to `mkstemp()`.

The returned object is a true file object on POSIX platforms. On other platforms, it is a file-like object whose `file` attribute is the underlying true file object. This file-like object can be used in a `with` statement, just like a normal file.

```
tempfile.NamedTemporaryFile(mode='w+b',
buffering=None, encoding=None, newline=None, suffix='', prefix='tmp',
dir=None, delete=True)
```

This function operates exactly as `TemporaryFile()` does, except that the file is guaranteed to have a visible name in the file system (on Unix, the directory entry is not unlinked). That name can be retrieved from the name attribute of the file object. Whether the name can be used to open the file a second time, while the named temporary file is still open, varies across platforms (it can be so used on Unix; it cannot on Windows NT or later). If `delete` is true (the default), the file is deleted as soon as it is closed. The returned object is always a file-like object whose `file` attribute is the underlying true file object. This file-like object can be used in a `with` statement, just like a normal file.

```
tempfile.SpooledTemporaryFile(max_size=0, mode='w+b',
buffering=None, encoding=None, newline=None, suffix='', prefix='tmp',
dir=None)
```
This function operates exactly as `TemporaryFile()` does, except that data is spooled in memory until the file size exceeds `max_size`, or until the file's `fileno()` method is called, at which point the contents are written to disk and operation proceeds as with `TemporaryFile()`.

The resulting file has one additional method, `rollover()`, which causes the file to roll over to an on-disk file regardless of its size.

The returned object is a file-like object whose `_file` attribute is either a `io.BytesIO` or `io.StringIO` object (depending on whether binary or text `mode` was specified) or a true file object, depending on whether `rollover()` has been called. This file-like object can be used in a `with` statement, just like a normal file.

*Changed in version 3.3:* the truncate method now accepts a `size` argument.

`tempfile.TemporaryDirectory(suffix='', prefix='tmp', dir=None)`

This function creates a temporary directory using `mkdtemp()` (the supplied arguments are passed directly to the underlying function). The resulting object can be used as a context manager (see *With Statement Context Managers*). On completion of the context or destruction of the temporary directory object the newly created temporary directory and all its contents are removed from the filesystem.

The directory name can be retrieved from the name attribute of the returned object. When the returned object is used as a context manager, the name will be assigned to the target of the `as` clause in the `with` statement, if there is one.
The directory can be explicitly cleaned up by calling the cleanup() method.

*New in version 3.2.*

tempfile.mkstemp(suffix='', prefix='tmp', dir=None, text=False)

Creates a temporary file in the most secure manner possible. There are no race conditions in the file's creation, assuming that the platform properly implements the os.O_EXCL flag for os.open(). The file is readable and writable only by the creating user ID. If the platform uses permission bits to indicate whether a file is executable, the file is executable by no one. The file descriptor is not inherited by child processes.

Unlike TemporaryFile(), the user of mkstemp() is responsible for deleting the temporary file when done with it.

If suffix is specified, the file name will end with that suffix, otherwise there will be no suffix. mkstemp() does not put a dot between the file name and the suffix; if you need one, put it at the beginning of suffix.

If prefix is specified, the file name will begin with that prefix; otherwise, a default prefix is used.

If dir is specified, the file will be created in that directory; otherwise, a default directory is used. The default directory is chosen from a platform-dependent list, but the user of the application can control the directory location by setting the TMPDIR, TEMP or TMP environment variables. There is thus no guarantee that the generated filename will have any nice properties, such as not requiring quoting when passed to external commands via os.popen().
If text is specified, it indicates whether to open the file in binary mode (the default) or text mode. On some platforms, this makes no difference.

**mkstemp()** returns a tuple containing an OS-level handle to an open file (as would be returned by `os.open()`) and the absolute pathname of that file, in that order.

```python
mkstemp(suffix='', prefix='tmp', dir=None)
```

Creates a temporary directory in the most secure manner possible. There are no race conditions in the directory's creation. The directory is readable, writable, and searchable only by the creating user ID.

The user of **mkdtemp()** is responsible for deleting the temporary directory and its contents when done with it.

The *prefix*, *suffix*, and *dir* arguments are the same as for **mkstemp()**.

**mkdtemp()** returns the absolute pathname of the new directory.

```python
mkdtemp(suffix='', prefix='tmp', dir=None)
```

**tempfile. mkdtemp(suffix='', prefix='tmp', dir=None)**

**Deprecated since version 2.3:** Use **mkstemp()** instead.

Return an absolute pathname of a file that did not exist at the time the call is made. The *prefix*, *suffix*, and *dir* arguments are the same as for **mkstemp()**.

**Warning:** Use of this function may introduce a security hole in your program. By the time you get around to doing anything with the file name it returns, someone else may have beaten you to the punch. **mktemp()** usage can be replaced easily with
NamedTemporaryFile(), passing it the delete=False parameter:

```python
>>> f = NamedTemporaryFile(delete=False)
>>> f.name
'/tmp/tmptjujijt'
>>> f.write(b"Hello World!\n")
13
>>> f.close()
>>> os.unlink(f.name)
>>> os.path.exists(f.name)
False
```

The module uses two global variables that tell it how to construct a temporary name. They are initialized at the first call to any of the functions above. The caller may change them, but this is discouraged; use the appropriate function arguments, instead.

`tempfile.tempdir`

When set to a value other than `None`, this variable defines the default value for the `dir` argument to all the functions defined in this module.

If `tempdir` is unset or `None` at any call to any of the above functions, Python searches a standard list of directories and sets `tempdir` to the first one which the calling user can create files in. The list is:

1. The directory named by the `TMPDIR` environment variable.
2. The directory named by the `TEMP` environment variable.
3. The directory named by the `TMP` environment variable.
4. A platform-specific location:
   - On Windows, the directories `C:\TEMP`, `C:\TMP`, `\TEMP`, `\TEMP`, ...
and \TMP, in that order.
- On all other platforms, the directories /tmp, /var/tmp, and /usr/tmp, in that order.

5. As a last resort, the current working directory.

tempfile.gettempdir()

Return the directory currently selected to create temporary files in. If tempdir is not None, this simply returns its contents; otherwise, the search described above is performed, and the result returned.

tempfile.gettempprefix()

Return the filename prefix used to create temporary files. This does not contain the directory component.
11.6.1. Examples

Here are some examples of typical usage of the `tempfile` module:

```python
>>> import tempfile

# create a temporary file and write some data to it
>>> fp = tempfile.TemporaryFile()
>>> fp.write(b'Hello world!')
# read data from file
>>> fp.seek(0)
>>> fp.read()
'b'Hello world!'
# close the file, it will be removed
>>> fp.close()

# create a temporary file using a context manager
>>> with tempfile.TemporaryFile() as fp:
...     fp.write(b'Hello world!')
...     fp.seek(0)
...     fp.read()
'b'Hello world!'

# file is now closed and removed

# create a temporary directory using the context manager
>>> with tempfile.TemporaryDirectory() as tmpdirname:
...     print('created temporary directory', tmpdirname)

# directory and contents have been removed
```
11.7. `glob` — Unix style pathname pattern expansion

**Source code:** Lib/glob.py

The `glob` module finds all the pathnames matching a specified pattern according to the rules used by the Unix shell. No tilde expansion is done, but *, ?, and character ranges expressed with `[]` will be correctly matched. This is done by using the `os.listdir()` and `fnmatch.fnmatch()` functions in concert, and not by actually invoking a subshell. Note that unlike `fnmatch.fnmatch()`, `glob` treats filenames beginning with a dot (.) as special cases. (For tilde and shell variable expansion, use `os.path.expanduser()` and `os.path.expandvars()`.)

For a literal match, wrap the meta-characters in brackets. For example, `'[?]'` matches the character `'?'.

**See also:** The `pathlib` module offers high-level path objects.

`glob.glob(pathname)`

Return a possibly-empty list of path names that match `pathname`, which must be a string containing a path specification. `pathname` can be either absolute (like `/usr/src/Python-1.5/Makefile`) or relative (like `../../Tools/*/.*.gif`), and can contain shell-style wildcards. Broken symlinks are included in the results (as in the shell).

`glob.iglob(pathname)`
Return an *iterator* which yields the same values as `glob()` without actually storing them all simultaneously.

`glob.escape(pathname)`

Escape all special characters (`'?', '*' and '['`). This is useful if you want to match an arbitrary literal string that may have special characters in it. Special characters in drive/UNC sharepoints are not escaped, e.g. on Windows `escape('//?/c:/Quovadis?.txt')` returns `//?/c:/Quovadis[?].txt`.

*New in version 3.4.*

For example, consider a directory containing only the following files: 1.gif, 2.txt, and card.gif. `glob()` will produce the following results. Notice how any leading components of the path are preserved.

```python
>>> import glob
>>> glob.glob('./[0-9].*')
['./1.gif', './2.txt']
>>> glob.glob('*.*')
['1.gif', 'card.gif']
>>> glob.glob('?.gif')
['1.gif']
```

If the directory contains files starting with `.`, they won’t be matched by default. For example, consider a directory containing card.gif and .card.gif:

```python
>>> import glob
>>> glob.glob('*.*')
['card.gif']
>>> glob.glob('.c*')
['.card.gif']
```
See also:

**Module fnmatch**  
Shell-style filename (not path) expansion
11.8. fnmatch — Unix filename pattern matching

Source code: Lib/fnmatch.py

This module provides support for Unix shell-style wildcards, which are not the same as regular expressions (which are documented in the re module). The special characters used in shell-style wildcards are:

<table>
<thead>
<tr>
<th>Pattern</th>
<th>Meaning</th>
</tr>
</thead>
<tbody>
<tr>
<td>*</td>
<td>matches everything</td>
</tr>
<tr>
<td>?</td>
<td>matches any single character</td>
</tr>
<tr>
<td>[seq]</td>
<td>matches any character in seq</td>
</tr>
<tr>
<td>[!seq]</td>
<td>matches any character not in seq</td>
</tr>
</tbody>
</table>

For a literal match, wrap the meta-characters in brackets. For example, '?[?]' matches the character '?'.

Note that the filename separator ('/' on Unix) is not special to this module. See module glob for pathname expansion (glob uses fnmatch() to match pathname segments). Similarly, filenames starting with a period are not special for this module, and are matched by the * and ? patterns.

*fnmatch.fnmatch(filename, pattern)*

Test whether the filename string matches the pattern string, returning True or False. If the operating system is case-
Insensitive, then both parameters will be normalized to all lower- or upper-case before the comparison is performed. fnmatchcase() can be used to perform a case-sensitive comparison, regardless of whether that's standard for the operating system.

This example will print all file names in the current directory with the extension .txt:

```python
import fnmatch
import os

for file in os.listdir('. '):
    if fnmatch.fnmatch(file, '*.txt '):
        print(file)
```

fnmatch.fnmatchcase(filename, pattern)

Test whether filename matches pattern, returning True or False; the comparison is case-sensitive.

fnmatch.filter(names, pattern)

Return the subset of the list of names that match pattern. It is the same as [n for n in names if fnmatch(n, pattern)], but implemented more efficiently.

fnmatch.translate(pattern)

Return the shell-style pattern converted to a regular expression.

Example:

```python
>>> import fnmatch, re
>>> regex = fnmatch.translate('*.txt ')
>>> regex
'.*\\\.txt$'
```
```python
>>> reobj = re.compile(regex)
>>> reobj.match('foobar.txt')
<_sre.SRE_Match object; span=(0, 10), match='foob'>
```

**See also:**

**Module glob**

Unix shell-style path expansion.
11.9. **linecache** — Random access to text lines

**Source code:** `Lib/linecache.py`

The `linecache` module allows one to get any line from any file, while attempting to optimize internally, using a cache, the common case where many lines are read from a single file. This is used by the `traceback` module to retrieve source lines for inclusion in the formatted traceback.

The `linecache` module defines the following functions:

**linecache.getline(filename, lineno, module_globals=None)**
- Get line `lineno` from file named `filename`. This function will never raise an exception — it will return `'` on errors (the terminating newline character will be included for lines that are found).

  If a file named `filename` is not found, the function will look for it in the module search path, `sys.path`, after first checking for a PEP 302 `__loader__` in `module_globals`, in case the module was imported from a zipfile or other non-filesystem import source.

**linecache.clearcache()**
- Clear the cache. Use this function if you no longer need lines from files previously read using `getline()`.

**linecache.checkcache(filename=None)**
- Check the cache for validity. Use this function if files in the cache may have changed on disk, and you require the updated version. If
filename is omitted, it will check all the entries in the cache.

Example:

```python
>>> import linecache
>>> linecache.getline('/etc/passwd', 4)
'sys:x:3:3:sys:/dev:/bin/sh\n'
```
11.10. **shutil** — High-level file operations

**Source code:** Lib/shutil.py

The `shutil` module offers a number of high-level operations on files and collections of files. In particular, functions are provided which support file copying and removal. For operations on individual files, see also the `os` module.

**Warning:** Even the higher-level file copying functions (`shutil.copy()`, `shutil.copy2()`) cannot copy all file metadata.

On POSIX platforms, this means that file owner and group are lost as well as ACLs. On Mac OS, the resource fork and other metadata are not used. This means that resources will be lost and file type and creator codes will not be correct. On Windows, file owners, ACLs and alternate data streams are not copied.
11.10.1. Directory and files operations

**shutil.copyfileobj(fsrc, fdst[, length])**

Copy the contents of the file-like object `fsrc` to the file-like object `fdst`. The integer `length`, if given, is the buffer size. In particular, a negative `length` value means to copy the data without looping over the source data in chunks; by default the data is read in chunks to avoid uncontrolled memory consumption. Note that if the current file position of the `fsrc` object is not 0, only the contents from the current file position to the end of the file will be copied.

**shutil.copyfile(src, dst, *, follow_symlinks=True)**

Copy the contents (no metadata) of the file named `src` to a file named `dst` and return `dst`. `src` and `dst` are path names given as strings. `dst` must be the complete target file name; look at `shutil.copy()` for a copy that accepts a target directory path. If `src` and `dst` specify the same file, `SameFileError` is raised.

The destination location must be writable; otherwise, an `OSError` exception will be raised. If `dst` already exists, it will be replaced. Special files such as character or block devices and pipes cannot be copied with this function.

If `follow_symlinks` is false and `src` is a symbolic link, a new symbolic link will be created instead of copying the file `src` points to.

*Changed in version 3.3:* `IOError` used to be raised instead of `OSError`. Added `follow_symlinks` argument. Now returns `dst`.

*Changed in version 3.4:* Raise `SameFileError` instead of
Error. Since the former is a subclass of the latter, this change is backward compatible.

**exception** `shutil.SameFileError`

This exception is raised if source and destination in `copyfile()` are the same file.

*New in version 3.4.*

`shutil.copymode(src, dst, *, follow_symlinks=True)`

Copy the permission bits from `src` to `dst`. The file contents, owner, and group are unaffected. `src` and `dst` are path names given as strings. If `follow_symlinks` is false, and both `src` and `dst` are symbolic links, `copymode()` will attempt to modify the mode of `dst` itself (rather than the file it points to). This functionality is not available on every platform; please see `copystat()` for more information. If `copymode()` cannot modify symbolic links on the local platform, and it is asked to do so, it will do nothing and return.

*Changed in version 3.3*: Added `follow_symlinks` argument.

`shutil.copystat(src, dst, *, follow_symlinks=True)`

Copy the permission bits, last access time, last modification time, and flags from `src` to `dst`. On Linux, `copystat()` also copies the “extended attributes” where possible. The file contents, owner, and group are unaffected. `src` and `dst` are path names given as strings.

If `follow_symlinks` is false, and `src` and `dst` both refer to symbolic links, `copystat()` will operate on the symbolic links themselves rather than the files the symbolic links refer to—reading the information from the `src` symbolic link, and writing the information to the `dst` symbolic link.
Note: Not all platforms provide the ability to examine and modify symbolic links. Python itself can tell you what functionality is locally available.

- If `os.chmod in os.supports_follow_symlinks` is True, `copystat()` can modify the permission bits of a symbolic link.
- If `os.utime in os.supports_follow_symlinks` is True, `copystat()` can modify the last access and modification times of a symbolic link.
- If `os.chflags in os.supports_follow_symlinks` is True, `copystat()` can modify the flags of a symbolic link. (os.chflags is not available on all platforms.)

On platforms where some or all of this functionality is unavailable, when asked to modify a symbolic link, `copystat()` will copy everything it can. `copystat()` never returns failure.

Please see `os.supports_follow_symlinks` for more information.

*Changed in version 3.3:* Added `follow_symlinks` argument and support for Linux extended attributes.

```python
shutil.copy(src, dst, *, follow_symlinks=True)
```

Copies the file `src` to the file or directory `dst`. `src` and `dst` should be strings. If `dst` specifies a directory, the file will be copied into `dst` using the base filename from `src`. Returns the path to the newly created file.

If `follow_symlinks` is false, and `src` is a symbolic link, `dst` will be created as a symbolic link. If `follow_symlinks` is true and `src` is a symbolic link, `dst` will be a copy of the file `src` refers to.

`copy()` copies the file data and the file's permission mode (see
os.chmod(). Other metadata, like the file’s creation and modification times, is not preserved. To preserve all file metadata from the original, use copy2() instead.

*Changed in version 3.3:* Added follow_symlinks argument. Now returns path to the newly created file.

```
shutil.copy2(src, dst, *, follow_symlinks=True)
```

Identical to copy() except that copy2() also attempts to preserve all file metadata.

When follow_symlinks is false, and src is a symbolic link, copy2() attempts to copy all metadata from the src symbolic link to the newly-created dst symbolic link. However, this functionality is not available on all platforms. On platforms where some or all of this functionality is unavailable, copy2() will preserve all the metadata it can; copy2() never returns failure.

copy2() uses copystat() to copy the file metadata. Please see copystat() for more information about platform support for modifying symbolic link metadata.

*Changed in version 3.3:* Added follow_symlinks argument, try to copy extended file system attributes too (currently Linux only). Now returns path to the newly created file.

```
shutil.ignore_patterns(*patterns)
```

This factory function creates a function that can be used as a callable for copytree()’s ignore argument, ignoring files and directories that match one of the glob-style patterns provided. See the example below.

```
shutil.copytree(src, dst, symlinks=False, ignore=None,
```
Recursively copy an entire directory tree rooted at \texttt{src}, returning the destination directory. The destination directory, named by \texttt{dst}, must not already exist; it will be created as well as missing parent directories. Permissions and times of directories are copied with \texttt{copystat()}, individual files are copied using \texttt{shutil.copy2()}.

If \texttt{symlinks} is true, symbolic links in the source tree are represented as symbolic links in the new tree and the metadata of the original links will be copied as far as the platform allows; if false or omitted, the contents and metadata of the linked files are copied to the new tree.

When \texttt{symlinks} is false, if the file pointed by the symlink doesn’t exist, a exception will be added in the list of errors raised in a \texttt{Error} exception at the end of the copy process. You can set the optional \texttt{ignore_dangling_symlinks} flag to true if you want to silence this exception. Notice that this option has no effect on platforms that don’t support \texttt{os.symlink()}.

If \texttt{ignore} is given, it must be a callable that will receive as its arguments the directory being visited by \texttt{copytree()}, and a list of its contents, as returned by \texttt{os.listdir()}. Since \texttt{copytree()} is called recursively, the \texttt{ignore} callable will be called once for each directory that is copied. The callable must return a sequence of directory and file names relative to the current directory (i.e. a subset of the items in its second argument); these names will then be ignored in the copy process. \texttt{ignore_patterns()} can be used to create such a callable that ignores names based on glob-style patterns.

If exception(s) occur, an \texttt{Error} is raised with a list of reasons.
If `copy_function` is given, it must be a callable that will be used to copy each file. It will be called with the source path and the destination path as arguments. By default, `shutil.copy2()` is used, but any function that supports the same signature (like `shutil.copy()`) can be used.

*Changed in version 3.3:* Copy metadata when `symlinks` is false. Now returns `dst`.

*Changed in version 3.2:* Added the `copy_function` argument to be able to provide a custom copy function. Added the `ignore_dangling_symlinks` argument to silent dangling symlinks errors when `symlinks` is false.

```python
shutil.rmtree(path, ignore_errors=False, onerror=None)
```

Delete an entire directory tree; `path` must point to a directory (but not a symbolic link to a directory). If `ignore_errors` is true, errors resulting from failed removals will be ignored; if false or omitted, such errors are handled by calling a handler specified by `onerror` or, if that is omitted, they raise an exception.

**Note:** On platforms that support the necessary fd-based functions a symlink attack resistant version of `rmtree()` is used by default. On other platforms, the `rmtree()` implementation is susceptible to a symlink attack: given proper timing and circumstances, attackers can manipulate symlinks on the filesystem to delete files they wouldn’t be able to access otherwise. Applications can use the `rmtree.avoids_symlink_attacks` function attribute to determine which case applies.

If `onerror` is provided, it must be a callable that accepts three
parameters: function, path, and excinfo.

The first parameter, function, is the function which raised the exception; it depends on the platform and implementation. The second parameter, path, will be the path name passed to function. The third parameter, excinfo, will be the exception information returned by sys.exc_info(). Exceptions raised by onerror will not be caught.

*Changed in version 3.3:* Added a symlink attack resistant version that is used automatically if platform supports fd-based functions.

**rmtree**. avoids_symlink_attacks

Indicates whether the current platform and implementation provides a symlink attack resistant version of rmtree(). Currently this is only true for platforms supporting fd-based directory access functions.

*New in version 3.3.*

**shutil**. move(src, dst)

Recursively move a file or directory (src) to another location (dst) and return the destination.

If the destination is a directory or a symlink to a directory, then src is moved inside that directory.

The destination directory must not already exist. If the destination already exists but is not a directory, it may be overwritten depending on os.rename() semantics.

If the destination is on the current filesystem, then os.rename() is used. Otherwise, src is copied (using shutil.copy2()) to dst.
and then removed. In case of symlinks, a new symlink pointing to the target of src will be created in or as dst and src will be removed.

*Changed in version 3.3:* Added explicit symlink handling for foreign filesystems, thus adapting it to the behavior of GNU’s mv. Now returns dst.

**shutil.disk_usage(path)**

Return disk usage statistics about the given path as a *named tuple* with the attributes `total`, `used` and `free`, which are the amount of total, used and free space, in bytes.

*New in version 3.3.*

**Availability:** Unix, Windows.

**shutil.chown(path, user=None, group=None)**

Change owner `user` and/or `group` of the given `path`.

`user` can be a system user name or a uid; the same applies to `group`. At least one argument is required.

See also `os.chown()`, the underlying function.

**Availability:** Unix.

*New in version 3.3.*

**shutil.which(cmd, mode=os.F_OK | os.X_OK, path=None)**

Return the path to an executable which would be run if the given `cmd` was called. If no `cmd` would be called, return `None`.

`mode` is a permission mask passed a to `os.access()`, by default
determining if the file exists and executable.

When no path is specified, the results of os.environ() are used, returning either the “PATH” value or a fallback of os.defpath.

On Windows, the current directory is always prepended to the path whether or not you use the default or provide your own, which is the behavior the command shell uses when finding executables. Additionaly, when finding the cmd in the path, the PATHEXT environment variable is checked. For example, if you call shutil.which("python"), which() will search PATHEXT to know that it should look for python.exe within the path directories. For example, on Windows:

```python
>>> shutil.which("python")
'C:\\Python33\\python.EXE'
```

New in version 3.3.

exception shutil.Error

This exception collects exceptions that are raised during a multi-file operation. For copytree(), the exception argument is a list of 3-tuples (srcname, dstname, exception).

11.10.1.1. copytree example

This example is the implementation of the copytree() function, described above, with the docstring omitted. It demonstrates many of the other functions provided by this module.

```python
def copytree(src, dst, symlinks=False):
    names = os.listdir(src)
os.makedirs(dst)
```
errors = []
for name in names:
    srcname = os.path.join(src, name)
    dstname = os.path.join(dst, name)
    try:
        if symlinks and os.path.islink(srcname):
            linkto = os.readlink(srcname)
            os.symlink(linkto, dstname)
        elif os.path.isdir(srcname):
            copytree(srcname, dstname, symlinks)
        else:
            copy2(srcname, dstname)
            # XXX What about devices, sockets etc.?
    except OSError as why:
        errors.append((srcname, dstname, str(why))
        # catch the Error from the recursive copytree
        # continue with other files
    except Error as err:
        errors.extend(err.args[0])
try:
    copystat(src, dst)
except OSError as why:
    # can't copy file access times on Windows
    if why.winerror is None:
        errors.extend((src, dst, str(why)))
if errors:
    raise Error(errors)

Another example that uses the ignore_patterns() helper:

from shutil import copytree, ignore_patterns

copytree(source, destination, ignore=ignore_patterns)

This will copy everything except .pyc files and files or directories
whose name starts with `tmp`.

Another example that uses the `ignore` argument to add a logging call:

```python
from shutil import copytree
import logging

def _logpath(path, names):
    logging.info('Working in %s' % path)
    return []  # nothing will be ignored

copytree(source, destination, ignore=_logpath)
```
11.10.2. Archiving operations

New in version 3.2.

High-level utilities to create and read compressed and archived files are also provided. They rely on the zipfile and tarfile modules.

`shutil.make_archive(base_name, format[, root_dir[, base_dir[, verbose[, dry_run[, owner[, group[, logger]]]]]]])`

Create an archive file (such as zip or tar) and return its name.

`base_name` is the name of the file to create, including the path, minus any format-specific extension. `format` is the archive format: one of “zip”, “tar”, “bztar” (if the bz2 module is available) or “gztar”.

`root_dir` is a directory that will be the root directory of the archive; for example, we typically chdir into `root_dir` before creating the archive.

`base_dir` is the directory where we start archiving from; i.e. `base_dir` will be the common prefix of all files and directories in the archive.

`root_dir` and `base_dir` both default to the current directory.

`owner` and `group` are used when creating a tar archive. By default, uses the current owner and group.

`logger` must be an object compatible with PEP 282, usually an instance of `logging.Logger`.

`shutil.get_archive_formats()`

Return a list of supported formats for archiving. Each element of
the returned sequence is a tuple \((\text{name}, \text{description})\)

By default \texttt{shutil} provides these formats:

- \texttt{gztar}: gzip’ed tar-file
- \texttt{bztar}: bzip2’ed tar-file (if the \texttt{bz2} module is available.)
- \texttt{tar}: uncompressed tar file
- \texttt{zip}: ZIP file

You can register new formats or provide your own archiver for any existing formats, by using \texttt{register_archive_format()}. 

\texttt{shutil.register_archive_format(\text{name}, \text{function}[\text{, extra_args}[\text{, description}]])}

Register an archiver for the format \text{name}. \text{function} is a callable that will be used to invoke the archiver.

If given, \texttt{extra_args} is a sequence of \((\text{name, value})\) pairs that will be used as extra keywords arguments when the archiver callable is used.

\texttt{description} is used by \texttt{get_archive_formats()} which returns the list of archivers. Defaults to an empty list.

\texttt{shutil.unregister_archive_format(\text{name})}

Remove the archive format \text{name} from the list of supported formats.

\texttt{shutil.unpack_archive(\text{filename}[\text{, extract_dir}[\text{, format}]])}

Unpack an archive. \texttt{filename} is the full path of the archive.

\texttt{extract_dir} is the name of the target directory where the archive is unpacked. If not provided, the current working directory is used.
format is the archive format: one of “zip”, “tar”, or “gztar”. Or any other format registered with register_unpack_format(). If not provided, unpack_archive() will use the archive file name extension and see if an unpacker was registered for that extension. In case none is found, a ValueError is raised.

shutil.register_unpack_format(name, extensions, function[, extra_args[, description]])

Registers an unpack format. name is the name of the format and extensions is a list of extensions corresponding to the format, like .zip for Zip files.

function is the callable that will be used to unpack archives. The callable will receive the path of the archive, followed by the directory the archive must be extracted to.

When provided, extra_args is a sequence of (name, value) tuples that will be passed as keywords arguments to the callable.

description can be provided to describe the format, and will be returned by the get_unpack_formats() function.

shutil.unregister_unpack_format(name)

Unregister an unpack format. name is the name of the format.

shutil.get_unpack_formats()

Return a list of all registered formats for unpacking. Each element of the returned sequence is a tuple (name, extensions, description).

By default shutil provides these formats:

• gztar: gzip’ed tar-file
- **bztar**: bzip2'ed tar-file (if the **bz2** module is available.)
- **tar**: uncompressed tar file
- **zip**: ZIP file

You can register new formats or provide your own unpacker for any existing formats, by using `register_unpack_format()`.

### 11.10.2.1. Archiving example

In this example, we create a gzip'ed tar-file archive containing all files found in the `.ssh` directory of the user:

```python
>>> from shutil import make_archive
>>> import os
>>> archive_name = os.path.expanduser(os.path.join('~/
>>> root_dir = os.path.expanduser(os.path.join('~','
>>> make_archive(archive_name, 'gztar', root_dir)
'~/Users/tarek/myarchive.tar.gz'
```

The resulting archive contains:

```
$ tar -tzvf /Users/tarek/myarchive.tar.gz
drwx------ tarek/staff 0 2010-02-01 16:23:40 .
-rw-r--r-- tarek/staff 609 2008-06-09 13:26:54 ...
-rwxr-xr-x tarek/staff 65 2008-06-09 13:26:54 ...
-rwx------ tarek/staff 668 2008-06-09 13:26:54 ...
-rwxr-xr-x tarek/staff 609 2008-06-09 13:26:54 ...
-rw------- tarek/staff 1675 2008-06-09 13:26:54 ...
-rw-r--r-- tarek/staff 397 2008-06-09 13:26:54 ...
-rw-r--r-- tarek/staff 37192 2010-02-06 18:23:10 ...
```
11.10.3. Querying the size of the output terminal

New in version 3.3.

```python
shutil.get_terminal_size(fallback=(columns, lines))
```

Get the size of the terminal window.

For each of the two dimensions, the environment variable, `COLUMNS` and `LINES` respectively, is checked. If the variable is defined and the value is a positive integer, it is used.

When `COLUMNS` or `LINES` is not defined, which is the common case, the terminal connected to `sys.__stdout__` is queried by invoking `os.get_terminal_size()`.

If the terminal size cannot be successfully queried, either because the system doesn’t support querying, or because we are not connected to a terminal, the value given in `fallback` parameter is used. `fallback` defaults to `(80, 24)` which is the default size used by many terminal emulators.

The value returned is a named tuple of type `os.terminal_size`.

11.11. `macpath` — Mac OS 9 path manipulation functions

This module is the Mac OS 9 (and earlier) implementation of the `os.path` module. It can be used to manipulate old-style Macintosh pathnames on Mac OS X (or any other platform).

The following functions are available in this module: `normcase()`, `normpath()`, `isabs()`, `join()`, `split()`, `isdir()`, `isfile()`, `walk()`, `exists()`. For other functions available in `os.path` dummy counterparts are available.
12. Data Persistence

The modules described in this chapter support storing Python data in a persistent form on disk. The pickle and marshal modules can turn many Python data types into a stream of bytes and then recreate the objects from the bytes. The various DBM-related modules support a family of hash-based file formats that store a mapping of strings to other strings.

The list of modules described in this chapter is:

- **12.1. pickle — Python object serialization**
  - 12.1.1. Relationship to other Python modules
    - 12.1.1.1. Comparison with marshal
    - 12.1.1.2. Comparison with json
  - 12.1.2. Data stream format
  - 12.1.3. Module Interface
  - 12.1.4. What can be pickled and unpickled?
  - 12.1.5. Pickling Class Instances
    - 12.1.5.1. Persistence of External Objects
    - 12.1.5.2. Dispatch Tables
    - 12.1.5.3. Handling Stateful Objects
  - 12.1.6. Restricting Globals
  - 12.1.7. Performance
  - 12.1.8. Examples
- **12.2. copyreg — Register pickle support functions**
  - 12.2.1. Example
- **12.3. shelve — Python object persistence**
  - 12.3.1. Restrictions
  - 12.3.2. Example
- **12.4. marshal — Internal Python object serialization**
- **12.5. dbm — Interfaces to Unix “databases”**
- 12.5.1. dbm.gnu — GNU's reinterpretation of dbm
- 12.5.2. dbm.ndbm — Interface based on ndbm
- 12.5.3. dbm.dumb — Portable DBM implementation

- 12.6. sqlite3 — DB-API 2.0 interface for SQLite databases
  - 12.6.1. Module functions and constants
  - 12.6.2. Connection Objects
  - 12.6.3. Cursor Objects
  - 12.6.4. Row Objects
  - 12.6.5. SQLite and Python types
    - 12.6.5.1. Introduction
    - 12.6.5.2. Using adapters to store additional Python types in SQLite databases
      - 12.6.5.2.1. Letting your object adapt itself
      - 12.6.5.2.2. Registering an adapter callable
    - 12.6.5.3. Converting SQLite values to custom Python types
    - 12.6.5.4. Default adapters and converters
  - 12.6.6. Controlling Transactions
  - 12.6.7. Using sqlite3 efficiently
    - 12.6.7.1. Using shortcut methods
    - 12.6.7.2. Accessing columns by name instead of by index
    - 12.6.7.3. Using the connection as a context manager
  - 12.6.8. Common issues
    - 12.6.8.1. Multithreading
12.1. **pickle** — Python object serialization

The **pickle** module implements binary protocols for serializing and de-serializing a Python object structure. “Pickling” is the process whereby a Python object hierarchy is converted into a byte stream, and “unpickling” is the inverse operation, whereby a byte stream (from a binary file or bytes-like object) is converted back into an object hierarchy. Pickling (and unpickling) is alternatively known as “serialization”, “marshalling,” [1] or “flattening”; however, to avoid confusion, the terms used here are “pickling” and “unpickling”.

**Warning:** The **pickle** module is not intended to be secure against erroneous or maliciously constructed data. Never unpickle data received from an untrusted or unauthenticated source.
12.1.1. Relationship to other Python modules

12.1.1.1. Comparison with marshal

Python has a more primitive serialization module called *marshal*, but in general *pickle* should always be the preferred way to serialize Python objects. *marshal* exists primarily to support Python's `.pyc` files.

The *pickle* module differs from *marshal* in several significant ways:

- The *pickle* module keeps track of the objects it has already serialized, so that later references to the same object won’t be serialized again. *marshal* doesn’t do this.

  This has implications both for recursive objects and object sharing. Recursive objects are objects that contain references to themselves. These are not handled by marshal, and in fact, attempting to marshal recursive objects will crash your Python interpreter. Object sharing happens when there are multiple references to the same object in different places in the object hierarchy being serialized. *pickle* stores such objects only once, and ensures that all other references point to the master copy. Shared objects remain shared, which can be very important for mutable objects.

- *marshal* cannot be used to serialize user-defined classes and their instances. *pickle* can save and restore class instances transparently, however the class definition must be importable and live in the same module as when the object was stored.
The **marshal** serialization format is not guaranteed to be portable across Python versions. Because its primary job in life is to support `.pyc` files, the Python implementers reserve the right to change the serialization format in non-backwards compatible ways should the need arise. The **pickle** serialization format is guaranteed to be backwards compatible across Python releases.

### 12.1.1.2. Comparison with **json**

There are fundamental differences between the pickle protocols and **JSON (JavaScript Object Notation)**:

- **JSON** is a text serialization format (it outputs unicode text, although most of the time it is then encoded to `utf-8`), while pickle is a binary serialization format;
- **JSON** is human-readable, while pickle is not;
- **JSON** is interoperable and widely used outside of the Python ecosystem, while pickle is Python-specific;
- **JSON**, by default, can only represent a subset of the Python built-in types, and no custom classes; pickle can represent an extremely large number of Python types (many of them automatically, by clever usage of Python’s introspection facilities; complex cases can be tackled by implementing **specific object APIs**).

**See also:** The **json** module: a standard library module allowing JSON serialization and deserialization.
12.1.2. Data stream format

The data format used by pickle is Python-specific. This has the advantage that there are no restrictions imposed by external standards such as JSON or XDR (which can’t represent pointer sharing); however it means that non-Python programs may not be able to reconstruct pickled Python objects.

By default, the pickle data format uses a relatively compact binary representation. If you need optimal size characteristics, you can efficiently compress pickled data.

The module pickletools contains tools for analyzing data streams generated by pickle. pickletools source code has extensive comments about opcodes used by pickle protocols.

There are currently 5 different protocols which can be used for pickling. The higher the protocol used, the more recent the version of Python needed to read the pickle produced.

- Protocol version 0 is the original “human-readable” protocol and is backwards compatible with earlier versions of Python.
- Protocol version 1 is an old binary format which is also compatible with earlier versions of Python.
- Protocol version 2 was introduced in Python 2.3. It provides much more efficient pickling of new-style classes. Refer to PEP 307 for information about improvements brought by protocol 2.
- Protocol version 3 was added in Python 3.0. It has explicit support for bytes objects and cannot be unpickled by Python 2.x. This is the default protocol, and the recommended protocol when compatibility with other Python 3 versions is required.
- Protocol version 4 was added in Python 3.4. It adds support for very large objects, pickling more kinds of objects, and some data
format optimizations. Refer to **PEP 3154** for information about improvements brought by protocol 4.

**Note:** Serialization is a more primitive notion than persistence; although *pickle* reads and writes file objects, it does not handle the issue of naming persistent objects, nor the (even more complicated) issue of concurrent access to persistent objects. The *pickle* module can transform a complex object into a byte stream and it can transform the byte stream into an object with the same internal structure. Perhaps the most obvious thing to do with these byte streams is to write them onto a file, but it is also conceivable to send them across a network or store them in a database. The *shelve* module provides a simple interface to pickle and unpickle objects on DBM-style database files.
12.1.3. Module Interface

To serialize an object hierarchy, you simply call the `dumps()` function. Similarly, to de-serialize a data stream, you call the `loads()` function. However, if you want more control over serialization and de-serialization, you can create a `Pickler` or an `Unpickler` object, respectively.

The `pickle` module provides the following constants:

- `pickle.HIGHEST_PROTOCOL`
  - An integer, the highest protocol version available. This value can be passed as a protocol value to functions `dump()` and `dumps()` as well as the `Pickler` constructor.

- `pickle.DEFAULT_PROTOCOL`
  - An integer, the default protocol version used for pickling. May be less than `HIGHEST_PROTOCOL`. Currently the default protocol is 3, a new protocol designed for Python 3.

The `pickle` module provides the following functions to make the pickling process more convenient:

- `pickle.dump(obj, file, protocol=None, *, fix_imports=True)`
  - Write a pickled representation of `obj` to the open `file object file`. This is equivalent to `Pickler(file, protocol).dump(obj).

  The optional `protocol` argument, an integer, tells the pickler to use the given protocol; supported protocols are 0 to `HIGHEST_PROTOCOL`. If not specified, the default is `DEFAULT_PROTOCOL`. If a negative number is specified,
HIGHEST_PROTOCOL is selected.

The file argument must have a write() method that accepts a single bytes argument. It can thus be an on-disk file opened for binary writing, a io.BytesIO instance, or any other custom object that meets this interface.

If fix_imports is true and protocol is less than 3, pickle will try to map the new Python 3 names to the old module names used in Python 2, so that the pickle data stream is readable with Python 2.

 pickle.dumps(obj, protocol=None, *, fix_imports=True)

Return the pickled representation of the object as a bytes object, instead of writing it to a file.

Arguments protocol and fix_imports have the same meaning as in dump().

 pickle.load(file, *, fix_imports=True, encoding="ASCII", errors="strict")

Read a pickled object representation from the open file object file and return the reconstituted object hierarchy specified therein. This is equivalent to Unpickler(file).load().

The protocol version of the pickle is detected automatically, so no protocol argument is needed. Bytes past the pickled object's representation are ignored.

The argument file must have two methods, a read() method that takes an integer argument, and a readline() method that requires no arguments. Both methods should return bytes. Thus file can be an on-disk file opened for binary reading, a io.BytesIO object, or any other custom object that meets this interface.
Optional keyword arguments are `fix_imports`, `encoding` and `errors`, which are used to control compatibility support for pickle stream generated by Python 2. If `fix_imports` is true, pickle will try to map the old Python 2 names to the new names used in Python 3. The `encoding` and `errors` tell pickle how to decode 8-bit string instances pickled by Python 2; these default to ‘ASCII’ and ‘strict’, respectively. The `encoding` can be ‘bytes’ to read these 8-bit string instances as bytes objects.

```python
pickle.loads(bytes_object, *, fix_imports=True, encoding="ASCII", errors="strict")
```

Read a pickled object hierarchy from a `bytes` object and return the reconstituted object hierarchy specified therein.

The protocol version of the pickle is detected automatically, so no protocol argument is needed. Bytes past the pickled object's representation are ignored.

Optional keyword arguments are `fix_imports`, `encoding` and `errors`, which are used to control compatibility support for pickle stream generated by Python 2. If `fix_imports` is true, pickle will try to map the old Python 2 names to the new names used in Python 3. The `encoding` and `errors` tell pickle how to decode 8-bit string instances pickled by Python 2; these default to ‘ASCII’ and ‘strict’, respectively. The `encoding` can be ‘bytes’ to read these 8-bit string instances as bytes objects.

The `pickle` module defines three exceptions:

- `pickle.PickleError`
  Common base class for the other pickling exceptions. It inherits `Exception`. 
exception pickle.**PicklingError**

Error raised when an unpicklable object is encountered by **Pickler**. It inherits **PickleError**.

Refer to *What can be pickled and unpickled?* to learn what kinds of objects can be pickled.

exception pickle.**UnpicklingError**

Error raised when there is a problem unpickling an object, such as a data corruption or a security violation. It inherits **PickleError**.

Note that other exceptions may also be raised during unpickling, including (but not necessarily limited to) **AttributeError**, **EOFError**, **ImportError**, and **IndexError**.

The **pickle** module exports two classes, **Pickler** and **Unpickler**:

class pickle.**Pickler**(file, protocol=None, *, fix_imports=True)

This takes a binary file for writing a pickle data stream.

The optional **protocol** argument, an integer, tells the pickler to use the given protocol; supported protocols are 0 to **HIGHEST_PROTOCOL**. If not specified, the default is **DEFAULT_PROTOCOL**. If a negative number is specified, **HIGHEST_PROTOCOL** is selected.

The **file** argument must have a write() method that accepts a single bytes argument. It can thus be an on-disk file opened for binary writing, a **io.BytesIO** instance, or any other custom object that meets this interface.

If **fix_imports** is true and **protocol** is less than 3, pickle will try to map the new Python 3 names to the old module names used in
Python 2, so that the pickle data stream is readable with Python 2.

**dump**(obj)
Write a pickled representation of obj to the open file object given in the constructor.

**persistent_id**(obj)
Do nothing by default. This exists so a subclass can override it.

If **persistent_id()** returns `None`, obj is pickled as usual.

Any other value causes **Pickler** to emit the returned value as a persistent ID for obj. The meaning of this persistent ID should be defined by **Unpickler.persistent_load()**. Note that the value returned by **persistent_id()** cannot itself have a persistent ID.

See *Persistence of External Objects* for details and examples of uses.

**dispatch_table**
A pickler object's dispatch table is a registry of *reduction functions* of the kind which can be declared using **copyreg.pickle()**. It is a mapping whose keys are classes and whose values are reduction functions. A reduction function takes a single argument of the associated class and should conform to the same interface as a **__reduce__()** method.

By default, a pickler object will not have a **dispatch_table** attribute, and it will instead use the global dispatch table managed by the **copyreg** module. However, to customize the pickling for a specific pickler object one can set the **dispatch_table** attribute to a dict-like object. Alternatively, if
a subclass of Pickler has a dispatch_table attribute then this will be used as the default dispatch table for instances of that class.

See Dispatch Tables for usage examples.

New in version 3.3.

fast

Deprecated. Enable fast mode if set to a true value. The fast mode disables the usage of memo, therefore speeding the pickling process by not generating superfluous PUT opcodes. It should not be used with self-referential objects, doing otherwise will cause Pickler to recurse infinitely.

Use pickletools.optimize() if you need more compact pickles.

class pickle.Unpickler(file, *, fix_imports=True, encoding="ASCII", errors="strict")

This takes a binary file for reading a pickle data stream.

The protocol version of the pickle is detected automatically, so no protocol argument is needed.

The argument file must have two methods, a read() method that takes an integer argument, and a readline() method that requires no arguments. Both methods should return bytes. Thus file can be an on-disk file object opened for binary reading, a io.BytesIO object, or any other custom object that meets this interface.

Optional keyword arguments are fix_imports, encoding and errors, which are used to control compatibility support for pickle stream
generated by Python 2. If fix_imports is true, pickle will try to map the old Python 2 names to the new names used in Python 3. The encoding and errors tell pickle how to decode 8-bit string instances pickled by Python 2; these default to ‘ASCII’ and ‘strict’, respectively. The encoding can be ‘bytes’ to read these 8-bit string instances as bytes objects.

**load()**

Read a pickled object representation from the open file object given in the constructor, and return the reconstituted object hierarchy specified therein. Bytes past the pickled object’s representation are ignored.

**persistent_load(pid)**

Raise an UnpicklingError by default.

If defined, persistent_load() should return the object specified by the persistent ID pid. If an invalid persistent ID is encountered, an UnpicklingError should be raised.

See Persistence of External Objects for details and examples of uses.

**find_class(module, name)**

Import module if necessary and return the object called name from it, where the module and name arguments are str objects. Note, unlike its name suggests, find_class() is also used for finding functions.

Subclasses may override this to gain control over what type of objects and how they can be loaded, potentially reducing security risks. Refer to Restricting Globals for details.
12.1.4. What can be pickled and unpickled?

The following types can be pickled:

- None, True, and False
- integers, floating point numbers, complex numbers
- strings, bytes, bytearrays
- tuples, lists, sets, and dictionaries containing only picklable objects
- functions defined at the top level of a module (using `def`, not `lambda`)
- built-in functions defined at the top level of a module
- classes that are defined at the top level of a module
- instances of such classes whose `__dict__` or the result of calling `__getstate__()` is picklable (see section *Pickling Class Instances* for details).

Attempts to pickle unpicklable objects will raise the `PicklingError` exception; when this happens, an unspecified number of bytes may have already been written to the underlying file. Trying to pickle a highly recursive data structure may exceed the maximum recursion depth, a `RuntimeError` will be raised in this case. You can carefully raise this limit with `sys.setrecursionlimit()`.

Note that functions (built-in and user-defined) are pickled by “fully qualified” name reference, not by value. [2] This means that only the function name is pickled, along with the name of the module the function is defined in. Neither the function’s code, nor any of its function attributes are pickled. Thus the defining module must be importable in the unpickling environment, and the module must contain the named object, otherwise an exception will be raised. [3]
Similarly, classes are pickled by named reference, so the same restrictions in the unpickling environment apply. Note that none of the class’s code or data is pickled, so in the following example the class attribute `attr` is not restored in the unpickling environment:

```python
class Foo:
    attr = 'A class attribute'

picklestring = pickle.dumps(Foo)
```

These restrictions are why picklable functions and classes must be defined in the top level of a module.

Similarly, when class instances are pickled, their class’s code and data are not pickled along with them. Only the instance data are pickled. This is done on purpose, so you can fix bugs in a class or add methods to the class and still load objects that were created with an earlier version of the class. If you plan to have long-lived objects that will see many versions of a class, it may be worthwhile to put a version number in the objects so that suitable conversions can be made by the class's `__setstate__() method.
12.1.5. Pickling Class Instances

In this section, we describe the general mechanisms available to you to define, customize, and control how class instances are pickled and unpickled.

In most cases, no additional code is needed to make instances picklable. By default, pickle will retrieve the class and the attributes of an instance via introspection. When a class instance is unpickled, its \_\_init\_(\_) method is usually not invoked. The default behaviour first creates an uninitialized instance and then restores the saved attributes. The following code shows an implementation of this behaviour:

```python
def save(obj):
    return (obj.__class__, obj.__dict__)

def load(cls, attributes):
    obj = cls.__new__(cls)
    obj.__dict__.update(attributes)
    return obj
```

Classes can alter the default behaviour by providing one or several special methods:

`object.__getnewargs_ex__()`

In protocols 4 and newer, classes that implements the `__getnewargs_ex__()` method can dictate the values passed to the `__new__()` method upon unpickling. The method must return a pair `(args, kwargs)` where `args` is a tuple of positional arguments and `kwargs` a dictionary of named arguments for constructing the object. Those will be passed to the `__new__()`
method upon unpickling.

You should implement this method if the __new__() method of your class requires keyword-only arguments. Otherwise, it is recommended for compatibility to implement __getnewargs__().

object.__getnewargs__()

This method serve a similar purpose as __getnewargs_ex__() but for protocols 2 and newer. It must return a tuple of arguments args which will be passed to the __new__() method upon unpickling.

In protocols 4 and newer, __getnewargs__() will not be called if __getnewargs_ex__() is defined.

object.__getstate__()

Classes can further influence how their instances are pickled; if the class defines the method __getstate__(), it is called and the returned object is pickled as the contents for the instance, instead of the contents of the instance’s dictionary. If the __getstate__() method is absent, the instance's __dict__ is pickled as usual.

object.__setstate__(state)

Upon unpickling, if the class defines __setstate__(), it is called with the unpickled state. In that case, there is no requirement for the state object to be a dictionary. Otherwise, the pickled state must be a dictionary and its items are assigned to the new instance's dictionary.

Note: If __getstate__() returns a false value, the
The _setstate__() method will not be called upon unpickling.

Refer to the section *Handling Stateful Objects* for more information about how to use the methods _getstate__() and _setstate__().

**Note:** At unpickling time, some methods like _getattr__(), _getattribute__(), or _setattr__() may be called upon the instance. In case those methods rely on some internal invariant being true, the type should implement _getnewargs__() or _getnewargs_ex__() to establish such an invariant; otherwise, neither _new__() nor _init__() will be called.

As we shall see, pickle does not use directly the methods described above. In fact, these methods are part of the copy protocol which implements the _reduce__() special method. The copy protocol provides a unified interface for retrieving the data necessary for pickling and copying objects. [4]

Although powerful, implementing _reduce__() directly in your classes is error prone. For this reason, class designers should use the high-level interface (i.e., _getnewargs_ex__(), _getstate__() and _setstate__()) whenever possible. We will show, however, cases where using _reduce__() is the only option or leads to more efficient pickling or both.

**object._reduce__()**

The interface is currently defined as follows. The _reduce__() method takes no argument and shall return either a string or preferably a tuple (the returned object is often referred to as the “reduce value”).
If a string is returned, the string should be interpreted as the name of a global variable. It should be the object's local name relative to its module; the pickle module searches the module namespace to determine the object's module. This behaviour is typically useful for singletons.

When a tuple is returned, it must be between two and five items long. Optional items can either be omitted, or `None` can be provided as their value. The semantics of each item are in order:

- A callable object that will be called to create the initial version of the object.
- A tuple of arguments for the callable object. An empty tuple must be given if the callable does not accept any argument.
- Optionally, the object's state, which will be passed to the object's `__setstate__()` method as previously described. If the object has no such method then, the value must be a dictionary and it will be added to the object's `__dict__` attribute.
- Optionally, an iterator (and not a sequence) yielding successive items. These items will be appended to the object either using `obj.append(item)` or, in batch, using `obj.extend(list_of_items)`. This is primarily used for list subclasses, but may be used by other classes as long as they have `append()` and `extend()` methods with the appropriate signature. (Whether `append()` or `extend()` is used depends on which pickle protocol version is used as well as the number of items to append, so both must be supported.)
- Optionally, an iterator (not a sequence) yielding successive key-value pairs. These items will be stored to the object using `obj[key] = value`. This is primarily used for dictionary subclasses, but may be used by other classes as long as they
implement \_\_setitem\_\_().

object.\_\_reduce_ex\_\_(\textit{protocol})

Alternatively, a \_\_reduce_ex\_\_() method may be defined. The only difference is this method should take a single integer argument, the protocol version. When defined, pickle will prefer it over the \_\_reduce\_\_() method. In addition, \_\_reduce\_\_() automatically becomes a synonym for the extended version. The main use for this method is to provide backwards-compatible reduce values for older Python releases.

12.1.5.1. Persistence of External Objects

For the benefit of object persistence, the \texttt{pickle} module supports the notion of a reference to an object outside the pickled data stream. Such objects are referenced by a persistent ID, which should be either a string of alphanumeric characters (for protocol 0) [5] or just an arbitrary object (for any newer protocol).

The resolution of such persistent IDs is not defined by the \texttt{pickle} module; it will delegate this resolution to the user defined methods on the pickler and unpickler, \texttt{persistent\_id()} and \texttt{persistent\_load()} respectively.

To pickle objects that have an external persistent id, the pickler must have a custom \texttt{persistent\_id()} method that takes an object as an argument and returns either \texttt{None} or the persistent id for that object. When \texttt{None} is returned, the pickler simply pickles the object as normal. When a persistent ID string is returned, the pickler will pickle that object, along with a marker so that the unpickler will recognize it as a persistent ID.
To unpickle external objects, the unpickler must have a custom `persistent_load()` method that takes a persistent ID object and returns the referenced object.

Here is a comprehensive example presenting how persistent ID can be used to pickle external objects by reference.

```python
# Simple example presenting how persistent ID can be used to pickle external objects by reference.
import pickle
import sqlite3
from collections import namedtuple

# Simple class representing a record in our database.
MemoRecord = namedtuple("MemoRecord", "key, task")

class DBPickler(pickle.Pickler):
    def persistent_id(self, obj):
        # Instead of pickling MemoRecord as a regular class instance,
        # persistent ID.
        if isinstance(obj, MemoRecord):
            # Here, our persistent ID is simply a tuple,
            # key, which refers to a specific record.
            return ("MemoRecord", obj.key)
        else:
            # If obj does not have a persistent ID,
            # needs to be pickled as usual.
            return None

class DBUnpickler(pickle.Unpickler):
    def __init__(self, file, connection):
        super().__init__(file)
```
def persistent_load(self, pid):
    # This method is invoked whenever a persistent ID is encountered.
    # Here, pid is the tuple returned by DBPickler.
    cursor = self.connection.cursor()
    type_tag, key_id = pid
    if type_tag == "MemoRecord":
        # Fetch the referenced record from the database.
        cursor.execute("SELECT * FROM memos WHERE key=?", (key_id,))
        key, task = cursor.fetchone()
        return MemoRecord(key, task)
    else:
        # Always raises an error if you cannot return the correct object.
        # Otherwise, the unpickler will think None is the object referenced
        # by the persistent ID.
        raise pickle.UnpicklingError("unsupported persistent object")

def main():
    import io
    import pprint

    # Initialize and populate our database.
    conn = sqlite3.connect(":memory:")
    cursor = conn.cursor()
    cursor.execute("CREATE TABLE memos(key INTEGER PRIMARY KEY, task TEXT)"
    tasks = ("give food to fish",
             "prepare group meeting",
             "fight with a zebra",
    )
    for task in tasks:
        cursor.execute("INSERT INTO memos VALUES(NULL, ?)", (task,))

    # Fetch the records to be pickled.
    cursor.execute("SELECT * FROM memos")
memos = [MemoRecord(key, task) for key, task in 
# Save the records using our custom DBPickler.
file = io.BytesIO()
DBPickler(file).dump(memos)

print("Pickled records:")
pprint.pprint(memos)

# Update a record, just for good measure.
cursor.execute("UPDATE memos SET task='learn ita"

# Load the records from the pickle data stream.
file.seek(0)
memos = DBUnpickler(file, conn).load()

print("Unpickled records:")
pprint.pprint(memos)

if __name__ == '__main__':
    main()

12.1.5.2. Dispatch Tables

If one wants to customize pickling of some classes without disturbing any other code which depends on pickling, then one can create a pickler with a private dispatch table.

The global dispatch table managed by the copyreg module is available as copyreg.dispatch_table. Therefore, one may choose to use a modified copy of copyreg.dispatch_table as a private dispatch table.

For example
f = io.BytesIO()
p = pickle.Pickler(f)
p.dispatch_table = copyreg.dispatch_table.copy()
p.dispatch_table[SomeClass] = reduce_SomeClass

class MyPickler(pickle.Pickler):
    dispatch_table = copyreg.dispatch_table.copy()
    dispatch_table[SomeClass] = reduce_SomeClass
f = io.BytesIO()
p = MyPickler(f)

creates an instance of pickle.Pickler with a private dispatch table which handles the SomeClass class specially. Alternatively, the code does the same, but all instances of MyPickler will by default share the same dispatch table. The equivalent code using the copyreg module is

copyreg.pickle(SomeClass, reduce_SomeClass)
f = io.BytesIO()
p = pickle.Pickler(f)

12.1.5.3. Handling Stateful Objects

Here's an example that shows how to modify pickling behavior for a class. The TextReader class opens a text file, and returns the line number and line contents each time its readline() method is called. If a TextReader instance is pickled, all attributes except the file object member are saved. When the instance is unpickled, the file is reopened, and reading resumes from the last location. The __setstate__() and __getstate__() methods are used to implement this behavior.
class TextReader:
    """Print and number lines in a text file."""

def __init__(self, filename):
    self.filename = filename
    self.file = open(filename)
    self.lineno = 0

def readline(self):
    self.lineno += 1
    line = self.file.readline()
    if not line:
        return None
    if line.endswith('
'):
        line = line[:-1]
    return "%i: %s" % (self.lineno, line)

def __getstate__(self):
    # Copy the object's state from self.__dict__
    # all our instance attributes. Always use the
    # method to avoid modifying the original state.
    state = self.__dict__.copy()
    # Remove the unpicklable entries.
    del state['file']
    return state

def __setstate__(self, state):
    # Restore instance attributes (i.e., filename)
    self.__dict__.update(state)
    # Restore the previously opened file's state
    # reopen it and read from it until the line
    file = open(self.filename)
    for _ in range(self.lineno):
        file.readline()
    # Finally, save the file.
    self.file = file
A sample usage might be something like this:

```python
>>> reader = TextReader("hello.txt")
>>> reader.readline()
'1: Hello world!
' >>> reader.readline()
'2: I am line number two.'
' >>> new_reader = pickle.loads(pickle.dumps(reader))
' >>> new_reader.readline()
'3: Goodbye!
'```
12.1.6. Restricting Globals

By default, unpickling will import any class or function that it finds in the pickle data. For many applications, this behaviour is unacceptable as it permits the unpickler to import and invoke arbitrary code. Just consider what this hand-crafted pickle data stream does when loaded:

```
>>> import pickle
>>> pickle.loads(b"cos\nsystem\n(S'echo hello world'
hello world
0
```

In this example, the unpickler imports the `os.system()` function and then apply the string argument “echo hello world”. Although this example is inoffensive, it is not difficult to imagine one that could damage your system.

For this reason, you may want to control what gets unpickled by customizing `Unpickler.find_class()`. Unlike its name suggests, `Unpickler.find_class()` is called whenever a global (i.e., a class or a function) is requested. Thus it is possible to either completely forbid globals or restrict them to a safe subset.

Here is an example of an unpickler allowing only few safe classes from the `builtins` module to be loaded:

```
import builtins
import io
import pickle

safe_builtins = {
    'range',
```
class RestrictedUnpickler(pickle.Unpickler):

    def find_class(self, module, name):
        # Only allow safe classes from builtins.
        if module == "builtins" and name in safe_builtins:
            return getattr(builtins, name)
        # Forbid everything else.
        raise pickle.UnpicklingError("global '%s.%s' is forbidden" % (module, name))

    def restricted_loads(s):
        """Helper function analogous to pickle.loads().""
        return RestrictedUnpickler(io.BytesIO(s)).load()

A sample usage of our unpickler working has intended:

>>> restricted_loads(pickle.dumps([1, 2, range(15)]))
[1, 2, range(0, 15)]
>>> restricted_loads(b"cos\nsystem\n(S'echo hello world')")
Traceback (most recent call last):
  File "", line 1, in restricted_loads
pickle.UnpicklingError: global 'os.system' is forbidden
>>> restricted_loads(b"cbuiltins\neval\n"'
...    b'(S\'getattr(__import__('os'),\n...    b"'echo hello world'\n\nTraceback (most recent call last):
  File "", line 1, in restricted_loads
pickle.UnpicklingError: global 'builtins.eval' is forbidden
As our examples shows, you have to be careful with what you allow to be unpickled. Therefore if security is a concern, you may want to consider alternatives such as the marshalling API in `xmlrpc.client` or third-party solutions.
12.1.7. Performance

Recent versions of the pickle protocol (from protocol 2 and upwards) feature efficient binary encodings for several common features and built-in types. Also, the pickle module has a transparent optimizer written in C.
12.1.8. Examples

For the simplest code, use the \texttt{dump()} and \texttt{load()} functions.

```python
import pickle

# An arbitrary collection of objects supported by pickle.
data = {
    'a': [1, 2.0, 3, 4+6j],
    'b': ("character string", b"byte string"),
    'c': set([None, True, False])
}

with open('data.pickle', 'wb') as f:
    # Pickle the 'data' dictionary using the highest protocol available.
pickle.dump(data, f, pickle.HIGHEST_PROTOCOL)
```

The following example reads the resulting pickled data.

```python
import pickle

with open('data.pickle', 'rb') as f:
    # The protocol version used is detected automatically, so we do not have to specify it.
data = pickle.load(f)
```

\textbf{Module} \texttt{copyreg}

Pickle interface constructor registration for extension types.

\textbf{Module} \texttt{pickletools}

Tools for working with and analyzing pickled data.
Module **shelve**
Indexed databases of objects; uses **pickle**.

Module **copy**
Shallow and deep object copying.

Module **marshal**
High-performance serialization of built-in types.

**Footnotes**

[1] Don't confuse this with the **marshal** module

[2] This is why **lambda** functions cannot be pickled: all **lambda** functions share the same name: `<lambda>`.

[3] The exception raised will likely be an **ImportError** or an **AttributeError** but it could be something else.

[4] The **copy** module uses this protocol for shallow and deep copying operations.

[5] The limitation on alphanumerical characters is due to the fact the persistent IDs, in protocol 0, are delimited by the newline character. Therefore if any kind of newline characters occurs in persistent IDs, the resulting pickle will become unreadable.
12.2. copyreg — Register pickle support functions

The copyreg module offers a way to define functions used while pickling specific objects. The pickle and copy modules use those functions when pickling/copying those objects. The module provides configuration information about object constructors which are not classes. Such constructors may be factory functions or class instances.

copyreg.constructor(object)

Declares object to be a valid constructor. If object is not callable (and hence not valid as a constructor), raises TypeError.

copyreg.pickle(type, function, constructor=None)

Declares that function should be used as a “reduction” function for objects of type type. function should return either a string or a tuple containing two or three elements.

The optional constructor parameter, if provided, is a callable object which can be used to reconstruct the object when called with the tuple of arguments returned by function at pickling time. TypeError will be raised if object is a class or constructor is not callable.

See the pickle module for more details on the interface expected of function and constructor. Note that the dispatch_table attribute of a pickler object or subclass of pickle.Pickler can also be used for declaring reduction functions.
12.2.1. Example

The example below would like to show how to register a pickle function and how it will be used:

```python
>>> import copyreg, copy, pickle
>>> class C(object):
...     def __init__(self, a):
...         self.a = a
...
>>> def pickle_c(c):
...     print("pickling a C instance..."))
...     return C, (c.a,)
...
>>> copyreg.pickle(C, pickle_c)
>>> c = C(1)
>>> d = copy.copy(c)
pickling a C instance...
>>> p = pickle.dumps(c)
pickling a C instance...
```
12.3. `shelve` — Python object persistence

**Source code:** Lib/shelve.py

A “shelf” is a persistent, dictionary-like object. The difference with “dbm” databases is that the values (not the keys!) in a shelf can be essentially arbitrary Python objects — anything that the `pickle` module can handle. This includes most class instances, recursive data types, and objects containing lots of shared sub-objects. The keys are ordinary strings.

```
shelve.open(filename, flag='c', protocol=None, writeback=False)
```

Open a persistent dictionary. The filename specified is the base filename for the underlying database. As a side-effect, an extension may be added to the filename and more than one file may be created. By default, the underlying database file is opened for reading and writing. The optional `flag` parameter has the same interpretation as the `flag` parameter of `dbm.open()`.

By default, version 3 pickles are used to serialize values. The version of the pickle protocol can be specified with the `protocol` parameter.

Because of Python semantics, a shelf cannot know when a mutable persistent-dictionary entry is modified. By default modified objects are written *only* when assigned to the shelf (see *Example*). If the optional `writeback` parameter is set to `True`, all entries accessed are also cached in memory, and written back on `sync()`.
and close(); this can make it handier to mutate mutable entries in the persistent dictionary, but, if many entries are accessed, it can consume vast amounts of memory for the cache, and it can make the close operation very slow since all accessed entries are written back (there is no way to determine which accessed entries are mutable, nor which ones were actually mutated).

**Note:** Do not rely on the shelf being closed automatically; always call close() explicitly when you don’t need it any more, or use `shelve.open()` as a context manager:

```python
with shelve.open('spam') as db:
    db['eggs'] = 'eggs'
```

**Warning:** Because the `shelve` module is backed by `pickle`, it is insecure to load a shelf from an untrusted source. Like with pickle, loading a shelf can execute arbitrary code.

Shelf objects support all methods supported by dictionaries. This eases the transition from dictionary based scripts to those requiring persistent storage.

Two additional methods are supported:

**Shelf.** `sync()`

Write back all entries in the cache if the shelf was opened with `writeback` set to `True`. Also empty the cache and synchronize the persistent dictionary on disk, if feasible. This is called automatically when the shelf is closed with `close()`.

**Shelf.** `close()`

Synchronize and close the persistent `dict` object. Operations on a
closed shelf will fail with a `ValueError`.

**See also:** Persistent dictionary recipe with widely supported storage formats and having the speed of native dictionaries.
12.3.1. Restrictions

- The choice of which database package will be used (such as `dbm.ndbm` or `dbm.gnu`) depends on which interface is available. Therefore it is not safe to open the database directly using `dbm`. The database is also (unfortunately) subject to the limitations of `dbm`, if it is used — this means that (the pickled representation of) the objects stored in the database should be fairly small, and in rare cases key collisions may cause the database to refuse updates.

- The `shelve` module does not support *concurrent* read/write access to shelved objects. (Multiple simultaneous read accesses are safe.) When a program has a shelf open for writing, no other program should have it open for reading or writing. Unix file locking can be used to solve this, but this differs across Unix versions and requires knowledge about the database implementation used.

```python
class shelve.Shelf(dict, protocol=None, writeback=False, keyencoding='utf-8')
```

A subclass of `collections.abc.MutableMapping` which stores pickled values in the `dict` object.

By default, version 0 pickles are used to serialize values. The version of the pickle protocol can be specified with the `protocol` parameter. See the `pickle` documentation for a discussion of the pickle protocols.

If the `writeback` parameter is `True`, the object will hold a cache of all entries accessed and write them back to the `dict` at sync and close times. This allows natural operations on mutable entries, but can consume much more memory and make sync and close take a
long time.

The *keyencoding* parameter is the encoding used to encode keys before they are used with the underlying dict.

A *Shelf* object can also be used as a context manager, in which case it will be automatically closed when the `with` block ends.

*Changed in version 3.2:* Added the *keyencoding* parameter; previously, keys were always encoded in UTF-8.

*Changed in version 3.4:* Added context manager support.

class `shelve.BsdDbShelf`(dict, protocol=None, writeback=False, keyencoding='utf-8')

A subclass of *Shelf* which exposes `first()`, `next()`, `previous()`, `last()` and `set_location()` which are available in the third-party bsddb module from pybsddb but not in other database modules. The `dict` object passed to the constructor must support those methods. This is generally accomplished by calling one of `bsddb.hashopen()`, `bsddb.btopen()` or `bsddb.rnopen()`. The optional `protocol`, `writeback`, and `keyencoding` parameters have the same interpretation as for the *Shelf* class.

class `shelve.DbfilenameShelf`(filename, flag='c', protocol=None, writeback=False)

A subclass of *Shelf* which accepts a `filename` instead of a dict-like object. The underlying file will be opened using `dbm.open()`. By default, the file will be created and opened for both read and write. The optional `flag` parameter has the same interpretation as for the `open()` function. The optional `protocol` and `writeback`
parameters have the same interpretation as for the `Shelf` class.
12.3.2. Example

To summarize the interface (key is a string, data is an arbitrary object):

```python
import shelve

d = shelve.open(filename)  # open -- file may get suffix by low-level library

d[key] = data  # store data at key (overwrites old using an existing key)
data = d[key]  # retrieve a COPY of data at key (raises # such key)
del d[key]  # delete data stored at key (raises # if no such key)
flag = key in d  # true if the key exists
klist = list(d.keys())  # a list of all existing keys

# as d was opened WITHOUT writeback=True, beware:
d['xx'] = [0, 1, 2]  # this works as expected, but

d['xx'].append(3)  # *this doesn't!* -- d['xx']

# having opened d without writeback=True, you need to

temp = d['xx']  # extracts the copy
temp.append(5)  # mutates the copy
d['xx'] = temp  # stores the copy right back, to

# or, d=shelve.open(filename,writeback=True) would let
# d['xx'].append(5) and have it work as expected, but
# consume more memory and make the d.close() operation

d.close()  # close it
```
See also:

**Module dbm**
Generic interface to dbm-style databases.

**Module pickle**
Object serialization used by shelve.
12.4. `marshal` — Internal Python object serialization

This module contains functions that can read and write Python values in a binary format. The format is specific to Python, but independent of machine architecture issues (e.g., you can write a Python value to a file on a PC, transport the file to a Sun, and read it back there). Details of the format are undocumented on purpose; it may change between Python versions (although it rarely does). [1]

This is not a general “persistence” module. For general persistence and transfer of Python objects through RPC calls, see the modules `pickle` and `shelve`. The `marshal` module exists mainly to support reading and writing the “pseudo-compiled” code for Python modules of `.pyc` files. Therefore, the Python maintainers reserve the right to modify the marshal format in backward incompatible ways should the need arise. If you’re serializing and de-serializing Python objects, use the `pickle` module instead – the performance is comparable, version independence is guaranteed, and pickle supports a substantially wider range of objects than marshal.

**Warning:** The `marshal` module is not intended to be secure against erroneous or maliciously constructed data. Never unmarshal data received from an untrusted or unauthenticated source.

Not all Python object types are supported; in general, only objects whose value is independent from a particular invocation of Python can be written and read by this module. The following types are supported: booleans, integers, floating point numbers, complex numbers, strings, bytes, bytearrays, tuples, lists, sets, frozensets, dictionaries, and code
objects, where it should be understood that tuples, lists, sets, frozensets and dictionaries are only supported as long as the values contained therein are themselves supported. Singletons None, Ellipsis and StopIteration can also be marshalled and unmarshalled. For format version lower than 3, recursive lists, sets and dictionaries cannot be written (see below).

There are functions that read/write files as well as functions operating on strings.

The module defines these functions:

**marshal.dump(value, file[, version])**
Write the value on the open file. The value must be a supported type. The file must be an open file object such as `sys.stdout` or returned by `open()` or `os.popen()`. It must be opened in binary mode (`'wb'` or `'w+b'`).

If the value has (or contains an object that has) an unsupported type, a `ValueError` exception is raised — but garbage data will also be written to the file. The object will not be properly read back by `load()`.

The `version` argument indicates the data format that `dump` should use (see below).

**marshal.load(file)**
Read one value from the open file and return it. If no valid value is read (e.g. because the data has a different Python version's incompatible marshal format), raise `EOFError`, `ValueError` or `TypeError`. The file must be an open file object opened in binary mode (`'rb'` or `'r+b'`).
**Note:** If an object containing an unsupported type was marshalled with `dump()`, `load()` will substitute None for the unmarshallable type.

`marshal.dumps(value[, version])`

Return the string that would be written to a file by `dump(value, file)`. The value must be a supported type. Raise a `ValueError` exception if value has (or contains an object that has) an unsupported type.

The `version` argument indicates the data format that `dumps` should use (see below).

`marshal.loads(string)`

Convert the string to a value. If no valid value is found, raise `EOFError`, `ValueError` or `TypeError`. Extra characters in the string are ignored.

In addition, the following constants are defined:

`marshal.version`

Indicates the format that the module uses. Version 0 is the historical format, version 1 shares interned strings and version 2 uses a binary format for floating point numbers. Version 3 adds support for object instancing and recursion. The current version is 3.

**Footnotes**

The name of this module stems from a bit of terminology used by the designers of Modula-3 (amongst others), who use the term “marshalling” for shipping of data around in a self-
[1] contained form. Strictly speaking, “to marshal” means to convert some data from internal to external form (in an RPC buffer for instance) and “unmarshalling” for the reverse process.
12.5. dbm — Interfaces to Unix “databases”

dbm is a generic interface to variants of the DBM database — dbm.gnu or dbm.ndbm. If none of these modules is installed, the slow-but-simple implementation in module dbm.dumb will be used. There is a third party interface to the Oracle Berkeley DB.

exception dbm.error

A tuple containing the exceptions that can be raised by each of the supported modules, with a unique exception also named dbm.error as the first item — the latter is used when dbm.error is raised.

dbm.whichdb(filename)

This function attempts to guess which of the several simple database modules available — dbm.gnu, dbm.ndbm or dbm.dumb — should be used to open a given file.

Returns one of the following values: None if the file can’t be opened because it’s unreadable or doesn’t exist; the empty string ('') if the file’s format can’t be guessed; or a string containing the required module name, such as 'dbm.ndbm' or 'dbm.gnu'.

dbm.open(file, flag='r', mode=0o666)

Open the database file file and return a corresponding object.

If the database file already exists, the whichdb() function is used to determine its type and the appropriate module is used; if it does not exist, the first module listed above that can be imported is
used.

The optional *flag* argument can be:

<table>
<thead>
<tr>
<th>Value</th>
<th>Meaning</th>
</tr>
</thead>
<tbody>
<tr>
<td>'r'</td>
<td>Open existing database for reading only (default)</td>
</tr>
<tr>
<td>'w'</td>
<td>Open existing database for reading and writing</td>
</tr>
<tr>
<td>'c'</td>
<td>Open database for reading and writing, creating it if it doesn’t exist</td>
</tr>
<tr>
<td>'n'</td>
<td>Always create a new, empty database, open for reading and writing</td>
</tr>
</tbody>
</table>

The optional *mode* argument is the Unix mode of the file, used only when the database has to be created. It defaults to octal 0o666 (and will be modified by the prevailing umask).

The object returned by `open()` supports the same basic functionality as dictionaries; keys and their corresponding values can be stored, retrieved, and deleted, and the `in` operator and the `keys()` method are available, as well as `get()` and `setdefault()`.

*Changed in version 3.2:* `get()` and `setdefault()` are now available in all database modules.

Key and values are always stored as bytes. This means that when strings are used they are implicitly converted to the default encoding before being stored.

These objects also support being used in a `with` statement, which will automatically close them when done.

*Changed in version 3.4:* Added native support for the context management protocol to the objects returned by `open()`.
The following example records some hostnames and a corresponding title, and then prints out the contents of the database:

```python
import dbm

# Open database, creating it if necessary.
with dbm.open('cache', 'c') as db:

    # Record some values
    db[b'hello'] = b'there'
    db['www.python.org'] = 'Python Website'
    db['www.cnn.com'] = 'Cable News Network'

    # Note that the keys are considered bytes now.
    assert db[b'www.python.org'] == b'Python Website'
    # Notice how the value is now in bytes.
    assert db['www.cnn.com'] == b'Cable News Network'

    # Often-used methods of the dict interface work too.
    print(db.get('python.org', b'not present'))

    # Storing a non-string key or value will raise an exception (most likely a TypeError).
    db['www.yahoo.com'] = 4

    # db is automatically closed when leaving the with statement.
```

See also:

**Module** shelf
Persistence module which stores non-string data.

The individual submodules are described in the following sections.
12.5.1. dbm.gnu — GNU’s reinterpretation of dbm

This module is quite similar to the dbm module, but uses the GNU library gdbm instead to provide some additional functionality. Please note that the file formats created by dbm.gnu and dbm.ndbm are incompatible.

The dbm.gnu module provides an interface to the GNU DBM library. dbm.gnu.gdbm objects behave like mappings (dictionaries), except that keys and values are always converted to bytes before storing. Printing a gdbm object doesn’t print the keys and values, and the items() and values() methods are not supported.

exception dbm.gnu.error

Raised on dbm.gnu-specific errors, such as I/O errors. KeyError is raised for general mapping errors like specifying an incorrect key.

dbm.gnu.open(filename[, flag[, mode]])

Open a gdbm database and return a gdbm object. The filename argument is the name of the database file.

The optional flag argument can be:

<table>
<thead>
<tr>
<th>Value</th>
<th>Meaning</th>
</tr>
</thead>
<tbody>
<tr>
<td>'r'</td>
<td>Open existing database for reading only (default)</td>
</tr>
<tr>
<td>'w'</td>
<td>Open existing database for reading and writing</td>
</tr>
<tr>
<td>'c'</td>
<td>Open database for reading and writing, creating it if it doesn’t exist</td>
</tr>
<tr>
<td>'n'</td>
<td>Always create a new, empty database, open for</td>
</tr>
</tbody>
</table>
The following additional characters may be appended to the flag to control how the database is opened:

<table>
<thead>
<tr>
<th>Value</th>
<th>Meaning</th>
</tr>
</thead>
<tbody>
<tr>
<td>'f'</td>
<td>Open the database in fast mode. Writes to the database will not be synchronized.</td>
</tr>
<tr>
<td>'s'</td>
<td>Synchronized mode. This will cause changes to the database to be immediately written to the file.</td>
</tr>
<tr>
<td>'u'</td>
<td>Do not lock database.</td>
</tr>
</tbody>
</table>

Not all flags are valid for all versions of gdbm. The module constant open_flags is a string of supported flag characters. The exception error is raised if an invalid flag is specified.

The optional mode argument is the Unix mode of the file, used only when the database has to be created. It defaults to octal 0o666.

In addition to the dictionary-like methods, gdbm objects have the following methods:

**gdbm.firstkey()**

It’s possible to loop over every key in the database using this method and the nextkey() method. The traversal is ordered by gdbm’s internal hash values, and won’t be sorted by the key values. This method returns the starting key.

**gdbm.nextkey(key)**

Returns the key that follows key in the traversal. The following code prints every key in the database db, without having to create a list in memory that contains them all:
```python
k = db.firstkey()
while k != None:
    print(k)
    k = db.nextkey(k)
```

gdbm. **reorganize**()

If you have carried out a lot of deletions and would like to shrink the space used by the gdbm file, this routine will reorganize the database. gdbm objects will not shorten the length of a database file except by using this reorganization; otherwise, deleted file space will be kept and reused as new (key, value) pairs are added.

gdbm. **sync**()

When the database has been opened in fast mode, this method forces any unwritten data to be written to the disk.
12.5.2. dbm.ndbm — Interface based on ndbm

The dbm.ndbm module provides an interface to the Unix “(n)dbm” library. Dbm objects behave like mappings (dictionaries), except that keys and values are always stored as bytes. Printing a dbm object doesn’t print the keys and values, and the items() and values() methods are not supported.

This module can be used with the “classic” ndbm interface or the GNU GDBM compatibility interface. On Unix, the *configure* script will attempt to locate the appropriate header file to simplify building this module.

*exception* dbm.ndbm.error
Raised on dbm.ndbm-specific errors, such as I/O errors. *KeyError* is raised for general mapping errors like specifying an incorrect key.

dbm.ndbm.library
Name of the ndbm implementation library used.

dbm.ndbm.open(filename[, flag[, mode]])
Open a dbm database and return a dbm object. The *filename* argument is the name of the database file (without the .dir or .pag extensions).

The optional *flag* argument must be one of these values:

<table>
<thead>
<tr>
<th>Value</th>
<th>Meaning</th>
</tr>
</thead>
<tbody>
<tr>
<td>'r'</td>
<td>Open existing database for reading only (default)</td>
</tr>
<tr>
<td>'w'</td>
<td>Open existing database for reading and writing</td>
</tr>
<tr>
<td>-----</td>
<td>---------------------------------------------</td>
</tr>
<tr>
<td>'c'</td>
<td>Open database for reading and writing, creating it if it doesn’t exist</td>
</tr>
<tr>
<td>'n'</td>
<td>Always create a new, empty database, open for reading and writing</td>
</tr>
</tbody>
</table>

The optional *mode* argument is the Unix mode of the file, used only when the database has to be created. It defaults to octal 0o666 (and will be modified by the prevailing umask).
12.5.3. `dbm.dumb` — Portable DBM implementation

**Note:** The `dbm.dumb` module is intended as a last resort fallback for the `dbm` module when a more robust module is not available. The `dbm.dumb` module is not written for speed and is not nearly as heavily used as the other database modules.

The `dbm.dumb` module provides a persistent dictionary-like interface which is written entirely in Python. Unlike other modules such as `dbm.gnu` no external library is required. As with other persistent mappings, the keys and values are always stored as bytes.

The module defines the following:

`exception dbm.dumb.error`
Raised on `dbm.dumb`-specific errors, such as I/O errors. `KeyError` is raised for general mapping errors like specifying an incorrect key.

`dbm.dumb.open(filename[, flag[, mode]])`
Open a `dumbdbm` database and return a `dumbdbm` object. The `filename` argument is the basename of the database file (without any specific extensions). When a `dumbdbm` database is created, files with `.dat` and `.dir` extensions are created.

The optional `flag` argument is currently ignored; the database is always opened for update, and will be created if it does not exist.

The optional `mode` argument is the Unix mode of the file, used only when the database has to be created. It defaults to octal `0o666`
(and will be modified by the prevailing umask).

In addition to the methods provided by the `collections.abc.MutableMapping` class, `dumbdbm` objects provide the following method:

```python
dumbdbm.sync()
```

Synchronize the on-disk directory and data files. This method is called by the `Shelve.sync()` method.
12.6. **sqlite3 — DB-API 2.0 interface for SQLite databases**

SQLite is a C library that provides a lightweight disk-based database that doesn’t require a separate server process and allows accessing the database using a nonstandard variant of the SQL query language. Some applications can use SQLite for internal data storage. It's also possible to prototype an application using SQLite and then port the code to a larger database such as PostgreSQL or Oracle.

sqlite3 was written by Gerhard Häring and provides a SQL interface compliant with the DB-API 2.0 specification described by [PEP 249](https://www.python.org/dev/peps/pep-0249/).

To use the module, you must first create a `Connection` object that represents the database. Here the data will be stored in the `example.db` file:

```python
import sqlite3
conn = sqlite3.connect('example.db')
```

You can also supply the special name `:memory:` to create a database in RAM.

Once you have a `Connection`, you can create a `Cursor` object and call its `execute()` method to perform SQL commands:

```python
c = conn.cursor()

# Create table
c.execute('''create table stocks
(date text, trans text, symbol text,
```
Usually your SQL operations will need to use values from Python variables. You shouldn’t assemble your query using Python’s string operations because doing so is insecure; it makes your program vulnerable to an SQL injection attack.

Instead, use the DB-API’s parameter substitution. Put `?` as a placeholder wherever you want to use a value, and then provide a tuple of values as the second argument to the cursor’s `execute()` method. (Other database modules may use a different placeholder, such as `%s` or `:1`.) For example:

```python
# Never do this -- insecure!
symbol = 'IBM'
c.execute("select * from stocks where symbol = '%s'" % symbol)

# Do this instead
t = ('IBM',)
c.execute('select * from stocks where symbol=?', t)

# Larger example
for t in [(2006-03-28, 'BUY', 'IBM', 1000, 45.00),
          (2006-04-05, 'BUY', 'MSFT', 1000, 72.00),
          (2006-04-06, 'SELL', 'IBM', 500, 53.00),
          ]:
```
To retrieve data after executing a SELECT statement, you can either treat the cursor as an *iterator*, call the cursor's *fetchone()* method to retrieve a single matching row, or call *fetchall()* to get a list of the matching rows.

This example uses the iterator form:

```python
>>> c = conn.cursor()
>>> c.execute('select * from stocks order by price')
>>> for row in c:
...     print(row)
...
('2006-01-05', 'BUY', 'RHAT', 100, 35.14)
('2006-03-28', 'BUY', 'IBM', 1000, 45.0)
('2006-04-06', 'SELL', 'IBM', 500, 53.0)
('2006-04-05', 'BUY', 'MSOFT', 1000, 72.0)
```

PEP written by Marc-André Lemburg.
12.6.1. Module functions and constants

sqlite3.version
The version number of this module, as a string. This is not the version of the SQLite library.

sqlite3.version_info
The version number of this module, as a tuple of integers. This is not the version of the SQLite library.

sqlite3.sqlite_version
The version number of the run-time SQLite library, as a string.

sqlite3.sqlite_version_info
The version number of the run-time SQLite library, as a tuple of integers.

sqlite3.PARSE_DECLTYPES
This constant is meant to be used with the detect_types parameter of the connect() function.

Setting it makes the sqlite3 module parse the declared type for each column it returns. It will parse out the first word of the declared type, i.e. for “integer primary key”, it will parse out “integer”, or for “number(10)” it will parse out “number”. Then for that column, it will look into the converters dictionary and use the converter function registered for that type there.

sqlite3.PARSE_COLNAMES
This constant is meant to be used with the detect_types parameter of the connect() function.
Setting this makes the SQLite interface parse the column name for each column it returns. It will look for a string formed [mytype] in there, and then decide that ‘mytype’ is the type of the column. It will try to find an entry of ‘mytype’ in the converters dictionary and then use the converter function found there to return the value. The column name found in `Cursor.description` is only the first word of the column name, i.e. if you use something like 'as "x [datetime]"' in your SQL, then we will parse out everything until the first blank for the column name: the column name would simply be “x”.

```python
sqlite3.connect(database[, timeout, detect_types,
  isolation_level, check_same_thread, factory, cached_statements, uri])
```

Opens a connection to the SQLite database file `database`. You can use `":memory:"` to open a database connection to a database that resides in RAM instead of on disk.

When a database is accessed by multiple connections, and one of the processes modifies the database, the SQLite database is locked until that transaction is committed. The `timeout` parameter specifies how long the connection should wait for the lock to go away until raising an exception. The default for the timeout parameter is 5.0 (five seconds).

For the `isolation_level` parameter, please see the `Connection.isolation_level` property of `Connection` objects.

SQLite natively supports only the types TEXT, INTEGER, REAL, BLOB and NULL. If you want to use other types you must add support for them yourself. The `detect_types` parameter and the using custom `converters` registered with the module-level
**register_converter()** function allow you to easily do that.

*detect_types* defaults to 0 (i.e. off, no type detection), you can set it to any combination of **PARSE_DECLTYPES** and **PARSE_COLNAMES** to turn type detection on.

By default, the **sqlite3** module uses its **Connection** class for the connect call. You can, however, subclass the **Connection** class and make **connect()** use your class instead by providing your class for the **factory** parameter.

Consult the section *SQLite and Python types* of this manual for details.

The **sqlite3** module internally uses a statement cache to avoid SQL parsing overhead. If you want to explicitly set the number of statements that are cached for the connection, you can set the **cached_statements** parameter. The currently implemented default is to cache 100 statements.

If *uri* is true, *database* is interpreted as a URI. This allows you to specify options. For example, to open a database in read-only mode you can use:

```python
db = sqlite3.connect('file:path/to/database?mode=ro')
```

More information about this feature, including a list of recognized options, can be found in the **SQLite URI documentation**.

*Changed in version 3.4:* Added the **uri** parameter.

**sqlite3.register_converter**(typename, callable)

Registers a callable to convert a bytestring from the database into
a custom Python type. The callable will be invoked for all database values that are of the type typename. Confer the parameter detect_types of the connect() function for how the type detection works. Note that the case of typename and the name of the type in your query must match!

sqlite3.register_adapter(type, callable)

 Registers a callable to convert the custom Python type type into one of SQLite's supported types. The callable callable accepts as single parameter the Python value, and must return a value of the following types: int, float, str or bytes.

sqlite3.complete_statement(sql)

 Returns True if the string sql contains one or more complete SQL statements terminated by semicolons. It does not verify that the SQL is syntactically correct, only that there are no unclosed string literals and the statement is terminated by a semicolon.

This can be used to build a shell for SQLite, as in the following example:

```python
# A minimal SQLite shell for experiments
import sqlite3
con = sqlite3.connect(":memory:")
con.isolation_level = None
cur = con.cursor()

buffer = ""

print("Enter your SQL commands to execute in sqlite3.
print("Enter a blank line to exit.")
```
```python
while True:
    line = input()
    if line == "":
        break
    buffer += line
    if sqlite3.complete_statement(buffer):
        try:
            buffer = buffer.strip()
            cur.execute(buffer)

        except sqlite3.Error as e:
            print("An error occurred:", e.args[0])
            buffer = ""

    con.close()```

**sqlite3.enable_callback_tracebacks(flag)**

By default you will not get any tracebacks in user-defined functions, aggregates, converters, authorizer callbacks etc. If you want to debug them, you can call this function with `flag` set to `True`. Afterwards, you will get tracebacks from callbacks on `sys.stderr`. Use `False` to disable the feature again.
12.6.2. Connection Objects

class sqlite3.Connection

A SQLite database connection has the following attributes and methods:

isolation_level

Get or set the current isolation level. None for autocommit mode or one of “DEFERRED”, “IMMEDIATE” or “EXCLUSIVE”. See section Controlling Transactions for a more detailed explanation.

in_transaction

True if a transaction is active (there are uncommitted changes), False otherwise. Read-only attribute.

New in version 3.2.

cursor([cursorClass])

The cursor method accepts a single optional parameter cursorClass. If supplied, this must be a custom cursor class that extends sqlite3.Cursor.

commit()

This method commits the current transaction. If you don’t call this method, anything you did since the last call to commit() is not visible from other database connections. If you wonder why you don’t see the data you’ve written to the database, please check you didn’t forget to call this method.

rollback()
This method rolls back any changes to the database since the last call to `commit()`.

`close()`
This closes the database connection. Note that this does not automatically call `commit()`. If you just close your database connection without calling `commit()` first, your changes will be lost!

`execute(sql[, parameters])`
This is a nonstandard shortcut that creates an intermediate cursor object by calling the cursor method, then calls the cursor’s `execute` method with the parameters given.

`executemany(sql[, parameters])`
This is a nonstandard shortcut that creates an intermediate cursor object by calling the cursor method, then calls the cursor’s `executemany` method with the parameters given.

`executescript(sql_script)`
This is a nonstandard shortcut that creates an intermediate cursor object by calling the cursor method, then calls the cursor’s `executescript` method with the parameters given.

`create_function(name, num_params, func)`
Creates a user-defined function that you can later use from within SQL statements under the function name `name`. `num_params` is the number of parameters the function accepts, and `func` is a Python callable that is called as the SQL function.

The function can return any of the types supported by SQLite: bytes, str, int, float and None.
Example:

```python
import sqlite3
import hashlib

def md5sum(t):
    return hashlib.md5(t).hexdigest()

con = sqlite3.connect(":memory:")
con.create_function("md5", 1, md5sum)
cur = con.cursor()
cur.execute("select md5(?)", (b"foo",))
print(cur.fetchone()[0])
```

`create_aggregate(name, num_params, aggregate_class)`

Creates a user-defined aggregate function.

The aggregate class must implement a `step` method, which accepts the number of parameters `num_params`, and a `finalize` method which will return the final result of the aggregate.

The `finalize` method can return any of the types supported by SQLite: bytes, str, int, float and None.

Example:

```python
import sqlite3

class MySum:
    def __init__(self):
        self.count = 0

    def step(self, value):
        self.count += value
```
```
def finalize(self):
    return self.count

con = sqlite3.connect(':memory:)
con.create_aggregate("mysum", 1, MySum)
cur = con.cursor()
cur.execute("create table test(i)")
cur.execute("insert into test(i) values (1)")
cur.execute("insert into test(i) values (2)")
cur.execute("select mysum(i) from test")
print(cur.fetchone()[0])
```

**create_collation**(name, callable)

Creates a collation with the specified name and callable. The callable will be passed two string arguments. It should return -1 if the first is ordered lower than the second, 0 if they are ordered equal and 1 if the first is ordered higher than the second. Note that this controls sorting (ORDER BY in SQL) so your comparisons don’t affect other SQL operations.

Note that the callable will get its parameters as Python bytestrings, which will normally be encoded in UTF-8.

The following example shows a custom collation that sorts “the wrong way”:

```
import sqlite3

def collate_reverse(string1, string2):
    if string1 == string2:
        return 0
    elif string1 < string2:
        return 1
    else:
```
```
return -1

con = sqlite3.connect(":memory:"
con.create_collation("reverse", collate_reverse

cur = con.cursor()
cur.execute("create table test(x)"
cur.executemany("insert into test(x) values (?)
cur.execute("select x from test order by x coll
for row in cur:
    print(row)
con.close()
```

To remove a collation, call create_collation with None as callable:

```
con.create_collation("reverse", None)
```

**interrupt()**

You can call this method from a different thread to abort any queries that might be executing on the connection. The query will then abort and the caller will get an exception.

**set_authorizer(authorizer_callback)**

This routine registers a callback. The callback is invoked for each attempt to access a column of a table in the database. The callback should return SQLITE_OK if access is allowed, SQLITE_DENY if the entire SQL statement should be aborted with an error and SQLITE_IGNORE if the column should be treated as a NULL value. These constants are available in the sqlite3 module.

The first argument to the callback signifies what kind of
operation is to be authorized. The second and third argument will be arguments or `None` depending on the first argument. The 4th argument is the name of the database ("main", "temp", etc.) if applicable. The 5th argument is the name of the innermost trigger or view that is responsible for the access attempt or `None` if this access attempt is directly from input SQL code.

Please consult the SQLite documentation about the possible values for the first argument and the meaning of the second and third argument depending on the first one. All necessary constants are available in the `sqlite3` module.

### set_progress_handler

```
set_progress_handler(handler, n)
```

This routine registers a callback. The callback is invoked for every `n` instructions of the SQLite virtual machine. This is useful if you want to get called from SQLite during long-running operations, for example to update a GUI.

If you want to clear any previously installed progress handler, call the method with `None` for `handler`.

### set_trace_callback

```
set_trace_callback(trace_callback)
```

Registers `trace_callback` to be called for each SQL statement that is actually executed by the SQLite backend.

The only argument passed to the callback is the statement (as string) that is being executed. The return value of the callback is ignored. Note that the backend does not only run statements passed to the `Cursor.execute()` methods. Other sources include the transaction management of the Python module and the execution of triggers defined in the current database.

Passing `None` as `trace_callback` will disable the trace callback.
New in version 3.3.

**enable_load_extension**(enabled)

This routine allows/disallows the SQLite engine to load SQLite extensions from shared libraries. SQLite extensions can define new functions, aggregates or whole new virtual table implementations. One well-known extension is the fulltext-search extension distributed with SQLite.

Loadable extensions are disabled by default. See [1].

New in version 3.2.

```python
import sqlite3

con = sqlite3.connect(":memory:")

# enable extension loading
con.enable_load_extension(True)

# Load the fulltext search extension
con.execute("select load_extension('./fts3.so')")

# alternatively you can load the extension using
# con.load_extension('./fts3.so')

# disable extension loading again
con.enable_load_extension(False)

# example from SQLite wiki
con.execute("create virtual table recipe using fts3(name, ingredients)"
con.executescript(""
    insert into recipe (name, ingredients) values ('broccoli stew', 'broccoli peppers cheese tomatoes')
    insert into recipe (name, ingredients) values ('pumpkin stew', 'pumpkin onions garlic celery')
    insert into recipe (name, ingredients) values ('broccoli pie', 'broccoli cheese onions flour')
    insert into recipe (name, ingredients) values ('pumpkin pie', 'pumpkin sugar flour butter')
")
```
load_extension(path)

This routine loads a SQLite extension from a shared library. You have to enable extension loading with enable_load_extension() before you can use this routine.

Loadable extensions are disabled by default. See [1].

New in version 3.2.

row_factory

You can change this attribute to a callable that accepts the cursor and the original row as a tuple and will return the real result row. This way, you can implement more advanced ways of returning results, such as returning an object that can also access columns by name.

Example:

```python
import sqlite3

def dict_factory(cursor, row):
    d = {}
    for idx, col in enumerate(cursor.description):
        d[col[0]] = row[idx]
    return d

con = sqlite3.connect(":memory:"
con.row_factory = dict_factory
cur = con.cursor() cur.execute("select 1 as a")```
```python
print(cur.fetchone()['a'])
```

If returning a tuple doesn’t suffice and you want name-based access to columns, you should consider setting `row_factory` to the highly-optimized `sqlite3.Row` type. `Row` provides both index-based and case-insensitive name-based access to columns with almost no memory overhead. It will probably be better than your own custom dictionary-based approach or even a db_row based solution.

**text_factory**

Using this attribute you can control what objects are returned for the TEXT data type. By default, this attribute is set to `str` and the `sqlite3` module will return Unicode objects for TEXT. If you want to return bytestrings instead, you can set it to `bytes`.

For efficiency reasons, there’s also a way to return `str` objects only for non-ASCII data, and `bytes` otherwise. To activate it, set this attribute to `sqlite3.OptimizedUnicode`.

You can also set it to any other callable that accepts a single bytestring parameter and returns the resulting object.

See the following example code for illustration:

```python
import sqlite3

con = sqlite3.connect(':memory:)
cur = con.cursor()

AUSTRIA = '\xd6sterreich'
```
# by default, rows are returned as Unicode
cur.execute("select ?", (AUSTRIA,))
row = cur.fetchone()
assert row[0] == AUSTRIA

# but we can make sqlite3 always return bytestrings
con.text_factory = bytes
cur.execute("select ?", (AUSTRIA,))
row = cur.fetchone()
assert type(row[0]) is bytes
# the bytestrings will be encoded in UTF-8, unless...
# database ...
assert row[0] == AUSTRIA.encode("utf-8")

# we can also implement a custom text_factory.
# here we implement one that appends "foo" to all strings
con.text_factory = lambda x: x.decode("utf-8")
cur.execute("select ?", ("bar" ,))
row = cur.fetchone()
assert row[0] == "barfoo"

total_changes
Returns the total number of database rows that have been modified, inserted, or deleted since the database connection was opened.

iterdump
Returns an iterator to dump the database in an SQL text format. Useful when saving an in-memory database for later restoration. This function provides the same capabilities as the .dump command in the sqlite3 shell.

Example:

# Convert file existing_db.db to SQL dump file
import sqlite3, os

con = sqlite3.connect('existing_db.db')
with open('dump.sql', 'w') as f:
    for line in con.iterdump():
        f.write('%s
' % line)
12.6.3. Cursor Objects

class sqlite3.Cursor

A Cursor instance has the following attributes and methods.

**execute**(sql[, parameters])

Executes an SQL statement. The SQL statement may be parametrized (i.e. placeholders instead of SQL literals). The sqlite3 module supports two kinds of placeholders: question marks (qmark style) and named placeholders (named style).

Here’s an example of both styles:

```python
import sqlite3

con = sqlite3.connect(':memory:')
cur = con.cursor()
cur.execute("create table people (name_last, age)

who = "Yeltsin"
age = 72

# This is the qmark style:
cur.execute("insert into people values (?, ?)

# And this is the named style:
cur.execute("select * from people where name_last=",

print(cur.fetchone())
```

**execute()** will only execute a single SQL statement. If you try to execute more than one statement with it, it will raise a Warning. Use **executescript()** if you want to execute
multiple SQL statements with one call.

**executemany**(*sql, seq_of_parameters*)

Executes an SQL command against all parameter sequences or mappings found in the sequence *sql*. The *sqlite3* module also allows using an *iterator* yielding parameters instead of a sequence.

```python
import sqlite3
class IterChars:
    def __init__(self):
        self.count = ord('a')

    def __iter__(self):
        return self

    def __next__(self):
        if self.count > ord('z'):
            raise StopIteration
        self.count += 1
        return (chr(self.count - 1),)  # this is a 1-tuple

con = sqlite3.connect(':memory:)
cur = con.cursor()
cur.execute("create table characters(c)"

theIter = IterChars()
cur.executemany("insert into characters(c) values (?)")
cur.execute("select c from characters")
print(cur.fetchall())
```

Here's a shorter example using a *generator*:
import sqlite3  
import string

def char_generator():
    for c in string.ascii_lowercase:
        yield (c,)

con = sqlite3.connect(":memory:")
cur = con.cursor()
cur.execute("create table characters(c)"")
cur.executemany("insert into characters(c) values(?)")
cur.execute("select c from characters")
print(cur.fetchall())

executescript(sql_script)

This is a nonstandard convenience method for executing multiple SQL statements at once. It issues a COMMIT statement first, then executes the SQL script it gets as a parameter.

sql_script can be an instance of str or bytes.

Example:

import sqlite3

con = sqlite3.connect(":memory:")
cur = con.cursor()
cur.executescript(""
    create table person(
        firstname,
        lastname,
        age
    );
"""
create table book(
    title,
    author,
    published
);

insert into book(title, author, published)
values ('Dirk Gently''s Holistic Detective Agency',
        'Douglas Adams',
        1987
);

fetchone()
Fetches the next row of a query result set, returning a single sequence, or None when no more data is available.

fetchmany(size=cursor.arraysize)
Fetches the next set of rows of a query result, returning a list. An empty list is returned when no more rows are available.

The number of rows to fetch per call is specified by the size parameter. If it is not given, the cursor’s arraysize determines the number of rows to be fetched. The method should try to fetch as many rows as indicated by the size parameter. If this is not possible due to the specified number of rows not being available, fewer rows may be returned.

Note there are performance considerations involved with the size parameter. For optimal performance, it is usually best to use the arraysize attribute. If the size parameter is used, then it is best for it to retain the same value from one fetchmany()
call to the next.

**fetchall()**

Fetches all (remaining) rows of a query result, returning a list. Note that the cursor’s arraysize attribute can affect the performance of this operation. An empty list is returned when no rows are available.

**rowcount**

Although the Cursor class of the sqlite3 module implements this attribute, the database engine’s own support for the determination of “rows affected”/”rows selected” is quirky.

For `executemany()` statements, the number of modifications are summed up into `rowcount`.

As required by the Python DB API Spec, the `rowcount` attribute “is -1 in case no `executeXX()` has been performed on the cursor or the rowcount of the last operation is not determinable by the interface”. This includes `SELECT` statements because we cannot determine the number of rows a query produced until all rows were fetched.

With SQLite versions before 3.6.5, `rowcount` is set to 0 if you make a `DELETE FROM table` without any condition.

**lastrowid**

This read-only attribute provides the rowid of the last modified row. It is only set if you issued a `INSERT` statement using the `execute()` method. For operations other than `INSERT` or when `executemany()` is called, `lastrowid` is set to `None`.

**description**
This read-only attribute provides the column names of the last query. To remain compatible with the Python DB API, it returns a 7-tuple for each column where the last six items of each tuple are `None`.

It is set for `SELECT` statements without any matching rows as well.
12.6.4. Row Objects

class sqlite3.Row

A Row instance serves as a highly optimized row_factory for Connection objects. It tries to mimic a tuple in most of its features.

It supports mapping access by column name and index, iteration, representation, equality testing and len().

If two Row objects have exactly the same columns and their members are equal, they compare equal.

keys()

This method returns a tuple of column names. Immediately after a query, it is the first member of each tuple in Cursor.description.

Let's assume we initialize a table as in the example given above:

```python
conn = sqlite3.connect(':memory:)
c = conn.cursor()
c.execute('''create table stocks
  (date text, trans text, symbol text,
   qty real, price real)''')
c.execute('''insert into stocks
  values ('2006-01-05','BUY','RHAT',100,35.14)''')
conn.commit()
c.close()
```

Now we plug Row in:
>>> conn.row_factory = sqlite3.Row
>>> c = conn.cursor()
>>> c.execute('select * from stocks')
<sqlite3.Cursor object at 0x7f4e7dd8fa80>
>>> r = c.fetchone()
>>> type(r)
<class 'sqlite3.Row'>
>>> tuple(r)
('2006-01-05', 'BUY', 'RHAT', 100.0, 35.14)
>>> len(r)
5
>>> r[2]
'RHAT'
>>> r.keys()
['date', 'trans', 'symbol', 'qty', 'price']
>>> r['qty']
100.0
>>> for member in r:
...     print(member)
...
2006-01-05
BUY
RHAT
100.0
35.14
12.6.5. SQLite and Python types

12.6.5.1. Introduction

SQLite natively supports the following types: NULL, INTEGER, REAL, TEXT, BLOB.

The following Python types can thus be sent to SQLite without any problem:

<table>
<thead>
<tr>
<th>Python type</th>
<th>SQLite type</th>
</tr>
</thead>
<tbody>
<tr>
<td>None</td>
<td>NULL</td>
</tr>
<tr>
<td>int</td>
<td>INTEGER</td>
</tr>
<tr>
<td>float</td>
<td>REAL</td>
</tr>
<tr>
<td>str</td>
<td>TEXT</td>
</tr>
<tr>
<td>bytes</td>
<td>BLOB</td>
</tr>
</tbody>
</table>

This is how SQLite types are converted to Python types by default:

<table>
<thead>
<tr>
<th>SQLite type</th>
<th>Python type</th>
</tr>
</thead>
<tbody>
<tr>
<td>NULL</td>
<td>None</td>
</tr>
<tr>
<td>INTEGER</td>
<td>int</td>
</tr>
<tr>
<td>REAL</td>
<td>float</td>
</tr>
<tr>
<td>TEXT</td>
<td>depends on text_factory, str by default</td>
</tr>
<tr>
<td>BLOB</td>
<td>bytes</td>
</tr>
</tbody>
</table>

The type system of the sqlite3 module is extensible in two ways: you can store additional Python types in a SQLite database via object
adaptation, and you can let the `sqlite3` module convert SQLite types to different Python types via converters.

12.6.5.2. Using adapters to store additional Python types in SQLite databases

As described before, SQLite supports only a limited set of types natively. To use other Python types with SQLite, you must adapt them to one of the sqlite3 module's supported types for SQLite: one of NoneType, int, float, str, bytes.

The `sqlite3` module uses Python object adaptation, as described in PEP 246 for this. The protocol to use is PrepareProtocol.

There are two ways to enable the `sqlite3` module to adapt a custom Python type to one of the supported ones.

12.6.5.2.1. Letting your object adapt itself

This is a good approach if you write the class yourself. Let's suppose you have a class like this:

```python
class Point:
    def __init__(self, x, y):
        self.x, self.y = x, y
```

Now you want to store the point in a single SQLite column. First you'll have to choose one of the supported types first to be used for representing the point. Let's just use `str` and separate the coordinates using a semicolon. Then you need to give your class a method `__conform__(self, protocol)` which must return the converted value. The parameter `protocol` will be PrepareProtocol.
import sqlite3

class Point:
    def __init__(self, x, y):
        self.x, self.y = x, y

    def __conform__(self, protocol):
        if protocol is sqlite3.PrepareProtocol:
            return "%f;%f" % (self.x, self.y)

con = sqlite3.connect(":memory:")
cur = con.cursor()

p = Point(4.0, -3.2)
cur.execute("select ?", (p,))
print(cur.fetchone()[0])

12.6.5.2.2. Registering an adapter callable

The other possibility is to create a function that converts the type to the string representation and register the function with register_adapter().

import sqlite3

class Point:
    def __init__(self, x, y):
        self.x, self.y = x, y

def adapt_point(point):
    return "%f;%f" % (point.x, point.y)

sqlite3.register_adapter(Point, adapt_point)

con = sqlite3.connect(":memory:"
The `sqlite3` module has two default adapters for Python's built-in `datetime.date` and `datetime.datetime` types. Now let's suppose we want to store `datetime.datetime` objects not in ISO representation, but as a Unix timestamp.

```python
import sqlite3
import datetime
import time

def adapt_datetime(ts):
    return time.mktime(ts.timetuple())

sqlite3.register_adapter(datetime.datetime, adapt_datetime)

con = sqlite3.connect(':memory:)
cur = con.cursor()

now = datetime.datetime.now()
cur.execute("select ?", (now,))
print(cur.fetchone()[0])
```

12.6.5.3. Converting SQLite values to custom Python types

Writing an adapter lets you send custom Python types to SQLite. But to make it really useful we need to make the Python to SQLite to Python roundtrip work.
Enter converters.

Let's go back to the Point class. We stored the x and y coordinates separated via semicolons as strings in SQLite.

First, we'll define a converter function that accepts the string as a parameter and constructs a Point object from it.

Note: Converter functions always get called with a string, no matter under which data type you sent the value to SQLite.

```python
def convert_point(s):
    x, y = map(float, s.split(b";"))
    return Point(x, y)
```

Now you need to make the sqlite3 module know that what you select from the database is actually a point. There are two ways of doing this:

- Implicitly via the declared type
- Explicitly via the column name

Both ways are described in section Module functions and constants, in the entries for the constants PARSE_DECLTYPES and PARSE_COLNAMES.

The following example illustrates both approaches.

```python
import sqlite3
class Point:
    def __init__(self, x, y):
        self.x, self.y = x, y
```
def __repr__(self):
    return "(%f;%f)" % (self.x, self.y)

def adapt_point(point):
    return \"%f;%f\" % (point.x, point.y)).encode('ascii')

def convert_point(s):
    x, y = list(map(float, s.split(b";")))
    return Point(x, y)

# Register the adapter
sqlite3.register_adapter(Point, adapt_point)

# Register the converter
sqlite3.register_converter("point", convert_point)

p = Point(4.0, -3.2)

# 1) Using declared types
con = sqlite3.connect(":memory:", detect_types=ssqlite3.PARSE_DECLTYPES)
cur = con.cursor()
cur.execute("create table test(p point)"

cur.execute("insert into test(p) values (?)", (p,))
cur.execute("select p from test")
print("with declared types:", cur.fetchone()[0])
cur.close()
con.close()

# 1) Using column names
con = sqlite3.connect(":memory:", detect_types=ssqlite3.PARSE_DECLTYPES)
cur = con.cursor()
cur.execute("create table test(p)"

cur.execute("insert into test(p) values (?)", (p,))
12.6.5.4. Default adapters and converters

There are default adapters for the date and datetime types in the datetime module. They will be sent as ISO dates/ISO timestamps to SQLite.

The default converters are registered under the name “date” for `datetime.date` and under the name “timestamp” for `datetime.datetime`.

This way, you can use date/timestamps from Python without any additional fiddling in most cases. The format of the adapters is also compatible with the experimental SQLite date/time functions.

The following example demonstrates this.
print(today, "=>", row[0], type(row[0]))
print(now, "=>", row[1], type(row[1]))

cur.execute('select current_date as "d [date]", current_timestamp as "ts [timestamp]"')
row = cur.fetchone()
print("current_date", row[0], type(row[0]))
print("current_timestamp", row[1], type(row[1]))

If a timestamp stored in SQLite has a fractional part longer than 6 numbers, its value will be truncated to microsecond precision by the timestamp converter.
12.6.6. Controlling Transactions

By default, the sqlite3 module opens transactions implicitly before a Data Modification Language (DML) statement (i.e. INSERT/UPDATE/DELETE/REPLACE), and commits transactions implicitly before a non-DML, non-query statement (i.e. anything other than SELECT or the aforementioned).

So if you are within a transaction and issue a command like CREATE TABLE ... , VACUUM, PRAGMA, the sqlite3 module will commit implicitly before executing that command. There are two reasons for doing that. The first is that some of these commands don’t work within transactions. The other reason is that sqlite3 needs to keep track of the transaction state (if a transaction is active or not). The current transaction state is exposed through the Connection.in_transaction attribute of the connection object.

You can control which kind of BEGIN statements sqlite3 implicitly executes (or none at all) via the isolation_level parameter to the connect() call, or via the isolation_level property of connections.

If you want autocommit mode, then set isolation_level to None.

Otherwise leave it at its default, which will result in a plain “BEGIN” statement, or set it to one of SQLite’s supported isolation levels: “DEFERRED”, “IMMEDIATE” or “EXCLUSIVE”. 
12.6.7. Using **sqlite3** efficiently

12.6.7.1. Using shortcut methods

Using the nonstandard `execute()`, `executemany()` and `executescript()` methods of the `Connection` object, your code can be written more concisely because you don’t have to create the (often superfluous) `Cursor` objects explicitly. Instead, the `Cursor` objects are created implicitly and these shortcut methods return the cursor objects. This way, you can execute a `SELECT` statement and iterate over it directly using only a single call on the `Connection` object.

```python
import sqlite3

persons = [
    ("Hugo", "Boss"),
    ("Calvin", "Klein")
]

con = sqlite3.connect(':memory:)

# Create the table
con.execute("create table person(firstname, lastname)

# Fill the table
con.executemany("insert into person(firstname, lastname)

# Print the table contents
for row in con.execute("select firstname, lastname for
    print(row)

print("I just deleted", con.execute("delete from per
```
12.6.7.2. Accessing columns by name instead of by index

One useful feature of the sqlite3 module is the built-in sqlite3.Row class designed to be used as a row factory.

Rows wrapped with this class can be accessed both by index (like tuples) and case-insensitively by name:

```python
import sqlite3
con = sqlite3.connect(":memory:")
con.row_factory = sqlite3.Row

cur = con.cursor()
cur.execute("select 'John' as name, 42 as age")
for row in cur:
    assert row[0] == row["name"]
    assert row["name"] == row["nAmE"]
    assert row[1] == row["age"]
    assert row[1] == row["AgE"]
```

12.6.7.3. Using the connection as a context manager

Connection objects can be used as context managers that automatically commit or rollback transactions. In the event of an exception, the transaction is rolled back; otherwise, the transaction is committed:

```python
import sqlite3
con = sqlite3.connect(":memory:")
```
con.execute("create table person (id integer primary key, firstname varchar unique)\n# Successful, con.commit() is called automatically after\nwith con:
    con.execute("insert into person(firstname) values (?)\n# con.rollback() is called after the with block finishes\n# exception is still raised and must be caught\ntry:
    with con:
        con.execute("insert into person(firstname) values (?)\nexcept sqlite3.IntegrityError:
    print("couldn't add Joe twice")
12.6.8. Common issues

12.6.8.1. Multithreading

Older SQLite versions had issues with sharing connections between threads. That's why the Python module disallows sharing connections and cursors between threads. If you still try to do so, you will get an exception at runtime.

The only exception is calling the `interrupt()` method, which only makes sense to call from a different thread.

Footnotes

(1, 2) The sqlite3 module is not built with loadable extension support by default, because some platforms (notably Mac OS X) have SQLite libraries which are compiled without this feature. To get loadable extension support, you must pass –enable-loadable-sqlite-extensions to configure.
13. Data Compression and Archiving

The modules described in this chapter support data compression with the zlib, gzip, bzip2 and lzma algorithms, and the creation of ZIP- and tar-format archives. See also Archiving operations provided by the shutil module.

13.1. zlib — Compression compatible with gzip

For applications that require data compression, the functions in this module allow compression and decompression, using the zlib library. The zlib library has its own home page at http://www.zlib.net. There are known incompatibilities between the Python module and versions of the zlib library earlier than 1.1.3; 1.1.3 has a security vulnerability, so we recommend using 1.1.4 or later.

zlib's functions have many options and often need to be used in a particular order. This documentation doesn’t attempt to cover all of the permutations; consult the zlib manual at http://www.zlib.net/manual.html for authoritative information.

For reading and writing .gz files see the gzip module.

The available exception and functions in this module are:

exception zlib.error
   Exception raised on compression and decompression errors.

zlib.adler32(data[, value])
   Computes a Adler-32 checksum of data. (An Adler-32 checksum is almost as reliable as a CRC32 but can be computed much more quickly.) If value is present, it is used as the starting value of the checksum; otherwise, a fixed default value is used. This allows computing a running checksum over the concatenation of several inputs. The algorithm is not cryptographically strong, and should not be used for authentication or digital signatures. Since the
algorithm is designed for use as a checksum algorithm, it is not suitable for use as a general hash algorithm.

Always returns an unsigned 32-bit integer.

Note: To generate the same numeric value across all Python versions and platforms use adler32(data) & 0xffffffff. If you are only using the checksum in packed binary format this is not necessary as the return value is the correct 32bit binary representation regardless of sign.

zlib.compress(data[, level])
Compresses the bytes in data, returning a bytes object containing compressed data. level is an integer from 0 to 9 controlling the level of compression; 1 is fastest and produces the least compression, 9 is slowest and produces the most. 0 is no compression. The default value is 6. Raises the error exception if any error occurs.

zlib.compressobj(level=-1, method=DEFLATED, wbits=15, memlevel=8, strategy=Z_DEFAULT_STRATEGY[, zdict])
Returns a compression object, to be used for compressing data streams that won’t fit into memory at once.

level is the compression level – an integer from 0 to 9. A value of 1 is fastest and produces the least compression, while a value of 9 is slowest and produces the most. 0 is no compression. The default value is 6.

method is the compression algorithm. Currently, the only supported value is DEFLATED.
**wbits** is the base two logarithm of the size of the window buffer. This should be an integer from 8 to 15. Higher values give better compression, but use more memory.

**memlevel** controls the amount of memory used for internal compression state. Valid values range from 1 to 9. Higher values using more memory, but are faster and produce smaller output.

**strategy** is used to tune the compression algorithm. Possible values are `Z_DEFAULT_STRATEGY`, `Z_FILTERED`, and `Z_HUFFMAN_ONLY`.

**zdict** is a predefined compression dictionary. This is a sequence of bytes (such as a `bytes` object) containing subsequences that are expected to occur frequently in the data that is to be compressed. Those subsequences that are expected to be most common should come at the end of the dictionary.

*Changed in version 3.3:* Added the **zdict** parameter and keyword argument support.

**zlib.crc32(data[, value])**

Computes a CRC (Cyclic Redundancy Check) checksum of **data**. If **value** is present, it is used as the starting value of the checksum; otherwise, a fixed default value is used. This allows computing a running checksum over the concatenation of several inputs. The algorithm is not cryptographically strong, and should not be used for authentication or digital signatures. Since the algorithm is designed for use as a checksum algorithm, it is not suitable for use as a general hash algorithm.

Always returns an unsigned 32-bit integer.
Note: To generate the same numeric value across all Python versions and platforms, use \texttt{crc32(data) \& 0xffffffff}. If you are only using the checksum in packed binary format this is not necessary as the return value is the correct 32-bit binary representation regardless of sign.

\texttt{zlib.decompress(data[, wbits[, bufsize]])}

Decompresses the bytes in \texttt{data}, returning a bytes object containing the uncompressed data. The \texttt{wbits} parameter controls the size of the window buffer, and is discussed further below. If \texttt{bufsize} is given, it is used as the initial size of the output buffer. Raises the \texttt{error} exception if any error occurs.

The absolute value of \texttt{wbits} is the base two logarithm of the size of the history buffer (the “window size”) used when compressing data. Its absolute value should be between 8 and 15 for the most recent versions of the \texttt{zlib} library, larger values resulting in better compression at the expense of greater memory usage. When decompressing a stream, \texttt{wbits} must not be smaller than the size originally used to compress the stream; using a too-small value will result in an exception. The default value is therefore the highest value, 15. When \texttt{wbits} is negative, the standard \texttt{gzip} header is suppressed.

\texttt{bufsize} is the initial size of the buffer used to hold decompressed data. If more space is required, the buffer size will be increased as needed, so you don’t have to get this value exactly right; tuning it will only save a few calls to \texttt{malloc()}. The default size is 16384.

\texttt{zlib.decompressobj(wbits=15[, zdict])}

Returns a decompression object, to be used for decompressing
data streams that won’t fit into memory at once.

The \textit{wbits} parameter controls the size of the window buffer.

The \textit{zdict} parameter specifies a predefined compression dictionary. If provided, this must be the same dictionary as was used by the compressor that produced the data that is to be decompressed.

\begin{customnote}
\textbf{Note: } If \textit{zdict} is a mutable object (such as a \texttt{bytearray}), you must not modify its contents between the call to \texttt{decompressobj()} and the first call to the decompressor’s \texttt{decompress()} method.
\end{customnote}

\textit{Changed in version 3.3: Added the \textit{zdict} parameter.}

Compression objects support the following methods:

\textbf{Compress.\texttt{compress}(\textit{data})}

Compress \textit{data}, returning a bytes object containing compressed data for at least part of the data in \textit{data}. This data should be concatenated to the output produced by any preceding calls to the \texttt{compress()} method. Some input may be kept in internal buffers for later processing.

\textbf{Compress.\texttt{flush}([\textit{mode}])}

All pending input is processed, and a bytes object containing the remaining compressed output is returned. \textit{mode} can be selected from the constants \texttt{Z\_SYNC\_FLUSH}, \texttt{Z\_FULL\_FLUSH}, or \texttt{Z\_FINISH}, defaulting to \texttt{Z\_FINISH}. \texttt{Z\_SYNC\_FLUSH} and \texttt{Z\_FULL\_FLUSH} allow compressing further bytestrings of data, while \texttt{Z\_FINISH} finishes the compressed stream and prevents compressing any more data. After calling \texttt{flush()} with \textit{mode} set
to Z_FINISH, the `compress()` method cannot be called again; the only realistic action is to delete the object.

**Compress. `copy()`**

Returns a copy of the compression object. This can be used to efficiently compress a set of data that share a common initial prefix.

Decompression objects support the following methods and attributes:

**Decompress. `unused_data`**

A bytes object which contains any bytes past the end of the compressed data. That is, this remains `b""` until the last byte that contains compression data is available. If the whole bytestring turned out to contain compressed data, this is `b""`, an empty bytes object.

**Decompress. `unconsumed_tail`**

A bytes object that contains any data that was not consumed by the last `decompress()` call because it exceeded the limit for the uncompressed data buffer. This data has not yet been seen by the zlib machinery, so you must feed it (possibly with further data concatenated to it) back to a subsequent `decompress()` method call in order to get correct output.

**Decompress. `eof`**

A boolean indicating whether the end of the compressed data stream has been reached.

This makes it possible to distinguish between a properly-formed compressed stream, and an incomplete or truncated one.

*New in version 3.3.*
Decompress. **decompress**(data[, max_length])

Decompress data, returning a bytes object containing the uncompressed data corresponding to at least part of the data in string. This data should be concatenated to the output produced by any preceding calls to the decompress() method. Some of the input data may be preserved in internal buffers for later processing.

If the optional parameter max_length is supplied then the return value will be no longer than max_length. This may mean that not all of the compressed input can be processed; and unconsumed data will be stored in the attribute unconsumed_tail. This bytestring must be passed to a subsequent call to decompress() if decompression is to continue. If max_length is not supplied then the whole input is decompressed, and unconsumed_tail is empty.

Decompress. **flush**(length)

All pending input is processed, and a bytes object containing the remaining uncompressed output is returned. After calling flush(), the decompress() method cannot be called again; the only realistic action is to delete the object.

The optional parameter length sets the initial size of the output buffer.

Decompress. **copy**()

Returns a copy of the decompression object. This can be used to save the state of the decompressor midway through the data stream in order to speed up random seeks into the stream at a future point.

Information about the version of the zlib library in use is available
through the following constants:

**zlib.ZLIB_VERSION**

The version string of the zlib library that was used for building the module. This may be different from the zlib library actually used at runtime, which is available as `ZLIB_RUNTIME_VERSION`.

**zlib.ZLIB_RUNTIME_VERSION**

The version string of the zlib library actually loaded by the interpreter.

*New in version 3.3.*

13.2. **gzip** — Support for **gzip** files

**Source code:** Lib/gzip.py

This module provides a simple interface to compress and decompress files just like the GNU programs **gzip** and **gunzip** would.

The data compression is provided by the **zlib** module.

The **gzip** module provides the **GzipFile** class, as well as the **open()**, **compress()** and **decompress()** convenience functions. The **GzipFile** class reads and writes **gzip**-format files, automatically compressing or decompressing the data so that it looks like an ordinary **file object**.

Note that additional file formats which can be decompressed by the **gzip** and **gunzip** programs, such as those produced by **compress** and **pack**, are not supported by this module.

The module defines the following items:

**gzip.open**(filename, mode='rb', compresslevel=9, encoding=None, errors=None, newline=None)

Open a gzip-compressed file in binary or text mode, returning a **file object**.

The **filename** argument can be an actual filename (a **str** or **bytes** object), or an existing file object to read from or write to.
The *mode* argument can be any of `'r'`, `'rb'`, `'a'`, `'ab'`, `'w'`, `'wb'`, `'x'` or `'xb'` for binary mode, or `'rt'`, `'at'`, `'wt'`, or `'xt'` for text mode. The default is `'rb'`.

The *compresslevel* argument is an integer from 0 to 9, as for the `GzipFile` constructor.

For binary mode, this function is equivalent to the `GzipFile` constructor: `GzipFile(filename, mode, compresslevel)`. In this case, the *encoding*, *errors* and *newline* arguments must not be provided.

For text mode, a `GzipFile` object is created, and wrapped in an `io.TextIOWrapper` instance with the specified encoding, error handling behavior, and line ending(s).

*Changed in version 3.3:* Added support for *filename* being a file object, support for text mode, and the *encoding*, *errors* and *newline* arguments.

*Changed in version 3.4:* Added support for the `'x'`, `'xb'` and `'xt'` modes.

class gzip.GzipFile(filename=None, mode=None, compresslevel=9, fileobj=None, mtime=None)

Constructor for the `GzipFile` class, which simulates most of the methods of a `file object`, with the exception of the `truncate()` method. At least one of `fileobj` and `filename` must be given a non-trivial value.

The new class instance is based on `fileobj`, which can be a regular file, a `io.BytesIO` object, or any other object which simulates a file. It defaults to `None`, in which case `filename` is opened to
provide a file object.

When fileobj is not None, the filename argument is only used to be included in the gzip file header, which may include the original filename of the uncompressed file. It defaults to the filename of fileobj, if discernible; otherwise, it defaults to the empty string, and in this case the original filename is not included in the header.

The mode argument can be any of 'r', 'rb', 'a', 'ab', 'w', 'wb', 'x', or 'xb', depending on whether the file will be read or written. The default is the mode of fileobj if discernible; otherwise, the default is 'rb'.

Note that the file is always opened in binary mode. To open a compressed file in text mode, use open() (or wrap your GzipFile with an io.TextIOWrapper).

The compresslevel argument is an integer from 0 to 9 controlling the level of compression; 1 is fastest and produces the least compression, and 9 is slowest and produces the most compression. 0 is no compression. The default is 9.

The mtime argument is an optional numeric timestamp to be written to the stream when compressing. All gzip compressed streams are required to contain a timestamp. If omitted or None, the current time is used. This module ignores the timestamp when decompressing; however, some programs, such as gunzip, make use of it. The format of the timestamp is the same as that of the return value of time.time() and of the st_mtime attribute of the object returned by os.stat().

Calling a GzipFile object's close() method does not close
fileobj, since you might wish to append more material after the compressed data. This also allows you to pass a io.BytesIO object opened for writing as fileobj, and retrieve the resulting memory buffer using the io.BytesIO object's getvalue() method.

GzipFile supports the io.BufferedIOBase interface, including iteration and the with statement. Only the truncate() method isn't implemented.

GzipFile also provides the following method:

peek([n])

Read n uncompressed bytes without advancing the file position. At most one single read on the compressed stream is done to satisfy the call. The number of bytes returned may be more or less than requested.

Note: While calling peek() does not change the file position of the GzipFile, it may change the position of the underlying file object (e.g. if the GzipFile was constructed with the fileobj parameter).

New in version 3.2.

Changed in version 3.1: Support for the with statement was added, along with the mtime argument.

Changed in version 3.2: Support for zero-padded and unseekable files was added.

Changed in version 3.3: The io.BufferedIOBase.read1() method is now implemented.
Changed in version 3.4: Added support for the 'x' and 'xb' modes.

```python
gzip.compress(data, compresslevel=9)
```
Compress the `data`, returning a `bytes` object containing the compressed data. `compresslevel` has the same meaning as in the `GzipFile` constructor above.

*New in version 3.2.*

```python
gzip.decompress(data)
```
Decompress the `data`, returning a `bytes` object containing the uncompressed data.

*New in version 3.2.*
13.2.1. Examples of usage

Example of how to read a compressed file:

```python
import gzip
with gzip.open('/home/joe/file.txt.gz', 'rb') as f:
    file_content = f.read()
```

Example of how to create a compressed GZIP file:

```python
import gzip
content = b"Lots of content here"
with gzip.open('/home/joe/file.txt.gz', 'wb') as f:
    f.write(content)
```

Example of how to GZIP compress an existing file:

```python
import gzip
with open('/home/joe/file.txt', 'rb') as f_in:
    with gzip.open('/home/joe/file.txt.gz', 'wb') as f_out:
        f_out.writelines(f_in)
```

Example of how to GZIP compress a binary string:

```python
import gzip
s_in = b"Lots of content here"
s_out = gzip.compress(s_in)
```

See also:

Module zlib

The basic data compression module needed to support the gzip file format.
13.3. bz2 — Support for bzip2 compression

This module provides a comprehensive interface for compressing and decompressing data using the bzip2 compression algorithm.

The bz2 module contains:

- The `open()` function and `BZ2File` class for reading and writing compressed files.
- The `BZ2Compressor` and `BZ2Decompressor` classes for incremental (de)compression.
- The `compress()` and `decompress()` functions for one-shot (de)compression.

All of the classes in this module may safely be accessed from multiple threads.
13.3.1. (De)compression of files

bz2. open(filename, mode='r', compresslevel=9, encoding=None, errors=None, newline=None)

Open a bzip2-compressed file in binary or text mode, returning a file object.

As with the constructor for BZ2File, the filename argument can be an actual filename (a str or bytes object), or an existing file object to read from or write to.

The mode argument can be any of 'r', 'rb', 'w', 'wb', 'x', 'xb', 'a' or 'ab' for binary mode, or 'rt', 'wt', 'xt', or 'at' for text mode. The default is 'rb'.

The compresslevel argument is an integer from 1 to 9, as for the BZ2File constructor.

For binary mode, this function is equivalent to the BZ2File constructor: BZ2File(filename, mode, compresslevel=compresslevel). In this case, the encoding, errors and newline arguments must not be provided.

For text mode, a BZ2File object is created, and wrapped in an io.TextIOWrapper instance with the specified encoding, error handling behavior, and line ending(s).

New in version 3.3.

Changed in version 3.4: The 'x' (exclusive creation) mode was added.
class bz2.BZ2File(filename, mode='r', buffering=None, compresslevel=9)

Open a bzip2-compressed file in binary mode.

If filename is a str or bytes object, open the named file directly. Otherwise, filename should be a file object, which will be used to read or write the compressed data.

The mode argument can be either 'r' for reading (default), 'w' for overwriting, 'x' for exclusive creation, or 'a' for appending. These can equivalently be given as 'rb', 'wb', 'xb' and 'ab' respectively.

If filename is a file object (rather than an actual file name), a mode of 'w' does not truncate the file, and is instead equivalent to 'a'.

The buffering argument is ignored. Its use is deprecated.

If mode is 'w' or 'a', compresslevel can be a number between 1 and 9 specifying the level of compression: 1 produces the least compression, and 9 (default) produces the most compression.

If mode is 'r', the input file may be the concatenation of multiple compressed streams.

BZ2File provides all of the members specified by the io.BufferedIOBase, except for detach() and truncate(). Iteration and the with statement are supported.

BZ2File also provides the following method:

peek([n])

Return buffered data without advancing the file position. At least
one byte of data will be returned (unless at EOF). The exact number of bytes returned is unspecified.

**Note:** While calling `peek()` does not change the file position of the `BZ2File`, it may change the position of the underlying file object (e.g. if the `BZ2File` was constructed by passing a file object for `filename`).

*New in version 3.3.*

*Changed in version 3.1:* Support for the `with` statement was added.

*Changed in version 3.3:* The `fileno()`, `readable()`, `seekable()`, `writable()`, `read1()` and `readinto()` methods were added.

*Changed in version 3.3:* Support was added for `filename` being a `file object` instead of an actual filename.

*Changed in version 3.3:* The `'a'` (append) mode was added, along with support for reading multi-stream files.

*Changed in version 3.4:* The `'x'` (exclusive creation) mode was added.
13.3.2. Incremental (de)compression

```python
class bz2.BZ2Compressor(compresslevel=9)
    Create a new compressor object. This object may be used to compress data incrementally. For one-shot compression, use the `compress()` function instead.

    `compresslevel`, if given, must be a number between 1 and 9. The default is 9.

    `compress(data)`
    Provide data to the compressor object. Returns a chunk of compressed data if possible, or an empty byte string otherwise.

    When you have finished providing data to the compressor, call the `flush()` method to finish the compression process.

    `flush()`
    Finish the compression process. Returns the compressed data left in internal buffers.

    The compressor object may not be used after this method has been called.
```

```python
class bz2.BZ2Decompressor
    Create a new decompressor object. This object may be used to decompress data incrementally. For one-shot compression, use the `decompress()` function instead.
```

**Note:** This class does not transparently handle inputs containing multiple compressed streams, unlike `decompress()` and `BZ2File`. If you need to decompress a multi-stream input with
BZ2Decompressor, you must use a new decompressor for each stream.

`decompress(data)`

Provide data to the decompressor object. Returns a chunk of decompressed data if possible, or an empty byte string otherwise.

Attempting to decompress data after the end of the current stream is reached raises an EOFError. If any data is found after the end of the stream, it is ignored and saved in the `unused_data` attribute.

`eof`

True if the end-of-stream marker has been reached.

*New in version 3.3.*

`unused_data`

Data found after the end of the compressed stream.

If this attribute is accessed before the end of the stream has been reached, its value will be b''.
13.3.3. One-shot (de)compression

bz2. **compress**(data, compresslevel=9)

Compress data.

*compresslevel*, if given, must be a number between 1 and 9. The default is 9.

For incremental compression, use a BZ2Compressor instead.

bz2. **decompress**(data)

Decompress data.

If data is the concatenation of multiple compressed streams, decompress all of the streams.

For incremental decompression, use a BZ2Decompressor instead.

*Changed in version 3.3:* Support for multi-stream inputs was added.
13.4. **lzma** — Compression using the LZMA algorithm

*New in version 3.3.*

This module provides classes and convenience functions for compressing and decompressing data using the LZMA compression algorithm. Also included is a file interface supporting the `.xz` and legacy `.lzma` file formats used by the `xz` utility, as well as raw compressed streams.

The interface provided by this module is very similar to that of the `bz2` module. However, note that `LZMAFile` is *not* thread-safe, unlike `bz2.BZ2File`, so if you need to use a single `LZMAFile` instance from multiple threads, it is necessary to protect it with a lock.

*exception* `lzma.LZMAError`

This exception is raised when an error occurs during compression or decompression, or while initializing the compressor/decompressor state.
13.4.1. Reading and writing compressed files

```python
lzma.open(filename, mode="rb", *, format=None, check=-1,
preset=None, filters=None, encoding=None, errors=None,
newline=None)
```

Open an LZMA-compressed file in binary or text mode, returning a 
`file object`.

The `filename` argument can be either an actual file name (given as a `str` or `bytes` object), in which case the named file is opened, or it can be an existing file object to read from or write to.

The `mode` argument can be any of "r", "rb", "w", "wb", "x", "xb", "a" or "ab" for binary mode, or "rt", "wt", "xt", or "at" for text mode. The default is "rb".

When opening a file for reading, the `format` and `filters` arguments have the same meanings as for `LZMADecompressor`. In this case, the `check` and `preset` arguments should not be used.

When opening a file for writing, the `format`, `check`, `preset` and `filters` arguments have the same meanings as for `LZMACompressor`.

For binary mode, this function is equivalent to the `LZMAFile` constructor: `LZMAFile(filename, mode, ...)`. In this case, the `encoding`, `errors` and `newline` arguments must not be provided.

For text mode, a `LZMAFile` object is created, and wrapped in an `io.TextIOWrapper` instance with the specified encoding, error handling behavior, and line ending(s).
Changed in version 3.4: Added support for the "x", "xb" and "xt" modes.

```python
class lzma.LZMAFile(filename=None, mode="r", *, format=None, check=-1, preset=None, filters=None)
```

Open an LZMA-compressed file in binary mode.

An **LZMAFile** can wrap an already-open file object, or operate directly on a named file. The `filename` argument specifies either the file object to wrap, or the name of the file to open (as a str or bytes object). When wrapping an existing file object, the wrapped file will not be closed when the **LZMAFile** is closed.

The `mode` argument can be either "r" for reading (default), "w" for overwriting, "x" for exclusive creation, or "a" for appending. These can equivalently be given as "rb", "wb", "xb" and "ab" respectively.

If `filename` is a file object (rather than an actual file name), a mode of "w" does not truncate the file, and is instead equivalent to "a".

When opening a file for reading, the input file may be the concatenation of multiple separate compressed streams. These are transparently decoded as a single logical stream.

When opening a file for reading, the `format` and `filters` arguments have the same meanings as for **LZMADecompressor**. In this case, the `check` and `preset` arguments should not be used.

When opening a file for writing, the `format`, `check`, `preset` and `filters` arguments have the same meanings as for **LZMACompressor**.

**LZMAFile** supports all the members specified by
io.BufferedIOBase, except for detach() and truncate(). Iteration and the with statement are supported.

The following method is also provided:

**peek(size=-1)**

Return buffered data without advancing the file position. At least one byte of data will be returned, unless EOF has been reached. The exact number of bytes returned is unspecified (the size argument is ignored).

**Note:** While calling peek() does not change the file position of the LZMAFile, it may change the position of the underlying file object (e.g. if the LZMAFile was constructed by passing a file object for filename).

*Changed in version 3.4:* Added support for the "x" and "xb" modes.
13.4.2. Compressing and decompressing data in memory

```
class lzma.LZMACompressor(format=FORMAT_XZ, check=-1, preset=None, filters=None)
```

Create a compressor object, which can be used to compress data incrementally.

For a more convenient way of compressing a single chunk of data, see `compress()`.

The `format` argument specifies what container format should be used. Possible values are:

- **FORMAT_XZ**: The `.xz` container format.
  - This is the default format.

- **FORMAT_ALONE**: The legacy `.lzma` container format.
  - This format is more limited than `.xz` – it does not support integrity checks or multiple filters.

- **FORMAT_RAW**: A raw data stream, not using any container format.
  - This format specifier does not support integrity checks, and requires that you always specify a custom filter chain (for both compression and decompression). Additionally, data compressed in this manner cannot be decompressed using `FORMAT_AUTO` (see `LZMADecompressor`).

The `check` argument specifies the type of integrity check to include in the compressed data. This check is used when decompressing, to ensure that the data has not been corrupted. Possible values
are:

- **CHECK_NONE**: No integrity check. This is the default (and the only acceptable value) for FORMAT_ALONE and FORMAT_RAW.
- **CHECK_CRC32**: 32-bit Cyclic Redundancy Check.
- **CHECK_CRC64**: 64-bit Cyclic Redundancy Check. This is the default for FORMAT_XZ.
- **CHECK_SHA256**: 256-bit Secure Hash Algorithm.

If the specified check is not supported, an `LZMAError` is raised.

The compression settings can be specified either as a preset compression level (with the `preset` argument), or in detail as a custom filter chain (with the `filters` argument).

The `preset` argument (if provided) should be an integer between 0 and 9 (inclusive), optionally OR-ed with the constant PRESET_EXTREME. If neither `preset` nor `filters` are given, the default behavior is to use PRESET_DEFAULT (preset level 6). Higher presets produce smaller output, but make the compression process slower.

**Note:** In addition to being more CPU-intensive, compression with higher presets also requires much more memory (and produces output that needs more memory to decompress). With preset 9 for example, the overhead for an `LZMACompressor` object can be as high as 800 MiB. For this reason, it is generally best to stick with the default preset.

The `filters` argument (if provided) should be a filter chain specifier. See *Specifying custom filter chains* for details.

```cpp
compress(data)
```
Compress \textit{data} (a \texttt{bytes} object), returning a \texttt{bytes} object containing compressed data for at least part of the input. Some of \textit{data} may be buffered internally, for use in later calls to \texttt{compress()} and \texttt{flush()}. The returned data should be concatenated with the output of any previous calls to \texttt{compress()}.

\texttt{flush()}

Finish the compression process, returning a \texttt{bytes} object containing any data stored in the compressor’s internal buffers.

The compressor cannot be used after this method has been called.

\texttt{class lzma.LZMADecompressor(format=FORMAT\_AUTO, memlimit=None, filters=None)}

Create a decompressor object, which can be used to decompress data incrementally.

For a more convenient way of decompressing an entire compressed stream at once, see \texttt{decompress()}. The \texttt{format} argument specifies the container format that should be used. The default is \texttt{FORMAT\_AUTO}, which can decompress both \texttt{.xz} and \texttt{.lzma} files. Other possible values are \texttt{FORMAT\_XZ}, \texttt{FORMAT\_ALONE}, and \texttt{FORMAT\_RAW}.

The \texttt{memlimit} argument specifies a limit (in bytes) on the amount of memory that the decompressor can use. When this argument is used, decompression will fail with an \texttt{LZMAError} if it is not possible to decompress the input within the given memory limit.

The \texttt{filters} argument specifies the filter chain that was used to
create the stream being decompressed. This argument is required
if format is FORMAT_RAW, but should not be used for other formats.
See *Specifying custom filter chains* for more information about filter chains.

**Note:** This class does not transparently handle inputs containing
multiple compressed streams, unlike `decompress()` and
LZMAFile. To decompress a multi-stream input with
LZMADecompressor, you must create a new decompressor for
each stream.

**decompress**(data)

Decompress data (a bytes object), returning a bytes object
containing the decompressed data for at least part of the input.
Some of data may be buffered internally, for use in later calls to
decompress(). The returned data should be concatenated
with the output of any previous calls to `decompress()`.

**check**

The ID of the integrity check used by the input stream. This may
be CHECK_UNKNOWN until enough of the input has been
decoded to determine what integrity check it uses.

**eof**

True if the end-of-stream marker has been reached.

**unused_data**

Data found after the end of the compressed stream.

Before the end of the stream is reached, this will be b"".

```
lzma.compress(data, format=FORMAT_XZ, check=-1,
```
Compress `data` (a `bytes` object), returning the compressed data as a `bytes` object.

See `LZMACompressor` above for a description of the `format`, `check`, `preset` and `filters` arguments.

```python
lzma.decompress(data, format=FORMAT_AUTO, memlimit=None, filters=None)
```

Decompress `data` (a `bytes` object), returning the uncompressed data as a `bytes` object.

If `data` is the concatenation of multiple distinct compressed streams, decompress all of these streams, and return the concatenation of the results.

See `LZMADecompressor` above for a description of the `format`, `memlimit` and `filters` arguments.
13.4.3. Miscellaneous

lzma.is_check_supported(check)

Returns true if the given integrity check is supported on this system.

CHECK_NONE and CHECK_CRC32 are always supported. CHECK_CRC64 and CHECK_SHA256 may be unavailable if you are using a version of liblzma that was compiled with a limited feature set.
13.4.4. Specifying custom filter chains

A filter chain specifier is a sequence of dictionaries, where each dictionary contains the ID and options for a single filter. Each dictionary must contain the key "id", and may contain additional keys to specify filter-dependent options. Valid filter IDs are as follows:

- **Compression filters:**
  - FILTER_LZMA1 (for use with FORMAT_ALONE)
  - FILTER_LZMA2 (for use with FORMAT_XZ and FORMAT_RAW)

- **Delta filter:**
  - FILTER_DELTA

- **Branch-Call-Jump (BCJ) filters:**
  - FILTER_X86
  - FILTER_IA64
  - FILTER_ARM
  - FILTER_ARMTHUMB
  - FILTER_POWERPC
  - FILTER_SPARC

A filter chain can consist of up to 4 filters, and cannot be empty. The last filter in the chain must be a compression filter, and any other filters must be delta or BCJ filters.

Compression filters support the following options (specified as additional entries in the dictionary representing the filter):

- **preset:** A compression preset to use as a source of default values for options that are not specified explicitly.
- **dict_size:** Dictionary size in bytes. This should be
between 4 KiB and 1.5 GiB (inclusive).

- **lc**: Number of literal context bits.
- **lp**: Number of literal position bits. The sum $lc + lp$ must be at most 4.
- **pb**: Number of position bits; must be at most 4.
- **mode**: MOD_FAST or MOD_NORMAL.
- **nice_len**: What should be considered a “nice length” for a match. This should be 273 or less.
- **mf**: What match finder to use – MF_HC3, MF_HC4, MF_BT2, MF_BT3, or MF_BT4.
- **depth**: Maximum search depth used by match finder. 0 (default) means to select automatically based on other filter options.

The delta filter stores the differences between bytes, producing more repetitive input for the compressor in certain circumstances. It only supports a single option, **dist**. This indicates the distance between bytes to be subtracted. The default is 1, i.e. take the differences between adjacent bytes.

The BCJ filters are intended to be applied to machine code. They convert relative branches, calls and jumps in the code to use absolute addressing, with the aim of increasing the redundancy that can be exploited by the compressor. These filters support one option, **start_offset**. This specifies the address that should be mapped to the beginning of the input data. The default is 0.
13.4.5. Examples

Reading in a compressed file:

```python
import lzma
with lzma.open("file.xz") as f:
    file_content = f.read()
```

Creating a compressed file:

```python
import lzma
data = b"Insert Data Here"
with lzma.open("file.xz", "w") as f:
    f.write(data)
```

Compressing data in memory:

```python
import lzma
data_in = b"Insert Data Here"
data_out = lzma.compress(data_in)
```

Incremental compression:

```python
import lzma
lzc = lzma.LZMACompressor()
out1 = lzc.compress(b"Some data\n")
out2 = lzc.compress(b"Another piece of data\n")
out3 = lzc.compress(b"Even more data\n")
out4 = lzc.flush()
# Concatenate all the partial results:
result = b"".join([out1, out2, out3, out4])
```

Writing compressed data to an already-open file:
import lzma

with open("file.xz", "wb") as f:
    f.write(b"This data will not be compressed\n")
    with lzma.open(f, "w") as lzf:
        lzf.write(b"This *will* be compressed\n")
    f.write(b"Not compressed\n")

Creating a compressed file using a custom filter chain:

import lzma

my_filters = [
    {"id": lzma.FILTER_DELTA, "dist": 5},
    {"id": lzma.FILTER_LZMA2, "preset": 7 | lzma.PRESET_EXTREME}
]

with lzma.open("file.xz", "w", filters=my_filters) as f:
    f.write(b"blah blah blah")
13.5. zipfile — Work with ZIP archives

Source code: Lib/zipfile.py

The ZIP file format is a common archive and compression standard. This module provides tools to create, read, write, append, and list a ZIP file. Any advanced use of this module will require an understanding of the format, as defined in PKZIP Application Note.

This module does not currently handle multi-disk ZIP files. It can handle ZIP files that use the ZIP64 extensions (that is ZIP files that are more than 4 GiB in size). It supports decryption of encrypted files in ZIP archives, but it currently cannot create an encrypted file. Decryption is extremely slow as it is implemented in native Python rather than C.

The module defines the following items:

exception zipfile.BadZipFile
   The error raised for bad ZIP files.

   New in version 3.2.

exception zipfile.BadZipfile
   Alias of BadZipFile, for compatibility with older Python versions.

   Deprecated since version 3.2.

exception zipfile.LargeZipFile
The error raised when a ZIP file would require ZIP64 functionality but that has not been enabled.

class zipfile.ZipFile
The class for reading and writing ZIP files. See section *ZipFile Objects* for constructor details.

class zipfile.PyZipFile
Class for creating ZIP archives containing Python libraries.

class zipfile.ZipInfo(filename='NoName', date_time=(1980, 1, 1, 0, 0, 0))
Class used to represent information about a member of an archive. Instances of this class are returned by the `getinfo()` and `infolist()` methods of `ZipFile` objects. Most users of the `zipfile` module will not need to create these, but only use those created by this module. *filename* should be the full name of the archive member, and *date_time* should be a tuple containing six fields which describe the time of the last modification to the file; the fields are described in section *ZipInfo Objects*.

`zipfile.is_zipfile(filename)`
Returns `True` if *filename* is a valid ZIP file based on its magic number, otherwise returns `False`. *filename* may be a file or file-like object too.

*Changed in version 3.1:* Support for file and file-like objects.

`zipfile.ZIP_STORED`
The numeric constant for an uncompressed archive member.

`zipfile.ZIP_DEFLATED`
The numeric constant for the usual ZIP compression method. This
requires the \texttt{zlib} module.

\texttt{zipfile.ZIP\_BZIP2}

The numeric constant for the BZIP2 compression method. This requires the \texttt{bz2} module.

\textit{New in version 3.3.}

\texttt{zipfile.ZIP\_LZMA}

The numeric constant for the LZMA compression method. This requires the \texttt{lzma} module.

\textit{New in version 3.3.}

\textbf{Note:} The ZIP file format specification has included support for bzip2 compression since 2001, and for LZMA compression since 2006. However, some tools (including older Python releases) do not support these compression methods, and may either refuse to process the ZIP file altogether, or fail to extract individual files.

\textbf{See also:}

\textbf{PKZIP Application Note}

Documentation on the ZIP file format by Phil Katz, the creator of the format and algorithms used.

\textbf{Info-ZIP Home Page}

Information about the Info-ZIP project’s ZIP archive programs and development libraries.
13.5.1. ZipFile Objects

```python
class zipfile.ZipFile(file, mode='r',
                     compression=ZIP_STORED, allowZip64=True)
```

Open a ZIP file, where `file` can be either a path to a file (a string) or a file-like object. The `mode` parameter should be `'r'` to read an existing file, `'w'` to truncate and write a new file, or `'a'` to append to an existing file. If `mode` is `'a'` and `file` refers to an existing ZIP file, then additional files are added to it. If `file` does not refer to a ZIP file, then a new ZIP archive is appended to the file. This is meant for adding a ZIP archive to another file (such as `python.exe`). If `mode` is `a` and the file does not exist at all, it is created. `compression` is the ZIP compression method to use when writing the archive, and should be `ZIP_STORED`, `ZIP_DEFLATED`, `ZIP_BZIP2` or `ZIP_LZMA`; unrecognized values will cause `RuntimeError` to be raised. If `ZIP_DEFLATED`, `ZIP_BZIP2` or `ZIP_LZMA` is specified but the corresponding module (`zlib`, `bz2` or `lzma`) is not available, `RuntimeError` is also raised. The default is `ZIP_STORED`. If `allowZip64` is `True` (the default) zipfile will create ZIP files that use the ZIP64 extensions when the zipfile is larger than 2 GiB. If it is false `zipfile` will raise an exception when the ZIP file would require ZIP64 extensions.

If the file is created with mode `'a'` or `'w'` and then `closed` without adding any files to the archive, the appropriate ZIP structures for an empty archive will be written to the file.

ZipFile is also a context manager and therefore supports the `with` statement. In the example, `myzip` is closed after the `with` statement’s suite is finished—even if an exception occurs:
```python
with ZipFile('spam.zip', 'w') as myzip:
    myzip.write('eggs.txt')
```

*New in version 3.2:* Added the ability to use `ZipFile` as a context manager.

*Changed in version 3.3:* Added support for `bzip2` and `lzma` compression.

*Changed in version 3.4:* ZIP64 extensions are enabled by default.

`ZipFile.close()`

Close the archive file. You must call `close()` before exiting your program or essential records will not be written.

`ZipFile.getinfo(name)`

Return a `ZipInfo` object with information about the archive member `name`. Calling `getinfo()` for a name not currently contained in the archive will raise a `KeyError`.

`ZipFile.infolist()`

Return a list containing a `ZipInfo` object for each member of the archive. The objects are in the same order as their entries in the actual ZIP file on disk if an existing archive was opened.

`ZipFile.namelist()`

Return a list of archive members by name.

`ZipFile.open(name, mode='r', pwd=None)`

Extract a member from the archive as a file-like object (ZipExtFile). `name` is the name of the file in the archive, or a `ZipInfo` object. The `mode` parameter, if included, must be one of the following: `'r'`
(the default), 'U', or 'rU'. Choosing 'U' or 'rU' will enable *universal newlines* support in the read-only object. *pwd* is the password used for encrypted files. Calling `open()` on a closed `ZipFile` will raise a `RuntimeError`.

**Note:** The file-like object is read-only and provides the following methods: `read()`, `readline()`, `readlines()`, `__iter__`, `__next__`.

**Note:** If the `ZipFile` was created by passing in a file-like object as the first argument to the constructor, then the object returned by `open()` shares the `ZipFile`'s file pointer. Under these circumstances, the object returned by `open()` should not be used after any additional operations are performed on the `ZipFile` object. If the `ZipFile` was created by passing in a string (the filename) as the first argument to the constructor, then `open()` will create a new file object that will be held by the `ZipExtFile`, allowing it to operate independently of the `ZipFile`.

**Note:** The `open()`, `read()` and `extract()` methods can take a filename or a `ZipInfo` object. You will appreciate this when trying to read a ZIP file that contains members with duplicate names.

*Deprecated since version 3.4, will be removed in version 3.6:* The 'U' or 'rU' mode. Use `io.TextIOWrapper` for reading compressed text files in *universal newlines* mode.

`ZipFile.extract(member, path=None, pwd=None)`

Extract a member from the archive to the current working directory; *member* must be its full name or a `ZipInfo` object. Its file
information is extracted as accurately as possible. *path* specifies a different directory to extract to. *member* can be a filename or a *ZipInfo* object. *pwd* is the password used for encrypted files.

**Note:** If a member filename is an absolute path, a drive/UNC sharepoint and leading (back)slashes will be stripped, e.g.: ///foo/bar becomes foo/bar on Unix, and C: \foo\bar becomes foo\bar on Windows. And all ".." components in a member filename will be removed, e.g.: ../../foo/../../ba../..r becomes foo/../../ba../..r. On Windows illegal characters (:, <, >, |, ", ?, and *) replaced by underscore (_).

**ZipFile**. `extractall(path=None, members=None, pwd=None)`

Extract all members from the archive to the current working directory. *path* specifies a different directory to extract to. *members* is optional and must be a subset of the list returned by `namelist()`. *pwd* is the password used for encrypted files.

**Warning:** Never extract archives from untrusted sources without prior inspection. It is possible that files are created outside of *path*, e.g. members that have absolute filenames starting with "/" or filenames with two dots ".". This module attempts to prevent that. See `extract()` note.

**ZipFile**. `printdir()`

Print a table of contents for the archive to `sys.stdout`.

**ZipFile**. `setpassword(pwd)`

Set *pwd* as default password to extract encrypted files.
ZipFile. **read**(*name*, *pwd=None*)

Return the bytes of the file *name* in the archive. *name* is the name of the file in the archive, or a *ZipInfo* object. The archive must be open for read or append. *pwd* is the password used for encrypted files and, if specified, it will override the default password set with **setpassword()**. Calling **read()** on a closed ZipFile will raise a **RuntimeError**.

ZipFile. **testzip**()

Read all the files in the archive and check their CRC's and file headers. Return the name of the first bad file, or else return None. Calling **testzip()** on a closed ZipFile will raise a **RuntimeError**.

ZipFile. **write**(*filename*, *arcname=None*, *compress_type=None*)

Write the file named *filename* to the archive, giving it the archive name *arcname* (by default, this will be the same as *filename*, but without a drive letter and with leading path separators removed). If given, *compress_type* overrides the value given for the *compression* parameter to the constructor for the new entry. The archive must be open with mode 'w' or 'a' – calling **write()** on a ZipFile created with mode 'r' will raise a **RuntimeError**. Calling **write()** on a closed ZipFile will raise a **RuntimeError**.

**Note:** There is no official file name encoding for ZIP files. If you have unicode file names, you must convert them to byte strings in your desired encoding before passing them to **write()**. WinZip interprets all file names as encoded in CP437, also known as DOS Latin.

**Note:** Archive names should be relative to the archive root, that
is, they should not start with a path separator.

**Note:** If arcname (or filename, if arcname is not given) contains a null byte, the name of the file in the archive will be truncated at the null byte.

**ZipFile**.writestr(zinfo_or_arcname, bytes[, compress_type])

Write the string bytes to the archive; zinfo_or_arcname is either the file name it will be given in the archive, or a **ZipInfo** instance. If it’s an instance, at least the filename, date, and time must be given. If it’s a name, the date and time is set to the current date and time. The archive must be opened with mode 'w' or 'a' – calling writestr() on a ZipFile created with mode 'r' will raise a **RuntimeError**. Calling writestr() on a closed ZipFile will raise a **RuntimeError**.

If given, compress_type overrides the value given for the compression parameter to the constructor for the new entry, or in the zinfo_or_arcname (if that is a **ZipInfo** instance).

**Note:** When passing a **ZipInfo** instance as the zinfo_or_arcname parameter, the compression method used will be that specified in the compress_type member of the given **ZipInfo** instance. By default, the **ZipInfo** constructor sets this member to **ZIP_STORED**.

*Changed in version 3.2:* The compress_type argument.

The following data attributes are also available:

**ZipFile**.debug

The level of debug output to use. This may be set from 0 (the
default, no output) to 3 (the most output). Debugging information is written to `sys.stdout`.

**ZipFile**. `comment`

The comment text associated with the ZIP file. If assigning a comment to a `ZipFile` instance created with mode `‘a’` or `‘w’`, this should be a string no longer than 65535 bytes. Comments longer than this will be truncated in the written archive when `close()` is called.
13.5.2. PyZipFile Objects

The **PyZipFile** constructor takes the same parameters as the **ZipFile** constructor, and one additional parameter, *optimize*.

```python
class zipfile.PyZipFile(file, mode='r',
    compression=ZIP_STORED, allowZip64=True, optimize=-1)
```

*New in version 3.2:* The *optimize* parameter.

*Changed in version 3.4:* ZIP64 extensions are enabled by default.

Instances have one method in addition to those of **ZipFile** objects:

```python
writepy(pathname, basename='', filterfunc=None)
```

Search for files `*.py` and add the corresponding file to the archive.

If the *optimize* parameter to **PyZipFile** was not given or `-1`, the corresponding file is a `*.pyo` file if available, else a `*.pyc` file, compiling if necessary.

If the *optimize* parameter to **PyZipFile** was 0, 1 or 2, only files with that optimization level (see `compile()`) are added to the archive, compiling if necessary.

If `pathname` is a file, the filename must end with `.py`, and just the (corresponding `*.py[co]`) file is added at the top level (no path information). If `pathname` is a file that does not end with `.py`, a **RuntimeError** will be raised. If it is a directory, and the directory is not a package directory, then all the files `*.py[co]` are added at the top level. If the directory is a package...
directory, then all `*.py[co]` are added under the package name as a file path, and if any subdirectories are package directories, all of these are added recursively.

`basename` is intended for internal use only.

`filterfunc`, if given, must be a function taking a single string argument. It will be passed each path (including each individual full file path) before it is added to the archive. If `filterfunc` returns a false value, the path will not be added, and if it is a directory its contents will be ignored. For example, if our test files are all either in `test` directories or start with the string `test_`, we can use a `filterfunc` to exclude them:

```python
>>> zf = PyZipFile('myprog.zip')
>>> def notests(s):
...     fn = os.path.basename(s)
...     return (not (fn == 'test' or fn.startswith('test_')))
>>> zf.writepy('myprog', filterfunc=notests)
```

The `writepy()` method makes archives with file names like this:

```text
string.pyc                # Top level name
test/__init__.pyc         # Package directory
test/testall.pyc          # Module `test.test`
```

```
```text
test/bogus/__init__.pyc       # Subpackage directory
```

```
```text
test/bogus/myfile.pyc        # Submodule `test.bogus`
```
13.5.3. ZipInfo Objects

Instances of the `ZipInfo` class are returned by the `getinfo()` and `infolist()` methods of `ZipFile` objects. Each object stores information about a single member of the ZIP archive.

Instances have the following attributes:

`ZipInfo.filename`
Name of the file in the archive.

`ZipInfo.date_time`
The time and date of the last modification to the archive member. This is a tuple of six values:

<table>
<thead>
<tr>
<th>Index</th>
<th>Value</th>
</tr>
</thead>
<tbody>
<tr>
<td>0</td>
<td>Year (&gt;= 1980)</td>
</tr>
<tr>
<td>1</td>
<td>Month (one-based)</td>
</tr>
<tr>
<td>2</td>
<td>Day of month (one-based)</td>
</tr>
<tr>
<td>3</td>
<td>Hours (zero-based)</td>
</tr>
<tr>
<td>4</td>
<td>Minutes (zero-based)</td>
</tr>
<tr>
<td>5</td>
<td>Seconds (zero-based)</td>
</tr>
</tbody>
</table>

*Note:* The ZIP file format does not support timestamps before 1980.

`ZipInfo.compress_type`
Type of compression for the archive member.

`ZipInfo.comment`
Comment for the individual archive member.

**ZipInfo**.extra
Expansion field data. The PKZIP Application Note contains some comments on the internal structure of the data contained in this string.

**ZipInfo**.create_system
System which created ZIP archive.

**ZipInfo**.create_version
PKZIP version which created ZIP archive.

**ZipInfo**.extract_version
PKZIP version needed to extract archive.

**ZipInfo**.reserved
Must be zero.

**ZipInfo**.flag_bits
ZIP flag bits.

**ZipInfo**.volume
Volume number of file header.

**ZipInfo**.internal_attr
Internal attributes.

**ZipInfo**.external_attr
External file attributes.

**ZipInfo**.header_offset
Byte offset to the file header.
**ZipInfo**. **CRC**
CRC-32 of the uncompressed file.

**ZipInfo**. **compress_size**
Size of the compressed data.

**ZipInfo**. **file_size**
Size of the uncompressed file.
13.6. tarfile — Read and write tar archive files

Source code: Lib/tarfile.py

The tarfile module makes it possible to read and write tar archives, including those using gzip, bz2 and lzma compression. Use the zipfile module to read or write .zip files, or the higher-level functions in shutil.

Some facts and figures:

- reads and writes gzip, bz2 and lzma compressed archives.
- read/write support for the POSIX.1-1988 (ustar) format.
- read/write support for the GNU tar format including longname and longlink extensions, read-only support for all variants of the sparse extension including restoration of sparse files.
- read/write support for the POSIX.1-2001 (pax) format.
- handles directories, regular files, hardlinks, symbolic links, fifos, character devices and block devices and is able to acquire and restore file information like timestamp, access permissions and owner.

Changed in version 3.3: Added support for lzma compression.

tarfile.open(name=None, mode='r', fileobj=None, bufsize=10240, **kwargs)

    Return a TarFile object for the pathname name. For detailed information on TarFile objects and the keyword arguments that are allowed, see TarFile Objects.
mode has to be a string of the form 'filemode[:compression]', it defaults to 'r'. Here is a full list of mode combinations:

<table>
<thead>
<tr>
<th>mode</th>
<th>action</th>
</tr>
</thead>
<tbody>
<tr>
<td>'r' or 'r:*'</td>
<td>Open for reading with transparent compression (recommended).</td>
</tr>
<tr>
<td>'r:'</td>
<td>Open for reading exclusively without compression.</td>
</tr>
<tr>
<td>'r:gz'</td>
<td>Open for reading with gzip compression.</td>
</tr>
<tr>
<td>'r:bz2'</td>
<td>Open for reading with bzip2 compression.</td>
</tr>
<tr>
<td>'r:xz'</td>
<td>Open for reading with lzma compression.</td>
</tr>
<tr>
<td>'a' or 'a:'</td>
<td>Open for appending with no compression. The file is created if it does not exist.</td>
</tr>
<tr>
<td>'w' or 'w:'</td>
<td>Open for uncompressed writing.</td>
</tr>
<tr>
<td>'w:gz'</td>
<td>Open for gzip compressed writing.</td>
</tr>
<tr>
<td>'w:bz2'</td>
<td>Open for bzip2 compressed writing.</td>
</tr>
<tr>
<td>'w:xz'</td>
<td>Open for lzma compressed writing.</td>
</tr>
</tbody>
</table>

Note that 'a:gz', 'a:bz2' or 'a:xz' is not possible. If mode is not suitable to open a certain (compressed) file for reading, ReadError is raised. Use mode 'r' to avoid this. If a compression method is not supported, CompressionError is raised.

If fileobj is specified, it is used as an alternative to a file object opened in binary mode for name. It is supposed to be at position 0.

For special purposes, there is a second format for mode: 'filemode|[compression]'. tarfile.open() will return a
**TarFile** object that processes its data as a stream of blocks. No random seeking will be done on the file. If given, *fileobj* may be any object that has a `read()` or `write()` method (depending on the *mode*). *bufsize* specifies the blocksize and defaults to $20 \times 512$ bytes. Use this variant in combination with e.g. `sys.stdin`, a socket *file object* or a tape device. However, such a **TarFile** object is limited in that it does not allow to be accessed randomly, see *Examples*. The currently possible modes:

<table>
<thead>
<tr>
<th>Mode</th>
<th>Action</th>
</tr>
</thead>
<tbody>
<tr>
<td>`'r</td>
<td>*'`</td>
</tr>
<tr>
<td>`'r</td>
<td>'</td>
</tr>
<tr>
<td>`'r</td>
<td>gz'</td>
</tr>
<tr>
<td>`'r</td>
<td>bz2'</td>
</tr>
<tr>
<td>`'r</td>
<td>xz'</td>
</tr>
<tr>
<td>`'w</td>
<td>'</td>
</tr>
<tr>
<td>`'w</td>
<td>gz'</td>
</tr>
<tr>
<td>`'w</td>
<td>bz2'</td>
</tr>
<tr>
<td>`'w</td>
<td>xz'</td>
</tr>
</tbody>
</table>

**Class** `tarfile.TarFile`

Class for reading and writing tar archives. Do not use this class directly, better use `tarfile.open()` instead. See **TarFile Objects**.

`tarfile.is_tarfile(name)`

Return **True** if *name* is a tar archive file, that the **tarfile** module
The **tarfile** module defines the following exceptions:

*exception* `tarfile.TarError`
Base class for all `tarfile` exceptions.

*exception* `tarfile.ReadError`
Is raised when a tar archive is opened, that either cannot be handled by the `tarfile` module or is somehow invalid.

*exception* `tarfile.CompressionError`
Is raised when a compression method is not supported or when the data cannot be decoded properly.

*exception* `tarfile.StreamError`
Is raised for the limitations that are typical for stream-like `TarFile` objects.

*exception* `tarfile.ExtractError`
Is raised for non-fatal errors when using `TarFile.extract()`, but only if `TarFile.errorlevel==2`.

*exception* `tarfile.HeaderError`
Is raised by `TarInfo.frombuf()` if the buffer it gets is invalid.

Each of the following constants defines a tar archive format that the `tarfile` module is able to create. See section *Supported tar formats* for details.

*tarfile.**USTAR_FORMAT**
  POSIX.1-1988 (ustar) format.
**tarfile.** **GNU_FORMAT**

GNU tar format.

**tarfile.** **PAX_FORMAT**

POSIX.1-2001 (pax) format.

**tarfile.** **DEFAULT_FORMAT**

The default format for creating archives. This is currently **GNU_FORMAT**.

The following variables are available on module level:

**tarfile.** **ENCODING**

The default character encoding: 'utf-8' on Windows, `sys.getfilesystemencoding()` otherwise.

---

**See also:**

**Module zipfile**

Documentation of the **zipfile** standard module.

**GNU tar manual, Basic Tar Format**

Documentation for tar archive files, including GNU tar extensions.
13.6.1. TarFile Objects

The TarFile object provides an interface to a tar archive. A tar archive is a sequence of blocks. An archive member (a stored file) is made up of a header block followed by data blocks. It is possible to store a file in a tar archive several times. Each archive member is represented by a TarInfo object, see TarInfo Objects for details.

A TarFile object can be used as a context manager in a with statement. It will automatically be closed when the block is completed. Please note that in the event of an exception an archive opened for writing will not be finalized; only the internally used file object will be closed. See the Examples section for a use case.

New in version 3.2: Added support for the context manager protocol.

class tarfile.TarFile(name=None, mode='r', fileobj=None, format=DEFAULT_FORMAT, tarinfo=TarInfo, dereference=False, ignore_zeros=False, encoding=ENCODING, errors='surrogateescape', pax_headers=None, debug=0, errorlevel=0)

All following arguments are optional and can be accessed as instance attributes as well.

name is the pathname of the archive. It can be omitted if fileobj is given. In this case, the file object’s name attribute is used if it exists.

mode is either 'r' to read from an existing archive, 'a' to append data to an existing file or 'w' to create a new file overwriting an existing one.

If fileobj is given, it is used for reading or writing data. If it can be
determined, mode is overridden by fileobj’s mode. fileobj will be used from position 0.

**Note:** fileobj is not closed, when TarFile is closed.

format controls the archive format. It must be one of the constants USTAR_FORMAT, GNU_FORMAT or PAX_FORMAT that are defined at module level.

The tarinfo argument can be used to replace the default TarInfo class with a different one.

If dereference is False, add symbolic and hard links to the archive. If it is True, add the content of the target files to the archive. This has no effect on systems that do not support symbolic links.

If ignore_zeros is False, treat an empty block as the end of the archive. If it is True, skip empty (and invalid) blocks and try to get as many members as possible. This is only useful for reading concatenated or damaged archives.

debug can be set from 0 (no debug messages) up to 3 (all debug messages). The messages are written to sys.stderr.

If errorlevel is 0, all errors are ignored when using TarFile.extract(). Nevertheless, they appear as error messages in the debug output, when debugging is enabled. If 1, all fatal errors are raised as OSError exceptions. If 2, all non-fatal errors are raised as TarError exceptions as well.

The encoding and errors arguments define the character encoding to be used for reading or writing the archive and how conversion
errors are going to be handled. The default settings will work for most users. See section *Unicode issues* for in-depth information.

*Changed in version 3.2:* Use 'surrogateescape' as the default for the *errors* argument.

The *pax_headers* argument is an optional dictionary of strings which will be added as a pax global header if *format* is *PAX_FORMAT*.

**TarFile.** `open(...)`

Alternative constructor. The `tarfile.open()` function is actually a shortcut to this classmethod.

**TarFile.** `getmember(name)`

Return a *TarInfo* object for member *name*. If *name* can not be found in the archive, *KeyError* is raised.

**Note:** If a member occurs more than once in the archive, its last occurrence is assumed to be the most up-to-date version.

**TarFile.** `getmembers()`

Return the members of the archive as a list of *TarInfo* objects. The list has the same order as the members in the archive.

**TarFile.** `getnames()`

Return the members as a list of their names. It has the same order as the list returned by `getmembers()`.

**TarFile.** `list(verbosetrue)`

Print a table of contents to *sys.stdout*. If *verbosetrue* is *False*, only the names of the members are printed. If it is *True*, output similar
to that of `ls -l` is produced.

**TarFile**. `next()`

Return the next member of the archive as a `TarInfo` object, when `TarFile` is opened for reading. Return `None` if there is no more available.

**TarFile**. `extractall(path=".", members=None)`

Extract all members from the archive to the current working directory or directory path. If optional `members` is given, it must be a subset of the list returned by `getmembers()`. Directory information like owner, modification time and permissions are set after all members have been extracted. This is done to work around two problems: A directory's modification time is reset each time a file is created in it. And, if a directory's permissions do not allow writing, extracting files to it will fail.

**Warning:** Never extract archives from untrusted sources without prior inspection. It is possible that files are created outside of `path`, e.g. members that have absolute filenames starting with `"/"` or filenames with two dots `".."`.

**TarFile**. `extract(member, path="", set_attrs=True)`

Extract a member from the archive to the current working directory, using its full name. Its file information is extracted as accurately as possible. `member` may be a filename or a `TarInfo` object. You can specify a different directory using `path`. File attributes (owner, mtime, mode) are set unless `set_attrs` is false.

**Note:** The `extract()` method does not take care of several extraction issues. In most cases you should consider using the
extractall() method.

**Warning:** See the warning for `extractall()`.

*Changed in version 3.2:* Added the `set_attrs` parameter.

**TarFile**. *extractfile*(member)

Extract a member from the archive as a file object. *member* may be a filename or a `TarInfo` object. If *member* is a regular file or a link, an `io.BufferedReader` object is returned. Otherwise, `None` is returned.

*Changed in version 3.3:* Return an `io.BufferedReader` object.

**TarFile**. *add*(name, arcname=None, recursive=True, exclude=None, *, filter=None)

Add the file *name* to the archive. *name* may be any type of file (directory, fifo, symbolic link, etc.). If given, *arcname* specifies an alternative name for the file in the archive. Directories are added recursively by default. This can be avoided by setting `recursive` to `False`. If *exclude* is given, it must be a function that takes one filename argument and returns a boolean value. Depending on this value the respective file is either excluded (`True`) or added (`False`). If *filter* is specified it must be a keyword argument. It should be a function that takes a `TarInfo` object argument and returns the changed `TarInfo` object. If it instead returns `None` the `TarInfo` object will be excluded from the archive. See `Examples` for an example.

*Changed in version 3.2:* Added the `filter` parameter.

**Deprecated since version 3.2:** The `exclude` parameter is
TarFile. **addfile**(*tarinfo*, *fileobj=None*)

Add the TarInfo object *tarinfo* to the archive. If *fileobj* is given, *tarinfo.size* bytes are read from it and added to the archive. You can create TarInfo objects using gettarinfo().

**Note:** On Windows platforms, *fileobj* should always be opened with mode 'rb' to avoid irritation about the file size.

TarFile. **gettarinfo**(*name=None, arcname=None, fileobj=None*)

Create a TarInfo object for either the file *name* or the file object *fileobj* (using os.fstat() on its file descriptor). You can modify some of the TarInfo's attributes before you add it using addfile(). If given, *arcname* specifies an alternative name for the file in the archive.

TarFile. **close**()

Close the TarFile. In write mode, two finishing zero blocks are appended to the archive.

TarFile. **pax_headers**

A dictionary containing key-value pairs of pax global headers.
13.6.2. TarInfo Objects

A **TarInfo** object represents one member in a **TarFile**. Aside from storing all required attributes of a file (like file type, size, time, permissions, owner etc.), it provides some useful methods to determine its type. It does *not* contain the file's data itself.

**TarInfo** objects are returned by **TarFile**'s methods `getmember()`, `getmembers()` and `gettarinfo()`.

```python
class tarfile.TarInfo(name='')
    Create a TarInfo object.

TarInfo.frombuf(buf)
    Create and return a TarInfo object from string buffer buf.

    Raises HeaderError if the buffer is invalid.

TarInfo.fromtarfile(tarfile)
    Read the next member from the TarFile object tarfile and return it as a TarInfo object.

TarInfo.tobuf(format=DEFAULT_FORMAT, encoding=ENCODING, errors='surrogateescape')
    Create a string buffer from a TarInfo object. For information on the arguments see the constructor of the TarFile class.

    Changed in version 3.2: Use 'surrogateescape' as the default for the errors argument.
```

A **TarInfo** object has the following public data attributes:
**TarInfo.name**
Name of the archive member.

**TarInfo.size**
Size in bytes.

**TarInfo.mtime**
Time of last modification.

**TarInfo.mode**
Permission bits.

**TarInfo.type**
File type. `type` is usually one of these constants: REGTYPE, AREGTYPE, LNKTYPE, SYMTYPE, DIRTYPE, FIFOTYPE, CONTTYPE, CHRTYPE, BLKTYPE, GNUTYPE_SPARSE. To determine the type of a `TarInfo` object more conveniently, use the `is_*()` methods below.

**TarInfo.linkname**
Name of the target file name, which is only present in `TarInfo` objects of type LNKTYPE and SYMTYPE.

**TarInfo.uid**
User ID of the user who originally stored this member.

**TarInfo.gid**
Group ID of the user who originally stored this member.

**TarInfo.uname**
User name.

**TarInfo.gname**
Group name.

**TarInfo. pax_headers**
A dictionary containing key-value pairs of an associated pax extended header.

A **TarInfo** object also provides some convenient query methods:

**TarInfo. isfile()**
Return True if the Tarinfo object is a regular file.

**TarInfo. isreg()**
Same as isfile().

**TarInfo. isdir()**
Return True if it is a directory.

**TarInfo. issym()**
Return True if it is a symbolic link.

**TarInfo. islnk()**
Return True if it is a hard link.

**TarInfo. ischr()**
Return True if it is a character device.

**TarInfo. isblk()**
Return True if it is a block device.

**TarInfo. isfifo()**
Return True if it is a FIFO.
Return True if it is one of character device, block device or FIFO.
13.6.3. Command Line Interface

New in version 3.4.

The `tarfile` module provides a simple command line interface to interact with tar archives.

If you want to create a new tar archive, specify its name after the `-c` option and then list the filename(s) that should be included:

```
$ python -m tarfile -c monty.tar spam.txt eggs.txt
```

Passing a directory is also acceptable:

```
$ python -m tarfile -c monty.tar life-of-brian_1979/
```

If you want to extract a tar archive into the current directory, use the `-e` option:

```
$ python -m tarfile -e monty.tar
```

You can also extract a tar archive into a different directory by passing the directory’s name:

```
$ python -m tarfile -e monty.tar other-dir/
```

For a list of the files in a tar archive, use the `-l` option:

```
$ python -m tarfile -l monty.tar
```

13.6.3.1. Command line options
-l <tarfile>
--list <tarfile>
List files in a tarfile.

-c <tarfile> <source1> <sourceN>
--create <tarfile> <source1> <sourceN>
Create tarfile from source files.

-e <tarfile> [<output_dir>]
--extract <tarfile> [<output_dir>]
Extract tarfile into the current directory if \texttt{output\_dir} is not specified.

-t <tarfile>
--test <tarfile>
Test whether the tarfile is valid or not.

-v, --verbose
Verbose output
13.6.4. Examples

How to extract an entire tar archive to the current working directory:

```python
import tarfile
tar = tarfile.open("sample.tar.gz")
tar.extractall()
tar.close()
```

How to extract a subset of a tar archive with `TarFile.extractall()` using a generator function instead of a list:

```python
import os
import tarfile
def py_files(members):
    for tarinfo in members:
        if os.path.splitext(tarinfo.name)[1] == ".py"
            yield tarinfo
tar = tarfile.open("sample.tar.gz")
tar.extractall(members=py_files(tar))
tar.close()
```

How to create an uncompressed tar archive from a list of filenames:

```python
import tarfile
tar = tarfile.open("sample.tar", "w")
for name in ["foo", "bar", "quux"]:
    tar.add(name)
tar.close()
```

The same example using the `with` statement:
import tarfile

with tarfile.open("sample.tar", "w") as tar:
    for name in ["foo", "bar", "quux"]:
        tar.add(name)

How to read a gzip compressed tar archive and display some member information:

```python
import tarfile
tar = tarfile.open("sample.tar.gz", "r:gz")
for tarinfo in tar:
    print(tarinfo.name, "is", tarinfo.size, "bytes in size and is"
    if tarinfo.isreg():
        print("a regular file."
    elif tarinfo.isdir():
        print("a directory."
    else:
        print("something else."
    tar.close()
```

How to create an archive and reset the user information using the filter parameter in `TarFile.add()`:

```python
import tarfile
def reset(tarinfo):
    tarinfo.uid = tarinfo.gid = 0
    tarinfo.uname = tarinfo.gname = "root"
    return tarinfo
tar = tarfile.open("sample.tar.gz", "w:gz")
tar.add("foo", filter=reset)
tar.close()
```
13.6.5. Supported tar formats

There are three tar formats that can be created with the `tarfile` module:

- The POSIX.1-1988 ustar format (**USTAR_FORMAT**). It supports filenames up to a length of at best 256 characters and linknames up to 100 characters. The maximum file size is 8 GiB. This is an old and limited but widely supported format.

- The GNU tar format (**GNU_FORMAT**). It supports long filenames and linknames, files bigger than 8 GiB and sparse files. It is the de facto standard on GNU/Linux systems. `tarfile` fully supports the GNU tar extensions for long names, sparse file support is read-only.

- The POSIX.1-2001 pax format (**PAX_FORMAT**). It is the most flexible format with virtually no limits. It supports long filenames and linknames, large files and stores pathnames in a portable way. However, not all tar implementations today are able to handle pax archives properly.

The `pax` format is an extension to the existing `ustar` format. It uses extra headers for information that cannot be stored otherwise. There are two flavours of pax headers: Extended headers only affect the subsequent file header, global headers are valid for the complete archive and affect all following files. All the data in a pax header is encoded in **UTF-8** for portability reasons.

There are some more variants of the tar format which can be read, but not created:
• The ancient V7 format. This is the first tar format from Unix Seventh Edition, storing only regular files and directories. Names must not be longer than 100 characters, there is no user/group name information. Some archives have miscalculated header checksums in case of fields with non-ASCII characters.
• The SunOS tar extended format. This format is a variant of the POSIX.1-2001 pax format, but is not compatible.
13.6.6. Unicode issues

The tar format was originally conceived to make backups on tape drives with the main focus on preserving file system information. Nowadays tar archives are commonly used for file distribution and exchanging archives over networks. One problem of the original format (which is the basis of all other formats) is that there is no concept of supporting different character encodings. For example, an ordinary tar archive created on a UTF-8 system cannot be read correctly on a Latin-1 system if it contains non-ASCII characters. Textual metadata (like filenames, linknames, user/group names) will appear damaged. Unfortunately, there is no way to autodetect the encoding of an archive. The pax format was designed to solve this problem. It stores non-ASCII metadata using the universal character encoding UTF-8.

The details of character conversion in tarfile are controlled by the encoding and errors keyword arguments of the TarFile class.

encoding defines the character encoding to use for the metadata in the archive. The default value is sys.getfilesystemencoding() or 'ascii' as a fallback. Depending on whether the archive is read or written, the metadata must be either decoded or encoded. If encoding is not set appropriately, this conversion may fail.

The errors argument defines how characters are treated that cannot be converted. Possible values are listed in section Codec Base Classes. The default scheme is surrogateescape which Python also uses for its file system calls, see File Names, Command Line Arguments, and Environment Variables.

In case of PAX_FORMAT archives, encoding is generally not needed
because all the metadata is stored using UTF-8. encoding is only used in the rare cases when binary pax headers are decoded or when strings with surrogate characters are stored.
14. File Formats

The modules described in this chapter parse various miscellaneous file formats that aren’t markup languages and are not related to e-mail.

14.1. csv — CSV File Reading and Writing

The so-called CSV (Comma Separated Values) format is the most common import and export format for spreadsheets and databases. CSV format was used for many years prior to attempts to describe the format in a standardized way in RFC 4180. The lack of a well-defined standard means that subtle differences often exist in the data produced and consumed by different applications. These differences can make it annoying to process CSV files from multiple sources. Still, while the delimiters and quoting characters vary, the overall format is similar enough that it is possible to write a single module which can efficiently manipulate such data, hiding the details of reading and writing the data from the programmer.

The csv module implements classes to read and write tabular data in CSV format. It allows programmers to say, “write this data in the format preferred by Excel,” or “read data from this file which was generated by Excel,” without knowing the precise details of the CSV format used by Excel. Programmers can also describe the CSV formats understood by other applications or define their own special-purpose CSV formats.

The csv module’s reader and writer objects read and write sequences. Programmers can also read and write data in dictionary form using the DictReader and DictWriter classes.

PEP 305 - CSV File API
The Python Enhancement Proposal which proposed this addition to Python.
14.1.1. Module Contents

The `csv` module defines the following functions:

`csv.reader(csvfile, dialect='excel', **fmtparams)`

Return a reader object which will iterate over lines in the given `csvfile`. `csvfile` can be any object which supports the `iterator` protocol and returns a string each time its `__next__()` method is called — `file objects` and list objects are both suitable. If `csvfile` is a file object, it should be opened with `newline=''`. [1] An optional `dialect` parameter can be given which is used to define a set of parameters specific to a particular CSV dialect. It may be an instance of a subclass of the `Dialect` class or one of the strings returned by the `list_dialects()` function. The other optional `fmtparams` keyword arguments can be given to override individual formatting parameters in the current dialect. For full details about the dialect and formatting parameters, see section `Dialects and Formatting Parameters`.

Each row read from the csv file is returned as a list of strings. No automatic data type conversion is performed unless the `QUOTE_NONNUMERIC` format option is specified (in which case unquoted fields are transformed into floats).

A short usage example:

```python
>>> import csv
>>> with open('eggs.csv', newline='') as csvfile:
...     spamreader = csv.reader(csvfile, delimiter=','
...     for row in spamreader:
...         print(', '.join(row))
Spam, Spam, Spam, Spam, Spam, Baked Beans
```
csv.writer(csvfile, dialect='excel', **fmtparams)

Return a writer object responsible for converting the user’s data into delimited strings on the given file-like object. csvfile can be any object with a write() method. If csvfile is a file object, it should be opened with newline='' [1]. An optional dialect parameter can be given which is used to define a set of parameters specific to a particular CSV dialect. It may be an instance of a subclass of the Dialect class or one of the strings returned by the list_dialects() function. The other optional fmtparams keyword arguments can be given to override individual formatting parameters in the current dialect. For full details about the dialect and formatting parameters, see section Dialects and Formatting Parameters. To make it as easy as possible to interface with modules which implement the DB API, the value None is written as the empty string. While this isn’t a reversible transformation, it makes it easier to dump SQL NULL data values to CSV files without preprocessing the data returned from a cursor.fetch* call. All other non-string data are stringified with str() before being written.

A short usage example:

```python
import csv
with open('eggs.csv', 'w', newline='') as csvfile:
    spamwriter = csv.writer(csvfile, delimiter=''
quotechar='|', quoting=csv.QUOTE_MINIMAL)
    spamwriter.writerow(['Spam'] * 5 + ['Baked Beans'])
    spamwriter.writerow(['Spam', 'Lovely Spam', 'Wonderful Spam'])
```
**csv.register_dialect**(*name*, *dialect*, **fmtparams*)

Associate *dialect* with *name*. *name* must be a string. The dialect can be specified either by passing a sub-class of *Dialect*, or by *fmtparams* keyword arguments, or both, with keyword arguments overriding parameters of the dialect. For full details about the dialect and formatting parameters, see section *Dialects and Formatting Parameters*.

**csv.unregister_dialect**(*name*)

Delete the dialect associated with *name* from the dialect registry. An *Error* is raised if *name* is not a registered dialect name.

**csv.get_dialect**(*name*)

Return the dialect associated with *name*. An *Error* is raised if *name* is not a registered dialect name. This function returns an immutable *Dialect*.

**csv.list_dialects**()

Return the names of all registered dialects.

**csv.field_size_limit**([^new_limit])

Returns the current maximum field size allowed by the parser. If *new_limit* is given, this becomes the new limit.

The **csv** module defines the following classes:

**class csv.DictReader**(*csvfile*, *fieldnames=None*, *restkey=None*, *restval=None*, *dialect='excel'*-*args*, **kwds*)

Create an object which operates like a regular reader but maps the information read into a dict whose keys are given by the optional *fieldnames* parameter. The *fieldnames* parameter is a sequence whose elements are associated with the fields of the input data in
order. These elements become the keys of the resulting dictionary. If the fieldnames parameter is omitted, the values in the first row of the csvfile will be used as the fieldnames. If the row read has more fields than the fieldnames sequence, the remaining data is added as a sequence keyed by the value of restkey. If the row read has fewer fields than the fieldnames sequence, the remaining keys take the value of the optional restval parameter. Any other optional or keyword arguments are passed to the underlying reader instance.

```python
class csv.DictWriter(csvfile, fieldnames, restval='', extrasaction='raise', dialect='excel', *args, **kwds)
```

Create an object which operates like a regular writer but maps dictionaries onto output rows. The fieldnames parameter is a sequence of keys that identify the order in which values in the dictionary passed to the writerow() method are written to the csvfile. The optional restval parameter specifies the value to be written if the dictionary is missing a key in fieldnames. If the dictionary passed to the writerow() method contains a key not found in fieldnames, the optional extrasaction parameter indicates what action to take. If it is set to 'raise' a ValueError is raised. If it is set to 'ignore', extra values in the dictionary are ignored. Any other optional or keyword arguments are passed to the underlying writer instance.

Note that unlike the DictReader class, the fieldnames parameter of the DictWriter is not optional. Since Python's dict objects are not ordered, there is not enough information available to deduce the order in which the row should be written to the csvfile.

```python
class csv.Dialect
```

The Dialect class is a container class relied on primarily for its
attributes, which are used to define the parameters for a specific reader or writer instance.

**class csv.excel**

The excel class defines the usual properties of an Excel-generated CSV file. It is registered with the dialect name 'excel'.

**class csv.excel_tab**

The excel_tab class defines the usual properties of an Excel-generated TAB-delimited file. It is registered with the dialect name 'excel-tab'.

**class csv.unix_dialect**

The unix_dialect class defines the usual properties of a CSV file generated on UNIX systems, i.e. using '
' as line terminator and quoting all fields. It is registered with the dialect name 'unix'.

*New in version 3.2.*

**class csv.Sniffer**

The Sniffer class is used to deduce the format of a CSV file.

The Sniffer class provides two methods:

**sniff**(sample, delimiters=None)

Analyze the given sample and return a Dialect subclass reflecting the parameters found. If the optional delimiters parameter is given, it is interpreted as a string containing possible valid delimiter characters.

**has_header**(sample)

Analyze the sample text (presumed to be in CSV format) and
return True if the first row appears to be a series of column headers.

An example for Sniffer use:

```python
with open('example.csv') as csvfile:
    dialect = csv.Sniffer().sniff(csvfile.read(1024))
    csvfile.seek(0)
    reader = csv.reader(csvfile, dialect)
    # ... process CSV file contents here ...
```

The csv module defines the following constants:

**csv.QUOTE_ALL**
- Instructs writer objects to quote all fields.

**csv.QUOTE_MINIMAL**
- Instructs writer objects to only quote those fields which contain special characters such as delimiter, quotechar or any of the characters in lineterminator.

**csv.QUOTE_NONNUMERIC**
- Instructs writer objects to quote all non-numeric fields.

Instructs the reader to convert all non-quoted fields to type float.

**csv.QUOTE_NONE**
- Instructs writer objects to never quote fields. When the current delimiter occurs in output data it is preceded by the current escapechar character. If escapechar is not set, the writer will raise Error if any characters that require escaping are encountered.

Instructs reader to perform no special processing of quote
characters.

The csv module defines the following exception:

```python
exception csv.Error

Raised by any of the functions when an error is detected.
```
14.1.2. Dialects and Formatting Parameters

To make it easier to specify the format of input and output records, specific formatting parameters are grouped together into dialects. A dialect is a subclass of the Dialect class having a set of specific methods and a single validate() method. When creating reader or writer objects, the programmer can specify a string or a subclass of the Dialect class as the dialect parameter. In addition to, or instead of, the dialect parameter, the programmer can also specify individual formatting parameters, which have the same names as the attributes defined below for the Dialect class.

Dialects support the following attributes:

**Dialect.delimiter**
A one-character string used to separate fields. It defaults to ',',

**Dialect.doublequote**
Controls how instances of quotechar appearing inside a field should be themselves be quoted. When True, the character is doubled. When False, the escapechar is used as a prefix to the quotechar. It defaults to True.

On output, if doublequote is False and no escapechar is set, Error is raised if a quotechar is found in a field.

**Dialect.escapechar**
A one-character string used by the writer to escape the delimiter if quoting is set to QUOTE_NONE and the quotechar if doublequote is False. On reading, the escapechar removes any special meaning
from the following character. It defaults to \texttt{None}, which disables escaping.

**Dialect.\texttt{lineterminator}**

The string used to terminate lines produced by the \texttt{writer}. It defaults to \texttt{\textbackslash r\textbackslash n}.

\begin{center}
\textbf{Note}: The \texttt{reader} is hard-coded to recognise either \texttt{\textbackslash r} or \texttt{\textbackslash n} as end-of-line, and ignores \textit{lineterminator}. This behavior may change in the future.
\end{center}

**Dialect.\texttt{quotechar}**

A one-character string used to quote fields containing special characters, such as the \texttt{delimiter} or \texttt{quotechar}, or which contain new-line characters. It defaults to \texttt{''}.

**Dialect.\texttt{quoting}**

Controls when quotes should be generated by the writer and recognised by the reader. It can take on any of the \texttt{QUOTE_*} constants (see section \textit{Module Contents}) and defaults to \texttt{QUOTE_MINIMAL}.

**Dialect.\texttt{skipinitialspace}**

When \texttt{True}, whitespace immediately following the \texttt{delimiter} is ignored. The default is \texttt{False}.

**Dialect.\texttt{strict}**

When \texttt{True}, raise exception \texttt{Error} on bad CSV input. The default is \texttt{False}. 
14.1.3. Reader Objects

Reader objects (*DictReader* instances and objects returned by the `reader()` function) have the following public methods:

**csvreader.** __next__()

Return the next row of the reader’s iterable object as a list, parsed according to the current dialect. Usually you should call this as `next(reader)`.

Reader objects have the following public attributes:

**csvreader.** dialect

A read-only description of the dialect in use by the parser.

**csvreader.** line_num

The number of lines read from the source iterator. This is not the same as the number of records returned, as records can span multiple lines.

*DictReader* objects have the following public attribute:

**csvreader.** fieldnames

If not passed as a parameter when creating the object, this attribute is initialized upon first access or when the first record is read from the file.
14.1.4. Writer Objects

Writer objects (DictWriter instances and objects returned by the writer() function) have the following public methods. A row must be a sequence of strings or numbers for Writer objects and a dictionary mapping fieldnames to strings or numbers (by passing them through str() first) for DictWriter objects. Note that complex numbers are written out surrounded by parens. This may cause some problems for other programs which read CSV files (assuming they support complex numbers at all).

```python
csvwriter.writerow(row)
```
Write the row parameter to the writer’s file object, formatted according to the current dialect.

```python
csvwriter.writerows(rows)
```
Write all the rows parameters (a list of row objects as described above) to the writer’s file object, formatted according to the current dialect.

Writer objects have the following public attribute:

```python
csvwriter.dialect
```
A read-only description of the dialect in use by the writer.

DictWriter objects have the following public method:

```python
DictWriter.writeheader()
```
Write a row with the field names (as specified in the constructor).

*New in version 3.2.*
14.1.5. Examples

The simplest example of reading a CSV file:

```python
import csv
with open('some.csv', newline='') as f:
    reader = csv.reader(f)
    for row in reader:
        print(row)
```

Reading a file with an alternate format:

```python
import csv
with open('passwd', newline='') as f:
    reader = csv.reader(f, delimiter=':', quoting=csv.QUOTE_MINIMAL)
    for row in reader:
        print(row)
```

The corresponding simplest possible writing example is:

```python
import csv
with open('some.csv', 'w', newline='') as f:
    writer = csv.writer(f)
    writer.writerows(someiterable)
```

Since `open()` is used to open a CSV file for reading, the file will by default be decoded into unicode using the system default encoding (see `locale.getpreferredencoding()`). To decode a file using a different encoding, use the `encoding` argument of `open`:

```python
import csv
with open('some.csv', newline='', encoding='utf-8') as f:
    reader = csv.reader(f)
```
for row in reader:
    print(row)

The same applies to writing in something other than the system default encoding: specify the encoding argument when opening the output file.

Registering a new dialect:

```python
import csv
csv.register_dialect('unixpwd', delimiter=':', quoting=csv.QUOTE_ALL)
with open('passwd', newline='') as f:
    reader = csv.reader(f, 'unixpwd')
```

A slightly more advanced use of the reader — catching and reporting errors:

```python
import csv, sys
filename = 'some.csv'
with open(filename, newline='') as f:
    reader = csv.reader(f)
    try:
        for row in reader:
            print(row)
    except csv.Error as e:
        sys.exit('file {}, line {}: {}'.format(filename, e.lineno, e))
```

And while the module doesn’t directly support parsing strings, it can easily be done:

```python
import csv
for row in csv.reader(['one,two,three']):
    print(row)
```
Footnotes

(1, 2) If `newline=''` is not specified, newlines embedded inside quoted fields will not be interpreted correctly, and on platforms that use `\r\n` linendings on write an extra `\r` will be added. It should always be safe to specify `newline=''`, since the csv module does its own (`universal`) newline handling.
14.2. `configparser` — Configuration file parser

This module provides the `ConfigParser` class which implements a basic configuration language which provides a structure similar to what's found in Microsoft Windows INI files. You can use this to write Python programs which can be customized by end users easily.

**Note:** This library does *not* interpret or write the value-type prefixes used in the Windows Registry extended version of INI syntax.

**See also:**

- **Module `shlex`**
  Support for creating Unix shell-like mini-languages which can be used as an alternate format for application configuration files.

- **Module `json`**
  The `json` module implements a subset of JavaScript syntax which can also be used for this purpose.
14.2.1. Quick Start

Let's take a very basic configuration file that looks like this:

```
[DEFAULT]
ServerAliveInterval = 45
Compression = yes
CompressionLevel = 9
ForwardX11 = yes

[bitbucket.org]
User = hg

[topsecret.server.com]
Port = 50022
ForwardX11 = no
```

The structure of INI files is described in the following section. Essentially, the file consists of sections, each of which contains keys with values. `configparser` classes can read and write such files. Let's start by creating the above configuration file programatically.

```python
>>> import configparser
>>> config = configparser.ConfigParser()
>>> config['DEFAULT'] = {'ServerAliveInterval': '45',
...                      'Compression': 'yes',
...                      'CompressionLevel': '9'}
>>> config['bitbucket.org'] = {}
>>> config['bitbucket.org']['User'] = 'hg'
>>> config['topsecret.server.com'] = {}
>>> topsecret = config['topsecret.server.com']
>>> topsecret['Port'] = '50022'  # mutates the parser
>>> topsecret['ForwardX11'] = 'no'  # same here
>>> config['DEFAULT']['ForwardX11'] = 'yes'
>>> with open('example.ini', 'w') as configfile:
...     config.write(configfile)
```
As you can see, we can treat a config parser much like a dictionary. There are differences, outlined later, but the behavior is very close to what you would expect from a dictionary.

Now that we have created and saved a configuration file, let's read it back and explore the data it holds.

```python
>>> import configparser
>>> config = configparser.ConfigParser()
>>> config.sections()
[]
>>> config.read('example.ini')
['example.ini']
>>> config.sections()
['bitbucket.org', 'topsecret.server.com']
>>> 'bitbucket.org' in config
True
>>> 'bytebong.com' in config
False
>>> config['bitbucket.org']['User']
'hg'
>>> config['DEFAULT']['Compression']
'yes'
>>> topsecret = config['topsecret.server.com']
>>> topsecret['ForwardX11']
'no'
>>> topsecret['Port']
'50022'
>>> for key in config['bitbucket.org']: print(key)
... user
... compressionlevel
... serveraliveinterval
```
As we can see above, the API is pretty straightforward. The only bit of magic involves the DEFAULT section which provides default values for all other sections [1]. Note also that keys in sections are case-insensitive and stored in lowercase [1].
14.2.2. Supported Datatypes

Config parsers do not guess datatypes of values in configuration files, always storing them internally as strings. This means that if you need other datatypes, you should convert on your own:

```python
>>> int(topsecret['Port'])
50022
>>> float(topsecret['CompressionLevel'])
9.0
```

Extracting Boolean values is not that simple, though. Passing the value to `bool()` would do no good since `bool('False')` is still `True`. This is why config parsers also provide `getboolean()`. This method is case-insensitive and recognizes Boolean values from `'yes'/'no', 'on'/'off' and '1'/'0' [1]. For example:

```python
>>> topsecret.getboolean('ForwardX11')
False
>>> config['bitbucket.org'].getboolean('ForwardX11')
True
>>> config.getboolean('bitbucket.org', 'Compression')
True
```

Apart from `getboolean()`, config parsers also provide equivalent `getint()` and `getfloat()` methods, but these are far less useful since conversion using `int()` and `float()` is sufficient for these types.
14.2.3. Fallback Values

As with a dictionary, you can use a section’s get() method to provide fallback values:

```python
>>> topsecret.get('Port')
'50022'
>>> topsecret.get('CompressionLevel')
'9'
>>> topsecret.get('Cipher')
>>> topsecret.get('Cipher', '3des-cbc')
'3des-cbc'
```

Please note that default values have precedence over fallback values. For instance, in our example the `CompressionLevel` key was specified only in the `'DEFAULT'` section. If we try to get it from the section `'topsecret.server.com'`, we will always get the default, even if we specify a fallback:

```python
>>> topsecret.get('CompressionLevel', '3')
'9'
```

One more thing to be aware of is that the parser-level get() method provides a custom, more complex interface, maintained for backwards compatibility. When using this method, a fallback value can be provided via the `fallback` keyword-only argument:

```python
>>> config.get('bitbucket.org', 'monster', ...
... fallback='No such things as monsters'
'No such things as monsters'
```

The same `fallback` argument can be used with the getint(),
getfloat() and getboolean() methods, for example:

```python
>>> 'BatchMode' in topsecret
False
>>> topsecret.getboolean('BatchMode', fallback=True)
True
>>> config['DEFAULT']['BatchMode'] = 'no'
>>> topsecret.getboolean('BatchMode', fallback=True)
False
```
14.2.4. Supported INI File Structure

A configuration file consists of sections, each led by a [section] header, followed by key/value entries separated by a specific string (= or : by default [1]). By default, section names are case sensitive but keys are not [1]. Leading and trailing whitespace is removed from keys and values. Values can be omitted, in which case the key/value delimiter may also be left out. Values can also span multiple lines, as long as they are indented deeper than the first line of the value. Depending on the parser’s mode, blank lines may be treated as parts of multiline values or ignored.

Configuration files may include comments, prefixed by specific characters (# and ; by default [1]). Comments may appear on their own on an otherwise empty line, possibly indented. [1]

For example:

```plaintext
[Simple Values]
key=value
spaces in keys=allowed
spaces in values=allowed as well
spaces around the delimiter = obviously
you can also use : to delimit keys from values

[All Values Are Strings]
values like this: 1000000
or this: 3.14159265359
are they treated as numbers? : no
integers, floats and booleans are held as: strings
can use the API to get converted values directly: tr

[Multiline Values]
```
chorus: I'm a lumberjack, and I'm okay
          I sleep all night and I work all day

[No Values]
key_without_value
empty_string_value_here =

[You can use comments]
# like this
; or this

# By default only in an empty line.
# Inline comments can be harmful because they prevent
# from using the delimiting characters as parts of values.
# That being said, this can be customized.

[Sections Can Be Indented]
  can_values_be_as_well = True
  does_that_mean_anything_special = False
  purpose = formatting for readability
  multiline_values = are
    handled just fine as
    long as they are indented
deeper than the first line
    of a value
  # Did I mention we can indent comments, too?
14.2.5. Interpolation of values

On top of the core functionality, ConfigParser supports interpolation. This means values can be preprocessed before returning them from `get()` calls.

**class configparser.BasicInterpolation**

The default implementation used by ConfigParser. It enables values to contain format strings which refer to other values in the same section, or values in the special default section [1]. Additional default values can be provided on initialization.

For example:

```
[Paths]
home_dir: /Users
my_dir: %(home_dir)s/lumberjack
my_pictures: %(my_dir)s/Pictures
```

In the example above, ConfigParser with `interpolation` set to `BasicInterpolation()` would resolve `%(home_dir)s` to the value of `home_dir` (/Users in this case). `%(my_dir)s` in effect would resolve to /Users/lumberjack. All interpolations are done on demand so keys used in the chain of references do not have to be specified in any specific order in the configuration file.

With `interpolation` set to `None`, the parser would simply return `%(my_dir)s/Pictures` as the value of `my_pictures` and `%(home_dir)s/lumberjack` as the value of `my_dir`.

**class configparser.ExtendedInterpolation**

An alternative handler for interpolation which implements a more
advanced syntax, used for instance in zc.buildout. Extended interpolation is using \$\{section:option\} to denote a value from a foreign section. Interpolation can span multiple levels. For convenience, if the section: part is omitted, interpolation defaults to the current section (and possibly the default values from the special section).

For example, the configuration specified above with basic interpolation, would look like this with extended interpolation:

```
[Paths]
home_dir: /Users
my_dir: \$\{home_dir\}/lumberjack
my_photos: \$\{my_dir\}/Pictures
```

Values from other sections can be fetched as well:

```
[Common]

14.2.6. Mapping Protocol Access

New in version 3.2.

Mapping protocol access is a generic name for functionality that enables using custom objects as if they were dictionaries. In case of `configparser`, the mapping interface implementation is using the `parser['section']['option']` notation.

`parser['section']` in particular returns a proxy for the section’s data in the parser. This means that the values are not copied but they are taken from the original parser on demand. What’s even more important is that when values are changed on a section proxy, they are actually mutated in the original parser.

`configparser` objects behave as close to actual dictionaries as possible. The mapping interface is complete and adheres to the `MutableMapping` ABC. However, there are a few differences that should be taken into account:

- By default, all keys in sections are accessible in a case-insensitive manner [1]. E.g. for `option in parser['section']` yields only `optionxform`ed option key names. This means lowercased keys by default. At the same time, for a section that holds the key 'a', both expressions return `True`:

  ```
  "a" in parser["section"]
  "A" in parser["section"]
  ```

- All sections include DEFAULTSECT values as well which means that `.clear()` on a section may not leave the section visibly empty. This is because default values cannot be deleted from the
section (because technically they are not there). If they are overridden in the section, deleting causes the default value to be visible again. Trying to delete a default value causes a KeyError.

- DEFAULTSECT cannot be removed from the parser:
  - trying to delete it raises ValueError,
  - parser.clear() leaves it intact,
  - parser.popitem() never returns it.

- parser.get(section, option, **kwargs) - the second argument is not a fallback value. Note however that the section-level get() methods are compatible both with the mapping protocol and the classic ConfigParser API.

- parser.items() is compatible with the mapping protocol (returns a list of section_name, section_proxy pairs including the DEFAULTSECT). However, this method can also be invoked with arguments: parser.items(section, raw, vars). The latter call returns a list of option, value pairs for a specified section, with all interpolations expanded (unless raw=True is provided).

The mapping protocol is implemented on top of the existing legacy API so that subclasses overriding the original interface still should have mappings working as expected.
14.2.7. Customizing Parser Behaviour

There are nearly as many INI format variants as there are applications using it. `configparser` goes a long way to provide support for the largest sensible set of INI styles available. The default functionality is mainly dictated by historical background and it’s very likely that you will want to customize some of the features.

The most common way to change the way a specific config parser works is to use the `__init__()` options:

- **defaults**, default value: `None`

  This option accepts a dictionary of key-value pairs which will be initially put in the `DEFAULT` section. This makes for an elegant way to support concise configuration files that don’t specify values which are the same as the documented default.

  Hint: if you want to specify default values for a specific section, use `read_dict()` before you read the actual file.

- **dict_type**, default value: `collections.OrderedDict`

  This option has a major impact on how the mapping protocol will behave and how the written configuration files look. With the default ordered dictionary, every section is stored in the order they were added to the parser. Same goes for options within sections.

  An alternative dictionary type can be used for example to sort sections and options on write-back. You can also use a regular dictionary for performance reasons.

  Please note: there are ways to add a set of key-value pairs in a
single operation. When you use a regular dictionary in those operations, the order of the keys may be random. For example:

```python
>>> parser = configparser.ConfigParser()
>>> parser.read_dict({'section1': {'key1': 'value',
                               'key2': 'value',
                               'key3': 'value',
                               'section2': {'keyA': 'value',
                                             'keyB': 'value',
                                             'keyC': 'value',
                                             'section3': {'foo': 'x',
                                                          'bar': 'y',
                                                          'baz': 'z'}},
                               'section2': {}
                               ...
})
>>> parser.sections()
['section3', 'section2', 'section1']
>>> [option for option in parser['section3']]  
['baz', 'foo', 'bar']
```

In these operations you need to use an ordered dictionary as well:

```python
>>> from collections import OrderedDict
>>> parser = configparser.ConfigParser()
>>> parser.read_dict(O
```
allow_no_value, default value: False

Some configuration files are known to include settings without values, but which otherwise conform to the syntax supported by configparser. The allow_no_value parameter to the constructor can be used to indicate that such values should be accepted:

```python
>>> import configparser
>>> sample_config = ""
... [mysqld]
... user = mysql
... pid-file = /var/run/mysqld/mysqld.pid
... skip-external-locking
... old_passwords = 1
... skip-bdb
... # we don't need ACID today
... skip-innodb
... ""
>>> config = configparser.ConfigParser(allow_no_value)
>>> config.read_string(sample_config)
```
delimiters, default value: ('=', ':')

Delimiters are substrings that delimit keys from values within a section. The first occurrence of a delimiting substring on a line is considered a delimiter. This means values (but not keys) can contain the delimiters.

See also the space_around_delimiters argument to ConfigParser.write().

comment_prefixes, default value: ('#', ';')

inline_comment_prefixes, default value: None

Comment prefixes are strings that indicate the start of a valid comment within a config file. comment_prefixes are used only on otherwise empty lines (optionally indented) whereas inline_comment_prefixes can be used after every valid value (e.g. section names, options and empty lines as well). By default inline comments are disabled and '#' and ';' are used as prefixes for whole line comments.
*Changed in version 3.2:* In previous versions of `configparser` behaviour matched `comment_prefixes=('#',';')` and `inline_comment_prefixes=(';')`.

Please note that config parsers don’t support escaping of comment prefixes so using `inline_comment_prefixes` may prevent users from specifying option values with characters used as comment prefixes. When in doubt, avoid setting `inline_comment_prefixes`. In any circumstances, the only way of storing comment prefix characters at the beginning of a line in multiline values is to interpolate the prefix, for example:

```python
>>> from configparser import ConfigParser, ExtendedInterpolation
>>> parser = ConfigParser(interpolation=ExtendedInterpolation)
>>> # the default BasicInterpolation could be used
>>> parser.read_string(""
... [DEFAULT]
... hash = #
...
... [hashes]
... shebang =
... ${hash}!/usr/bin/env python
... ${hash} -*- coding: utf-8 -*-
...
... extensions =
... enabled_extension
... another_extension
... #disabled_by_comment
... yet_another_extension
...
... interpolation not necessary = if # is not at even in multiline values = line #1
... line #2
... line #3
... """
```
>>> print(parser['hashes']['shebang'])
#!/usr/bin/env python
# -*- coding: utf-8 -*-

>>> print(parser['hashes']['extensions'])
enabled_extension
another_extension
yet_another_extension

>>> print(parser['hashes']['interpolation not necessary'])
if # is not at line start

>>> print(parser['hashes']['even in multiline values'])
line #1
line #2
line #3

- **strict**, default value: `True`

When set to `True`, the parser will not allow for any section or option duplicates while reading from a single source (using `read_file()`, `read_string()` or `read_dict()`). It is recommended to use strict parsers in new applications.

*Changed in version 3.2:* In previous versions of `configparser` behaviour matched `strict=False`.

- **empty_lines_in_values**, default value: `True`

In config parsers, values can span multiple lines as long as they are indented more than the key that holds them. By default parsers also let empty lines to be parts of values. At the same time, keys can be arbitrarily indented themselves to improve readability. In consequence, when configuration files get big and complex, it is easy for the user to lose track of the file structure.
Take for instance:

```
[Section]
key = multiline
   value with a gotcha
this = is still a part of the multiline value of key
```

This can be especially problematic for the user to see if she's using a proportional font to edit the file. That is why when your application does not need values with empty lines, you should consider disallowing them. This will make empty lines split keys every time. In the example above, it would produce two keys, key and this.

- **default_section**, default value: `configparser.DEFAULTSECT` (that is: "DEFAULT")

The convention of allowing a special section of default values for other sections or interpolation purposes is a powerful concept of this library, letting users create complex declarative configurations. This section is normally called "DEFAULT" but this can be customized to point to any other valid section name. Some typical values include: "general" or "common". The name provided is used for recognizing default sections when reading from any source and is used when writing configuration back to a file. Its current value can be retrieved using the `parser_instance.default_section` attribute and may be modified at runtime (i.e. to convert files from one format to another).

- **interpolation**, default value:
Interpolation behaviour may be customized by providing a custom handler through the `interpolation` argument. None can be used to turn off interpolation completely, `ExtendedInterpolation()` provides a more advanced variant inspired by `zc.buildout`. More on the subject in the dedicated documentation section.

RawConfigParser has a default value of None.

More advanced customization may be achieved by overriding default values of these parser attributes. The defaults are defined on the classes, so they may be overridden by subclasses or by attribute assignment.

```
>>> custom = configparser.ConfigParser()
>>> custom['section1'] = {'funky': 'nope'}
>>> custom['section1'].getboolean('funky')
Traceback (most recent call last):
...
ValueError: Not a boolean: nope
```

```
>>> custom.BOOLEAN_STATES = {'sure': True, 'nope'
>>> custom['section1'].getboolean('funky')
False
```

Other typical Boolean pairs include accept/reject or enabled/disabled.
configparser. **optionxform**(option)

This method transforms option names on every read, get, or set operation. The default converts the name to lowercase. This also means that when a configuration file gets written, all keys will be lowercase. Override this method if that's unsuitable. For example:

```python
>>> config = ""
... [Section1]
... Key = Value
...
... [Section2]
... AnotherKey = Value
... ""
>>> typical = configparser.ConfigParser()
>>> typical.read_string(config)
>>> list(typical['Section1'].keys())
['key']
>>> list(typical['Section2'].keys())
['anotherkey']
>>> custom = configparser.RawConfigParser()
>>> custom.optionxform = lambda option: option
>>> custom.read_string(config)
>>> list(custom['Section1'].keys())
['Key']
>>> list(custom['Section2'].keys())
['AnotherKey']
```

cconfigparser. **SECTCRE**

A compiled regular expression used to parse section headers. The default matches \[section\] to the name "section". Whitespace is considered part of the section name, thus \[larch\] will be read as a section of name " larch ". Override this attribute if that's unsuitable. For example:
>>> config = ""
... [Section 1]
... option = value
...
... [ Section 2 ]
... another = val
... ""
>>> typical = ConfigParser()
>>> typical.read_string(config)
>>> typical.sections()
['Section 1', ' Section 2 ']
>>> custom = ConfigParser()
>>> custom(SECTCRE = re.compile(r"[^\[	*] *(?P<header>[^\]
>>> custom.read_string(config)
>>> custom.sections()
['Section 1', 'Section 2']

Note: While ConfigParser objects also use an OPTCRE attribute for recognizing option lines, it's not recommended to override it because that would interfere with constructor options allow_no_value and delimiters.
14.2.8. Legacy API Examples

Mainly because of backwards compatibility concerns, `configparser` provides also a legacy API with explicit `get`/`set` methods. While there are valid use cases for the methods outlined below, mapping protocol access is preferred for new projects. The legacy API is at times more advanced, low-level and downright counterintuitive.

An example of writing to a configuration file:

```python
import configparser
config = configparser.RawConfigParser()
# Please note that using RawConfigParser's set function to assign non-string values to keys internally, but will receive an error when attempting to write to a file or when you get it in non-raw mode. Setting values using the mapping protocol or ConfigParser's set() does not allow such assignments to take place.
config.add_section('Section1')
config.set('Section1', 'an_int', '15')
config.set('Section1', 'a_bool', 'true')
config.set('Section1', 'a_float', '3.1415')
config.set('Section1', 'baz', 'fun')
config.set('Section1', 'bar', 'Python')
config.set('Section1', 'foo', '%(bar)s is %(baz)s!')

# Writing our configuration file to 'example.cfg'
with open('example.cfg', 'w') as configfile:
    config.write(configfile)
```

An example of reading the configuration file again:

```python
import configparser
```
config = configparser.RawConfigParser()
config.read('example.cfg')

# getfloat() raises an exception if the value is not a float
# getint() and getboolean() also do this for their respective types

a_float = config.getfloat('Section1', 'a_float')
an_int = config.getint('Section1', 'an_int')
print(a_float + an_int)

# Notice that the next output does not interpolate '%(bar)s' and '%(baz)s'
# This is because we are using a RawConfigParser().
if config.getboolean('Section1', 'a_bool'):
    print(config.get('Section1', 'foo'))

To get interpolation, use ConfigParser:

import configparser

cfg = configparser.ConfigParser()
cfg.read('example.cfg')

# Set the optional *raw* argument of get() to True in a single get operation.
print(cfg.get('Section1', 'foo', raw=False))  # -> "Python is fun!"
print(cfg.get('Section1', 'foo', raw=True))   # -> "%(bar)s is %(baz)s!"

# The optional *vars* argument is a dict with member precedence in interpolation.
print(cfg.get('Section1', 'foo', vars={'bar': 'Documentation', 'baz': 'evil'}))

# The optional *fallback* argument can be used to provide a fallback value
print(cfg.get('Section1', 'foo'))  # -> "Python is fun!"
Default values are available in both types of ConfigParsers. They are used in interpolation if an option used is not defined elsewhere.

```python
import configparser

# New instance with 'bar' and 'baz' defaulting to 'Life'
config = configparser.ConfigParser({'bar': 'Life', 'baz': 'hard'}
config.read('example.cfg')

print(config.get('Section1', 'foo')) # -> "Python is fun!"
config.remove_option('Section1', 'bar')
config.remove_option('Section1', 'baz')
print(config.get('Section1', 'foo')) # -> "Life is hard!"
```
14.2.9. ConfigParser Objects

class configparser.ConfigParser(defaults=None, 
dict_type=OrderedDict, allow_no_value=False, delimiters=(‘=’, ‘:’), comment_prefixes=('#', ';'), inline_comment_prefixes=None, 
strict=True, empty_lines_in_values=True, 
default_section=DEFAULTSECT, 
interpolation=BasicInterpolation())

The main configuration parser. When defaults is given, it is initialized into the dictionary of intrinsic defaults. When dict_type is given, it will be used to create the dictionary objects for the list of sections, for the options within a section, and for the default values.

When delimiters is given, it is used as the set of substrings that divide keys from values. When comment_prefixes is given, it will be used as the set of substrings that prefix comments in otherwise empty lines. Comments can be indented. When inline_comment_prefixes is given, it will be used as the set of substrings that prefix comments in non-empty lines.

When strict is True (the default), the parser won’t allow for any section or option duplicates while reading from a single source (file, string or dictionary), raising DuplicateSectionError or DuplicateOptionError. When empty_lines_in_values is False (default: True), each empty line marks the end of an option. Otherwise, internal empty lines of a multiline option are kept as part of the value. When allow_no_value is True (default: False), options without values are accepted; the value held for these is None and they are serialized without the trailing delimiter.

When default_section is given, it specifies the name for the special section holding default values for other sections and interpolation
purposes (normally named "DEFAULT"). This value can be retrieved and changed on runtime using the `default_section` instance attribute.

Interpolation behaviour may be customized by providing a custom handler through the `interpolation` argument. None can be used to turn off interpolation completely, `ExtendedInterpolation()` provides a more advanced variant inspired by `zc.buildout`. More on the subject in the dedicated documentation section.

All option names used in interpolation will be passed through the `optionxform()` method just like any other option name reference. For example, using the default implementation of `optionxform()` (which converts option names to lower case), the values `foo %(bar)s` and `foo %(BAR)s` are equivalent.

*Changed in version 3.1:* The default `dict_type` is `collections.OrderedDict`.

*Changed in version 3.2:* `allow_no_value`, `delimiters`, `comment_prefixes`, `strict`, `empty_lines_in_values`, `default_section` and `interpolation` were added.

**defaults()**

- Return a dictionary containing the instance-wide defaults.

**sections()**

- Return a list of the sections available; the `default section` is not included in the list.

**add_section(section)**

- Add a section named `section` to the instance. If a section by the given name already exists, `DuplicateSectionError` is
raised. If the default section name is passed, ValueError is raised. The name of the section must be a string; if not, TypeError is raised.

*Changed in version 3.2:* Non-string section names raise TypeError.

**has_section(section)**

Indicates whether the named section is present in the configuration. The default section is not acknowledged.

**options(section)**

Return a list of options available in the specified section.

**has_option(section, option)**

If the given section exists, and contains the given option, return True; otherwise return False. If the specified section is None or an empty string, DEFAULT is assumed.

**read(filenames, encoding=None)**

Attempt to read and parse a list of filenames, returning a list of filenames which were successfully parsed. If filenames is a string, it is treated as a single filename. If a file named in filenames cannot be opened, that file will be ignored. This is designed so that you can specify a list of potential configuration file locations (for example, the current directory, the user’s home directory, and some system-wide directory), and all existing configuration files in the list will be read. If none of the named files exist, the ConfigParser instance will contain an empty dataset. An application which requires initial values to be loaded from a file should load the required file or files using read_file() before calling read() for any optional files:
import configparser, os

config = configparser.ConfigParser()
config.read_file(open('defaults.cfg'))
config.read(["site.cfg", os.path.expanduser('~/encoding=\'cp1250\'')])

New in version 3.2: The encoding parameter. Previously, all files were read using the default encoding for open().

read_file(f, source=None)
Read and parse configuration data from f which must be an iterable yielding Unicode strings (for example files opened in text mode).

Optional argument source specifies the name of the file being read. If not given and f has a name attribute, that is used for source; the default is '<???>'.

New in version 3.2: Replaces readfp().

read_string(string, source='<string>')
Parse configuration data from a string.

Optional argument source specifies a context-specific name of the string passed. If not given, '<string>' is used. This should commonly be a filesystem path or a URL.

New in version 3.2.

read_dict(dictionary, source='<dict>')
Load configuration from any object that provides a dict-like items() method. Keys are section names, values are
dictionaries with keys and values that should be present in the section. If the used dictionary type preserves order, sections and their keys will be added in order. Values are automatically converted to strings.

Optional argument source specifies a context-specific name of the dictionary passed. If not given, `<dict>` is used.

This method can be used to copy state between parsers.

*New in version 3.2.*

```python
get(section, option, *, raw=False, vars=None[, fallback])
```

Get an option value for the named section. If vars is provided, it must be a dictionary. The option is looked up in vars (if provided), section, and in DEFAULTSECT in that order. If the key is not found and fallback is provided, it is used as a fallback value. None can be provided as a fallback value.

All the '% interpolations are expanded in the return values, unless the raw argument is true. Values for interpolation keys are looked up in the same manner as the option.

*Changed in version 3.2:* Arguments raw, vars and fallback are keyword only to protect users from trying to use the third argument as the fallback fallback (especially when using the mapping protocol).

```python
getint(section, option, *, raw=False, vars=None[, fallback])
```

A convenience method which coerces the option in the specified section to an integer. See `get()` for explanation of raw, vars and fallback.
**getfloat**(*section, option, *, raw=False, vars=None[, fallback])

A convenience method which coerces the option in the specified section to a floating point number. See `get()` for explanation of raw, vars and fallback.

**getboolean**(*section, option, *, raw=False, vars=None[, fallback])

A convenience method which coerces the option in the specified section to a Boolean value. Note that the accepted values for the option are '1', 'yes', 'true', and 'on', which cause this method to return True, and '0', 'no', 'false', and 'off', which cause it to return False. These string values are checked in a case-insensitive manner. Any other value will cause it to raise `ValueError`. See `get()` for explanation of raw, vars and fallback.

**items**(*raw=False, vars=None)

**items**(*section, raw=False, vars=None)

When section is not given, return a list of section_name, section_proxy pairs, including DEFAULTSECT.

Otherwise, return a list of name, value pairs for the options in the given section. Optional arguments have the same meaning as for the `get()` method.

*Changed in version 3.2:* Items present in vars no longer appear in the result. The previous behaviour mixed actual parser options with variables provided for interpolation.

**set**(*section, option, value)*

If the given section exists, set the given option to the specified
value; otherwise raise :exc:`NoSectionError`. :paramref:`option` and :paramref:`value` must be strings; if not, :class:`TypeError` is raised.

.. function:: write(fileobject, space_around_delimiters=True)

   Write a representation of the configuration to the specified :term:`file object`, which must be opened in text mode (accepting strings). This representation can be parsed by a future :func:`read()` call. If :paramref:`space_around_delimiters` is true, delimiters between keys and values are surrounded by spaces.

.. function:: remove_option(section, option)

   Remove the specified :paramref:`option` from the specified :paramref:`section`. If the section does not exist, raise :exc:`NoSectionError`. If the option existed to be removed, return :obj:`True`; otherwise return :obj:`False`.

.. function:: remove_section(section)

   Remove the specified :paramref:`section` from the configuration. If the section in fact existed, return :obj:`True`. Otherwise return :obj:`False`.

.. function:: optionxform(option)

   Transforms the option name :paramref:`option` as found in an input file or as passed in by client code to the form that should be used in the internal structures. The default implementation returns a lower-case version of :paramref:`option`; subclasses may override this or client code can set an attribute of this name on instances to affect this behavior.

   You don't need to subclass the parser to use this method, you can also set it on an instance, to a function that takes a string argument and returns a string. Setting it to :obj:`str`, for example, would make option names case sensitive:
cfgparser = ConfigParser()
cfgparser.optionxform = str

Note that when reading configuration files, whitespace around the option names is stripped before `optionxform()` is called.

**`readfp(fp, filename=None)`**

*Deprecated since version 3.2: Use `read_file()` instead.*

*Changed in version 3.2: `readfp()` now iterates on `f` instead of calling `f.readline()`.*

For existing code calling `readfp()` with arguments which don’t support iteration, the following generator may be used as a wrapper around the file-like object:

```python
def readline_generator(f):
    line = f.readline()
    while line:
        yield line
        line = f.readline()
```

Instead of `parser.readfp(f)` use `parser.read_file(readline_generator(f)).`

**`configparser.MAX_INTERPOLATION_DEPTH`**

The maximum depth for recursive interpolation for `get()` when the `raw` parameter is false. This is relevant only when the default `interpolation` is used.
14.2.10. RawConfigParser Objects

```python
class configparser.RawConfigParser(defaults=None,
dict_type=OrderedDict, allow_no_value=False, *
delimiters=('=', ':'), comment_prefixes=('#', ';'),
inline_comment_prefixes=None, strict=True,
empty_lines_in_values=True,
default_section=configparser.DEFAULTSECT)
```

Legacy variant of the `ConfigParser` with interpolation disabled by default and unsafe `add_section` and `set` methods.

**Note:** Consider using `ConfigParser` instead which checks types of the values to be stored internally. If you don't want interpolation, you can use `ConfigParser(interpolation=None)`.

**add_section**(section)

Add a section named `section` to the instance. If a section by the given name already exists, `DuplicateSectionError` is raised. If the default section name is passed, `ValueError` is raised.

Type of `section` is not checked which lets users create non-string named sections. This behaviour is unsupported and may cause internal errors.

**set**(section, option, value)

If the given section exists, set the given option to the specified value; otherwise raise `NoSectionError`. While it is possible to use `RawConfigParser` (or `ConfigParser` with `raw` parameters set to true) for internal storage of non-string values,
full functionality (including interpolation and output to files) can only be achieved using string values.

This method lets users assign non-string values to keys internally. This behaviour is unsupported and will cause errors when attempting to write to a file or get it in non-raw mode. **Use the mapping protocol API** which does not allow such assignments to take place.
14.2.11. Exceptions

(exception) configparser.Error
Base class for all other configparser exceptions.

(exception) configparser.NoSectionError
Exception raised when a specified section is not found.

(exception) configparser.DuplicateSectionError
Exception raised if add_section() is called with the name of a section that is already present or in strict parsers when a section if found more than once in a single input file, string or dictionary.

New in version 3.2: Optional source and lineno attributes and arguments to __init__() were added.

(exception) configparser.DuplicateOptionError
Exception raised by strict parsers if a single option appears twice during reading from a single file, string or dictionary. This catches misspellings and case sensitivity-related errors, e.g. a dictionary may have two keys representing the same case-insensitive configuration key.

(exception) configparser.NoOptionError
Exception raised when a specified option is not found in the specified section.

(exception) configparser.InterpolationError
Base class for exceptions raised when problems occur performing string interpolation.

(exception) configparser.InterpolationDepthError
Exception raised when string interpolation cannot be completed because the number of iterations exceeds MAX_INTERPOLATION_DEPTH. Subclass of InterpolationError.

```
exception configparser.InterpolationMissingOptionError
```

Exception raised when an option referenced from a value does not exist. Subclass of InterpolationError.

```
exception configparser.InterpolationSyntaxError
```

Exception raised when the source text into which substitutions are made does not conform to the required syntax. Subclass of InterpolationError.

```
exception configparser.MissingSectionHeaderError
```

Exception raised when attempting to parse a file which has no section headers.

```
exception configparser.ParsingError
```

Exception raised when errors occur attempting to parse a file.

**Changed in version 3.2:** The filename attribute and __init__() argument were renamed to source for consistency.

### Footnotes

(1, 2, 3, 4, 5, 6, 7, 8, 9) Config parsers allow for heavy customization. If you are interested in changing the behaviour outlined by the footnote reference, consult the Customizing Parser Behaviour section.
14.3. netrc — netrc file processing

Source code: Lib/netrc.py

The netrc class parses and encapsulates the netrc file format used by the Unix ftp program and other FTP clients.

```python
class netrc.
netrc([file])
```

A netrc instance or subclass instance encapsulates data from a netrc file. The initialization argument, if present, specifies the file to parse. If no argument is given, the file .netrc in the user’s home directory will be read. Parse errors will raise NetrcParseError with diagnostic information including the file name, line number, and terminating token. If no argument is specified on a POSIX system, the presence of passwords in the .netrc file will raise a NetrcParseError if the file ownership or permissions are insecure (owned by a user other than the user running the process, or accessible for read or write by any other user). This implements security behavior equivalent to that of ftp and other programs that use .netrc.

Changed in version 3.4: Added the POSIX permission check.

```python
exception netrc.
NetrcParseError
```

Exception raised by the netrc class when syntactical errors are encountered in source text. Instances of this exception provide three interesting attributes: msg is a textual explanation of the error, filename is the name of the source file, and lineno gives
the line number on which the error was found.
14.3.1. netrc Objects

A netrc instance has the following methods:

netrc.authenticate(host)

Return a 3-tuple (login, account, password) of authenticators for host. If the netrc file did not contain an entry for the given host, return the tuple associated with the ‘default’ entry. If neither matching host nor default entry is available, return None.

netrc.__repr__()

Dump the class data as a string in the format of a netrc file. (This discards comments and may reorder the entries.)

Instances of netrc have public instance variables:

netrc.hosts

Dictionary mapping host names to (login, account, password) tuples. The ‘default’ entry, if any, is represented as a pseudo-host by that name.

netrc.macros

Dictionary mapping macro names to string lists.

Note: Passwords are limited to a subset of the ASCII character set. All ASCII punctuation is allowed in passwords, however, note that whitespace and non-printable characters are not allowed in passwords. This is a limitation of the way the .netrc file is parsed and may be removed in the future.
14.4. **xdrlib** — Encode and decode XDR data

**Source code:** Lib/xdrlib.py

The **xdrlib** module supports the External Data Representation Standard as described in **RFC 1014**, written by Sun Microsystems, Inc. June 1987. It supports most of the data types described in the RFC.

The **xdrlib** module defines two classes, one for packing variables into XDR representation, and another for unpacking from XDR representation. There are also two exception classes.

```python
class xdrlib.Packer
    Packer is the class for packing data into XDR representation. The Packer class is instantiated with no arguments.

class xdrlib.Unpacker(data)
    Unpacker is the complementary class which unpacks XDR data values from a string buffer. The input buffer is given as `data`.
```

**See also:**

**RFC 1014** - XDR: External Data Representation Standard

This RFC defined the encoding of data which was XDR at the time this module was originally written. It has apparently been obsoleted by **RFC 1832**.

**RFC 1832** - XDR: External Data Representation Standard

Newer RFC that provides a revised definition of XDR.
14.4.1. Packer Objects

Packer instances have the following methods:

Packer\, .\, .\, .\, .\, get\, buffer()\n
Returns the current pack buffer as a string.

Packer\, .\, .\, .\, .\, reset()\n
Resets the pack buffer to the empty string.

In general, you can pack any of the most common XDR data types by calling the appropriate pack\_type() method. Each method takes a single argument, the value to pack. The following simple data type packing methods are supported: pack\_uint(), pack\_int(), pack\_enum(), pack\_bool(), pack\_uhyper(), and pack\_hyper().

Packer\, .\, .\, .\, .\, pack\_float(value)\n
Packs the single-precision floating point number value.

Packer\, .\, .\, .\, .\, pack\_double(value)\n
Packs the double-precision floating point number value.

The following methods support packing strings, bytes, and opaque data:

Packer\, .\, .\, .\, .\, pack\_fstring(n, s)\n
Packs a fixed length string, s. n is the length of the string but it is not packed into the data buffer. The string is padded with null bytes if necessary to guaranteed 4 byte alignment.

Packer\, .\, .\, .\, .\, pack\_fopaque(n, data)
Packs a fixed length opaque data stream, similarly to `pack_fstring()`.

**Packer.** `pack_string(s)`

Packs a variable length string, s. The length of the string is first packed as an unsigned integer, then the string data is packed with `pack_fstring()`.

**Packer.** `pack_opaque(data)`

Packs a variable length opaque data string, similarly to `pack_string()`.

**Packer.** `pack_bytes(bytes)`

Packs a variable length byte stream, similarly to `pack_string()`.

The following methods support packing arrays and lists:

**Packer.** `pack_list(list, pack_item)`

Packs a list of homogeneous items. This method is useful for lists with an indeterminate size; i.e. the size is not available until the entire list has been walked. For each item in the list, an unsigned integer 1 is packed first, followed by the data value from the list. `pack_item` is the function that is called to pack the individual item. At the end of the list, an unsigned integer 0 is packed.

For example, to pack a list of integers, the code might appear like this:

```python
import xdrlib
p = xdrlib.Packer()
p.pack_list([1, 2, 3], p.pack_int)
```

**Packer.** `pack_farray(n, array, pack_item)`
Packs a fixed length list (`array`) of homogeneous items. \( n \) is the length of the list; it is *not* packed into the buffer, but a `ValueError` exception is raised if `len(array)` is not equal to \( n \). As above, `pack_item` is the function used to pack each element.

Packer. **pack_array**(*list, pack_item*)

Packs a variable length *list* of homogeneous items. First, the length of the list is packed as an unsigned integer, then each element is packed as in `pack_farray()` above.
14.4.2. Unpacker Objects

The Unpacker class offers the following methods:

Unpacker.**reset**(*data*)

Resets the string buffer with the given *data*.

Unpacker.**get_position**()

Returns the current unpack position in the data buffer.

Unpacker.**set_position**(*position*)

Sets the data buffer unpack position to *position*. You should be careful about using **get_position**() and **set_position**().

Unpacker.**get_buffer**()

Returns the current unpack data buffer as a string.

Unpacker.**done**()

Indicates unpack completion. Raises an **Error** exception if all of the data has not been unpacked.

In addition, every data type that can be packed with a Packer, can be unpacked with an Unpacker. Unpacking methods are of the form unpack_type(), and take no arguments. They return the unpacked object.

Unpacker.**unpack_float**()

Unpacks a single-precision floating point number.

Unpacker.**unpack_double**()

Unpacks a double-precision floating point number, similarly to unpack_float().
In addition, the following methods unpack strings, bytes, and opaque data:

**Unpacker.**\texttt{unpack\_fstring}(n)

Unpacks and returns a fixed length string. \textit{n} is the number of characters expected. Padding with null bytes to guaranteed 4 byte alignment is assumed.

**Unpacker.**\texttt{unpack\_fopaque}(n)

Unpacks and returns a fixed length opaque data stream, similarly to \texttt{unpack\_fstring}().

**Unpacker.**\texttt{unpack\_string}()

Unpacks and returns a variable length string. The length of the string is first unpacked as an unsigned integer, then the string data is unpacked with \texttt{unpack\_fstring}().

**Unpacker.**\texttt{unpack\_opaque}()

Unpacks and returns a variable length opaque data string, similarly to \texttt{unpack\_string}().

**Unpacker.**\texttt{unpack\_bytes}()

Unpacks and returns a variable length byte stream, similarly to \texttt{unpack\_string}().

The following methods support unpacking arrays and lists:

**Unpacker.**\texttt{unpack\_list}(\texttt{unpack\_item})

Unpacks and returns a list of homogeneous items. The list is unpacked one element at a time by first unpacking an unsigned integer flag. If the flag is 1, then the item is unpacked and appended to the list. A flag of 0 indicates the end of the list.
unpack_item is the function that is called to unpack the items.

Unpacker. **unpack_farray**(*n*, **unpack_item**)

Unpacks and returns (as a list) a fixed length array of homogeneous items. *n* is number of list elements to expect in the buffer. As above, **unpack_item** is the function used to unpack each element.

Unpacker. **unpack_array**(**unpack_item**)

Unpacks and returns a variable length list of homogeneous items. First, the length of the list is unpacked as an unsigned integer, then each element is unpacked as in **unpack_farray()** above.
14.4.3. Exceptions

Exceptions in this module are coded as class instances:

```python
import xdrlib
p = xdrlib.Packer()
try:
    p.pack_double(8.01)
except xdrlib.ConversionError as instance:
    print('packing the double failed:', instance.msg)
```

**exception xdrlib.Error**

The base exception class. `Error` has a single public attribute `msg` containing the description of the error.

**exception xdrlib.ConversionError**

Class derived from `Error`. Contains no additional instance variables.

Here is an example of how you would catch one of these exceptions:
14.5. **plistlib** — Generate and parse Mac OS X `.plist` files

**Source code:** Lib/plistlib.py

This module provides an interface for reading and writing the “property list” files used mainly by Mac OS X and supports both binary and XML plist files.

The property list (.plist) file format is a simple serialization supporting basic object types, like dictionaries, lists, numbers and strings. Usually the top level object is a dictionary.

To write out and to parse a plist file, use the `dump()` and `load()` functions.

To work with plist data in bytes objects, use `dumps()` and `loads()`.

Values can be strings, integers, floats, booleans, tuples, lists, dictionaries (but only with string keys), `Data`, `bytes`, `bytesarray` or `datetime.datetime` objects.

*Changed in version 3.4:* New API, old API deprecated. Support for binary format plists added.

**See also:**

**PList manual page**
Apple’s documentation of the file format.
This module defines the following functions:

**plistlib.load**(*fp, *, fmt=None, use_builtin_types=True, dict_type=dict*)

Read a plist file. *fp* should be a readable and binary file object. Return the unpacked root object (which usually is a dictionary).

The *fmt* is the format of the file and the following values are valid:

- **None**: Autodetect the file format
- **FMT_XML**: XML file format
- **FMT_BINARY**: Binary plist format

If *use_builtin_types* is true (the default) binary data will be returned as instances of *bytes*, otherwise it is returned as instances of *Data*.

The *dict_type* is the type used for dictionaries that are read from the plist file. The exact structure of the plist can be recovered by using *collections.OrderedDict* (although the order of keys shouldn’t be important in plist files).

XML data for the **FMT_XML** format is parsed using the Expat parser from *xml.parsers.expat* – see its documentation for possible exceptions on ill-formed XML. Unknown elements will simply be ignored by the plist parser.

The parser for the binary format raises *InvalidFileException* when the file cannot be parsed.

*New in version 3.4.*

**plistlib.loads**(*data, *, fmt=None, use_builtin_types=True, dict_type=dict*)
Load a plist from a bytes object. See `load()` for an explanation of the keyword arguments.

*New in version 3.4.*

```python
plistlib.dump(value, fp, *, fmt=FMT_XML, sort_keys=True, skipkeys=False)
```

Write `value` to a plist file. `fp` should be a writable, binary file object.

The `fmt` argument specifies the format of the plist file and can be one of the following values:

- **FMT_XML**: XML formatted plist file
- **FMT_BINARY**: Binary formatted plist file

When `sort_keys` is true (the default) the keys for dictionaries will be written to the plist in sorted order, otherwise they will be written in the iteration order of the dictionary.

When `skipkeys` is false (the default) the function raises `TypeError` when a key of a dictionary is not a string, otherwise such keys are skipped.

A `TypeError` will be raised if the object is of an unsupported type or a container that contains objects of unsupported types.

An `OverflowError` will be raised for integer values that cannot be represented in (binary) plist files.

*New in version 3.4.*

```python
plistlib.dumps(value, *, fmt=FMT_XML, sort_keys=True, skipkeys=False)
```

Return `value` as a plist-formatted bytes object. See the
documentation for `dump()` for an explanation of the keyword arguments of this function.

*New in version 3.4.*

The following functions are deprecated:

**plistlib.** `readPlist(pathOrFile)`

Read a plist file. *pathOrFile* may be either a file name or a (readable and binary) file object. Returns the unpacked root object (which usually is a dictionary).

This function calls `load()` to do the actual work, the the documentation of *that function* for an explanation of the keyword arguments.

**Note:** Dict values in the result have a `__getattr__` method that defers to `__getitem__`. This means that you can use attribute access to access items of these dictionaries.

*Deprecated since version 3.4:* Use `load()` instead.

**plistlib.** `writePlist(rootObject, pathOrFile)`

Write `rootObject` to an XML plist file. *pathOrFile* may be either a file name or a (writable and binary) file object

*Deprecated since version 3.4:* Use `dump()` instead.

**plistlib.** `readPlistFromBytes(data)`

Read a plist data from a bytes object. Return the root object.

See `load()` for a description of the keyword arguments.
**Note:** Dict values in the result have a `__getattr__` method that defers to `__getitem__`. This means that you can use attribute access to access items of these dictionaries.

*Deprecated since version 3.4:* Use `loads()` instead.

`plistlib.writePlistToBytes(rootObject)`  
Return `rootObject` as an XML plist-formatted bytes object.

*Deprecated since version 3.4:* Use `dumps()` instead.

The following classes are available:

**Dict([dict]):**

Return an extended mapping object with the same value as dictionary `dict`.

This class is a subclass of `dict` where attribute access can be used to access items. That is, `aDict.key` is the same as `aDict['key']` for getting, setting and deleting items in the mapping.

*Deprecated since version 3.0.*

**class plistlib.Data(data)**

Return a “data” wrapper object around the bytes object `data`. This is used in functions converting from/to plists to represent the `<data>` type available in plists.

It has one attribute, `data`, that can be used to retrieve the Python bytes object stored in it.
The following constants are available:

`plistlib.FMT_XML`
   The XML format for plist files.

   *New in version 3.4.*

`plistlib.FMT_BINARY`
   The binary format for plist files

   *New in version 3.4.*
14.5.1. Examples

Generating a plist:

```python
pl = dict(
    aString = "Doodah",
    aList = ["A", "B", 12, 32.1, [1, 2, 3]],
    aFloat = 0.1,
    anInt = 728,
    aDict = dict(
        anotherString = "<hello & hi there!>",
        aThirdString = "M\xe4ssig, Ma\xdf",
        aTrueValue = True,
        aFalseValue = False,
    ),
    someData = b"<binary gunk>",
    someMoreData = b"<lots of binary gunk>" * 10,
    aDate = datetime.datetime.fromtimestamp(time.mktime(
            time.localtime())))
)
with open(fileName, 'wb') as fp:
    dump(pl, fp)
```

Parsing a plist:

```python
with open(fileName, 'rb') as fp:
    pl = load(fp)
print(pl["aKey"])
```
Created using Sphinx 1.2.
15. Cryptographic Services

The modules described in this chapter implement various algorithms of a cryptographic nature. They are available at the discretion of the installation. On Unix systems, the crypt module may also be available. Here’s an overview:

- **15.1. hashlib** — Secure hashes and message digests
  - 15.1.1. Hash algorithms
  - 15.1.2. Key Derivation Function
- **15.2. hmac** — Keyed-Hashing for Message Authentication

Hardcore cypherpunks will probably find the cryptographic modules written by A.M. Kuchling of further interest; the package contains modules for various encryption algorithms, most notably AES. These modules are not distributed with Python but available separately. See the URL [http://www.pycrypto.org](http://www.pycrypto.org) for more information.
This module implements a common interface to many different secure hash and message digest algorithms. Included are the FIPS secure hash algorithms SHA1, SHA224, SHA256, SHA384, and SHA512 (defined in FIPS 180-2) as well as RSA's MD5 algorithm (defined in Internet RFC 1321). The terms “secure hash” and “message digest” are interchangeable. Older algorithms were called message digests. The modern term is secure hash.

**Note:** If you want the adler32 or crc32 hash functions, they are available in the `zlib` module.

**Warning:** Some algorithms have known hash collision weaknesses, refer to the “See also” section at the end.
15.1.1. Hash algorithms

There is one constructor method named for each type of hash. All return a hash object with the same simple interface. For example: use sha1() to create a SHA1 hash object. You can now feed this object with bytes-like objects (normally bytes) using the update() method. At any point you can ask it for the digest of the concatenation of the data fed to it so far using the digest() or hexdigest() methods.

**Note:** For better multithreading performance, the Python GIL is released for data larger than 2047 bytes at object creation or on update.

**Note:** Feeding string objects into update() is not supported, as hashes work on bytes, not on characters.

Constructors for hash algorithms that are always present in this module are md5(), sha1(), sha224(), sha256(), sha384(), and sha512(). Additional algorithms may also be available depending upon the OpenSSL library that Python uses on your platform.

For example, to obtain the digest of the byte string b'Nobody inspects the spammish repetition':

```python
>>> import hashlib
>>> m = hashlib.md5()
>>> m.update(b"Nobody inspects"
>>> m.update(b" the spammish repetition")
>>> m.digest()
'b\xbbd\x9c\x83\xdd\x1e\xa5\xc9\xd9\xde\xc9\xa1\x8d'
>>> m.digest_size
16
```
```python
>>> m.block_size
64
```

More condensed:

```python
>>> hashlib.sha224(b"Nobody inspects the spammish repetition".encode())
'a4337bc45a8fc544c03f52dc550cd6e1e87021bc896588bd79e901e2'
```

```python
hashlib.new(name[, data])
```

Is a generic constructor that takes the string name of the desired algorithm as its first parameter. It also exists to allow access to the above listed hashes as well as any other algorithms that your OpenSSL library may offer. The named constructors are much faster than `new()` and should be preferred.

Using `new()` with an algorithm provided by OpenSSL:

```python
>>> h = hashlib.new('ripemd160')
>>> h.update(b"Nobody inspects the spammish repetition")
>>> h.hexdigest()
'cc4a5ce1b3df48aec5d22d1f16b894a0b894eccc'
```

Hashlib provides the following constant attributes:

```python
hashlib.algorithms_guaranteed
```

A set containing the names of the hash algorithms guaranteed to be supported by this module on all platforms.

*New in version 3.2.*

```python
hashlib.algorithms_available
```

A set containing the names of the hash algorithms that are
available in the running Python interpreter. These names will be recognized when passed to `new()`. `algorithms_guaranteed` will always be a subset. The same algorithm may appear multiple times in this set under different names (thanks to OpenSSL).

*New in version 3.2.*

The following values are provided as constant attributes of the hash objects returned by the constructors:

```python
hash.digest_size
```

The size of the resulting hash in bytes.

```python
hash.block_size
```

The internal block size of the hash algorithm in bytes.

A hash object has the following attributes:

```python
hash.name
```

The canonical name of this hash, always lowercase and always suitable as a parameter to `new()` to create another hash of this type.

*Changed in version 3.4:* The name attribute has been present in CPython since its inception, but until Python 3.4 was not formally specified, so may not exist on some platforms.

A hash object has the following methods:

```python
hash.update(arg)
```

Update the hash object with the object `arg`, which must be interpretable as a buffer of bytes. Repeated calls are equivalent to a single call with the concatenation of all the arguments: `m.update(a); m.update(b)` is equivalent to
m.update(a+b).

*Changed in version 3.1:* The Python GIL is released to allow other threads to run while hash updates on data larger than 2047 bytes is taking place when using hash algorithms supplied by OpenSSL.

**hash.digest()**
Return the digest of the data passed to the `update()` method so far. This is a bytes object of size `digest_size` which may contain bytes in the whole range from 0 to 255.

**hash.hexdigest()**
Like `digest()` except the digest is returned as a string object of double length, containing only hexadecimal digits. This may be used to exchange the value safely in email or other non-binary environments.

**hash.copy()**
Return a copy (“clone”) of the hash object. This can be used to efficiently compute the digests of data sharing a common initial substring.
15.1.2. Key Derivation Function

Key derivation and key stretching algorithms are designed for secure password hashing. Naive algorithms such as `sha1(password)` are not resistant against brute-force attacks. A good password hashing function must be tunable, slow and include a salt.

`hashlib.pbkdf2_hmac(name, password, salt, rounds, dklen=None)`

The function provides PKCS#5 password-based key derivation function 2. It uses HMAC as pseudorandom function.

The string `name` is the desired name of the hash digest algorithm for HMAC, e.g. ‘sha1’ or ‘sha256’. `password` and `salt` are interpreted as buffers of bytes. Applications and libraries should limit `password` to a sensible value (e.g. 1024). `salt` should be about 16 or more bytes from a proper source, e.g. `os.urandom()`.

The number of `rounds` should be chosen based on the hash algorithm and computing power. As of 2013 a value of at least 100,000 rounds of SHA-256 have been suggested.

`dklen` is the length of the derived key. If `dklen` is None then the digest size of the hash algorithm `name` is used, e.g. 64 for SHA-512.

```python
>>> import hashlib, binascii
>>> dk = hashlib.pbkdf2_hmac('sha256', b'password
>>> binascii.hexlify(dk)
b'0394a2ede332c9a13eb82e9b24631604c31df978b4e2f0f
```

New in version 3.4.
Note: A fast implementation of `pbkdf2_hmac` is available with OpenSSL. The Python implementation uses an inline version of `hmac`. It is about three times slower and doesn’t release the GIL.

See also:

Module **hmac**
A module to generate message authentication codes using hashes.

Module **base64**
Another way to encode binary hashes for non-binary environments.

The FIPS 180-2 publication on Secure Hash Algorithms.

http://en.wikipedia.org/wiki/Cryptographic_hash_function#Cryptographic_hash_algorithms
Wikipedia article with information on which algorithms have known issues and what that means regarding their use.

http://www.ietf.org/rfc/rfc2898.txt
PKCS #5: Password-Based Cryptography Specification Version 2.0
15.2. hmac — Keyed-Hashing for Message Authentication

Source code: Lib/hmac.py

This module implements the HMAC algorithm as described by RFC 2104.

hmac.new(key, msg=None, digestmod=None)

Return a new hmac object. key is a bytes or bytearray object giving the secret key. If msg is present, the method call update(msg) is made. digestmod is the digest name, digest constructor or module for the HMAC object to use. It supports any name suitable to hashlib.new() and defaults to the hashlib.md5 constructor.

Changed in version 3.4: Parameter key can be a bytes or bytearray object. Parameter msg can be of any type supported by hashlib. Parameter digestmod can be the name of a hash algorithm.

Deprecated since version 3.4: MD5 as implicit default digest for digestmod is deprecated.

An HMAC object has the following methods:

HMAC.update(msg)

Update the hmac object with msg. Repeated calls are equivalent to a single call with the concatenation of all the arguments: m.update(a); m.update(b) is equivalent to m.update(a + b).
Changed in version 3.4: Parameter msg can be of any type supported by hashlib.

**HMAC.digest()**

Return the digest of the bytes passed to the `update()` method so far. This bytes object will be the same length as the `digest_size` of the digest given to the constructor. It may contain non-ASCII bytes, including NUL bytes.

**Warning:** When comparing the output of `digest()` to an externally-supplied digest during a verification routine, it is recommended to use the `compare_digest()` function instead of the `==` operator to reduce the vulnerability to timing attacks.

**HMAC.hexdigest()**

Like `digest()` except the digest is returned as a string twice the length containing only hexadecimal digits. This may be used to exchange the value safely in email or other non-binary environments.

**Warning:** When comparing the output of `hexdigest()` to an externally-supplied digest during a verification routine, it is recommended to use the `compare_digest()` function instead of the `==` operator to reduce the vulnerability to timing attacks.

**HMAC.copy()**

Return a copy (“clone”) of the hmac object. This can be used to efficiently compute the digests of strings that share a common initial substring.

A hash object has the following attributes:
**HMAC.digest_size**

The size of the resulting HMAC digest in bytes.

**HMAC.block_size**

The internal block size of the hash algorithm in bytes.

*New in version 3.4.*

**HMAC.name**

The canonical name of this HMAC, always lowercase, e.g. `hmac-md5`.

*New in version 3.4.*

This module also provides the following helper function:

**hmac.compare_digest(a, b)**

Return `a == b`. This function uses an approach designed to prevent timing analysis by avoiding content-based short circuiting behaviour, making it appropriate for cryptography. `a` and `b` must both be of the same type: either `str` (ASCII only, as e.g. returned by `HMAC.hexdigest()`), or a `bytes-like object`.

**Note:** If `a` and `b` are of different lengths, or if an error occurs, a timing attack could theoretically reveal information about the types and lengths of `a` and `b`—but not their values.

*New in version 3.3.*

**See also:**

**Module** `hashlib`

The Python module providing secure hash functions.
16. Generic Operating System Services

The modules described in this chapter provide interfaces to operating system features that are available on (almost) all operating systems, such as files and a clock. The interfaces are generally modeled after the Unix or C interfaces, but they are available on most other systems as well. Here’s an overview:

- **16.1. os — Miscellaneous operating system interfaces**
  - 16.1.1. File Names, Command Line Arguments, and Environment Variables
  - 16.1.2. Process Parameters
  - 16.1.3. File Object Creation
  - 16.1.4. File Descriptor Operations
    - 16.1.4.1. Querying the size of a terminal
    - 16.1.4.2. Inheritance of File Descriptors
  - 16.1.5. Files and Directories
    - 16.1.5.1. Linux extended attributes
  - 16.1.6. Process Management
  - 16.1.7. Interface to the scheduler
  - 16.1.8. Miscellaneous System Information
  - 16.1.9. Miscellaneous Functions

- **16.2. io — Core tools for working with streams**
  - 16.2.1. Overview
    - 16.2.1.1. Text I/O
    - 16.2.1.2. Binary I/O
    - 16.2.1.3. Raw I/O
  - 16.2.2. High-level Module Interface
    - 16.2.2.1. In-memory streams
  - 16.2.3. Class hierarchy
16.2.3.1. I/O Base Classes
16.2.3.2. Raw File I/O
16.2.3.3. Buffered Streams
16.2.3.4. Text I/O

16.2.4. Performance

16.1. os — Miscellaneous operating system interfaces

This module provides a portable way of using operating system dependent functionality. If you just want to read or write a file see open(), if you want to manipulate paths, see the os.path module, and if you want to read all the lines in all the files on the command line see the fileinput module. For creating temporary files and directories see the tempfile module, and for high-level file and directory handling see the shutil module.

Notes on the availability of these functions:

- The design of all built-in operating system dependent modules of Python is such that as long as the same functionality is available, it uses the same interface; for example, the function os.stat(path) returns stat information about path in the same format (which happens to have originated with the POSIX interface).
- Extensions peculiar to a particular operating system are also available through the os module, but using them is of course a threat to portability.
- All functions accepting path or file names accept both bytes and string objects, and result in an object of the same type, if a path or file name is returned.
- An “Availability: Unix” note means that this function is commonly found on Unix systems. It does not make any claims about its existence on a specific operating system.
- If not separately noted, all functions that claim “Availability: Unix” are supported on Mac OS X, which builds on a Unix core.
**Note:** All functions in this module raise `OSError` in the case of invalid or inaccessible file names and paths, or other arguments that have the correct type, but are not accepted by the operating system.

`exception os.error`

An alias for the built-in `OSError` exception.

`os.name`

The name of the operating system dependent module imported. The following names have currently been registered: 'posix', 'nt', 'mac', 'ce', 'java'.

**See also:** `sys.platform` has a finer granularity. `os.uname()` gives system-dependent version information. The `platform` module provides detailed checks for the system's identity.
16.1.1. File Names, Command Line Arguments, and Environment Variables

In Python, file names, command line arguments, and environment variables are represented using the string type. On some systems, decoding these strings to and from bytes is necessary before passing them to the operating system. Python uses the file system encoding to perform this conversion (see `sys.getfilesystemencoding()`).

*Changed in version 3.1:* On some systems, conversion using the file system encoding may fail. In this case, Python uses the *surrogateescape* encoding error handler, which means that undecodable bytes are replaced by a Unicode character U+DCxx on decoding, and these are again translated to the original byte on encoding.

The file system encoding must guarantee to successfully decode all bytes below 128. If the file system encoding fails to provide this guarantee, API functions may raise UnicodeErrors.
16.1.2. Process Parameters

These functions and data items provide information and operate on the current process and user.

**os.ctermid()**

Return the filename corresponding to the controlling terminal of the process.

Availability: Unix.

**os.environ**

A *mapping* object representing the string environment. For example, `environ['HOME']` is the pathname of your home directory (on some platforms), and is equivalent to `getenv("HOME")` in C.

This mapping is captured the first time the `os` module is imported, typically during Python startup as part of processing `site.py`. Changes to the environment made after this time are not reflected in `os.environ`, except for changes made by modifying `os.environ` directly.

If the platform supports the `putenv()` function, this mapping may be used to modify the environment as well as query the environment. `putenv()` will be called automatically when the mapping is modified.

On Unix, keys and values use `sys.getfilesystemencoding()` and 'surrogatescape' error handler. Use `environb` if you would like to use a different encoding.
Note: Calling `putenv()` directly does not change `os.environ`, so it's better to modify `os.environ`.

Note: On some platforms, including FreeBSD and Mac OS X, setting `environ` may cause memory leaks. Refer to the system documentation for `putenv()`.

If `putenv()` is not provided, a modified copy of this mapping may be passed to the appropriate process-creation functions to cause child processes to use a modified environment.

If the platform supports the `unsetenv()` function, you can delete items in this mapping to unset environment variables. `unsetenv()` will be called automatically when an item is deleted from `os.environ`, and when one of the `pop()` or `clear()` methods is called.

**os.environb**

Bytes version of `environ`: a `mapping` object representing the environment as byte strings. `environ` and `environb` are synchronized (modify `environb` updates `environ`, and vice versa).

`environb` is only available if `supports_bytes_environ` is True.

*New in version 3.2.*

**os.chdir(path)**

**os.fchdir(fd)**

**os.getcwd()**

These functions are described in *Files and Directories*. 
os. **fsencode**(filename)

Encode *filename* to the filesystem encoding with 'surrogateescape' error handler, or 'strict' on Windows; return *bytes* unchanged.

 fsdecode() is the reverse function.

*New in version 3.2.*

os. **fsdecode**(filename)

Decode *filename* from the filesystem encoding with 'surrogateescape' error handler, or 'strict' on Windows; return *str* unchanged.

 fsencodex() is the reverse function.

*New in version 3.2.*

os. **getenv**(key, default=None)

Return the value of the environment variable *key* if it exists, or *default* if it doesn't. *key, default* and the result are *str*.

On Unix, keys and values are decoded with sys.getfilesystemencoding() and 'surrogateescape' error handler. Use os.getenvb() if you would like to use a different encoding.

*Availability: most flavors of Unix, Windows.*

os. **getenvb**(key, default=None)

Return the value of the environment variable *key* if it exists, or *default* if it doesn't. *key, default* and the result are *bytes*. 
Availability: most flavors of Unix.

>New in version 3.2.

**os.** `get_exec_path` *(env=None)*
Returns the list of directories that will be searched for a named executable, similar to a shell, when launching a process. `env`, when specified, should be an environment variable dictionary to lookup the PATH in. By default, when `env` is None, `environ` is used.

>New in version 3.2.

**os.** `getegid` *
Return the effective group id of the current process. This corresponds to the “set id” bit on the file being executed in the current process.

Availability: Unix.

**os.** `geteuid` *
Return the current process’s effective user id.

Availability: Unix.

**os.** `getgid` *
Return the real group id of the current process.

Availability: Unix.

**os.** `getgrouplist` *(user, group)*
Return list of group ids that `user` belongs to. If `group` is not in the list, it is included; typically, `group` is specified as the group ID field from the password record for `user`. 
Availability: Unix.

New in version 3.3.

```
import os

os.getgroups()
```

Return list of supplemental group ids associated with the current process.

Availability: Unix.

**Note:** On Mac OS X, `getgroups()` behavior differs somewhat from other Unix platforms. If the Python interpreter was built with a deployment target of 10.5 or earlier, `getgroups()` returns the list of effective group ids associated with the current user process; this list is limited to a system-defined number of entries, typically 16, and may be modified by calls to `setgroups()` if suitably privileged. If built with a deployment target greater than 10.5, `getgroups()` returns the current group access list for the user associated with the effective user id of the process; the group access list may change over the lifetime of the process, it is not affected by calls to `setgroups()`, and its length is not limited to 16. The deployment target value, MACOSX_DEPLOYMENT_TARGET, can be obtained with `sysconfig.get_config_var()`.

```
import os

os.getlogin()
```

Return the name of the user logged in on the controlling terminal of the process. For most purposes, it is more useful to use the environment variables LOGNAME or USERNAME to find out who the user is, or `pwd.getpwuid(os.getuid())[0]` to get the login name of the currently effective user id.
Availability: Unix, Windows.

**os.getpgid(pid)**

Return the process group id of the process with process id `pid`. If `pid` is 0, the process group id of the current process is returned.

Availability: Unix.

**os.getpgrp()**

Return the id of the current process group.

Availability: Unix.

**os.getpid()**

Return the current process id.

Availability: Unix, Windows.

**os.getppid()**

Return the parent's process id. When the parent process has exited, on Unix the id returned is the one of the init process (1), on Windows it is still the same id, which may be already reused by another process.

Availability: Unix, Windows.

*Changed in version 3.2:* Added support for Windows.

**os.getpriority(which, who)**

Get program scheduling priority. The value `which` is one of `PRI0_PROCESS`, `PRI0_PGRP`, or `PRI0_USER`, and `who` is interpreted relative to `which` (a process identifier for `PRI0_PROCESS`, process group identifier for `PRI0_PGRP`, and a user ID for `PRI0_USER`). A zero value for `who` denotes
(respectively) the calling process, the process group of the calling process, or the real user ID of the calling process.

Availability: Unix.

*New in version 3.3.*

```python
os.PRIO_PROCESS
os.PRIO_PGRP
os.PRIO_USER
```

Parameters for the `getpriority()` and `setpriority()` functions.

Availability: Unix.

*New in version 3.3.*

```python
os.getresuid()
```

Return a tuple `(ruid, euid, suid)` denoting the current process's real, effective, and saved user ids.

Availability: Unix.

*New in version 3.2.*

```python
os.getresgid()
```

Return a tuple `(rgid, egid, sgid)` denoting the current process's real, effective, and saved group ids.

Availability: Unix.

*New in version 3.2.*

```python
os.getuid()
```

Return the current process’s user id.
Availability: Unix.

**os.initgroups**(username, gid)

Call the system initgroups() to initialize the group access list with all of the groups of which the specified username is a member, plus the specified group id.

Availability: Unix.

*New in version 3.2.*

**os.putenv**(key, value)

Set the environment variable named key to the string value. Such changes to the environment affect subprocesses started with os.system(), popen() or fork() and execv().

Availability: most flavors of Unix, Windows.

---

**Note:** On some platforms, including FreeBSD and Mac OS X, setting environ may cause memory leaks. Refer to the system documentation for putenv.

When putenv() is supported, assignments to items in os.environ are automatically translated into corresponding calls to putenv(); however, calls to putenv() don’t update os.environ, so it is actually preferable to assign to items of os.environ.

**os.setegid**(egid)

Set the current process’s effective group id.

Availability: Unix.
**os.seteuid(euid)**
Set the current process's effective user id.

Availability: Unix.

**os.setgid(gid)**
Set the current process' group id.

Availability: Unix.

**os.setgroups(groups)**
Set the list of supplemental group ids associated with the current process to `groups`. `groups` must be a sequence, and each element must be an integer identifying a group. This operation is typically available only to the superuser.

Availability: Unix.

**Note:** On Mac OS X, the length of `groups` may not exceed the system-defined maximum number of effective group ids, typically 16. See the documentation for `getgroups()` for cases where it may not return the same group list set by calling `setgroups()`.

**os.setpgrp()**
Call the system call `setpgrp()` or `setpgrp(0, 0)` depending on which version is implemented (if any). See the Unix manual for the semantics.

Availability: Unix.

**os.setpgid(pid, pgrp)**
Call the system call `setpgid()` to set the process group id of the process with id `pid` to the process group with id `pgrp`. See the Unix
manual for the semantics.

Availability: Unix.

**os.setpriority**(which, who, priority)
Set program scheduling priority. The value which is one of PRI0_PROCESS, PRI0_PGRP, or PRI0_USER, and who is interpreted relative to which (a process identifier for PRI0_PROCESS, process group identifier for PRI0_PGRP, and a user ID for PRI0_USER). A zero value for who denotes (respectively) the calling process, the process group of the calling process, or the real user ID of the calling process. priority is a value in the range -20 to 19. The default priority is 0; lower priorities cause more favorable scheduling.

Availability: Unix

*New in version 3.3.*

**os.setregid**(rgid, egid)
Set the current process’s real and effective group ids.

Availability: Unix.

**os.setresgid**(rgid, egid, sgid)
Set the current process’s real, effective, and saved group ids.

Availability: Unix.

*New in version 3.2.*

**os.setresuid**(ruid, euid, suid)
Set the current process’s real, effective, and saved user ids.
Availability: Unix.

New in version 3.2.

**os.setreuid(ruid, euid)**

Set the current process’s real and effective user ids.

Availability: Unix.

**os.getsid(pid)**

Call the system call `getsid()`. See the Unix manual for the semantics.

Availability: Unix.

**os.setsid()**

Call the system call `setsid()`. See the Unix manual for the semantics.

Availability: Unix.

**os.setuid(uid)**

Set the current process’s user id.

Availability: Unix.

**os.strerror(code)**

Return the error message corresponding to the error code in `code`. On platforms where `strerror()` returns `NULL` when given an unknown error number, `ValueError` is raised.

Availability: Unix, Windows.

**os.supports_bytes_environ**
True if the native OS type of the environment is bytes (eg. False on Windows).

*New in version 3.2.*

**os.umask(mask)**

Set the current numeric umask and return the previous umask.

Availability: Unix, Windows.

**os.uname()**

Returns information identifying the current operating system. The return value is an object with five attributes:

- sysname - operating system name
- nodename - name of machine on network (implementation-defined)
- release - operating system release
- version - operating system version
- machine - hardware identifier

For backwards compatibility, this object is also iterable, behaving like a five-tuple containing sysname, nodename, release, version, and machine in that order.

Some systems truncate nodename to 8 characters or to the leading component; a better way to get the hostname is `socket.gethostname()` or even `socket.gethostbyaddr(socket.gethostname())`.

Availability: recent flavors of Unix.

*Changed in version 3.3:* Return type changed from a tuple to a tuple-like object with named attributes.
os.\texttt{unsetenv}(\texttt{key})

Unset (delete) the environment variable named \texttt{key}. Such changes to the environment affect subprocesses started with \texttt{os.system()}, \texttt{popen()} or \texttt{fork()} and \texttt{execv()}.

When \texttt{unsetenv()} is supported, deletion of items in \texttt{os.environ} is automatically translated into a corresponding call to \texttt{unsetenv()}; however, calls to \texttt{unsetenv()} don't update \texttt{os.environ}, so it is actually preferable to delete items of \texttt{os.environ}.

Availability: most flavors of Unix, Windows.
16.1.3. File Object Creation

This function creates new *file objects*. (See also *open()* for opening file descriptors.)

**os. `fdopen(fd, *args, **kwargs)`**

Return an open file object connected to the file descriptor `fd`. This is an alias of the *open()* built-in function and accepts the same arguments. The only difference is that the first argument of *fdopen()* must always be an integer.
16.1.4. File Descriptor Operations

These functions operate on I/O streams referenced using file descriptors.

File descriptors are small integers corresponding to a file that has been opened by the current process. For example, standard input is usually file descriptor 0, standard output is 1, and standard error is 2. Further files opened by a process will then be assigned 3, 4, 5, and so forth. The name “file descriptor” is slightly deceptive; on Unix platforms, sockets and pipes are also referenced by file descriptors.

The `fileno()` method can be used to obtain the file descriptor associated with a file object when required. Note that using the file descriptor directly will bypass the file object methods, ignoring aspects such as internal buffering of data.

`os.close(fd)`

Close file descriptor `fd`.

Availability: Unix, Windows.

**Note:** This function is intended for low-level I/O and must be applied to a file descriptor as returned by `os.open()` or `pipe()`. To close a “file object” returned by the built-in function `open()` or by `popen()` or `fdopen()`, use its `close()` method.

`os.closerange(fd_low, fd_high)`

Close all file descriptors from `fd_low` (inclusive) to `fd_high` (exclusive), ignoring errors. Equivalent to (but much faster than):
```
for fd in range(fd_low, fd_high):
    try:
        os.close(fd)
    except OSError:
        pass
```

Availability: Unix, Windows.

**os.device_encoding(fd)**

Return a string describing the encoding of the device associated with `fd` if it is connected to a terminal; else return `None`.

**os.dup(fd)**

Return a duplicate of file descriptor `fd`. The new file descriptor is *non-inheritable*.

On Windows, when duplicating a standard stream (0: stdin, 1: stdout, 2: stderr), the new file descriptor is *inheritable*.

Availability: Unix, Windows.

*Changed in version 3.4:* The new file descriptor is now non-inheritable.

**os.dup2(fd, fd2, inheritable=True)**

Duplicate file descriptor `fd` to `fd2`, closing the latter first if necessary. The file descriptor `fd2` is *inheritable* by default, or non-inheritable if `inheritable` is `False`.

Availability: Unix, Windows.

*Changed in version 3.4:* Add the optional `inheritable` parameter.

**os.fchmod(fd, mode)**
Change the mode of the file given by *fd* to the numeric *mode*. See the docs for *chmod()* for possible values of *mode*. As of Python 3.3, this is equivalent to `os.chmod(fd, mode)`.

Availability: Unix.

**os.** `fchown(fd, uid, gid)`

Change the owner and group id of the file given by *fd* to the numeric *uid* and *gid*. To leave one of the ids unchanged, set it to -1. See *chown()*. As of Python 3.3, this is equivalent to `os.chown(fd, uid, gid)`.

Availability: Unix.

**os.** `fdatasync(fd)`

Force write of file with filedescriptor *fd* to disk. Does not force update of metadata.

Availability: Unix.

**Note:** This function is not available on MacOS.

**os.** `fpathconf(fd, name)`

Return system configuration information relevant to an open file. *name* specifies the configuration value to retrieve; it may be a string which is the name of a defined system value; these names are specified in a number of standards (POSIX.1, Unix 95, Unix 98, and others). Some platforms define additional names as well. The names known to the host operating system are given in the `pathconf_names` dictionary. For configuration variables not included in that mapping, passing an integer for *name* is also accepted.
If *name* is a string and is not known, *ValueError* is raised. If a specific value for *name* is not supported by the host system, even if it is included in *pathconf_names*, an *OSError* is raised with *errno.EINVAL* for the error number.

As of Python 3.3, this is equivalent to `os.pathconf(fd, name)`.

**Availability:** Unix.

**os.fstat(fd)**

Return status for file descriptor *fd*, like `stat()`. As of Python 3.3, this is equivalent to `os.stat(fd)`.

**Availability:** Unix, Windows.

**os.fstatvfs(fd)**

Return information about the filesystem containing the file associated with file descriptor *fd*, like `statvfs()`. As of Python 3.3, this is equivalent to `os.statvfs(fd)`.

**Availability:** Unix.

**os.fsync(fd)**

Force write of file with filedescriptor *fd* to disk. On Unix, this calls the native `fsync()` function; on Windows, the MS _commit() function.

If you're starting with a buffered Python file object *f*, first do `f.flush()`, and then do `os.fsync(f.fileno())`, to ensure that all internal buffers associated with *f* are written to disk.

**Availability:** Unix, Windows.
os. `ftruncate(fd, length)`

Truncate the file corresponding to file descriptor `fd`, so that it is at most `length` bytes in size. As of Python 3.3, this is equivalent to `os.truncate(fd, length)`.

Availability: Unix.

os. `isatty(fd)`

Return `True` if the file descriptor `fd` is open and connected to a tty(-like) device, else `False`.

os. `lockf(fd, cmd, len)`

Apply, test or remove a POSIX lock on an open file descriptor. `fd` is an open file descriptor. `cmd` specifies the command to use - one of `F_LOCK`, `F_TLOCK`, `F_ULOCK` or `F_TEST`. `len` specifies the section of the file to lock.

Availability: Unix.

*New in version 3.3.*

- `os. F_LOCK`
- `os. F_TLOCK`
- `os. F_ULOCK`
- `os. F_TEST`

Flags that specify what action `lockf()` will take.

Availability: Unix.

*New in version 3.3.*

os. `lseek(fd, pos, how)`

Set the current position of file descriptor `fd` to position `pos`, modified
by how: SEEK_SET or 0 to set the position relative to the beginning of the file; SEEK_CUR or 1 to set it relative to the current position; SEEK_END or 2 to set it relative to the end of the file. Return the new cursor position in bytes, starting from the beginning.

Availability: Unix, Windows.

os.SEEK_SET
os.SEEK_CUR
os.SEEK_END
Parameters to the lseek() function. Their values are 0, 1, and 2, respectively.

Availability: Unix, Windows.

New in version 3.3: Some operating systems could support additional values, like os.SEEK_HOLE or os.SEEK_DATA.

os.open(file, flags, mode=0o777, *, dir_fd=None)
Open the file file and set various flags according to flags and possibly its mode according to mode. When computing mode, the current umask value is first masked out. Return the file descriptor for the newly opened file. The new file descriptor is non-inheritable.

For a description of the flag and mode values, see the C run-time documentation; flag constants (like O_RDONLY and O_WRONLY) are defined in the os module. In particular, on Windows adding O_BINARY is needed to open files in binary mode.

This function can support paths relative to directory descriptors with the dir_fd parameter.

Availability: Unix, Windows.
Changed in version 3.4: The new file descriptor is now non-inheritable.

Note: This function is intended for low-level I/O. For normal usage, use the built-in function open(), which returns a file object with read() and write() methods (and many more). To wrap a file descriptor in a file object, use fdopen().

New in version 3.3: The dir_fd argument.

The following constants are options for the flags parameter to the open() function. They can be combined using the bitwise OR operator |. Some of them are not available on all platforms. For descriptions of their availability and use, consult the open(2) manual page on Unix or the MSDN on Windows.

os.O_RDONLY
os.O_WRONLY
os.O_RDWR
os.O_APPEND
os.O_CREAT
os.O_EXCL
os.O_TRUNC

These constants are available on Unix and Windows.

os.O_DSYNC
os.O_RSYNC
os.O_SYNC
os.O_NDELAY
os.O_NONBLOCK
os.O_NOCTTY
os.O_SHLOCK
os.O_EXLOCK
os. **O_CLOEXEC**

These constants are only available on Unix.

*Changed in version 3.3:* Add **O_CLOEXEC** constant.

os. **O_BINARY**
o.s. **O_NOINHERIT**
o.s. **O_SHORT_LIVED**
o.s. **O_TEMPORARY**
o.s. **O_RANDOM**
o.s. **O_SEQUENTIAL**
o.s. **O_TEXT**

These constants are only available on Windows.

os. **O_ASYNC**
o.s. **O_DIRECT**
o.s. **O_DIRECTORY**
o.s. **O_NOFOLLOW**
o.s. **O_NOATIME**
o.s. **O_PATH**
o.s. **O_TMPFILE**

These constants are GNU extensions and not present if they are not defined by the C library.

*Changed in version 3.4:* Add **O_PATH** on systems that support it. Add **O_TMPFILE**, only available on Linux Kernel 3.11 or newer.

**os. openpty()**

Open a new pseudo-terminal pair. Return a pair of file descriptors (master, slave) for the pty and the tty, respectively. The new file descriptors are **non-inheritable**. For a (slightly) more portable approach, use the pty module.
Availability: some flavors of Unix.

*Changed in version 3.4:* The new file descriptors are now non-inheritable.

**os.pipe()**
Create a pipe. Return a pair of file descriptors \((r, w)\) usable for reading and writing, respectively. The new file descriptor is *non-inheritable*.

Availability: Unix, Windows.

*Changed in version 3.4:* The new file descriptors are now non-inheritable.

**os.pipe2(flags)**
Create a pipe with *flags* set atomically. *flags* can be constructed by ORing together one or more of these values: `O_NONBLOCK`, `O_CLOEXEC`. Return a pair of file descriptors \((r, w)\) usable for reading and writing, respectively.

Availability: some flavors of Unix.

*New in version 3.3.*

**os.posix_fallocate(fd, offset, len)**
Ensures that enough disk space is allocated for the file specified by *fd* starting from *offset* and continuing for *len* bytes.

Availability: Unix.

*New in version 3.3.*

**os.posix_fadvise(fd, offset, len, advice)**
Announces an intention to access data in a specific pattern thus allowing the kernel to make optimizations. The advice applies to the region of the file specified by `fd` starting at `offset` and continuing for `len` bytes. `advice` is one of `POSIX_FADV_NORMAL`, `POSIX_FADV_SEQUENTIAL`, `POSIX_FADV_RANDOM`, `POSIX_FADV_NOREUSE`, `POSIX_FADV_WILLNEED` or `POSIX_FADV_DONTNEED`.

Availability: Unix.

*New in version 3.3.*

```python
os.POSIX_FADV_NORMAL
os.POSIX_FADV_SEQUENTIAL
os.POSIX_FADV_RANDOM
os.POSIX_FADV_NOREUSE
os.POSIX_FADV_WILLNEED
os.POSIX_FADV_DONTNEED
```

Flags that can be used in `advice` in `posix_fadvise()` that specify the access pattern that is likely to be used.

Availability: Unix.

*New in version 3.3.*

```python
os.pread(fd, buffersize, offset)
```

Read from a file descriptor, `fd`, at a position of `offset`. It will read up to `buffersize` number of bytes. The file offset remains unchanged.

Availability: Unix.

*New in version 3.3.*

```python
os.pwrite(fd, string, offset)
```
Write string to a file descriptor, fd, from offset, leaving the file offset unchanged.

Availability: Unix.

New in version 3.3.

**os.read(fd, n)**

Read at most n bytes from file descriptor fd. Return a bytestring containing the bytes read. If the end of the file referred to by fd has been reached, an empty bytes object is returned.

Availability: Unix, Windows.

**Note:** This function is intended for low-level I/O and must be applied to a file descriptor as returned by os.open() or pipe(). To read a “file object” returned by the built-in function open() or by popen() or fdopen(), or sys.stdin, use its read() or readline() methods.

**os.sendfile(out, in, offset, nbytes)**

**os.sendfile(out, in, offset, nbytes, headers=None, trailers=None, flags=0)**

Copy nbytes bytes from file descriptor in to file descriptor out starting at offset. Return the number of bytes sent. When EOF is reached return 0.

The first function notation is supported by all platforms that define sendfile().

On Linux, if offset is given as None, the bytes are read from the current position of in and the position of in is updated.
The second case may be used on Mac OS X and FreeBSD where headers and trailers are arbitrary sequences of buffers that are written before and after the data from in is written. It returns the same as the first case.

On Mac OS X and FreeBSD, a value of 0 for nbytes specifies to send until the end of in is reached.

All platforms support sockets as out file descriptor, and some platforms allow other types (e.g. regular file, pipe) as well.

Availability: Unix.

New in version 3.3.

**os.SF_NODISKIO**

**os.SF_MNOWAIT**

**os.SF_SYNC**

Parameters to the `sendfile()` function, if the implementation supports them.

Availability: Unix.

New in version 3.3.

**os.readv(fd, buffers)**

Read from a file descriptor fd into a number of mutable bytes-like objects buffers. `readv()` will transfer data into each buffer until it is full and then move on to the next buffer in the sequence to hold the rest of the data. `readv()` returns the total number of bytes read (which may be less than the total capacity of all the objects).

Availability: Unix.
New in version 3.3.

**os.tcgetpgrp(fd)**

Return the process group associated with the terminal given by `fd` (an open file descriptor as returned by `os.open()`).

Availability: Unix.

**os.tcsetpgrp(fd, pg)**

Set the process group associated with the terminal given by `fd` (an open file descriptor as returned by `os.open()`) to `pg`.

Availability: Unix.

**os.ttyname(fd)**

Return a string which specifies the terminal device associated with file descriptor `fd`. If `fd` is not associated with a terminal device, an exception is raised.

Availability: Unix.

**os.write(fd, str)**

Write the bytestring in `str` to file descriptor `fd`. Return the number of bytes actually written.

Availability: Unix, Windows.

**Note:** This function is intended for low-level I/O and must be applied to a file descriptor as returned by `os.open()` or `pipe()`. To write a “file object” returned by the built-in function `open()` or by `popen()` or `fdopen()`, or `sys.stdout` or `sys.stderr`, use its `write()` method.
os.writev(fd, buffers)

Write the contents of buffers to file descriptor fd. buffers must be a sequence of bytes-like objects. writev() writes the contents of each object to the file descriptor and returns the total number of bytes written.

Availability: Unix.

New in version 3.3.

16.1.4.1. Querying the size of a terminal

New in version 3.3.

os.get_terminal_size(fd=STDOUT_FILENO)

Return the size of the terminal window as (columns, lines), tuple of type terminal_size.

The optional argument fd (default STDOUT_FILENO, or standard output) specifies which file descriptor should be queried.

If the file descriptor is not connected to a terminal, an OSError is raised.

shutil.get_terminal_size() is the high-level function which should normally be used, os.get_terminal_size is the low-level implementation.

Availability: Unix, Windows.

class os.terminal_size

A subclass of tuple, holding (columns, lines) of the terminal window size.
columns
   Width of the terminal window in characters.

lines
   Height of the terminal window in characters.

16.1.4.2. Inheritance of File Descriptors

*New in version 3.4.*

A file descriptor has an “inheritable” flag which indicates if the file descriptor can be inherited by child processes. Since Python 3.4, file descriptors created by Python are non-inheritable by default.

On UNIX, non-inheritable file descriptors are closed in child processes at the execution of a new program, other file descriptors are inherited.

On Windows, non-inheritable handles and file descriptors are closed in child processes, except for standard streams (file descriptors 0, 1 and 2: stdin, stdout and stderr), which are always inherited. Using spawn* functions, all inheritable handles and all inheritable file descriptors are inherited. Using the subprocess module, all file descriptors except standard streams are closed, and inheritable handles are only inherited if the close_fds parameter is False.

os.get_inheritable(fd)
   Get the “inheritable” flag of the specified file descriptor (a boolean).

os.set_inheritable(fd, inheritable)
   Set the “inheritable” flag of the specified file descriptor.

os.get_handle_inheritable(handle)
   Get the “inheritable” flag of the specified handle (a boolean).
Availability: Windows.

```
import os

os.set_handle_inheritable(handle, inheritable)
```

Set the “inheritable” flag of the specified handle.

Availability: Windows.
16.1.5. Files and Directories

On some Unix platforms, many of these functions support one or more of these features:

- **specifying a file descriptor:** For some functions, the *path* argument can be not only a string giving a path name, but also a file descriptor. The function will then operate on the file referred to by the descriptor. (For POSIX systems, Python will call the \texttt{f...} version of the function.)

  You can check whether or not *path* can be specified as a file descriptor on your platform using \texttt{os.supports_fd}. If it is unavailable, using it will raise a \texttt{NotImplementedError}.

  If the function also supports *dir_fd* or *follow_symlinks* arguments, it is an error to specify one of those when supplying *path* as a file descriptor.

- **paths relative to directory descriptors:** If \texttt{dir_fd} is not \texttt{None}, it should be a file descriptor referring to a directory, and the path to operate on should be relative; path will then be relative to that directory. If the path is absolute, \texttt{dir_fd} is ignored. (For POSIX systems, Python will call the \texttt{...at} or \texttt{f...at} version of the function.)

  You can check whether or not \texttt{dir_fd} is supported on your platform using \texttt{os.supports_dir_fd}. If it is unavailable, using it will raise a \texttt{NotImplementedError}.

- **not following symlinks:** If \texttt{follow_symlinks} is \texttt{False}, and the last element of the path to operate on is a symbolic link, the function
will operate on the symbolic link itself instead of the file the link points to. (For POSIX systems, Python will call the 1... version of the function.)

You can check whether or not `follow_symlinks` is supported on your platform using `os.supports_follow_symlinks`. If it is unavailable, using it will raise a `NotImplementedError`.

```python
os.access(path, mode, *, dir_fd=None, effective_ids=False, follow_symlinks=True)
```

Use the real uid/gid to test for access to `path`. Note that most operations will use the effective uid/gid, therefore this routine can be used in a suid/sgid environment to test if the invoking user has the specified access to `path`. `mode` should be `F_OK` to test the existence of `path`, or it can be the inclusive OR of one or more of `R_OK`, `W_OK`, and `X_OK` to test permissions. Return `True` if access is allowed, `False` if not. See the Unix man page `access(2)` for more information.

This function can support specifying `paths relative to directory descriptors` and `not following symlinks`.

If `effective_ids` is `True`, `access()` will perform its access checks using the effective uid/gid instead of the real uid/gid. `effective_ids` may not be supported on your platform; you can check whether or not it is available using `os.supports_effective_ids`. If it is unavailable, using it will raise a `NotImplementedError`.

Availability: Unix, Windows.

**Note:** Using `access()` to check if a user is authorized to e.g. open a file before actually doing so using `open()` creates a
security hole, because the user might exploit the short time interval between checking and opening the file to manipulate it. It’s preferable to use *EAFP* techniques. For example:

```python
if os.access("myfile", os.R_OK):
    with open("myfile") as fp:
        return fp.read()
return "some default data"
```

is better written as:

```python
try:
    fp = open("myfile")
except PermissionError:
    return "some default data"
else:
    with fp:
        return fp.read()
```

**Note:** I/O operations may fail even when `access()` indicates that they would succeed, particularly for operations on network filesystems which may have permissions semantics beyond the usual POSIX permission-bit model.

*Changed in version 3.3:* Added the `dir_fd`, `effective_ids`, and `follow_symlinks` parameters.

```
os.F_OK
os.R_OK
os.W_OK
os.X_OK
```

Values to pass as the `mode` parameter of `access()` to test the existence, readability, writability and executability of `path`, respectively.
os.\texttt{chdir}(\textit{path})

Change the current working directory to \textit{path}.

This function can support \textit{specifying a file descriptor}. The descriptor must refer to an opened directory, not an open file.

Availability: Unix, Windows.

\textit{New in version 3.3:} Added support for specifying \textit{path} as a file descriptor on some platforms.

os.\texttt{chflags}(\textit{path}, \textit{flags}, *, \textit{follow\_symlinks}=True)

Set the flags of \textit{path} to the numeric \textit{flags}. \textit{flags} may take a combination (bitwise OR) of the following values (as defined in the \texttt{stat} module):

- \texttt{stat.UF\_NODUMP}
- \texttt{stat.UF\_IMMUTABLE}
- \texttt{stat.UF\_APPEND}
- \texttt{stat.UF\_OPAQUE}
- \texttt{stat.UF\_NOUNLINK}
- \texttt{stat.UF\_COMPRESSED}
- \texttt{stat.UF\_HIDDEN}
- \texttt{stat.SF\_ARCHIVED}
- \texttt{stat.SF\_IMMUTABLE}
- \texttt{stat.SF\_APPEND}
- \texttt{stat.SF\_NOUNLINK}
- \texttt{stat.SF\_SNAPSHOT}

This function can support \textit{not following symlinks}.

Availability: Unix.

\textit{New in version 3.3:} The \textit{follow\_symlinks} argument.
os.chmod(path, mode, *, dir_fd=None, follow_symlinks=True)

Change the mode of path to the numeric mode. mode may take one of the following values (as defined in the stat module) or bitwise ORed combinations of them:

- stat.S_ISUID
- stat.S_ISGID
- stat.S_ENFMT
- stat.S_ISVTX
- stat.S_IREAD
- stat.S_IWRITE
- stat.S_IEXEC
- stat.S_IRWXU
- stat.S_IRUSR
- stat.S_IWUSR
- stat.S_IXUSR
- stat.S_IRWXG
- stat.S_IRGRP
- stat.S_IWGRP
- stat.S_IXGRP
- stat.S_IRWXO
- stat.S_IROTH
- stat.S_IWOTH
- stat.S_IXOTH

This function can support specifying a file descriptor, paths relative to directory descriptors and not following symlinks.

Availability: Unix, Windows.

Note: Although Windows supports chmod(), you can only set the file’s read-only flag with it (via the stat.S_IWRITE and
stat.S_IREAD constants or a corresponding integer value). All other bits are ignored.

*New in version 3.3:* Added support for specifying *path* as an open file descriptor, and the *dir_fd* and *follow_symlinks* arguments.

**os.chown**(path, uid, gid, *, dir_fd=None, follow_symlinks=True)
Change the owner and group id of *path* to the numeric *uid* and *gid*. To leave one of the ids unchanged, set it to -1.

This function can support *specifying a file descriptor, paths relative to directory descriptors* and *not following symlinks*.

See **shutil.chown()** for a higher-level function that accepts names in addition to numeric ids.

Availability: Unix.

*New in version 3.3:* Added support for specifying an open file descriptor for *path*, and the *dir_fd* and *follow_symlinks* arguments.

**os.chroot**(path)
Change the root directory of the current process to *path*.

Availability: Unix.

**os.fchdir**(fd)
Change the current working directory to the directory represented by the file descriptor *fd*. The descriptor must refer to an opened directory, not an open file. As of Python 3.3, this is equivalent to **os.chdir(fd)**.

Availability: Unix.
os. `getcwd()`  
Return a string representing the current working directory.

Availability: Unix, Windows.

os. `getcwdb()`  
Return a bytestring representing the current working directory.

Availability: Unix, Windows.

os. `lchflags(path, flags)`  
Set the flags of `path` to the numeric `flags`, like `chflags()`, but do not follow symbolic links. As of Python 3.3, this is equivalent to `os.chflags(path, flags, follow_symlinks=False)`.

Availability: Unix.

os. `lchmod(path, mode)`  
Change the mode of `path` to the numeric `mode`. If `path` is a symlink, this affects the symlink rather than the target. See the docs for `chmod()` for possible values of `mode`. As of Python 3.3, this is equivalent to `os.chmod(path, mode, follow_symlinks=False)`.

Availability: Unix.

os. `lchown(path, uid, gid)`  
Change the owner and group id of `path` to the numeric `uid` and `gid`. This function will not follow symbolic links. As of Python 3.3, this is equivalent to `os.chown(path, uid, gid, follow_symlinks=False)`.

Availability: Unix.
os. **link**(src, dst, *, src_dir_fd=None, dst_dir_fd=None, follow_symlinks=True)

Create a hard link pointing to src named dst.

This function can support specifying src_dir_fd and/or dst_dir_fd to supply *paths relative to directory descriptors*, and *not following symlinks*.

Availability: Unix, Windows.

*Changed in version 3.2*: Added Windows support.

*New in version 3.3*: Added the src_dir_fd, dst_dir_fd, and follow_symlinks arguments.

os. **listdir**(path='.')

Return a list containing the names of the entries in the directory given by `path`. The list is in arbitrary order, and does not include the special entries `. ` and `..` even if they are present in the directory.

`path` may be either of type `str` or of type `bytes`. If `path` is of type `bytes`, the filenames returned will also be of type `bytes`; in all other circumstances, they will be of type `str`.

This function can also support *specifying a file descriptor*; the file descriptor must refer to a directory.

**Note:** To encode `str` filenames to `bytes`, use `fsencode()`.

Availability: Unix, Windows.

*Changed in version 3.2*: The `path` parameter became optional.
New in version 3.3: Added support for specifying an open file descriptor for path.

`os.lstat(path, *, dir_fd=None)`

Perform the equivalent of an lstat() system call on the given path. Similar to `stat()`, but does not follow symbolic links. On platforms that do not support symbolic links, this is an alias for `stat()`. As of Python 3.3, this is equivalent to `os.stat(path, dir_fd=dir_fd, follow_symlinks=False)`.

This function can also support *paths relative to directory descriptors*.

*Changed in version 3.2:* Added support for Windows 6.0 (Vista) symbolic links.

*Changed in version 3.3:* Added the `dir_fd` parameter.

`os.mkdir(path, mode=0o777, *, dir_fd=None)`

Create a directory named `path` with numeric mode `mode`.

On some systems, `mode` is ignored. Where it is used, the current umask value is first masked out. If the directory already exists, `OSError` is raised.

This function can also support *paths relative to directory descriptors*.

It is also possible to create temporary directories; see the `tempfile` module's `tempfile.mkdtemp()` function.

Availability: Unix, Windows.

*New in version 3.3:* The `dir_fd` argument.
os.makedirs(path, mode=0o777, exist_ok=False)

Recursive directory creation function. Like mkdir(), but makes all intermediate-level directories needed to contain the leaf directory.

The default mode is 0o777 (octal). On some systems, mode is ignored. Where it is used, the current umask value is first masked out.

If exist_ok is False (the default), an OSError is raised if the target directory already exists. If exist_ok is True an OSError is still raised if the umask-masked mode is different from the existing mode, on systems where the mode is used. OSError will also be raised if the directory creation fails.

Note: makedirs() will become confused if the path elements to create include pardir (eg. "..") on UNIX systems).

This function handles UNC paths correctly.

New in version 3.2: The exist_ok parameter.

os.mkfifo(path, mode=0o666, *, dir_fd=None)

Create a FIFO (a named pipe) named path with numeric mode mode. The current umask value is first masked out from the mode.

This function can also support paths relative to directory descriptors.

FIFOs are pipes that can be accessed like regular files. FIFOs exist until they are deleted (for example with os.unlink()). Generally, FIFOs are used as rendezvous between “client” and “server” type processes: the server opens the FIFO for reading, and the client opens it for writing. Note that mkfifo() doesn't open the FIFO —
it just creates the rendezvous point.

Availability: Unix.

New in version 3.3: The dir_fd argument.

```
import os

os.mknod(filename, mode=0o600, device=0, *, dir_fd=None)
```

Create a filesystem node (file, device special file or named pipe) named `filename`. `mode` specifies both the permissions to use and the type of node to be created, being combined (bitwise OR) with one of `stat.S_IFREG`, `stat.S_IFCHR`, `stat.S_IFBLK`, and `stat.S_IFIFO` (those constants are available in `stat`). For `stat.S_IFCHR` and `stat.S_IFBLK`, `device` defines the newly created device special file (probably using `os.makedev()`), otherwise it is ignored.

This function can also support paths relative to directory descriptors.

New in version 3.3: The dir_fd argument.

```
import os

os.major(device)
```

Extract the device major number from a raw device number (usually the `st_dev` or `st_rdev` field from `stat`).

```
import os

os.minor(device)
```

Extract the device minor number from a raw device number (usually the `st_dev` or `st_rdev` field from `stat`).

```
import os

os.makedev(major, minor)
```

Compose a raw device number from the major and minor device numbers.
**os.** pathconf *(path, name)*

Return system configuration information relevant to a named file. *name* specifies the configuration value to retrieve; it may be a string which is the name of a defined system value; these names are specified in a number of standards (POSIX.1, Unix 95, Unix 98, and others). Some platforms define additional names as well. The names known to the host operating system are given in the pathconf_names dictionary. For configuration variables not included in that mapping, passing an integer for *name* is also accepted.

If *name* is a string and is not known, ValueError is raised. If a specific value for *name* is not supported by the host system, even if it is included in pathconf_names, an OSError is raised with errno.EINVAL for the error number.

This function can support specifying a file descriptor.

Availability: Unix.

**os.** pathconf_names

Dictionary mapping names accepted by pathconf() and fpathconf() to the integer values defined for those names by the host operating system. This can be used to determine the set of names known to the system.

Availability: Unix.

**os.** readlink *(path, *, dir_fd=None)*

Return a string representing the path to which the symbolic link points. The result may be either an absolute or relative pathname; if it is relative, it may be converted to an absolute pathname using

```
  os.path.join(os.path.dirname(path), result).
```
If the `path` is a string object, the result will also be a string object, and the call may raise an UnicodeDecodeError. If the `path` is a bytes object, the result will be a bytes object.

This function can also support *paths relative to directory descriptors*.

Availability: Unix, Windows

*Changed in version 3.2:* Added support for Windows 6.0 (Vista) symbolic links.

*New in version 3.3:* The `dir_fd` argument.

```python
os.remove(path, *, dir_fd=None)
```
Remove (delete) the file `path`. If `path` is a directory, `OSError` is raised. Use `rmdir()` to remove directories.

This function can support *paths relative to directory descriptors*.

On Windows, attempting to remove a file that is in use causes an exception to be raised; on Unix, the directory entry is removed but the storage allocated to the file is not made available until the original file is no longer in use.

This function is identical to `unlink()`.

Availability: Unix, Windows.

*New in version 3.3:* The `dir_fd` argument.

```python
os.removedirs(path)
```
Remove directories recursively. Works like `rmdir()` except that, if
the leaf directory is successfully removed, `removedirs()` tries to successively remove every parent directory mentioned in `path` until an error is raised (which is ignored, because it generally means that a parent directory is not empty). For example, `os.removedirs('foo/bar/baz')` will first remove the directory 'foo/bar/baz', and then remove 'foo/bar' and 'foo' if they are empty. Raises `OSError` if the leaf directory could not be successfully removed.

```python
os.rename(src, dst, *, src_dir_fd=None, dst_dir_fd=None)
```

Rename the file or directory `src` to `dst`. If `dst` is a directory, `OSError` will be raised. On Unix, if `dst` exists and is a file, it will be replaced silently if the user has permission. The operation may fail on some Unix flavors if `src` and `dst` are on different filesystems. If successful, the renaming will be an atomic operation (this is a POSIX requirement). On Windows, if `dst` already exists, `OSError` will be raised even if it is a file.

This function can support specifying `src_dir_fd` and/or `dst_dir_fd` to supply `paths relative to directory descriptors`.

If you want cross-platform overwriting of the destination, use `replace()`.

Availability: Unix, Windows.

`New in version 3.3`: The `src_dir_fd` and `dst_dir_fd` arguments.

```python
os.renames(old, new)
```

Recursive directory or file renaming function. Works like `rename()`, except creation of any intermediate directories needed to make the new pathname good is attempted first. After the rename, directories corresponding to rightmost path segments of
the old name will be pruned away using `removedirs()`.

**Note:** This function can fail with the new directory structure made if you lack permissions needed to remove the leaf directory or file.

```python
os.replace(src, dst, *, src_dir_fd=None, dst_dir_fd=None)
```

Rename the file or directory `src` to `dst`. If `dst` is a directory, `OSError` will be raised. If `dst` exists and is a file, it will be replaced silently if the user has permission. The operation may fail if `src` and `dst` are on different filesystems. If successful, the renaming will be an atomic operation (this is a POSIX requirement).

This function can support specifying `src_dir_fd` and/or `dst_dir_fd` to supply *paths relative to directory descriptors*.

Availability: Unix, Windows.

*New in version 3.3.*

```python
os.rmdir(path, *, dir_fd=None)
```

Remove (delete) the directory `path`. Only works when the directory is empty, otherwise, `OSError` is raised. In order to remove whole directory trees, `shutil.rmtree()` can be used.

This function can support *paths relative to directory descriptors*.

Availability: Unix, Windows.

*New in version 3.3:* The `dir_fd` parameter.

```python
os.stat(path, *, dir_fd=None, follow_symlinks=True)
```

Perform the equivalent of a `stat()` system call on the given path.
path may be specified as either a string or as an open file descriptor. (This function normally follows symlinks; to stat a symlink add the argument follow_symlinks=False, or use lstat().)

The return value is an object whose attributes correspond roughly to the members of the stat structure, namely:

- st_mode - protection bits,
- st_ino - inode number,
- st_dev - device,
- st_nlink - number of hard links,
- st_uid - user id of owner,
- st_gid - group id of owner,
- st_size - size of file, in bytes,
- st_atime - time of most recent access expressed in seconds,
- st_mtime - time of most recent content modification expressed in seconds,
- st_ctime - platform dependent; time of most recent metadata change on Unix, or the time of creation on Windows, expressed in seconds
- st_atime_ns - time of most recent access expressed in nanoseconds as an integer,
- st_mtime_ns - time of most recent content modification expressed in nanoseconds as an integer,
- st_ctime_ns - platform dependent; time of most recent metadata change on Unix, or the time of creation on Windows, expressed in nanoseconds as an integer

On some Unix systems (such as Linux), the following attributes may also be available:

- st_blocks - number of 512-byte blocks allocated for file
- `st_blksize` - filesystem blocksize for efficient file system I/O
- `st_rdev` - type of device if an inode device
- `st_flags` - user defined flags for file

On other Unix systems (such as FreeBSD), the following attributes may be available (but may be only filled out if root tries to use them):

- `st_gen` - file generation number
- `st_birthtime` - time of file creation

On Mac OS systems, the following attributes may also be available:

- `st_rsize`
- `st_creator`
- `st_type`

**Note:** The exact meaning and resolution of the `st_atime`, `st_mtime`, and `st_ctime` attributes depend on the operating system and the file system. For example, on Windows systems using the FAT or FAT32 file systems, `st_mtime` has 2-second resolution, and `st_atime` has only 1-day resolution. See your operating system documentation for details. Similarly, although `st_atime_ns`, `st_mtime_ns`, and `st_ctime_ns` are always expressed in nanoseconds, many systems do not provide nanosecond precision. On systems that do provide nanosecond precision, the floating-point object used to store `st_atime`, `st_mtime`, and `st_ctime` cannot preserve all of it, and as such will be slightly inexact. If you need the exact timestamps you should always use `st_atime_ns`, `st_mtime_ns`, and `st_ctime_ns.

For backward compatibility, the return value of `stat()` is also
accessible as a tuple of at least 10 integers giving the most important (and portable) members of the stat structure, in the order st_mode, st_ino, st_dev, st_nlink, st_uid, st_gid, st_size, st_atime, st_mtime, st_ctime. More items may be added at the end by some implementations.

This function can support specifying a file descriptor and not following symlinks.

The standard module stat defines functions and constants that are useful for extracting information from a stat structure. (On Windows, some items are filled with dummy values.)

Example:

```python
>>> import os
>>> statinfo = os.stat('somefile.txt')
>>> statinfo
posix.stat_result(st_mode=33188, st_ino=7876932, st_dev=234881026, st_nlink=1, st_uid=501, st_gid=501, st_size=264, st_mtime=1297230027, st_ctime=1297230027)
>>> statinfo.st_size
264
```

Availability: Unix, Windows.

New in version 3.3: Added the dir_fd and follow_symlinks arguments, specifying a file descriptor instead of a path, and the st_atime_ns, st_mtime_ns, and st_ctime_ns members.

```python
os.stat_float_times([newvalue])
```

Determine whether stat_result represents time stamps as float objects. If newvalue is True, future calls to stat() return floats, if
it is `False`, future calls return ints. If `newvalue` is omitted, return the current setting.

For compatibility with older Python versions, accessing `stat_result` as a tuple always returns integers.

Python now returns float values by default. Applications which do not work correctly with floating point time stamps can use this function to restore the old behaviour.

The resolution of the timestamps (that is the smallest possible fraction) depends on the system. Some systems only support second resolution; on these systems, the fraction will always be zero.

It is recommended that this setting is only changed at program startup time in the `__main__` module; libraries should never change this setting. If an application uses a library that works incorrectly if floating point time stamps are processed, this application should turn the feature off until the library has been corrected.

```
Deprecated since version 3.3.
```

`os.statvfs(path)`

Perform a `statvfs()` system call on the given path. The return value is an object whose attributes describe the filesystem on the given path, and correspond to the members of the `statvfs` structure, namely: `f_bsize`, `f_frsize`, `f_blocks`, `f_bfree`, `f_bavail`, `f_files`, `f_ffree`, `f_favail`, `f_flag`, `f_namemax`.

Two module-level constants are defined for the `f_flag` attribute's
bit-flags: if ST_RDONLY is set, the filesystem is mounted read-only, and if ST_NOSUID is set, the semantics of setuid/setgid bits are disabled or not supported.

Additional module-level constants are defined for GNU/glibc based systems. These are ST_NODEV (disallow access to device special files), ST_NOEXEC (disallow program execution), ST_SYNCHRONOUS (writes are synced at once), ST_MANDLOCK (allow mandatory locks on an FS), ST_WRITE (write on file/directory/symlink), ST_APPEND (append-only file), ST_IMMUTABLE (immutable file), ST_NOATIME (do not update access times), ST_NODIRATIME (do not update directory access times), ST_RELATIME (update atime relative to mtime/ctime).

This function can support specifying a file descriptor.

*Changed in version 3.2:* The ST_RDONLY and ST_NOSUID constants were added.

*Changed in version 3.4:* The ST_NODEV, ST_NOEXEC, ST_SYNCHRONOUS, ST_MANDLOCK, ST_WRITE, ST_APPEND, ST_IMMUTABLE, ST_NOATIME, ST_NODIRATIME, and ST_RELATIME constants were added.

Availability: Unix.

*New in version 3.3:* Added support for specifying an open file descriptor for path.

```python
os.supports_dir_fd
```

A Set object indicating which functions in the os module permit use of their dir_fd parameter. Different platforms provide different
functionality, and an option that might work on one might be unsupported on another. For consistency's sakes, functions that support \texttt{dir\_fd} always allow specifying the parameter, but will raise an exception if the functionality is not actually available.

To check whether a particular function permits use of its \texttt{dir\_fd} parameter, use the \texttt{in} operator on \texttt{supports\_dir\_fd}. As an example, this expression determines whether the \texttt{dir\_fd} parameter of \texttt{os.stat()} is locally available:

\begin{verbatim}
os.stat in os.supports_dir_fd
\end{verbatim}

Currently \texttt{dir\_fd} parameters only work on Unix platforms; none of them work on Windows.

\textit{New in version 3.3.}

\texttt{os.supports_effective_ids}

A \texttt{Set} object indicating which functions in the \texttt{os} module permit use of the \texttt{effective\_ids} parameter for \texttt{os.access()}. If the local platform supports it, the collection will contain \texttt{os.access()}, otherwise it will be empty.

To check whether you can use the \texttt{effective\_ids} parameter for \texttt{os.access()}, use the \texttt{in} operator on \texttt{supports\_dir\_fd}, like so:

\begin{verbatim}
os.access in os.supports_effective_ids
\end{verbatim}

Currently \texttt{effective\_ids} only works on Unix platforms; it does not work on Windows.

\textit{New in version 3.3.}
**os.supports_fd**

A Set object indicating which functions in the os module permit specifying their path parameter as an open file descriptor. Different platforms provide different functionality, and an option that might work on one might be unsupported on another. For consistency's sakes, functions that support fd always allow specifying the parameter, but will raise an exception if the functionality is not actually available.

To check whether a particular function permits specifying an open file descriptor for its path parameter, use the in operator on supports_fd. As an example, this expression determines whether os.chdir() accepts open file descriptors when called on your local platform:

```python
os.chdir in os.supports_fd
```

*New in version 3.3.*

**os.supports_follow_symlinks**

A Set object indicating which functions in the os module permit use of their follow_symlinks parameter. Different platforms provide different functionality, and an option that might work on one might be unsupported on another. For consistency's sakes, functions that support follow_symlinks always allow specifying the parameter, but will raise an exception if the functionality is not actually available.

To check whether a particular function permits use of its follow_symlinks parameter, use the in operator on supports_follow_symlinks. As an example, this expression determines whether the follow_symlinks parameter of os.stat() is locally available:
os.stat in os.supports_follow_symlinks

New in version 3.3.

```python
os.symlink(source, link_name, target_is_directory=False, *,
dir_fd=None)
```

Create a symbolic link pointing to `source` named `link_name`.

On Windows, a symlink represents either a file or a directory, and does not morph to the target dynamically. If the target is present, the type of the symlink will be created to match. Otherwise, the symlink will be created as a directory if `target_is_directory` is `True` or a file symlink (the default) otherwise. On non-Window platforms, `target_is_directory` is ignored.

Symbolic link support was introduced in Windows 6.0 (Vista). `symlink()` will raise a `NotImplementedError` on Windows versions earlier than 6.0.

This function can support *paths relative to directory descriptors*.

**Note:** On Windows, the `SeCreateSymbolicLinkPrivilege` is required in order to successfully create symlinks. This privilege is not typically granted to regular users but is available to accounts which can escalate privileges to the administrator level. Either obtaining the privilege or running your application as an administrator are ways to successfully create symlinks. `OSError` is raised when the function is called by an unprivileged user.

Availability: Unix, Windows.

*Changed in version 3.2:* Added support for Windows 6.0 (Vista)
symbolic links.

New in version 3.3: Added the `dir_fd` argument, and now allow `target_is_directory` on non-Windows platforms.

**os.sync()**

Force write of everything to disk.

Availability: Unix.

New in version 3.3.

**os.truncate(path, length)**

Truncate the file corresponding to `path`, so that it is at most `length` bytes in size.

This function can support specifying a file descriptor.

Availability: Unix.

New in version 3.3.

**os.unlink(path, *, dir_fd=None)**

Remove (delete) the file `path`. This function is identical to `remove()`; the `unlink` name is its traditional Unix name. Please see the documentation for `remove()` for further information.

Availability: Unix, Windows.

New in version 3.3: The `dir_fd` parameter.

**os.utime(path, times=None, *, ns=None, dir_fd=None, follow_symlinks=True)**

Set the access and modified times of the file specified by `path`.
The `utime()` function takes two optional parameters, `times` and `ns`. These specify the times set on `path` and are used as follows:

- If `ns` is not `None`, it must be a 2-tuple of the form `(atime_ns, mtime_ns)` where each member is an int expressing nanoseconds.
- If `times` is not `None`, it must be a 2-tuple of the form `(atime, mtime)` where each member is an int or float expressing seconds.
- If `times` and `ns` are both `None`, this is equivalent to specifying `ns=(atime_ns, mtime_ns)` where both times are the current time.

It is an error to specify tuples for both `times` and `ns`.

Whether a directory can be given for `path` depends on whether the operating system implements directories as files (for example, Windows does not). Note that the exact times you set here may not be returned by a subsequent `stat()` call, depending on the resolution with which your operating system records access and modification times; see `stat()`. The best way to preserve exact times is to use the `st_atime_ns` and `st_mtime_ns` fields from the `os.stat()` result object with the `ns` parameter to `utime`.

This function can support specifying a file descriptor, paths relative to directory descriptors and not following symlinks.

Availability: Unix, Windows.

*New in version 3.3:* Added support for specifying an open file descriptor for `path`, and the `dir_fd`, `follow_symlinks`, and `ns` parameters.
Generate the file names in a directory tree by walking the tree either top-down or bottom-up. For each directory in the tree rooted at directory `top` (including `top` itself), it yields a 3-tuple `(dirpath, dirnames, filenames).

`dirpath` is a string, the path to the directory. `dirnames` is a list of the names of the subdirectories in `dirpath` (excluding `.' and '..'`). `filenames` is a list of the names of the non-directory files in `dirpath`. Note that the names in the lists contain no path components. To get a full path (which begins with `top`) to a file or directory in `dirpath`, do `os.path.join(dirpath, name)`.

If optional argument `topdown` is True or not specified, the triple for a directory is generated before the triples for any of its subdirectories (directories are generated top-down). If `topdown` is False, the triple for a directory is generated after the triples for all of its subdirectories (directories are generated bottom-up).

When `topdown` is True, the caller can modify the `dirnames` list in-place (perhaps using `del` or slice assignment), and `walk()` will only recurse into the subdirectories whose names remain in `dirnames`; this can be used to prune the search, impose a specific order of visiting, or even to inform `walk()` about directories the caller creates or renames before it resumes `walk()` again. Modifying `dirnames` when `topdown` is False is ineffective, because in bottom-up mode the directories in `dirnames` are generated before `dirpath` itself is generated.

By default, errors from the `listdir()` call are ignored. If optional argument `onerror` is specified, it should be a function; it will be called with one argument, an `OSError` instance. It can report the error to continue with the walk, or raise the exception to abort the
walk. Note that the filename is available as the `filename` attribute of the exception object.

By default, `walk()` will not walk down into symbolic links that resolve to directories. Set `followlinks` to `True` to visit directories pointed to by symlinks, on systems that support them.

**Note:** Be aware that setting `followlinks` to `True` can lead to infinite recursion if a link points to a parent directory of itself. `walk()` does not keep track of the directories it visited already.

**Note:** If you pass a relative pathname, don’t change the current working directory between resumptions of `walk()`. `walk()` never changes the current directory, and assumes that its caller doesn’t either.

This example displays the number of bytes taken by non-directory files in each directory under the starting directory, except that it doesn’t look under any CVS subdirectory:

```python
import os
from os.path import join, getsize
for root, dirs, files in os.walk('python/Lib/email', topdown=True):
    if 'CVS' in dirs:
        dirs.remove('CVS')  # don't visit CVS dir

    print(root, 'consumes', end=': ')
    print(sum(getsize(join(root, name)) for name in files), 'bytes in', len(files), 'non-directory files')
```

In the next example, walking the tree bottom-up is essential: `rmdir()` doesn’t allow deleting a directory before the directory is empty:
# Delete everything reachable from the directory named in `top`, assuming there are no symbolic links.
# CAUTION: This is dangerous! For example, if `top` == '/', it could delete all your disk files.

```python
import os
for root, dirs, files in os.walk(top, topdown=False):
    for name in files:
        os.remove(os.path.join(root, name))
    for name in dirs:
        os.rmdir(os.path.join(root, name))
```

```python
os.fwalk(top='.', topdown=True, onerror=None, *
follow_symlinks=False, dir_fd=None)
```

This behaves exactly like `walk()`, except that it yields a 4-tuple `(dirpath, dirnames, filenames, dirfd)`, and it supports `dir_fd`.

`dirpath`, `dirnames` and `filenames` are identical to `walk()` output, and `dirfd` is a file descriptor referring to the directory `dirpath`.

This function always supports *paths relative to directory descriptors* and *not following symlinks*. Note however that, unlike other functions, the `fwalk()` default value for `follow_symlinks` is `False`.

**Note:** Since `fwalk()` yields file descriptors, those are only valid until the next iteration step, so you should duplicate them (e.g. with `dup()`) if you want to keep them longer.

This example displays the number of bytes taken by non-directory files in each directory under the starting directory, except that it doesn’t look under any CVS subdirectory:

```python
import os
```
for root, dirs, files, rootfd in os.fwalk('python/Lib/email'):
    print(root, "consumes", end="")
    print(sum([os.stat(name, dir_fd=rootfd).st_size for name in files]), end="")
print("bytes in", len(files), "non-directory files")
if 'CVS' in dirs:
    dirs.remove('CVS')  # don't visit CVS directories

In the next example, walking the tree bottom-up is essential: rmdir() doesn't allow deleting a directory before the directory is empty:

# Delete everything reachable from the directory in 'top', assuming there are no symbolic links.
# CAUTION: This is dangerous! For example, if 'top' == '/',
# it could delete all your disk files.
import os
for root, dirs, files, rootfd in os.fwalk('top', topdown=True):
    for name in files:
        os.unlink(name, dir_fd=rootfd)
    for name in dirs:
        os.rmdir(name, dir_fd=rootfd)

Availability: Unix.

New in version 3.3.

16.1.5.1. Linux extended attributes

New in version 3.3.

These functions are all available on Linux only.

os.getxattr(path, attribute, *, follow_symlinks=True)
Return the value of the extended filesystem attribute *attribute* for *path*. *attribute* can be bytes or str. If it is str, it is encoded with the filesystem encoding.

This function can support *specifying a file descriptor* and *not following symlinks*.

```python
os.listxattr(path=None, *, follow_symlinks=True)
```

Return a list of the extended filesystem attributes on *path*. The attributes in the list are represented as strings decoded with the filesystem encoding. If *path* is None, `listxattr()` will examine the current directory.

This function can support *specifying a file descriptor* and *not following symlinks*.

```python
os.removexattr(path, attribute, *, follow_symlinks=True)
```

Removes the extended filesystem attribute *attribute* from *path*. *attribute* should be bytes or str. If it is a string, it is encoded with the filesystem encoding.

This function can support *specifying a file descriptor* and *not following symlinks*.

```python
os.setxattr(path, attribute, value, flags=0, *, follow_symlinks=True)
```

Set the extended filesystem attribute *attribute* on *path* to *value*. *attribute* must be a bytes or str with no embedded NULs. If it is a str, it is encoded with the filesystem encoding. *flags* may be `XATTR_REPLACE` or `XATTR_CREATE`. If `XATTR_REPLACE` is given and the attribute does not exist, EEXISTS will be raised. If `XATTR_CREATE` is given and the attribute already exists, the attribute will not be created and ENODATA will be raised.
This function can support *specifying a file descriptor* and *not following symlinks*.

**Note:** A bug in Linux kernel versions less than 2.6.39 caused the flags argument to be ignored on some filesystems.

**os. XATTR_SIZE_MAX**

The maximum size the value of an extended attribute can be. Currently, this is 64 KiB on Linux.

**os. XATTR_CREATE**

This is a possible value for the flags argument in `setxattr()`. It indicates the operation must create an attribute.

**os. XATTR_REPLACE**

This is a possible value for the flags argument in `setxattr()`. It indicates the operation must replace an existing attribute.
16.1.6. Process Management

These functions may be used to create and manage processes.

The various `exec*` functions take a list of arguments for the new program loaded into the process. In each case, the first of these arguments is passed to the new program as its own name rather than as an argument a user may have typed on a command line. For the C programmer, this is the `argv[0]` passed to a program's `main()`. For example, `os.execv('/bin/echo', ['foo', 'bar'])` will only print `bar` on standard output; `foo` will seem to be ignored.

```python
os.abort()
```

Generate a SIGABRT signal to the current process. On Unix, the default behavior is to produce a core dump; on Windows, the process immediately returns an exit code of 3. Be aware that calling this function will not call the Python signal handler registered for SIGABRT with `signal.signal()`.

Availability: Unix, Windows.

```python
os.execcl(path, arg0, arg1, ...)
os.execle(path, arg0, arg1, ..., env)
os.execlp(file, arg0, arg1, ...)
os.execlpe(file, arg0, arg1, ..., env)
os.execv(path, args)
os.execve(path, args, env)
os.execvp(file, args)
os.execvpe(file, args, env)
```

These functions all execute a new program, replacing the current process; they do not return. On Unix, the new executable is loaded
into the current process, and will have the same process id as the caller. Errors will be reported as **OSError** exceptions.

The current process is replaced immediately. Open file objects and descriptors are not flushed, so if there may be data buffered on these open files, you should flush them using `sys.stdout.flush()` or `os.fsync()` before calling an `exec*` function.

The “l” and “v” variants of the `exec*` functions differ in how command-line arguments are passed. The “l” variants are perhaps the easiest to work with if the number of parameters is fixed when the code is written; the individual parameters simply become additional parameters to the `execl*()` functions. The “v” variants are good when the number of parameters is variable, with the arguments being passed in a list or tuple as the `args` parameter. In either case, the arguments to the child process should start with the name of the command being run, but this is not enforced.

The variants which include a “p” near the end (`execlp()`, `execlpe()`, `execvp()`, and `execvpe()`) will use the PATH environment variable to locate the program file. When the environment is being replaced (using one of the `exec*e` variants, discussed in the next paragraph), the new environment is used as the source of the PATH variable. The other variants, `exec1()`, `execle()`, `execv()`, and `execve()`, will not use the PATH variable to locate the executable; path must contain an appropriate absolute or relative path.

For `execle()`, `execlpe()`, `execve()`, and `execvpe()` (note that these all end in “e”), the `env` parameter must be a mapping which is used to define the environment variables for the new
process (these are used instead of the current process' environment); the functions `execl()`, `execlp()`, `execv()`, and `execvp()` all cause the new process to inherit the environment of the current process.

For `execve()` on some platforms, `path` may also be specified as an open file descriptor. This functionality may not be supported on your platform; you can check whether or not it is available using `os.supports_fd`. If it is unavailable, using it will raise a `NotImplementedError`.

Availability: Unix, Windows.

*New in version 3.3:* Added support for specifying an open file descriptor for `path` for `execve()`.

`os._exit(n)`

Exit the process with status `n`, without calling cleanup handlers, flushing stdio buffers, etc.

Availability: Unix, Windows.

**Note:** The standard way to exit is `sys.exit(n)`. `_exit()` should normally only be used in the child process after a `fork()`.

The following exit codes are defined and can be used with `_exit()`, although they are not required. These are typically used for system programs written in Python, such as a mail server's external command delivery program.

**Note:** Some of these may not be available on all Unix platforms,
since there is some variation. These constants are defined where they are defined by the underlying platform.

`os.EX_OK`
Exit code that means no error occurred.
Availability: Unix.

`os.EX_USAGE`
Exit code that means the command was used incorrectly, such as when the wrong number of arguments are given.
Availability: Unix.

`os.EX_DATAERR`
Exit code that means the input data was incorrect.
Availability: Unix.

`os.EX_NOINPUT`
Exit code that means an input file did not exist or was not readable.
Availability: Unix.

`os.EX_NOUSER`
Exit code that means a specified user did not exist.
Availability: Unix.

`os.EX_NOHOST`
Exit code that means a specified host did not exist.
Availability: Unix.

`os.EX_UNAVAILABLE`
Exit code that means that a required service is unavailable.

Availability: Unix.

**os. EXSOFTWARE**
Exit code that means an internal software error was detected.

Availability: Unix.

**os. EXOSERR**
Exit code that means an operating system error was detected, such as the inability to fork or create a pipe.

Availability: Unix.

**os. EXOSFILE**
Exit code that means some system file did not exist, could not be opened, or had some other kind of error.

Availability: Unix.

**os. EXCANTCREAT**
Exit code that means a user specified output file could not be created.

Availability: Unix.

**os. EXIOERR**
Exit code that means that an error occurred while doing I/O on some file.

Availability: Unix.

**os. EXTEMPFAIL**
Exit code that means a temporary failure occurred. This indicates
something that may not really be an error, such as a network connection that couldn’t be made during a retryable operation.

Availability: Unix.

**os.EX_PROTOCOL**

Exit code that means that a protocol exchange was illegal, invalid, or not understood.

Availability: Unix.

**os.EX_NOPERM**

Exit code that means that there were insufficient permissions to perform the operation (but not intended for file system problems).

Availability: Unix.

**os.EX_CONFIG**

Exit code that means that some kind of configuration error occurred.

Availability: Unix.

**os.EX_NOTFOUND**

Exit code that means something like “an entry was not found”.

Availability: Unix.

**os.fork()**

Fork a child process. Return 0 in the child and the child’s process id in the parent. If an error occurs **OSERROR** is raised.

Note that some platforms including FreeBSD <= 6.3 and Cygwin have known issues when using fork() from a thread.
Warning: See ssl for applications that use the SSL module with fork().

Availability: Unix.

**os. forkpty()**

Fork a child process, using a new pseudo-terminal as the child's controlling terminal. Return a pair of (pid, fd), where pid is 0 in the child, the new child's process id in the parent, and fd is the file descriptor of the master end of the pseudo-terminal. For a more portable approach, use the pty module. If an error occurs OSError is raised.

Availability: some flavors of Unix.

**os. kill(pid, sig)**

Send signal sig to the process pid. Constants for the specific signals available on the host platform are defined in the signal module.

Windows: The signal.CTRL_C_EVENT and signal.CTRL_BREAK_EVENT signals are special signals which can only be sent to console processes which share a common console window, e.g., some subprocesses. Any other value for sig will cause the process to be unconditionally killed by the TerminateProcess API, and the exit code will be set to sig. The Windows version of kill() additionally takes process handles to be killed.

See also signal.pthread_kill().

*New in version 3.2:* Windows support.
os. **killpg**(*pgid, sig*)
Send the signal *sig* to the process group *pgid*.

Availability: Unix.

os. **nice**(*increment*)
Add *increment* to the process's “niceness”. Return the new niceness.

Availability: Unix.

os. **plock**(*op*)
Lock program segments into memory. The value of *op* (defined in `<sys/lock.h>`) determines which segments are locked.

Availability: Unix.

os. **popen**(...)
Run child processes, returning opened pipes for communications. These functions are described in section *File Object Creation*.

os. **spawnl**(*mode, path, ...*)

os. **spawnle**(*mode, path, ..., env*)

os. **spawnlp**(*mode, file, ...*)

os. **spawnlpe**(*mode, file, ..., env*)

os. **spawnv**(*mode, path, args*)

os. **spawnve**(*mode, path, args, env*)

os. **spawnvp**(*mode, file, args*)

os. **spawnvpe**(*mode, file, args, env*)
Execute the program *path* in a new process.

(Note that the *subprocess* module provides more powerful facilities for spawning new processes and retrieving their results;
using that module is preferable to using these functions. Check especially the *Replacing Older Functions with the subprocess Module* section.)

If \textit{mode} is \texttt{P\_NOWAIT}, this function returns the process id of the new process; if \textit{mode} is \texttt{P\_WAIT}, returns the process's exit code if it exits normally, or -\textit{signal}, where \textit{signal} is the signal that killed the process. On Windows, the process id will actually be the process handle, so can be used with the \texttt{waitpid()} function.

The “l” and “v” variants of the \texttt{spawn*} functions differ in how command-line arguments are passed. The “l” variants are perhaps the easiest to work with if the number of parameters is fixed when the code is written; the individual parameters simply become additional parameters to the \texttt{spawnl*()} functions. The “v” variants are good when the number of parameters is variable, with the arguments being passed in a list or tuple as the \texttt{args} parameter. In either case, the arguments to the child process must start with the name of the command being run.

The variants which include a second “p” near the end (\texttt{spawnlp()}, \texttt{spawnlpe()}, \texttt{spawnvp()}, and \texttt{spawnvpe()}) will use the \texttt{PATH} environment variable to locate the program \texttt{file}. When the environment is being replaced (using one of the \texttt{spawn*e} variants, discussed in the next paragraph), the new environment is used as the source of the \texttt{PATH} variable. The other variants, \texttt{spawnl()}, \texttt{spawnle()}, \texttt{spawnv()}, and \texttt{spawnve()}, will not use the \texttt{PATH} variable to locate the executable; \texttt{path} must contain an appropriate absolute or relative path.

For \texttt{spawnle()}, \texttt{spawnlpe()}, \texttt{spawnve()}, and \texttt{spawnvpe()} (note that these all end in “e”), the \texttt{env} parameter must be a
mapping which is used to define the environment variables for the new process (they are used instead of the current process' environment); the functions `spawnl()`, `spawnlp()`, `spawnv()`, and `spawnvp()` all cause the new process to inherit the environment of the current process. Note that keys and values in the `env` dictionary must be strings; invalid keys or values will cause the function to fail, with a return value of 127.

As an example, the following calls to `spawnlp()` and `spawnvpe()` are equivalent:

```python
import os
os.spawnlp(os.P_WAIT, 'cp', 'cp', 'index.html', '
L = ['cp', 'index.html', '/dev/null']
os.spawnvpe(os.P_WAIT, 'cp', L, os.environ)
```

Availability: Unix, Windows. `spawnlp()`, `spawnlpe()`, `spawnvp()` and `spawnvpe()` are not available on Windows. `spawnle()` and `spawnve()` are not thread-safe on Windows; we advise you to use the `subprocess` module instead.

```
os.P_NOWAIT
os.P_NOWAITO
```

Possible values for the `mode` parameter to the `spawn*` family of functions. If either of these values is given, the `spawn*()` functions will return as soon as the new process has been created, with the process id as the return value.

Availability: Unix, Windows.

```
os.P_WAIT
```
Possible value for the *mode* parameter to the *spawn* family of functions. If this is given as *mode*, the *spawn*(*) functions will not return until the new process has run to completion and will return the exit code of the process the run is successful, or *-signal* if a signal kills the process.

Availability: Unix, Windows.

**os.P_DETACH**

**os.P_OVERLAY**

Possible values for the *mode* parameter to the *spawn* family of functions. These are less portable than those listed above. *P_DETACH* is similar to *P_NOWAIT*, but the new process is detached from the console of the calling process. If *P_OVERLAY* is used, the current process will be replaced; the *spawn* function will not return.

Availability: Windows.

**os.startfile(path[, operation])**

Start a file with its associated application.

When *operation* is not specified or "$\text{open}$", this acts like double-clicking the file in Windows Explorer, or giving the file name as an argument to the *start* command from the interactive command shell: the file is opened with whatever application (if any) its extension is associated.

When another *operation* is given, it must be a “command verb” that specifies what should be done with the file. Common verbs documented by Microsoft are "$\text{print}$" and "$\text{edit}$" (to be used on files) as well as "$\text{explore}$" and "$\text{find}$" (to be used on
directories).

**startfile()** returns as soon as the associated application is launched. There is no option to wait for the application to close, and no way to retrieve the application's exit status. The *path* parameter is relative to the current directory. If you want to use an absolute path, make sure the first character is not a slash ('/'); the underlying Win32 ShellExecute() function doesn't work if it is. Use the **os.path.normpath()** function to ensure that the path is properly encoded for Win32.

Availability: Windows.

**os.system(command)**
Execute the command (a string) in a subshell. This is implemented by calling the Standard C function system(), and has the same limitations. Changes to **sys.stdin**, etc. are not reflected in the environment of the executed command. If *command* generates any output, it will be sent to the interpreter standard output stream.

On Unix, the return value is the exit status of the process encoded in the format specified for **wait()**. Note that POSIX does not specify the meaning of the return value of the C system() function, so the return value of the Python function is system-dependent.

On Windows, the return value is that returned by the system shell after running *command*. The shell is given by the Windows environment variable COMSPEC: it is usually **cmd.exe**, which returns the exit status of the command run; on systems using a non-native shell, consult your shell documentation.

The **subprocess** module provides more powerful facilities for
spawning new processes and retrieving their results; using that module is preferable to using this function. See the Replacing Older Functions with the subprocess Module section in the subprocess documentation for some helpful recipes.

Availability: Unix, Windows.

**os.times()**

Returns the current global process times. The return value is an object with five attributes:

- `user` - user time
- `system` - system time
- `children_user` - user time of all child processes
- `children_system` - system time of all child processes
- `elapsed` - elapsed real time since a fixed point in the past

For backwards compatibility, this object also behaves like a five-tuple containing `user`, `system`, `children_user`, `children_system`, and `elapsed` in that order.

See the Unix manual page `times(2)` or the corresponding Windows Platform API documentation. On Windows, only `user` and `system` are known; the other attributes are zero.

Availability: Unix, Windows.

*Changed in version 3.3:* Return type changed from a tuple to a tuple-like object with named attributes.

**os.wait()**

Wait for completion of a child process, and return a tuple containing its pid and exit status indication: a 16-bit number, whose low byte is the signal number that killed the process, and whose high byte is
the exit status (if the signal number is zero); the high bit of the low byte is set if a core file was produced.

Availability: Unix.

**os.waitid(idtype, id, options)**

Wait for the completion of one or more child processes. *idtype* can be **P_PID**, **P_PGID** or **P_ALL**. *id* specifies the pid to wait on. *options* is constructed from the ORing of one or more of **WEXITED**, **WSTOPPED** or **WCONTINUED** and additionally may be ORed with **WNOHANG** or **WNOWAIT**. The return value is an object representing the data contained in the siginfo_t structure, namely: si_pid, si_uid, si_signo, si_status, si_code or None if **WNOHANG** is specified and there are no children in a waitable state.

Availability: Unix.

*New in version 3.3.*

**os.P_PID**  
**os.P_PGID**  
**os.P_ALL**  

These are the possible values for *idtype* in **waitid()**. They affect how *id* is interpreted.

Availability: Unix.

*New in version 3.3.*

**os.WEXITED**  
**os.WSTOPPED**  
**os.WNOWAIT**  

Flags that can be used in **options** in **waitid()** that specify what
child signal to wait for.

Availability: Unix.

New in version 3.3.

`os.CLD_EXITED`
`os.CLD_DUMPED`
`os.CLD_TRAPPED`
`os.CLD_CONTINUED`

These are the possible values for `si_code` in the result returned by `waitid()`.

Availability: Unix.

New in version 3.3.

`os.waitpid(pid, options)`

The details of this function differ on Unix and Windows.

On Unix: Wait for completion of a child process given by process id `pid`, and return a tuple containing its process id and exit status indication (encoded as for `wait()`). The semantics of the call are affected by the value of the integer `options`, which should be 0 for normal operation.

If `pid` is greater than 0, `waitpid()` requests status information for that specific process. If `pid` is 0, the request is for the status of any child in the process group of the current process. If `pid` is -1, the request pertains to any child of the current process. If `pid` is less than -1, status is requested for any process in the process group `-pid` (the absolute value of `pid`).
An **OSError** is raised with the value of errno when the syscall returns -1.

On Windows: Wait for completion of a process given by process handle *pid*, and return a tuple containing *pid*, and its exit status shifted left by 8 bits (shifting makes cross-platform use of the function easier). A *pid* less than or equal to 0 has no special meaning on Windows, and raises an exception. The value of integer *options* has no effect. *pid* can refer to any process whose id is known, not necessarily a child process. The *spawn* functions called with **P_NOWAIT** return suitable process handles.

```python
os.wait3(options)
```

Similar to **waitpid()**, except no process id argument is given and a 3-element tuple containing the child’s process id, exit status indication, and resource usage information is returned. Refer to **resource.getrusage()** for details on resource usage information. The option argument is the same as that provided to **waitpid()** and **wait4()**.

**Availability:** Unix.

```python
os.wait4(pid, options)
```

Similar to **waitpid()**, except a 3-element tuple, containing the child’s process id, exit status indication, and resource usage information is returned. Refer to **resource.getrusage()** for details on resource usage information. The arguments to **wait4()** are the same as those provided to **waitpid()**.

**Availability:** Unix.

```python
os.WNOHANG
```
The option for `waitpid()` to return immediately if no child process status is available immediately. The function returns $\langle 0, 0 \rangle$ in this case.

Availability: Unix.

**os. WCONTINUED**

This option causes child processes to be reported if they have been continued from a job control stop since their status was last reported.

Availability: some Unix systems.

**os. WUNTRACED**

This option causes child processes to be reported if they have been stopped but their current state has not been reported since they were stopped.

Availability: Unix.

The following functions take a process status code as returned by `system()`, `wait()`, or `waitpid()` as a parameter. They may be used to determine the disposition of a process.

**os. WCOREDUMP(status)**

Return `True` if a core dump was generated for the process, otherwise return `False`.

Availability: Unix.

**os. WIFCONTINUED(status)**

Return `True` if the process has been continued from a job control stop, otherwise return `False`.
Availability: Unix.

**os.WIFSTOPPED(status)**
Return `True` if the process has been stopped, otherwise return `False`.

Availability: Unix.

**os.WIFSIGNALED(status)**
Return `True` if the process exited due to a signal, otherwise return `False`.

Availability: Unix.

**os.WIFEXITED(status)**
Return `True` if the process exited using the `exit(2)` system call, otherwise return `False`.

Availability: Unix.

**os.WEXITSTATUS(status)**
If `WIFEXITED(status)` is true, return the integer parameter to the `exit(2)` system call. Otherwise, the return value is meaningless.

Availability: Unix.

**os.WSTOPSIG(status)**
Return the signal which caused the process to stop.

Availability: Unix.

**os.WTERMSIG(status)**
Return the signal which caused the process to exit.
Availability: Unix.
16.1.7. Interface to the scheduler

These functions control how a process is allocated CPU time by the operating system. They are only available on some Unix platforms. For more detailed information, consult your Unix manpages.

*New in version 3.3.*

The following scheduling policies are exposed if they are supported by the operating system.

- **os. SCHED_OTHER**
  - The default scheduling policy.

- **os. SCHED_BATCH**
  - Scheduling policy for CPU-intensive processes that tries to preserve interactivity on the rest of the computer.

- **os. SCHED_IDLE**
  - Scheduling policy for extremely low priority background tasks.

- **os. SCHED_SPORADIC**
  - Scheduling policy for sporadic server programs.

- **os. SCHED_FIFO**
  - A First In First Out scheduling policy.

- **os. SCHED_RR**
  - A round-robin scheduling policy.

- **os. SCHED_RESET_ON_FORK**
  - This flag can OR'ed with any other scheduling policy. When a process with this flag set forks, its child’s scheduling policy and
Priority are reset to the default.

```python
class os.sched_param(sched_priority)
```
This class represents tunable scheduling parameters used in `sched_setparam()`, `sched_setscheduler()`, and `sched_getparam()`. It is immutable.

At the moment, there is only one possible parameter:

```python
sched_priority
```

The scheduling priority for a scheduling policy.

```python
os.sched_get_priority_min(policy)
```
Get the minimum priority value for `policy`. `policy` is one of the scheduling policy constants above.

```python
os.sched_get_priority_max(policy)
```
Get the maximum priority value for `policy`. `policy` is one of the scheduling policy constants above.

```python
os.sched_setscheduler(pid, policy, param)
```
Set the scheduling policy for the process with PID `pid`. A `pid` of 0 means the calling process. `policy` is one of the scheduling policy constants above. `param` is a `sched_param` instance.

```python
os.sched_getscheduler(pid)
```
Return the scheduling policy for the process with PID `pid`. A `pid` of 0 means the calling process. The result is one of the scheduling policy constants above.

```python
os.sched_setparam(pid, param)
```
Set a scheduling parameters for the process with PID `pid`. A `pid` of 0 means the calling process. `param` is a `sched_param` instance.
os. **sched_getparam**(pid)
Return the scheduling parameters as a **sched_param** instance for the process with PID `pid`. A `pid` of 0 means the calling process.

os. **sched_rr_get_interval**(pid)
Return the round-robin quantum in seconds for the process with PID `pid`. A `pid` of 0 means the calling process.

os. **sched_yield**( )
Voluntarily relinquish the CPU.

os. **sched_setaffinity**(pid, mask)
Restrict the process with PID `pid` (or the current process if zero) to a set of CPUs. `mask` is an iterable of integers representing the set of CPUs to which the process should be restricted.

os. **sched_getaffinity**(pid)
Return the set of CPUs the process with PID `pid` (or the current process if zero) is restricted to.
16.1.8. Miscellaneous System Information

**os.confstr(name)**

Return string-valued system configuration values. *name* specifies the configuration value to retrieve; it may be a string which is the name of a defined system value; these names are specified in a number of standards (POSIX, Unix 95, Unix 98, and others). Some platforms define additional names as well. The names known to the host operating system are given as the keys of the `confstr_names` dictionary. For configuration variables not included in that mapping, passing an integer for *name* is also accepted.

If the configuration value specified by *name* isn’t defined, `None` is returned.

If *name* is a string and is not known, `ValueError` is raised. If a specific value for *name* is not supported by the host system, even if it is included in `confstr_names`, an `OSError` is raised with `errno.EINVAL` for the error number.

Availability: Unix.

**os.confstr_names**

Dictionary mapping names accepted by `confstr()` to the integer values defined for those names by the host operating system. This can be used to determine the set of names known to the system.

Availability: Unix.

**os.cpu_count()**

Return the number of CPUs in the system. Returns None if
undetermined.

*New in version 3.4.*

**os. `getloadavg()`**

Return the number of processes in the system run queue averaged over the last 1, 5, and 15 minutes or raises *OSError* if the load average was unobtainable.

*Availability: Unix.*

**os. `sysconf(name)`**

Return integer-valued system configuration values. If the configuration value specified by `name` isn’t defined, `-1` is returned. The comments regarding the `name` parameter for `confstr()` apply here as well; the dictionary that provides information on the known names is given by `sysconf_names`.

*Availability: Unix.*

**os. `sysconf_names`**

Dictionary mapping names accepted by `sysconf()` to the integer values defined for those names by the host operating system. This can be used to determine the set of names known to the system.

*Availability: Unix.*

The following data values are used to support path manipulation operations. These are defined for all platforms.

Higher-level operations on pathnames are defined in the *os.path* module.

**os. `curdir`**
The constant string used by the operating system to refer to the current directory. This is '. ' for Windows and POSIX. Also available via os.path.

**os.pardir**

The constant string used by the operating system to refer to the parent directory. This is '..' for Windows and POSIX. Also available via os.path.

**os.sep**

The character used by the operating system to separate pathname components. This is '/ ' for POSIX and '\\' for Windows. Note that knowing this is not sufficient to be able to parse or concatenate pathnames — use os.path.split() and os.path.join() — but it is occasionally useful. Also available via os.path.

**os.altsep**

An alternative character used by the operating system to separate pathname components, or None if only one separator character exists. This is set to '/' on Windows systems where sep is a backslash. Also available via os.path.

**os.extsep**

The character which separates the base filename from the extension; for example, the '.' in os.py. Also available via os.path.

**os.pathsep**

The character conventionally used by the operating system to separate search path components (as in PATH), such as ':' for POSIX or ';' for Windows. Also available via os.path.
os. **defpath**

The default search path used by *exec*p* and *spawn*p* if the environment doesn’t have a `PATH` key. Also available via `os.path`.

os. **linesep**

The string used to separate (or, rather, terminate) lines on the current platform. This may be a single character, such as `\n` for POSIX, or multiple characters, for example, `\r\n` for Windows. Do not use `os.linesep` as a line terminator when writing files opened in text mode (the default); use a single `\n` instead, on all platforms.

os. **devnull**

The file path of the null device. For example: `/dev/null` for POSIX, `\null` for Windows. Also available via `os.path`.

os. **RTLD_LAZY**

os. **RTLD_NOW**

os. **RTLD_GLOBAL**

os. **RTLD_LOCAL**

os. **RTLD_NODELETE**

os. **RTLD_NOLOAD**

os. **RTLD_DEEPBIND**

Flags for use with the setdlopenflags() and getdlopenflags() functions. See the Unix manual page `dlopen(3)` for what the different flags mean.

*New in version 3.3.*
16.1.9. Miscellaneous Functions

**os.urandom(n)**

Return a string of \( n \) random bytes suitable for cryptographic use.

This function returns random bytes from an OS-specific randomness source. The returned data should be unpredictable enough for cryptographic applications, though its exact quality depends on the OS implementation. On a Unix-like system this will query `/dev/urandom`, and on Windows it will use `CryptGenRandom()`. If a randomness source is not found, `NotImplementedError` will be raised.

For an easy-to-use interface to the random number generator provided by your platform, please see `random.SystemRandom`.
16.2. io — Core tools for working with streams
16.2.1. Overview

The io module provides Python’s main facilities for dealing with various types of I/O. There are three main types of I/O: text I/O, binary I/O and raw I/O. These are generic categories, and various backing stores can be used for each of them. A concrete object belonging to any of these categories is called a file object. Other common terms are stream and file-like object.

Independently of its category, each concrete stream object will also have various capabilities: it can be read-only, write-only, or read-write. It can also allow arbitrary random access (seeking forwards or backwards to any location), or only sequential access (for example in the case of a socket or pipe).

All streams are careful about the type of data you give to them. For example giving a str object to the write() method of a binary stream will raise a TypeError. So will giving a bytes object to the write() method of a text stream.

*Changed in version 3.3:* Operations that used to raise IOError now raise OSError, since IOError is now an alias of OSError.

16.2.1.1. Text I/O

Text I/O expects and produces str objects. This means that whenever the backing store is natively made of bytes (such as in the case of a file), encoding and decoding of data is made transparently as well as optional translation of platform-specific newline characters.

The easiest way to create a text stream is with open(), optionally
specifying an encoding:

```python
f = open("myfile.txt", "r", encoding="utf-8")
```

In-memory text streams are also available as `StringIO` objects:

```python
f = io.StringIO("some initial text data")
```

The text stream API is described in detail in the documentation of `TextIOWrapper`.

### 16.2.1.2. Binary I/O

Binary I/O (also called *buffered I/O*) expects and produces `bytes` objects. No encoding, decoding, or newline translation is performed. This category of streams can be used for all kinds of non-text data, and also when manual control over the handling of text data is desired.

The easiest way to create a binary stream is with `open()` with `'b'` in the mode string:

```python
f = open("myfile.jpg", "rb")
```

In-memory binary streams are also available as `BytesIO` objects:

```python
f = io.BytesIO(b"some initial binary data: \x00\x01")
```

The binary stream API is described in detail in the docs of `BufferedIOWrapper`.

Other library modules may provide additional ways to create text or binary streams. See `socket.socket.makefile()` for example.
16.2.1.3. Raw I/O

Raw I/O (also called *unbuffered I/O*) is generally used as a low-level building-block for binary and text streams; it is rarely useful to directly manipulate a raw stream from user code. Nevertheless, you can create a raw stream by opening a file in binary mode with buffering disabled:

```python
f = open("myfile.jpg", "rb", buffering=0)
```

The raw stream API is described in detail in the docs of `RawI0Base`.
16.2.2. High-level Module Interface

**io. DEFAULT_BUFFER_SIZE**

An int containing the default buffer size used by the module's buffered I/O classes. `open()` uses the file's blksize (as obtained by `os.stat()`) if possible.

```python
io.open(file, mode='r', buffering=-1, encoding=None, errors=None, newline=None, closefd=True, opener=None)
```

This is an alias for the builtin `open()` function.

**exception io. BlockingIOError**

This is a compatibility alias for the builtin `BlockingIOError` exception.

**exception io. UnsupportedOperation**

An exception inheriting `OSError` and `ValueError` that is raised when an unsupported operation is called on a stream.

16.2.2.1. In-memory streams

It is also possible to use a str or bytes-like object as a file for both reading and writing. For strings `StringIO` can be used like a file opened in text mode. `BytesIO` can be used like a file opened in binary mode. Both provide full read-write capabilities with random access.

**See also:**

`sys`

contains the standard IO streams: `sys.stdin`, `sys.stdout`,...
and `sys.stderr`.
16.2.3. Class hierarchy

The implementation of I/O streams is organized as a hierarchy of classes. First **abstract base classes** (ABCs), which are used to specify the various categories of streams, then concrete classes providing the standard stream implementations.

**Note:** The abstract base classes also provide default implementations of some methods in order to help implementation of concrete stream classes. For example, `BufferedIOBase` provides unoptimized implementations of `readinto()` and `readline()`.

At the top of the I/O hierarchy is the abstract base class `IOBase`. It defines the basic interface to a stream. Note, however, that there is no separation between reading and writing to streams; implementations are allowed to raise `UnsupportedOperation` if they do not support a given operation.

The `RawIOBase` ABC extends `IOBase`. It deals with the reading and writing of bytes to a stream. `FileIO` subclasses `RawIOBase` to provide an interface to files in the machine's file system.

The `BufferedIOBase` ABC deals with buffering on a raw byte stream (`RawIOBase`). Its subclasses, `BufferedWriter`, `BufferedReader`, and `BufferedRWPair` buffer streams that are readable, writable, and both readable and writable. `BufferedRandom` provides a buffered interface to random access streams. Another `BufferedIOBase` subclass, `BytesIO`, is a stream of in-memory bytes.
The **TextIOBase** ABC, another subclass of **IOBase**, deals with streams whose bytes represent text, and handles encoding and decoding to and from strings. **TextIOWrapper**, which extends it, is a buffered text interface to a buffered raw stream (**BufferedIOBase**). Finally, **StringIO** is an in-memory stream for text.

Argument names are not part of the specification, and only the arguments of **open()** are intended to be used as keyword arguments.

The following table summarizes the ABCs provided by the **io** module:

<table>
<thead>
<tr>
<th>ABC</th>
<th>Inherits</th>
<th>Stub Methods</th>
<th>Mixin Methods and Properties</th>
</tr>
</thead>
<tbody>
<tr>
<td>IOBase</td>
<td></td>
<td>fileno, seek, and truncate</td>
<td>close, closed, <strong>enter</strong>, <strong>exit</strong>, flush, isatty, <strong>iter</strong>, <strong>next</strong>, readable, readline, readlines, seekable, tell, writable, and writelines</td>
</tr>
<tr>
<td>RawIOBase</td>
<td>IOBase</td>
<td>readinto and write</td>
<td>Inherited <strong>IOBase</strong> methods, read, and readall</td>
</tr>
<tr>
<td>BufferedIOBase</td>
<td>IOBase</td>
<td>detach, read, read1, and write</td>
<td>Inherited <strong>IOBase</strong> methods, readinto</td>
</tr>
<tr>
<td>TextIOBase</td>
<td>IOBase</td>
<td>detach, read</td>
<td>Inherited <strong>IOBase</strong> methods,</td>
</tr>
</tbody>
</table>
16.2.3.1. I/O Base Classes

class io.IOBase

The abstract base class for all I/O classes, acting on streams of bytes. There is no public constructor.

This class provides empty abstract implementations for many methods that derived classes can override selectively; the default implementations represent a file that cannot be read, written or seeked.

Even though IOBase does not declare read(), readinto(), or write() because their signatures will vary, implementations and clients should consider those methods part of the interface. Also, implementations may raise a ValueError (or UnsupportedOperation) when operations they do not support are called.

The basic type used for binary data read from or written to a file is bytes. bytearrays are accepted too, and in some cases (such as readinto()) required. Text I/O classes work with str data.

Note that calling any method (even inquiries) on a closed stream is undefined. Implementations may raise ValueError in this case.

IOBase (and its subclasses) supports the iterator protocol, meaning that an IOBase object can be iterated over yielding the lines in a stream. Lines are defined slightly differently depending on whether the stream is a binary stream (yielding bytes), or a text
stream (yielding character strings). See `readline()` below.

**`IOBase`** is also a context manager and therefore supports the `with` statement. In this example, `file` is closed after the `with` statement’s suite is finished—even if an exception occurs:

```python
with open('spam.txt', 'w') as file:
    file.write('Spam and eggs!')
```

**`IOBase`** provides these data attributes and methods:

**`close()`**

Flush and close this stream. This method has no effect if the file is already closed. Once the file is closed, any operation on the file (e.g. reading or writing) will raise a `ValueError`.

As a convenience, it is allowed to call this method more than once; only the first call, however, will have an effect.

**`closed`**

`True` if the stream is closed.

**`fileno()`**

Return the underlying file descriptor (an integer) of the stream if it exists. An `OSError` is raised if the IO object does not use a file descriptor.

**`flush()`**

Flush the write buffers of the stream if applicable. This does nothing for read-only and non-blocking streams.

**`isatty()`**

Return `True` if the stream is interactive (i.e., connected to a
terminal/tty device).

**readable()**

Return `True` if the stream can be read from. If `False`, `read()` will raise `OSError`.

**readline(size=-1)**

Read and return one line from the stream. If `size` is specified, at most `size` bytes will be read.

The line terminator is always `b'\n'` for binary files; for text files, the `newlines` argument to `open()` can be used to select the line terminator(s) recognized.

**readlines(hint=-1)**

Read and return a list of lines from the stream. `hint` can be specified to control the number of lines read: no more lines will be read if the total size (in bytes/characters) of all lines so far exceeds `hint`.

Note that it's already possible to iterate on file objects using

```
for line in file: ... without calling file.readlines().
```

**seek(offset, whence=SEEK_SET)**

Change the stream position to the given byte `offset`. `offset` is interpreted relative to the position indicated by `whence`. Values for `whence` are:

- SEEK_SET or `0` – start of the stream (the default); `offset` should be zero or positive
- SEEK_CUR or `1` – current stream position; `offset` may be negative
- SEEK_END or \texttt{2} – end of the stream; \textit{offset} is usually negative

Return the new absolute position.

\textit{New in version 3.1:} The \texttt{SEEK\_*} constants.

\textit{New in version 3.3:} Some operating systems could support additional values, like \texttt{os.SEEK\_HOLE} or \texttt{os.SEEK\_DATA}. The valid values for a file could depend on it being open in text or binary mode.

\texttt{seekable()}

Return \texttt{True} if the stream supports random access. If \texttt{False}, \texttt{seek()}, \texttt{tell()} and \texttt{truncate()} will raise \texttt{OSError}.

\texttt{tell()}

Return the current stream position.

\texttt{truncate(size=None)}

Resize the stream to the given \texttt{size} in bytes (or the current position if \texttt{size} is not specified). The current stream position isn't changed. This resizing can extend or reduce the current file size. In case of extension, the contents of the new file area depend on the platform (on most systems, additional bytes are zero-filled, on Windows they're undetermined). The new file size is returned.

\texttt{writable()}

Return \texttt{True} if the stream supports writing. If \texttt{False}, \texttt{write()} and \texttt{truncate()} will raise \texttt{OSError}.

\texttt{writelines(lines)}
Write a list of lines to the stream. Line separators are not added, so it is usual for each of the lines provided to have a line separator at the end.

\texttt{class \textbf{io.RawIOBase}}

Base class for raw binary I/O. It inherits \texttt{IOBase}. There is no public constructor.

Raw binary I/O typically provides low-level access to an underlying OS device or API, and does not try to encapsulate it in high-level primitives (this is left to Buffered I/O and Text I/O, described later in this page).

In addition to the attributes and methods from \texttt{IOBase}, \texttt{RawIOBase} provides the following methods:

\texttt{read(size=-1)}

Read up to \texttt{size} bytes from the object and return them. As a convenience, if \texttt{size} is unspecified or -1, \texttt{readall()} is called. Otherwise, only one system call is ever made. Fewer than \texttt{size} bytes may be returned if the operating system call returns fewer than \texttt{size} bytes.

If 0 bytes are returned, and \texttt{size} was not 0, this indicates end of file. If the object is in non-blocking mode and no bytes are available, None is returned.

\texttt{readall()}

Read and return all the bytes from the stream until EOF, using multiple calls to the stream if necessary.

\texttt{readinto(b)}

Read up to \texttt{len(b)} bytes into \texttt{bytearray b} and return the
number of bytes read. If the object is in non-blocking mode and no bytes are available, `None` is returned.

**write(b)**
Write the given `bytes` or `bytearray` object, `b`, to the underlying raw stream and return the number of bytes written. This can be less than `len(b)`, depending on specifics of the underlying raw stream, and especially if it is in non-blocking mode. `None` is returned if the raw stream is set not to block and no single byte could be readily written to it.

**class io.BufferedIOBase**
Base class for binary streams that support some kind of buffering. It inherits `IOBase`. There is no public constructor.

The main difference with `RawIOBase` is that methods `read()`, `readinto()` and `write()` will try (respectively) to read as much input as requested or to consume all given output, at the expense of making perhaps more than one system call.

In addition, those methods can raise `BlockingIOError` if the underlying raw stream is in non-blocking mode and cannot take or give enough data; unlike their `RawIOBase` counterparts, they will never return `None`.

Besides, the `read()` method does not have a default implementation that defers to `readinto()`.

A typical `BufferedIOBase` implementation should not inherit from a `RawIOBase` implementation, but wrap one, like `BufferedWriter` and `BufferedReader` do.
BufferedIOBase provides or overrides these methods and attribute in addition to those from I0Base:

**raw**

The underlying raw stream (a RawIOBase instance) that BufferedIOBase deals with. This is not part of the BufferedIOBase API and may not exist on some implementations.

**detach()**

Separate the underlying raw stream from the buffer and return it.

After the raw stream has been detached, the buffer is in an unusable state.

Some buffers, like BytesIO, do not have the concept of a single raw stream to return from this method. They raise UnsupportedOperation.

*New in version 3.1.*

**read(size=-1)**

Read and return up to size bytes. If the argument is omitted, None, or negative, data is read and returned until EOF is reached. An empty bytes object is returned if the stream is already at EOF.

If the argument is positive, and the underlying raw stream is not interactive, multiple raw reads may be issued to satisfy the byte count (unless EOF is reached first). But for interactive raw streams, at most one raw read will be issued, and a short result does not imply that EOF is imminent.
A **BlockingIOError** is raised if the underlying raw stream is in non-blocking-mode, and has no data available at the moment.

**read1**(size=-1)
Read and return up to size bytes, with at most one call to the underlying raw stream’s **read()** method. This can be useful if you are implementing your own buffering on top of a **BufferedIOBase** object.

**readinto**(b)
Read up to `len(b)` bytes into bytearray `b` and return the number of bytes read.

Like **read()**, multiple reads may be issued to the underlying raw stream, unless the latter is interactive.

A **BlockingIOError** is raised if the underlying raw stream is in non-blocking-mode, and has no data available at the moment.

**write**(b)
Write the given **bytes** or **bytearray** object, `b` and return the number of bytes written (never less than `len(b)`, since if the write fails an **OSError** will be raised). Depending on the actual implementation, these bytes may be readily written to the underlying stream, or held in a buffer for performance and latency reasons.

When in non-blocking mode, a **BlockingIOError** is raised if the data needed to be written to the raw stream but it couldn’t accept all the data without blocking.
16.2.3.2. Raw File I/O

```python
class io.FileIO(name, mode='r', closefd=True, opener=None)
```

FileIO represents an OS-level file containing bytes data. It implements the RawIOBase interface (and therefore the IOBase interface, too).

The *name* can be one of two things:

- a character string or *bytes* object representing the path to the file which will be opened;
- an integer representing the number of an existing OS-level file descriptor to which the resulting FileIO object will give access.

The *mode* can be `'r'`, `'w'`, `'x'` or `'a'` for reading (default), writing, exclusive creation or appending. The file will be created if it doesn’t exist when opened for writing or appending; it will be truncated when opened for writing. FileExistsError will be raised if it already exists when opened for creating. Opening a file for creating implies writing, so this mode behaves in a similar way to `'w'`. Add a `'+'` to the mode to allow simultaneous reading and writing.

The `read()` (when called with a positive argument), `readinto()` and `write()` methods on this class will only make one system call.

A custom opener can be used by passing a callable as *opener*. The underlying file descriptor for the file object is then obtained by calling *opener* with (*name*, *flags*). *opener* must return an open file descriptor (passing `os.open` as *opener* results in functionality
similar to passing None).

The newly created file is non-inheritable.

See the open() built-in function for examples on using the opener parameter.

*Changed in version 3.3:* The opener parameter was added. The 'x' mode was added.

*Changed in version 3.4:* The file is now non-inheritable.

In addition to the attributes and methods from IOBase and RawIOBase, FileIO provides the following data attributes:

- **mode**
  - The mode as given in the constructor.

- **name**
  - The file name. This is the file descriptor of the file when no name is given in the constructor.

### 16.2.3.3. Buffered Streams

Buffered I/O streams provide a higher-level interface to an I/O device than raw I/O does.

```python
class io.BytesIO([initial_bytes])
```

A stream implementation using an in-memory bytes buffer. It inherits BufferedIOBase.

The argument initial_bytes contains optional initial bytes data.
BytesIO provides or overrides these methods in addition to those from BufferedReader and IOBase:

**getbuffer()**

Return a readable and writable view over the contents of the buffer without copying them. Also, mutating the view will transparently update the contents of the buffer:

```python
>>> b = io.BytesIO(b"abcdef")
>>> view = b.getbuffer()
>>> view[2:4] = b"56"
>>> b.getvalue()
'b\'ab56ef'
```

*Note:* As long as the view exists, the BytesIO object cannot be resized.

*New in version 3.2.*

**getvalue()**

Return bytes containing the entire contents of the buffer.

**read1()**

In BytesIO, this is the same as read().

```python
class io.BufferedReader(raw,
buffer_size=DEFAULT_BUFFER_SIZE)
```

A buffer providing higher-level access to a readable, sequential RawIOBase object. It inherits BufferedReader. When reading data from this object, a larger amount of data may be requested from the underlying raw stream, and kept in an internal buffer. The buffered data can then be returned directly on subsequent reads.
The constructor creates a `BufferedReader` for the given readable raw stream and `buffer_size`. If `buffer_size` is omitted, `DEFAULT_BUFFER_SIZE` is used.

`BufferedReader` provides or overrides these methods in addition to those from `BufferedReader` and `IOBase`:

**`peek([size])`**  
Return bytes from the stream without advancing the position. At most one single read on the raw stream is done to satisfy the call. The number of bytes returned may be less or more than requested.

**`read([size])`**  
Read and return `size` bytes, or if `size` is not given or negative, until EOF or if the read call would block in non-blocking mode.

**`read1(size)`**  
Read and return up to `size` bytes with only one call on the raw stream. If at least one byte is buffered, only buffered bytes are returned. Otherwise, one raw stream read call is made.

```python
class io.BufferedWriter(raw,  
buffer_size=DEFAULT_BUFFER_SIZE)
```

A buffer providing higher-level access to a writeable, sequential `RawIOBase` object. It inherits `BufferedReader`. When writing to this object, data is normally placed into an internal buffer. The buffer will be written out to the underlying `RawIOBase` object under various conditions, including:

- when the buffer gets too small for all pending data;
- when `flush()` is called;
• when a seek() is requested (for BufferedRandom objects);
• when the BufferedWriter object is closed or destroyed.

The constructor creates a BufferedWriter for the given writeable raw stream. If the buffer_size is not given, it defaults to DEFAULT_BUFFER_SIZE.

BufferedWriter provides or overrides these methods in addition to those from BufferedReader and IOBase:

```python
def flush()
    Force bytes held in the buffer into the raw stream. A BlockingIOError should be raised if the raw stream blocks.

def write(b)
    Write the bytes or bytearray object, b and return the number of bytes written. When in non-blocking mode, a BlockingIOError is raised if the buffer needs to be written out but the raw stream blocks.
```

```python
class io.BufferedRandom(raw,
buffer_size=DEFAULT_BUFFER_SIZE)
A buffered interface to random access streams. It inherits BufferedReader and BufferedWriter, and further supports seek() and tell() functionality.

The constructor creates a reader and writer for a seekable raw stream, given in the first argument. If the buffer_size is omitted it defaults to DEFAULT_BUFFER_SIZE.

BufferedRandom is capable of anything BufferedReader or BufferedWriter can do.
```
class io.**BufferedReader**(reader, writer,  
*buffer_size=DEFAULT_BUFFER_SIZE*)

A buffered I/O object combining two unidirectional RawIOBase objects – one readable, the other writeable – into a single bidirectional endpoint. It inherits BufferedIOBase.

`reader` and `writer` are RawIOBase objects that are readable and writeable respectively. If the `buffer_size` is omitted it defaults to DEFAULT_BUFFER_SIZE.

BufferedReader implements all of BufferedIOBase's methods except for `detach()`, which raises UnsupportedOperation.

**Warning:** BufferedReader does not attempt to synchronize accesses to its underlying raw streams. You should not pass it the same object as reader and writer; use BufferedReader instead.

16.2.3.4. Text I/O

class io.**TextIOBase**

Base class for text streams. This class provides a character and line based interface to stream I/O. There is no `readinto()` method because Python’s character strings are immutable. It inherits IOBase. There is no public constructor.

TextIOBase provides or overrides these data attributes and methods in addition to those from IOBase:

**encoding**
The name of the encoding used to decode the stream’s bytes into strings, and to encode strings into bytes.

**errors**
The error setting of the decoder or encoder.

**newlines**
A string, a tuple of strings, or `None`, indicating the newlines translated so far. Depending on the implementation and the initial constructor flags, this may not be available.

**buffer**
The underlying binary buffer (a `BufferedIOBase` instance) that `TextIOBase` deals with. This is not part of the `TextIOBase` API and may not exist in some implementations.

**detach()**
Separate the underlying binary buffer from the `TextIOBase` and return it.

After the underlying buffer has been detached, the `TextIOBase` is in an unusable state.

Some `TextIOBase` implementations, like `StringIO`, may not have the concept of an underlying buffer and calling this method will raise `UnsupportedOperation`.

*New in version 3.1.*

**read**(size)
Read and return at most size characters from the stream as a single `str`. If size is negative or `None`, reads until EOF.
**readline**(*size*=-1)
Read until newline or EOF and return a single str. If the stream is already at EOF, an empty string is returned.

If *size* is specified, at most *size* characters will be read.

**seek**(*offset*, *whence*=SEEK_SET)
Change the stream position to the given *offset*. Behaviour depends on the *whence* parameter:

- SEEK_SET or 0: seek from the start of the stream (the default); *offset* must either be a number returned by TextIOBase.tell(), or zero. Any other *offset* value produces undefined behaviour.
- SEEK_CUR or 1: “seek” to the current position; *offset* must be zero, which is a no-operation (all other values are unsupported).
- SEEK_END or 2: seek to the end of the stream; *offset* must be zero (all other values are unsupported).

Return the new absolute position as an opaque number.

*New in version 3.1:* The SEEK_* constants.

**tell()**
Return the current stream position as an opaque number. The number does not usually represent a number of bytes in the underlying binary storage.

**write**(*s*)
Write the string *s* to the stream and return the number of characters written.

```python
class io.TextIOWrapper(buffer, encoding=None, errors=None,
```
newline=None, line_buffering=False, write_through=False)

A buffered text stream over a BufferedIOBase binary stream. It inherits TextIOBase.

encoding gives the name of the encoding that the stream will be decoded or encoded with. It defaults to locale.getpreferredencoding(False).

defaults to locale.getpreferredencoding(False).

errors is an optional string that specifies how encoding and decoding errors are to be handled. Pass 'strict' to raise a ValueError exception if there is an encoding error (the default of None has the same effect), or pass 'ignore' to ignore errors. (Note that ignoring encoding errors can lead to data loss.) 'replace' causes a replacement marker (such as '?' ) to be inserted where there is malformed data. When writing, 'xmlcharrefreplace' (replace with the appropriate XML character reference) or 'backslashreplace' (replace with backslashed escape sequences) can be used. Any other error handling name that has been registered with codecs.register_error() is also valid.

newline controls how line endings are handled. It can be None, '', '\n', '\r', and '\r\n'. It works as follows:

- When reading input from the stream, if newline is None, universal newlines mode is enabled. Lines in the input can end in '\n', '\r', or '\r\n', and these are translated into '\n' before being returned to the caller. If it is '', universal newlines mode is enabled, but line endings are returned to the caller untranslated. If it has any of the other legal values, input lines are only terminated by the given string, and the line ending is returned to the caller untranslated.
When writing output to the stream, if `newline` is `None`, any \n characters written are translated to the system default line separator, `os.linesep`. If `newline` is '' or '\n', no translation takes place. If `newline` is any of the other legal values, any \n characters written are translated to the given string.

If `line_buffering` is `True`, `flush` is implied when a call to `write` contains a newline character.

If `write_through` is `True`, calls to `write()` are guaranteed not to be buffered: any data written on the `TextIOWrapper` object is immediately handled to its underlying binary `buffer`.

*Changed in version 3.3:* The `write_through` argument has been added.

*Changed in version 3.3:* The default `encoding` is now `locale.getpreferredencoding(False)` instead of `locale.getpreferredencoding()`. Don't change temporary the locale encoding using `locale.setlocale()`, use the current locale encoding instead of the user preferred encoding.

`TextIOWrapper` provides one attribute in addition to those of `TextIOWrapper` and its parents:

**line_buffering**

Whether line buffering is enabled.

```python
class io.StringIO(initial_value='', newline='\n')
```

An in-memory stream for text I/O.

The initial value of the buffer (an empty string by default) can be set by providing `initial_value`. The `newline` argument works like that of
TextIOWrapper. The default is to consider only \n characters as end of lines and to do no newline translation.

StringIO provides this method in addition to those from TextIOWrapper and its parents:

**getvalue()**

Return a str containing the entire contents of the buffer at any time before the StringIO object's close() method is called.

Example usage:

```python
import io

output = io.StringIO()
output.write('First line.\n')
print('Second line.', file=output)

# Retrieve file contents -- this will be
# 'First line.\nSecond line.\n' contents = output.getvalue()

# Close object and discard memory buffer --
# .getvalue() will now raise an exception.
output.close()
```

class io.IncrementalNewlineDecoder

A helper codec that decodes newlines for universal newlines mode. It inherits codecs.IncrementalDecoder.
16.2.4. Performance

This section discusses the performance of the provided concrete I/O implementations.

16.2.4.1. Binary I/O

By reading and writing only large chunks of data even when the user asks for a single byte, buffered I/O hides any inefficiency in calling and executing the operating system's unbuffered I/O routines. The gain depends on the OS and the kind of I/O which is performed. For example, on some modern OSes such as Linux, unbuffered disk I/O can be as fast as buffered I/O. The bottom line, however, is that buffered I/O offers predictable performance regardless of the platform and the backing device. Therefore, it is almost always preferable to use buffered I/O rather than unbuffered I/O for binary data.

16.2.4.2. Text I/O

Text I/O over a binary storage (such as a file) is significantly slower than binary I/O over the same storage, because it requires conversions between unicode and binary data using a character codec. This can become noticeable handling huge amounts of text data like large log files. Also, TextIOWrapper.tell() and TextIOWrapper.seek() are both quite slow due to the reconstruction algorithm used.

StringIO, however, is a native in-memory unicode container and will exhibit similar speed to BytesIO.
16.2.4.3. Multi-threading

FileIO objects are thread-safe to the extent that the operating system calls (such as `read(2)` under Unix) they wrap are thread-safe too.

Binary buffered objects (instances of `BufferedReader`, `BufferedWriter`, `BufferedRandom` and `BufferedRWPair`) protect their internal structures using a lock; it is therefore safe to call them from multiple threads at once.

`TextIOWrapper` objects are not thread-safe.

16.2.4.4. Reentrancy

Binary buffered objects (instances of `BufferedReader`, `BufferedWriter`, `BufferedRandom` and `BufferedRWPair`) are not reentrant. While reentrant calls will not happen in normal situations, they can arise from doing I/O in a `signal` handler. If a thread tries to re-enter a buffered object which it is already accessing, a `RuntimeError` is raised. Note this doesn’t prohibit a different thread from entering the buffered object.

The above implicitly extends to text files, since the `open()` function will wrap a buffered object inside a `TextIOWrapper`. This includes standard streams and therefore affects the built-in function `print()` as well.
16.3. time — Time access and conversions

This module provides various time-related functions. For related functionality, see also the datetime and calendar modules.

Although this module is always available, not all functions are available on all platforms. Most of the functions defined in this module call platform C library functions with the same name. It may sometimes be helpful to consult the platform documentation, because the semantics of these functions varies among platforms.

An explanation of some terminology and conventions is in order.

- The epoch is the point where the time starts. On January 1st of that year, at 0 hours, the “time since the epoch” is zero. For Unix, the epoch is 1970. To find out what the epoch is, look at gmtime(0).

- The functions in this module may not handle dates and times before the epoch or far in the future. The cut-off point in the future is determined by the C library; for 32-bit systems, it is typically in 2038.

- Year 2000 (Y2K) issues: Python depends on the platform’s C library, which generally doesn’t have year 2000 issues, since all dates and times are represented internally as seconds since the epoch. Function strptime() can parse 2-digit years when given %y format code. When 2-digit years are parsed, they are converted according to the POSIX and ISO C standards: values 69–99 are mapped to 1969–1999, and values 0–68 are mapped to 2000–2068.
UTC is Coordinated Universal Time (formerly known as Greenwich Mean Time, or GMT). The acronym UTC is not a mistake but a compromise between English and French.

DST is Daylight Saving Time, an adjustment of the timezone by (usually) one hour during part of the year. DST rules are magic (determined by local law) and can change from year to year. The C library has a table containing the local rules (often it is read from a system file for flexibility) and is the only source of True Wisdom in this respect.

The precision of the various real-time functions may be less than suggested by the units in which their value or argument is expressed. E.g. on most Unix systems, the clock “ticks” only 50 or 100 times a second.

On the other hand, the precision of time() and sleep() is better than their Unix equivalents: times are expressed as floating point numbers, time() returns the most accurate time available (using Unix gettimeofday() where available), and sleep() will accept a time with a nonzero fraction (Unix select() is used to implement this, where available).

The time value as returned by gmtime(), localtime(), and strftime(), and accepted by asctime(), mktime() and strftime(), is a sequence of 9 integers. The return values of gmtime(), localtime(), and strftime() also offer attribute names for individual fields.

See struct_time for a description of these objects.

Changed in version 3.3: The struct_time type was extended to provide the tm_gmtoff and tm_zone attributes when platform
supports corresponding \texttt{struct tm} members.

- Use the following functions to convert between time representations:

<table>
<thead>
<tr>
<th>From</th>
<th>To</th>
<th>Use</th>
</tr>
</thead>
<tbody>
<tr>
<td>seconds since the epoch</td>
<td>\texttt{struct_time} in UTC</td>
<td>\texttt{gmtime()}</td>
</tr>
<tr>
<td>seconds since the epoch</td>
<td>\texttt{struct_time} in local time</td>
<td>\texttt{localtime()}</td>
</tr>
<tr>
<td>\texttt{struct_time} in UTC</td>
<td>seconds since the epoch</td>
<td>\texttt{calendar.timegm()}</td>
</tr>
<tr>
<td>\texttt{struct_time} in local time</td>
<td>seconds since the epoch</td>
<td>\texttt{mktime()}</td>
</tr>
</tbody>
</table>

The module defines the following functions and data items:

\texttt{time.altzone}

The offset of the local DST timezone, in seconds west of UTC, if one is defined. This is negative if the local DST timezone is east of UTC (as in Western Europe, including the UK). Only use this if \texttt{daylight} is nonzero.

\texttt{time.asctime([t])}

Convert a tuple or \texttt{struct_time} representing a time as returned by \texttt{gmtime()} or \texttt{localtime()} to a string of the following form: 'Sun Jun  20  23:21:05 1993'. If \texttt{t} is not provided, the current time as returned by \texttt{localtime()} is used. Locale information is not used by \texttt{asctime()}.

\textbf{Note}: Unlike the C function of the same name, \texttt{asctime()}
time.\texttt{clock()}

On Unix, return the current processor time as a floating point number expressed in seconds. The precision, and in fact the very definition of the meaning of “processor time”, depends on that of the C function of the same name, but in any case, this is the function to use for benchmarking Python or timing algorithms.

On Windows, this function returns wall-clock seconds elapsed since the first call to this function, as a floating point number, based on the Win32 function \texttt{QueryPerformanceCounter()}. The resolution is typically better than one microsecond.

\textit{Deprecated since version 3.3:} The behaviour of this function depends on the platform: use \texttt{perf_counter()} or \texttt{process_time()} instead, depending on your requirements, to have a well defined behaviour.

\begin{Verbatim}
\textbf{time.\texttt{clock_getres}}(\texttt{clk_id})
\end{Verbatim}

Return the resolution (precision) of the specified clock \texttt{clk_id}.

Availability: Unix.

\textit{New in version 3.3.}

\begin{Verbatim}
\textbf{time.\texttt{clock_gettime}}(\texttt{clk_id})
\end{Verbatim}

Return the time of the specified clock \texttt{clk_id}.

Availability: Unix.

\textit{New in version 3.3.}
time.\texttt{clock_settime}(\texttt{clk\_id}, \texttt{time})
Set the time of the specified clock \texttt{clk\_id}.

Availability: Unix.

\textit{New in version 3.3.}

time.\texttt{CLOCK\_HIGHRES}
The Solaris OS has a CLOCK\_HIGHRES timer that attempts to use an optimal hardware source, and may give close to nanosecond resolution. CLOCK\_HIGHRES is the nonadjustable, high-resolution clock.

Availability: Solaris.

\textit{New in version 3.3.}

time.\texttt{CLOCK\_MONOTONIC}
Clock that cannot be set and represents monotonic time since some unspecified starting point.

Availability: Unix.

\textit{New in version 3.3.}

time.\texttt{CLOCK\_MONOTONIC\_RAW}
Similar to \texttt{CLOCK\_MONOTONIC}, but provides access to a raw hardware-based time that is not subject to NTP adjustments.

Availability: Linux 2.6.28 or later.

\textit{New in version 3.3.}

time.\texttt{CLOCK\_PROCESS\_CPUTIME\_ID}
High-resolution per-process timer from the CPU.
Availability: Unix.

New in version 3.3.

time.CLOCK_REALTIME
System-wide real-time clock. Setting this clock requires appropriate privileges.

Availability: Unix.

New in version 3.3.

time.CLOCK_THREAD_CPUTIME_ID
Thread-specific CPU-time clock.

Availability: Unix.

New in version 3.3.

time.ctime([secs])
Convert a time expressed in seconds since the epoch to a string representing local time. If secs is not provided or None, the current time as returned by time() is used. ctime(secs) is equivalent to asctime(localtime(secs)). Locale information is not used by ctime().

time.daylight
Nonzero if a DST timezone is defined.

time.get_clock_info(name)
Get information on the specified clock as a namespace object. Supported clock names and the corresponding functions to read their value are:
- 'clock': time.clock()
- 'monotonic': time.monotonic()
- 'perf_counter': time.perf_counter()
- 'process_time': time.process_time()
- 'time': time.time()

The result has the following attributes:

- **adjustable**: True if the clock can be changed automatically (e.g. by a NTP daemon) or manually by the system administrator, False otherwise
- **implementation**: The name of the underlying C function used to get the clock value
- **monotonic**: True if the clock cannot go backward, False otherwise
- **resolution**: The resolution of the clock in seconds (float)

*New in version 3.3.*

time.gmtime([secs])
Convert a time expressed in seconds since the epoch to a struct_time in UTC in which the dst flag is always zero. If secs is not provided or None, the current time as returned by time() is used. Fractions of a second are ignored. See above for a description of the struct_time object. See calendar.timegm() for the inverse of this function.

time.localtime([secs])
Like gmtime() but converts to local time. If secs is not provided or None, the current time as returned by time() is used. The dst flag is set to 1 when DST applies to the given time.

time.mktime(t)
This is the inverse function of `localtime()`. Its argument is the `struct_time` or full 9-tuple (since the dst flag is needed; use `-1` as the dst flag if it is unknown) which expresses the time in local time, not UTC. It returns a floating point number, for compatibility with `time()`. If the input value cannot be represented as a valid time, either `OverflowError` or `ValueError` will be raised (which depends on whether the invalid value is caught by Python or the underlying C libraries). The earliest date for which it can generate a time is platform-dependent.

**time.**`monotonic()`

Return the value (in fractional seconds) of a monotonic clock, i.e. a clock that cannot go backwards. The clock is not affected by system clock updates. The reference point of the returned value is undefined, so that only the difference between the results of consecutive calls is valid.

On Windows versions older than Vista, `monotonic()` detects `GetTickCount()` integer overflow (32 bits, roll-over after 49.7 days). It increases an internal epoch (reference time) by $2^{32}$ each time that an overflow is detected. The epoch is stored in the process-local state and so the value of `monotonic()` may be different in two Python processes running for more than 49 days. On more recent versions of Windows and on other operating systems, `monotonic()` is system-wide.

Availability: Windows, Mac OS X, Linux, FreeBSD, OpenBSD, Solaris.

*New in version 3.3.*

**time.**`perf_counter()`
Return the value (in fractional seconds) of a performance counter, i.e. a clock with the highest available resolution to measure a short duration. It does include time elapsed during sleep and is system-wide. The reference point of the returned value is undefined, so that only the difference between the results of consecutive calls is valid.

*New in version 3.3.*

**time.process_time()**

Return the value (in fractional seconds) of the sum of the system and user CPU time of the current process. It does not include time elapsed during sleep. It is process-wide by definition. The reference point of the returned value is undefined, so that only the difference between the results of consecutive calls is valid.

*New in version 3.3.*

**time.sleep(secs)**

Suspend execution for the given number of seconds. The argument may be a floating point number to indicate a more precise sleep time. The actual suspension time may be less than that requested because any caught signal will terminate the `sleep()` following execution of that signal’s catching routine. Also, the suspension time may be longer than requested by an arbitrary amount because of the scheduling of other activity in the system.

**time.strftime(format[, t])**

Convert a tuple or `struct_time` representing a time as returned by `gmtime()` or `localtime()` to a string as specified by the `format` argument. If `t` is not provided, the current time as returned by `localtime()` is used. `format` must be a string. `ValueError`
is raised if any field in \( t \) is outside of the allowed range.

0 is a legal argument for any position in the time tuple; if it is normally illegal the value is forced to a correct one.

The following directives can be embedded in the \textit{format} string. They are shown without the optional field width and precision specification, and are replaced by the indicated characters in the \texttt{strftime()} result:

<table>
<thead>
<tr>
<th>Directive</th>
<th>Meaning</th>
<th>Notes</th>
</tr>
</thead>
<tbody>
<tr>
<td>%a</td>
<td>Locale’s abbreviated weekday name.</td>
<td></td>
</tr>
<tr>
<td>%A</td>
<td>Locale’s full weekday name.</td>
<td></td>
</tr>
<tr>
<td>%b</td>
<td>Locale’s abbreviated month name.</td>
<td></td>
</tr>
<tr>
<td>%B</td>
<td>Locale’s full month name.</td>
<td></td>
</tr>
<tr>
<td>%C</td>
<td>Locale’s appropriate date and time representation.</td>
<td></td>
</tr>
<tr>
<td>%d</td>
<td>Day of the month as a decimal number ([01,31]).</td>
<td></td>
</tr>
<tr>
<td>%H</td>
<td>Hour (24-hour clock) as a decimal number ([00,23]).</td>
<td></td>
</tr>
<tr>
<td>%I</td>
<td>Hour (12-hour clock) as a decimal number ([01,12]).</td>
<td></td>
</tr>
<tr>
<td>%j</td>
<td>Day of the year as a decimal number ([001,366]).</td>
<td></td>
</tr>
<tr>
<td>%m</td>
<td>Month as a decimal number ([01,12]).</td>
<td></td>
</tr>
<tr>
<td>%M</td>
<td>Minute as a decimal number ([00,59]).</td>
<td></td>
</tr>
<tr>
<td>%p</td>
<td>Locale’s equivalent of either AM or PM.</td>
<td>(1)</td>
</tr>
<tr>
<td>%S</td>
<td>Second as a decimal number ([00,61]).</td>
<td>(2)</td>
</tr>
<tr>
<td>Format</td>
<td>Description</td>
<td></td>
</tr>
<tr>
<td>--------</td>
<td>-------------</td>
<td></td>
</tr>
<tr>
<td>%U</td>
<td>Week number of the year (Sunday as the first day of the week) as a decimal number [00,53]. All days in a new year preceding the first Sunday are considered to be in week 0.</td>
<td></td>
</tr>
<tr>
<td>%W</td>
<td>Week number of the year (Monday as the first day of the week) as a decimal number [00,53]. All days in a new year preceding the first Monday are considered to be in week 0.</td>
<td></td>
</tr>
<tr>
<td>%x</td>
<td>Locale’s appropriate date representation.</td>
<td></td>
</tr>
<tr>
<td>%X</td>
<td>Locale’s appropriate time representation.</td>
<td></td>
</tr>
<tr>
<td>%y</td>
<td>Year without century as a decimal number [00,99].</td>
<td></td>
</tr>
<tr>
<td>%Y</td>
<td>Year with century as a decimal number.</td>
<td></td>
</tr>
<tr>
<td>%z</td>
<td>Time zone offset indicating a positive or negative time difference from UTC/GMT of the form +HHMM or -HHMM, where H represents decimal hour digits and M represents decimal minute digits [-23:59, +23:59].</td>
<td></td>
</tr>
<tr>
<td>%Z</td>
<td>Time zone name (no characters if no time zone exists).</td>
<td></td>
</tr>
<tr>
<td>%%</td>
<td>A literal '%' character.</td>
<td></td>
</tr>
</tbody>
</table>

Notes:

1. When used with the `strptime()` function, the `%p` directive only affects the output hour field if the `%I` directive is used to parse the hour.
2. The range really is 0 to 61; value 60 is valid in timestamps.
representing leap seconds and value 61 is supported for historical reasons.

3. When used with the `strptime()` function, `%U` and `%W` are only used in calculations when the day of the week and the year are specified.

Here is an example, a format for dates compatible with that specified in the RFC 2822 Internet email standard. [1]

```
>>> from time import gmtime, strftime
>>> strftime("%a, %d %b %Y %H:%M:%S +0000", gmtime)
'Thu, 28 Jun 2001 14:17:15 +0000'
```

Additional directives may be supported on certain platforms, but only the ones listed here have a meaning standardized by ANSI C. To see the full set of format codes supported on your platform, consult the `strftime(3)` documentation.

On some platforms, an optional field width and precision specification can immediately follow the initial `%' of a directive in the following order; this is also not portable. The field width is normally 2 except for `%j` where it is 3.

```
from time import strftime
```

Parse a string representing a time according to a format. The return value is a `struct_time` as returned by `gmtime()` or `localtime()`.

The `format` parameter uses the same directives as those used by `strftime()`; it defaults to "'%a %b %d %H:%M:%S %Y" which matches the formatting returned by `ctime()`. If `string` cannot be parsed according to `format`, or if it has excess data after parsing, `ValueError` is raised. The default values used to fill in any
missing data when more accurate values cannot be inferred are (1900, 1, 1, 0, 0, 0, 0, 1, -1). Both string and format must be strings.

For example:

```python
>>> import time
>>> time.strptime("30 Nov 00", "%d %b %y")
time.struct_time(tm_year=2000, tm_mon=11, tm_mday=30, tm_hour=0, tm_min=0, tm_sec=0, tm_wday=3, tm_yday=335)
```

Support for the `%Z` directive is based on the values contained in tzname and whether daylight is true. Because of this, it is platform-specific except for recognizing UTC and GMT which are always known (and are considered to be non-daylight savings timezones).

Only the directives specified in the documentation are supported. Because `strftime()` is implemented per platform it can sometimes offer more directives than those listed. But `strptime()` is independent of any platform and thus does not necessarily support all directives available that are not documented as supported.

```python
class time.struct_time
```

The type of the time value sequence returned by `gmtime()`, `localtime()`, and `strptime()`. It is an object with a `named tuple` interface: values can be accessed by index and by attribute name. The following values are present:

<table>
<thead>
<tr>
<th>Index</th>
<th>Attribute</th>
<th>Values</th>
</tr>
</thead>
<tbody>
<tr>
<td></td>
<td></td>
<td></td>
</tr>
<tr>
<td></td>
<td></td>
<td></td>
</tr>
<tr>
<td>---</td>
<td>---</td>
<td>---</td>
</tr>
<tr>
<td>0</td>
<td>tm_year</td>
<td>(for example, 1993)</td>
</tr>
<tr>
<td>1</td>
<td>tm_mon</td>
<td>range [1, 12]</td>
</tr>
<tr>
<td>2</td>
<td>tm_mday</td>
<td>range [1, 31]</td>
</tr>
<tr>
<td>3</td>
<td>tm_hour</td>
<td>range [0, 23]</td>
</tr>
<tr>
<td>4</td>
<td>tm_min</td>
<td>range [0, 59]</td>
</tr>
<tr>
<td>5</td>
<td>tm_sec</td>
<td>range [0, 61]; see (2) in strftime() description</td>
</tr>
<tr>
<td>6</td>
<td>tm_wday</td>
<td>range [0, 6], Monday is 0</td>
</tr>
<tr>
<td>7</td>
<td>tm_yday</td>
<td>range [1, 366]</td>
</tr>
<tr>
<td>8</td>
<td>tm_isdst</td>
<td>0, 1 or -1; see below</td>
</tr>
<tr>
<td>N/A</td>
<td>tm_zone</td>
<td>abbreviation of timezone name</td>
</tr>
<tr>
<td>N/A</td>
<td>tm_gmtoff</td>
<td>offset east of UTC in seconds</td>
</tr>
</tbody>
</table>

Note that unlike the C structure, the month value is a range of [1, 12], not [0, 11]. A -1 argument as the daylight savings flag, passed to mktime() will usually result in the correct daylight savings state to be filled in.

When a tuple with an incorrect length is passed to a function expecting a struct_time, or having elements of the wrong type, a TypeError is raised.

*Changed in version 3.3:* tm_gmtoff and tm_zone attributes are available on platforms with C library supporting the corresponding fields in struct tm.

**time.time()**

Return the time in seconds since the epoch as a floating point number. Note that even though the time is always returned as a floating point number, not all systems provide time with a better
precision than 1 second. While this function normally returns non-decreasing values, it can return a lower value than a previous call if the system clock has been set back between the two calls.

`time.timezone`

The offset of the local (non-DST) timezone, in seconds west of UTC (negative in most of Western Europe, positive in the US, zero in the UK).

`time.tzname`

A tuple of two strings: the first is the name of the local non-DST timezone, the second is the name of the local DST timezone. If no DST timezone is defined, the second string should not be used.

`time.tzset()`

Resets the time conversion rules used by the library routines. The environment variable TZ specifies how this is done.

Availability: Unix.

**Note:** Although in many cases, changing the TZ environment variable may affect the output of functions like `localtime()` without calling `tzset()`, this behavior should not be relied on. The TZ environment variable should contain no whitespace.

The standard format of the TZ environment variable is (whitespace added for clarity):

```
std offset [dst [offset [,start[/time], end[/time]]], end[/time]
```

Where the components are:
std and dst

Three or more alphanumerics giving the timezone abbreviations. These will be propagated into time.tzname

offset

The offset has the form: ± hh[:mm[:ss]]. This indicates the value added the local time to arrive at UTC. If preceded by a '-', the timezone is east of the Prime Meridian; otherwise, it is west. If no offset follows dst, summer time is assumed to be one hour ahead of standard time.

start[/time], end[/time]

Indicates when to change to and back from DST. The format of the start and end dates are one of the following:

Jn

The Julian day $n$ ($1 \leq n \leq 365$). Leap days are not counted, so in all years February 28 is day 59 and March 1 is day 60.

$n$

The zero-based Julian day ($0 \leq n \leq 365$). Leap days are counted, and it is possible to refer to February 29.

Mm.n.d

The $d$'th day ($0 \leq d \leq 6$) or week $n$ of month $m$ of the year ($1 \leq n \leq 5$, $1 \leq m \leq 12$, where week 5 means “the last $d$ day in month $m$” which may occur in either the fourth or the fifth week). Week 1 is the first week in which the $d$'th day occurs. Day zero is Sunday.

time has the same format as offset except that no leading sign (‘-‘ or ‘+’) is allowed. The default, if time is not given, is 02:00:00.

```python
>>> os.environ['TZ'] = 'EST+05EDT,M4.1.0,M10.5.0'
```
On many Unix systems (including *BSD, Linux, Solaris, and Darwin), it is more convenient to use the system's zoneinfo (tzfile(5)) database to specify the timezone rules. To do this, set the TZ environment variable to the path of the required timezone datafile, relative to the root of the systems `zoneinfo` timezone database, usually located at `/usr/share/zoneinfo`. For example, 'US/Eastern', 'Australia/Melbourne', 'Egypt' or 'Europe/Amsterdam'.

See also:

**Module datetime**
More object-oriented interface to dates and times.

**Module locale**
Internationalization services. The locale setting affects the interpretation of many format specifiers in `strftime()` and
Module calendar

General calendar-related functions. `timegm()` is the inverse of `gmtime()` from this module.

Footnotes

The use of `%Z` is now deprecated, but the `%z` escape that expands to the preferred hour/minute offset is not supported by all ANSI C libraries. Also, a strict reading of the original 1982 RFC 822 standard calls for a two-digit year (%y rather than %Y), but practice moved to 4-digit years long before the year 2000. After that, RFC 822 became obsolete and the 4-digit year has been first recommended by RFC 1123 and then mandated by RFC 2822.

[1]
16.4. argparse — Parser for command-line options, arguments and sub-commands

New in version 3.2.

Source code: Lib/argparse.py

The argparse module makes it easy to write user-friendly command-line interfaces. The program defines what arguments it requires, and argparse will figure out how to parse those out of sys.argv. The argparse module also automatically generates help and usage messages and issues errors when users give the program invalid arguments.

Tutorial

This page contains the API reference information. For a more gentle introduction to Python command-line parsing, have a look at the argparse tutorial.
16.4.1. Example

The following code is a Python program that takes a list of integers and produces either the sum or the max:

```python
import argparse

parser = argparse.ArgumentParser(description='Process some integers.
help='an integer for the accumulator

parser.add_argument('integers', metavar='N', type=int,
help='an integer for the accumulator

parser.add_argument('--sum', dest='accumulate',
const=sum, default=max,
help='sum the integers (default: find the max)

args = parser.parse_args()
print(args.accumulate(args.integers))
```

Assuming the Python code above is saved into a file called `prog.py`, it can be run at the command line and provides useful help messages:

```
$ python prog.py -h
usage: prog.py [-h] [--sum] N [N ...]

Process some integers.

positional arguments:
  N  an integer for the accumulator

optional arguments:
  -h, --help  show this help message and exit
  --sum  sum the integers (default: find the max)
```

When run with the appropriate arguments, it prints either the sum or
the max of the command-line integers:

```
$ python prog.py 1 2 3 4
4
$ python prog.py 1 2 3 4 --sum
10
```

If invalid arguments are passed in, it will issue an error:

```
$ python prog.py a b c
usage: prog.py [-h] [--sum] N [N ...]
prog.py: error: argument N: invalid int value: 'a'
```

The following sections walk you through this example.

### 16.4.1.1. Creating a parser

The first step in using the `argparse` is creating an `ArgumentParser` object:

```
>>> parser = argparse.ArgumentParser(description='Process some integers.'

```

The `ArgumentParser` object will hold all the information necessary to parse the command line into Python data types.

### 16.4.1.2. Adding arguments

Filling an `ArgumentParser` with information about program arguments is done by making calls to the `add_argument()` method. Generally, these calls tell the `ArgumentParser` how to take the strings on the command line and turn them into objects. This
information is stored and used when `parse_args()` is called. For example:

```python
>>> parser.add_argument('integers', metavar='N', type=int,
... help='an integer for the accumulator')
>>> parser.add_argument('--sum', dest='accumulate',
... const=sum, default=max,
... help='sum the integers (default: find the max)')
```

Later, calling `parse_args()` will return an object with two attributes, `integers` and `accumulate`. The `integers` attribute will be a list of one or more ints, and the `accumulate` attribute will be either the `sum()` function, if `--sum` was specified at the command line, or the `max()` function if it was not.

### 16.4.1.3. Parsing arguments

`ArgumentParser` parses arguments through the `parse_args()` method. This will inspect the command line, convert each argument to the appropriate type and then invoke the appropriate action. In most cases, this means a simple `Namespace` object will be built up from attributes parsed out of the command line:

```python
>>> parser.parse_args(['--sum', '7', '-1', '42'])
Namespace(accumulate=<built-in function sum>, integers=[7, -1, 42])
```

In a script, `parse_args()` will typically be called with no arguments, and the `ArgumentParser` will automatically determine the command-line arguments from `sys.argv`. 
16.4.2. ArgumentParser objects

class argparse.ArgumentParser(prog=None, usage=None,
description=None, epilog=None, parents=[],
formatter_class=argparse.HelpFormatter, prefix_chars='-',
fromfile_prefix_chars=None, argument_default=None,
conflict_handler='error', add_help=True)

Create a new ArgumentParser object. All parameters should be passed as keyword arguments. Each parameter has its own more detailed description below, but in short they are:

- **prog** - The name of the program (default: `sys.argv[0]`)
- **usage** - The string describing the program usage (default: generated from arguments added to parser)
- **description** - Text to display before the argument help (default: none)
- **epilog** - Text to display after the argument help (default: none)
- **parents** - A list of ArgumentParser objects whose arguments should also be included
- **formatter_class** - A class for customizing the help output
- **prefix_chars** - The set of characters that prefix optional arguments (default: ‘-‘)
- **fromfile_prefix_chars** - The set of characters that prefix files from which additional arguments should be read (default: `None`)
- **argument_default** - The global default value for arguments (default: `None`)
- **conflict_handler** - The strategy for resolving conflicting optionals (usually unnecessary)
- **add_help** - Add a -h/--help option to the parser (default: `True`)

The following sections describe how each of these are used.
16.4.2.1. prog

By default, ArgumentParser objects uses sys.argv[0] to determine how to display the name of the program in help messages. This default is almost always desirable because it will make the help messages match how the program was invoked on the command line. For example, consider a file named myprogram.py with the following code:

```python
import argparse
parser = argparse.ArgumentParser()
parser.add_argument('--foo', help='foo help')
args = parser.parse_args()
```

The help for this program will display myprogram.py as the program name (regardless of where the program was invoked from):

```bash
$ python myprogram.py --help
usage: myprogram.py [-h] [--foo FOO]

optional arguments:
  -h, --help    show this help message and exit
  --foo FOO     foo help
$ cd ..
$ python subdir\myprogram.py --help
usage: myprogram.py [-h] [--foo FOO]

optional arguments:
  -h, --help    show this help message and exit
  --foo FOO     foo help
```

To change this default behavior, another value can be supplied using the prog= argument to ArgumentParser:
Note that the program name, whether determined from `sys.argv[0]` or from the `prog=` argument, is available to help messages using the `%(prog)s` format specifier.

16.4.2.2. usage

By default, `ArgumentParser` calculates the usage message from the arguments it contains:

```python
>>> parser = argparse.ArgumentParser(prog='myprogram')
>>> parser.print_help()
usage: myprogram [-h]

optional arguments:
 -h, --help    show this help message and exit
```

```python
>>> parser.add_argument('--foo', help='foo of the %prog program')
>>> parser.print_help()
usage: myprogram [-h] [--foo FOO]

optional arguments:
 -h, --help    show this help message and exit
 --foo FOO     foo of the myprogram program
```

```python
>>> parser = argparse.ArgumentParser(prog='PROG')
>>> parser.add_argument('--foo', nargs='?', help='foo of the %prog')
>>> parser.add_argument('bar', nargs='+', help='bar help')
>>> parser.print_help()
usage: PROG [-h] [--foo [F00]] bar [bar ...]

positional arguments:
 bar     bar help
```
optional arguments:
   -h, --help     show this help message and exit
   --foo [FOO]    foo help

The default message can be overridden with the `usage=` keyword argument:

```python
>>> parser = argparse.ArgumentParser(prog='PROG', usage='%(prog)s [options]

>>> parser.add_argument('--foo', nargs='?', help='foo help')
>>> parser.add_argument('bar', nargs='+', help='bar help')

>>> parser.print_help()
usage: PROG [options]

positional arguments:
   bar               bar help

optional arguments:
   -h, --help     show this help message and exit
   --foo [FOO]    foo help
```

The `%(prog)s` format specifier is available to fill in the program name in your usage messages.

### 16.4.2.3. description

Most calls to the `ArgumentParser` constructor will use the `description=` keyword argument. This argument gives a brief description of what the program does and how it works. In help messages, the description is displayed between the command-line usage string and the help messages for the various arguments:

```python
>>> parser = argparse.ArgumentParser(description='A foo that bars'
```
A foo that bars

optional arguments:
   -h, --help   show this help message and exit

And that's how you'd foo a bar

As with the description argument, the epilog= text is by default line-wrapped, but this behavior can be adjusted with the formatter_class argument to ArgumentParser.
16.4.2.5. parents

Sometimes, several parsers share a common set of arguments. Rather than repeating the definitions of these arguments, a single parser with all the shared arguments and passed to `parents=` argument to `ArgumentParser` can be used. The `parents=` argument takes a list of `ArgumentParser` objects, collects all the positional and optional actions from them, and adds these actions to the `ArgumentParser` object being constructed:

```python
>>> parent_parser = argparse.ArgumentParser(add_help=True)
>>> parent_parser.add_argument('--parent', type=int)

>>> foo_parser = argparse.ArgumentParser(parents=[parent_parser])
>>> foo_parser.add_argument('foo')
>>> foo_parser.parse_args(['--parent', '2', 'XXX'])
Namespace(foo='XXX', parent=2)

>>> bar_parser = argparse.ArgumentParser(parents=[parent_parser])
>>> bar_parser.add_argument('--bar')
>>> bar_parser.parse_args(['--bar', 'YYY'])
Namespace(bar='YYY', parent=None)
```

Note that most parent parsers will specify `add_help=False`. Otherwise, the `ArgumentParser` will see two `-h/--help` options (one in the parent and one in the child) and raise an error.

**Note:** You must fully initialize the parsers before passing them via `parents=`. If you change the parent parsers after the child parser, those changes will not be reflected in the child.

16.4.2.6. formatter_class
**ArgumentParser** objects allow the help formatting to be customized by specifying an alternate formatting class. Currently, there are four such classes:

```python
class argparse.RawDescriptionHelpFormatter
class argparse.RawTextHelpFormatter
class argparse.ArgumentDefaultsHelpFormatter
class argparse.MetavarTypeHelpFormatter
```

`RawDescriptionHelpFormatter` and `RawTextHelpFormatter` give more control over how textual descriptions are displayed. By default, `ArgumentParser` objects line-wrap the description and epilog texts in command-line help messages:

```python
>>> parser = argparse.ArgumentParser(
...   prog='PROG',
...   description='''this description
was indented weird
but that is okay''',
...   epilog='''
likewise for this epilog whose whitespace will be cleaned up and whose words will be wrapped across a couple lines'''
)
>>> parser.print_help()
usage: PROG [-h]

this description was indented weird but that is okay

optional arguments:
   -h, --help   show this help message and exit

likewise for this epilog whose whitespace will be cleaned up and whose words will be wrapped across a couple lines
```
Passing `RawDescriptionHelpFormatter` as `formatter_class=` indicates that `description` and `epilog` are already correctly formatted and should not be line-wrapped:

```python
>>> parser = argparse.ArgumentParser(
...     prog='PROG',
...     formatter_class=argparse.RawDescriptionHelpFormatter,
...     description=textwrap.dedent('''
...     Please do not mess up this text!
...     --------------------------------
...     I have indented it exactly the way I want it
...     '''),
... )
>>> parser.print_help()
usage: PROG [-h]

Please do not mess up this text!
--------------------------------
I have indented it exactly the way I want it

optional arguments:
-h, --help   show this help message and exit
```

`RawTextHelpFormatter` maintains whitespace for all sorts of help text, including argument descriptions.

`ArgumentDefaultsHelpFormatter` automatically adds information about default values to each of the argument help messages:

```python
>>> parser = argparse.ArgumentParser(
...     prog='PROG',
...     formatter_class=argparse.ArgumentDefaultsHelpFormatter,
... )
```
>>> parser.add_argument('--foo', type=int, default=42)
>>> parser.add_argument('bar', nargs='*', default=[1, 2, 3])
>>> parser.print_help()
usage: PROG [-h] [--foo FOO] [bar [bar ...]]

positional arguments:
  bar               BAR! (default: [1, 2, 3])

optional arguments:
  -h, --help       show this help message and exit
  --foo FOO        FOO! (default: 42)

`MetavarTypeHelpFormatter` uses the name of the `type` argument for each argument as the display name for its values (rather than using the `dest` as the regular formatter does):

```python
>>> parser = argparse.ArgumentParser(
...     prog='PROG',
...     formatter_class=argparse.MetavarTypeHelpFormatter
>>> parser.add_argument('--foo', type=int)
>>> parser.add_argument('bar', type=float)
>>> parser.print_help()
usage: PROG [-h] [--foo int] float

positional arguments:
  float

optional arguments:
  -h, --help       show this help message and exit
  --foo int
```

### 16.4.2.7. prefix_chars

Most command-line options will use `-` as the prefix, e.g. `-f/--foo`. 
Parsers that need to support different or additional prefix characters, e.g. for options like `+f` or `/foo`, may specify them using the `prefix_chars=` argument to the `ArgumentParser` constructor:

```python
g>>> parser = argparse.ArgumentParser(prog='PROG', prefix_chars='-')
g>>> parser.add_argument('+f')
g>>> parser.add_argument('++bar')
g>>> parser.parse_args('+f X ++bar Y'.split())
Namespace(bar='Y', f='X')
```

The `prefix_chars=` argument defaults to `'-` . Supplying a set of characters that does not include `-` will cause `-f/--foo` options to be disallowed.

### 16.4.2.8. fromfile_prefix_chars

Sometimes, for example when dealing with a particularly long argument lists, it may make sense to keep the list of arguments in a file rather than typing it out at the command line. If the `fromfile_prefix_chars=` argument is given to the `ArgumentParser` constructor, then arguments that start with any of the specified characters will be treated as files, and will be replaced by the arguments they contain. For example:

```python
g>>> with open('args.txt', 'w') as fp:
...     fp.write('-f\nbar')
g>>> parser = argparse.ArgumentParser(fromfile_prefix_chars='-')
g>>> parser.add_argument('-f')

>>> parser.parse_args(['-f', 'foo', '@args.txt'])
Namespace(f='bar')
```

Arguments read from a file must by default be one per line (but see
also `convert_arg_line_to_args()`) and are treated as if they were in the same place as the original file referencing argument on the command line. So in the example above, the expression `['-f', 'foo', '@args.txt']` is considered equivalent to the expression `['-f', 'foo', '-f', 'bar']`.

The `fromfile_prefix_chars=` argument defaults to `None`, meaning that arguments will never be treated as file references.

### 16.4.2.9. argument_default

Generally, argument defaults are specified either by passing a default to `add_argument()` or by calling the `set_defaults()` methods with a specific set of name-value pairs. Sometimes however, it may be useful to specify a single parser-wide default for arguments. This can be accomplished by passing the `argument_default=` keyword argument to `ArgumentParser`. For example, to globally suppress attribute creation on `parse_args()` calls, we supply `argument_default=SUPPRESS`:

```python
>>> parser = argparse.ArgumentParser(argument_default=None)
>>> parser.add_argument('--foo')
>>> parser.add_argument('bar', nargs='?')
>>> parser.parse_args(['--foo', 'BAR'])
Namespace(bar='BAR', foo='1')
>>> parser.parse_args([])
Namespace()
```

### 16.4.2.10. conflict_handler

`ArgumentParser` objects do not allow two actions with the same
option string. By default, `ArgumentParser` objects raises an exception if an attempt is made to create an argument with an option string that is already in use:

```python
>>> parser = argparse.ArgumentParser(prog='PROG')
>>> parser.add_argument('-f', '--foo', help='old foo help')
>>> parser.add_argument('--foo', help='new foo help')
Traceback (most recent call last):
  ... ArgumentsError: argument --foo: conflicting option string(s):
```

```
Sometimes (e.g. when using parents) it may be useful to simply override any older arguments with the same option string. To get this behavior, the value `'resolve'` can be supplied to the `conflict_handler=` argument of `ArgumentParser`:

```python
>>> parser = argparse.ArgumentParser(prog='PROG', conflict_handler='resolve')
>>> parser.add_argument('-f', '--foo', help='old foo help')
>>> parser.add_argument('--foo', help='new foo help')
>>> parser.print_help()
usage: PROG [-h] [-f FOO] [--foo FOO]
optional arguments:
  -h, --help    show this help message and exit
  -f FOO        old foo help
  --foo FOO     new foo help
```

Note that `ArgumentParser` objects only remove an action if all of its option strings are overridden. So, in the example above, the old `--foo` action is retained as the `-f` action, because only the `--foo` option string was overridden.
16.4.2.11. add_help

By default, ArgumentParser objects add an option which simply displays the parser's help message. For example, consider a file named `myprogram.py` containing the following code:

```python
import argparse
parser = argparse.ArgumentParser()
parser.add_argument('--foo', help='foo help')
args = parser.parse_args()
```

If `-h` or `--help` is supplied at the command line, the ArgumentParser help will be printed:

```
$ python myprogram.py --help
usage: myprogram.py [-h] [--foo FOO]

optional arguments:
  -h, --help    show this help message and exit
  --foo FOO     foo help
```

Occasionally, it may be useful to disable the addition of this help option. This can be achieved by passing `False` as the `add_help` argument to `ArgumentParser`:

```python
>>> parser = argparse.ArgumentParser(prog='PROG', add_help=False)
>>> parser.add_argument('--foo', help='foo help')
>>> parser.print_help()
usage: PROG [-h]

optional arguments:
  --foo FOO  foo help
```
The help option is typically `-h/--help`. The exception to this is if the `prefix_chars=` is specified and does not include `-`, in which case `-h` and `--help` are not valid options. In this case, the first character in `prefix_chars` is used to prefix the help options:

```python
>>> parser = argparse.ArgumentParser(prog='PROG', prefix_chars='-h')
>>> parser.print_help()
usage: PROG [+h]

optional arguments:
  +h, ++help  show this help message and exit
```
16.4.3. The add_argument() method

```python
ArgumentParser.add_argument(name or flags..., action=[], nargs=[], const=[], default=[], type=[], choices=[], required=[], help=[], metavar=[], dest)
```

Define how a single command-line argument should be parsed. Each parameter has its own more detailed description below, but in short they are:

- **name or flags** - Either a name or a list of option strings, e.g. `foo` or `-f, --foo`.
- **action** - The basic type of action to be taken when this argument is encountered at the command line.
- **nargs** - The number of command-line arguments that should be consumed.
- **const** - A constant value required by some `action` and `nargs` selections.
- **default** - The value produced if the argument is absent from the command line.
- **type** - The type to which the command-line argument should be converted.
- **choices** - A container of the allowable values for the argument.
- **required** - Whether or not the command-line option may be omitted (optionals only).
- **help** - A brief description of what the argument does.
- **metavar** - A name for the argument in usage messages.
- **dest** - The name of the attribute to be added to the object returned by `parse_args()`.

The following sections describe how each of these are used.

16.4.3.1. name or flags
The `add_argument()` method must know whether an optional argument, like `-f` or `--foo`, or a positional argument, like a list of filenames, is expected. The first arguments passed to `add_argument()` must therefore be either a series of flags, or a simple argument name. For example, an optional argument could be created like:

```python
>>> parser.add_argument('-f', '--foo')
```

while a positional argument could be created like:

```python
>>> parser.add_argument('bar')
```

When `parse_args()` is called, optional arguments will be identified by the `-` prefix, and the remaining arguments will be assumed to be positional:

```python
>>> parser = argparse.ArgumentParser(prog='PROG')
>>> parser.add_argument('-f', '--foo')
>>> parser.add_argument('bar')
>>> parser.parse_args(['BAR'])
Namespace(bar='BAR', foo=None)
>>> parser.parse_args(['BAR', '--foo', 'FOO'])
Namespace(bar='BAR', foo='FOO')
>>> parser.parse_args(['--foo', 'FOO'])
usage: PROG [-h] [-f FOO] bar
PROG: error: too few arguments
```

16.4.3.2. action

`ArgumentParser` objects associate command-line arguments with actions. These actions can do just about anything with the command-
line arguments associated with them, though most actions simply add an attribute to the object returned by `parse_args()`. The `action` keyword argument specifies how the command-line arguments should be handled. The supported actions are:

- **'store'** - This just stores the argument's value. This is the default action. For example:

  ```python
  >>> parser = argparse.ArgumentParser()
  >>> parser.add_argument('--foo')
  >>> parser.parse_args('--foo 1'.split())
  Namespace(foo='1')
  ```

- **'store_const'** - This stores the value specified by the `const` keyword argument. (Note that the `const` keyword argument defaults to the rather unhelpful `None`.) The `store_const` action is most commonly used with optional arguments that specify some sort of flag. For example:

  ```python
  >>> parser = argparse.ArgumentParser()
  >>> parser.add_argument('--foo', action='store_const')
  >>> parser.parse_args('--foo'.split())
  Namespace(foo=42)
  ```

- **'store_true'** and **'store_false'** - These store the values `True` and `False` respectively. These are special cases of `store_const`. For example:

  ```python
  >>> parser = argparse.ArgumentParser()
  >>> parser.add_argument('--foo', action='store_true')
  >>> parser.add_argument('--bar', action='store_false')
  >>> parser.parse_args('--foo --bar'.split())
  Namespace(bar=False, foo=True)
  ```
'append' - This stores a list, and appends each argument value to the list. This is useful to allow an option to be specified multiple times. Example usage:

```python
>>> parser = argparse.ArgumentParser()
>>> parser.add_argument('--foo', action='append')
>>> parser.parse_args('--foo 1 --foo 2'.split())
Namespace(foo=['1', '2'])
```

'append_const' - This stores a list, and appends the value specified by the `const` keyword argument to the list. (Note that the `const` keyword argument defaults to `None`.) The 'append_const' action is typically useful when multiple arguments need to store constants to the same list. For example:

```python
>>> parser = argparse.ArgumentParser()
>>> parser.add_argument('--str', dest='types', action='append_const')
>>> parser.add_argument('--int', dest='types', action='append_const')
>>> parser.parse_args('--str --int'.split())
Namespace(types=[<class 'str'>, <class 'int'>])
```

'count' - This counts the number of times a keyword argument occurs. For example, this is useful for increasing verbosity levels:

```python
>>> parser = argparse.ArgumentParser()
>>> parser.add_argument('--verbose', '-v', action='count')
>>> parser.parse_args('--vvv'.split())
Namespace(verbose=3)
```

'help' - This prints a complete help message for all the options in the current parser and then exits. By default a help action is
automatically added to the parser. See ArgumentParser for details of how the output is created.

- `'version'` - This expects a version= keyword argument in the add_argument() call, and prints version information and exits when invoked:

```python
>>> import argparse
>>> parser = argparse.ArgumentParser(prog='PROG')
>>> parser.add_argument('--version', action='version')
>>> parser.parse_args(['--version'])
PROG 2.0
```

You can also specify an arbitrary action by passing an object that implements the Action API. The easiest way to do this is to extend argparse.Action, supplying an appropriate __call__ method. The __call__ method should accept four parameters:

- `parser` - The ArgumentParser object which contains this action.
- `namespace` - The Namespace object that will be returned by parse_args(). Most actions add an attribute to this object.
- `values` - The associated command-line arguments, with any type conversions applied. (Type conversions are specified with the type keyword argument to add_argument().)
- `option_string` - The option string that was used to invoke this action. The option_string argument is optional, and will be absent if the action is associated with a positional argument.

An example of a custom action:

```python
>>> class FooAction(argparse.Action):
...     def __call__(self, parser, namespace, values, option_string=None):
...         print('%r %r %r' % (namespace, values, option_string))
```
16.4.3.3. nargs

ArgumentParser objects usually associate a single command-line argument with a single action to be taken. The nargs keyword argument associates a different number of command-line arguments with a single action. The supported values are:

- N (an integer). N arguments from the command line will be gathered together into a list. For example:

```python
>>> parser = argparse.ArgumentParser()
>>> parser.add_argument('--foo', nargs=2)
>>> parser.add_argument('bar', nargs=1)
>>> parser.parse_args('c --foo a b'.split())
Namespace(bar=['c'], foo=['a', 'b'])
```

Note that nargs=1 produces a list of one item. This is different from the default, in which the item is produced by itself.

- '?'. One argument will be consumed from the command line if possible, and produced as a single item. If no command-line argument is present, the value from default will be produced. Note
that for optional arguments, there is an additional case - the option string is present but not followed by a command-line argument. In this case the value from `const` will be produced. Some examples to illustrate this:

```python
>>> parser = argparse.ArgumentParser()
>>> parser.add_argument('--foo', nargs='?', const='bar', default='XX --foo YY'.split())
>>> parser.add_argument('bar', nargs='?', default='c')
>>> parser.parse_args('XX --foo YY'.split())
Namespace(bar='XX', foo='YY')
>>> parser.parse_args('XX --foo'.split())
Namespace(bar='XX', foo='c')
>>> parser.parse_args('').split())
Namespace(bar='d', foo='d')
```

One of the more common uses of `nargs='?'` is to allow optional input and output files:

```python
>>> parser = argparse.ArgumentParser()
>>> parser.add_argument('infile', nargs='?', type=..., default=sys.stdin)
... parser.add_argument('outfile', nargs='?', type=..., default=sys.stdout)
>>> parser.parse_args(['input.txt', 'output.txt'])
Namespace(infile=<_io.TextIOWrapper name='input.txt' encoding='UTF-8'>, outfile=<_io.TextIOWrapper name='output.txt' encoding='UTF-8'>)
>>> parser.parse_args([])
Namespace(infile=<_io.TextIOWrapper name='<stdin>' encoding='UTF-8'>, outfile=<_io.TextIOWrapper name='<stdout>' encoding='UTF-8'>)
```

- `'*'`. All command-line arguments present are gathered into a list.
  Note that it generally doesn’t make much sense to have more than one positional argument with `nargs='*'`, but multiple...
optional arguments with `nargs='*'` is possible. For example:

```python
>>> parser = argparse.ArgumentParser()
>>> parser.add_argument('--foo', nargs='*')
>>> parser.add_argument('--bar', nargs='*')
>>> parser.add_argument('baz', nargs='*')
>>> parser.parse_args('a b --foo x y --bar 1 2'.split())
Namespace(bar=['1', '2'], baz=['a', 'b'], foo=['x', 'y'])
```

- `'+'`. Just like `'*'`, all command-line args present are gathered into a list. Additionally, an error message will be generated if there wasn't at least one command-line argument present. For example:

```python
>>> parser = argparse.ArgumentParser(prog='PROG')
>>> parser.add_argument('foo', nargs='+')
>>> parser.parse_args('a b'.split())
Namespace(foo=['a', 'b'])
```

```python
>>> parser.parse_args('').split())
usage: PROG [-h] foo [foo ...]
PROG: error: too few arguments
```

- `argparse.REMAINDER` All the remaining command-line arguments are gathered into a list. This is commonly useful for command line utilities that dispatch to other command line utilities:

```python
>>> parser = argparse.ArgumentParser(prog='PROG')
>>> parser.add_argument('--foo')
>>> parser.add_argument('command')
>>> parser.add_argument('args', nargs=argparse.REMAINDER)
>>> print(parser.parse_args('--foo B cmd --arg1 XX ZZ'.split()))
Namespace(args=['--arg1', 'XX', 'ZZ'], command='cmd')
```
If the `nargs` keyword argument is not provided, the number of arguments consumed is determined by the `action`. Generally this means a single command-line argument will be consumed and a single item (not a list) will be produced.

### 16.4.3.4. const

The `const` argument of `add_argument()` is used to hold constant values that are not read from the command line but are required for the various `ArgumentParser` actions. The two most common uses of it are:

- When `add_argument()` is called with `action='store_const'` or `action='append_const'`. These actions add the `const` value to one of the attributes of the object returned by `parse_args()`. See the `action` description for examples.
- When `add_argument()` is called with option strings (like `-f` or `--foo`) and `nargs='?'`. This creates an optional argument that can be followed by zero or one command-line arguments. When parsing the command line, if the option string is encountered with no command-line argument following it, the value of `const` will be assumed instead. See the `nargs` description for examples.

The `const` keyword argument defaults to `None`.

### 16.4.3.5. default

All optional arguments and some positional arguments may be omitted at the command line. The `default` keyword argument of `add_argument()`, whose value defaults to `None`, specifies what value should be used if the command-line argument is not present. For
optional arguments, the `default` value is used when the option string was not present at the command line:

```python
>>> parser = argparse.ArgumentParser()
>>> parser.add_argument('--foo', default=42)
>>> parser.parse_args('--foo 2'.split())
Namespace(foo='2')
>>> parser.parse_args('').split())
Namespace(foo=42)
```

If the `default` value is a string, the parser parses the value as if it were a command-line argument. In particular, the parser applies any `type` conversion argument, if provided, before setting the attribute on the `Namespace` return value. Otherwise, the parser uses the value as is:

```python
>>> parser = argparse.ArgumentParser()
>>> parser.add_argument('--length', default='10', type=int)
>>> parser.add_argument('--width', default=10.5, type=float)
>>> parser.parse_args()
Namespace(length=10, width=10.5)
```

For positional arguments with `nargs` equal to `?` or `*`, the `default` value is used when no command-line argument was present:

```python
>>> parser = argparse.ArgumentParser()
>>> parser.add_argument('foo', nargs='?', default=42)
>>> parser.parse_args('a'.split())
Namespace(foo='a')
>>> parser.parse_args('').split())
Namespace(foo=42)
```

Providing `default=argparse.SUPPRESS` causes no attribute to be
added if the command-line argument was not present:

```python
>>> parser = argparse.ArgumentParser()
>>> parser.add_argument('--foo', default=argparse.SUPPRESS)
>>> parser.parse_args([])
Namespace()
>>> parser.parse_args(['--foo', '1'])
Namespace(foo='1')
```

16.4.3.6. type

By default, `ArgumentParser` objects read command-line arguments in as simple strings. However, quite often the command-line string should instead be interpreted as another type, like a `float` or `int`. The `type` keyword argument of `add_argument()` allows any necessary type-checking and type conversions to be performed. Common built-in types and functions can be used directly as the value of the `type` argument:

```python
>>> parser = argparse.ArgumentParser()
>>> parser.add_argument('foo', type=int)
>>> parser.add_argument('bar', type=open)
>>> parser.parse_args(['2 temp.txt'.split()])
Namespace(bar=<_io.TextIOWrapper name='temp.txt' mode='r' encoding='UTF-8'>, foo=2)
```

See the section on the `default` keyword argument for information on when the `type` argument is applied to default arguments.

To ease the use of various types of files, the `argparse` module provides the factory `FileType` which takes the `mode=`, `bufsize=`, `encoding=` and `errors=` arguments of the `open()` function. For example, `FileType('w')` can be used to create a writable file:
type= can take any callable that takes a single string argument and
returns the converted value:

```python
>>> def perfect_square(string):
...     value = int(string)
...     sqrt = math.sqrt(value)
...     if sqrt != int(sqrt):
...         msg = "%r is not a perfect square" % string
...         raise argparse.ArgumentTypeError(msg)
...     return value
...```

The choices keyword argument may be more convenient for type
checkers that simply check against a range of values:

```python
>>> parser = argparse.ArgumentParser(prog='PROG')
>>> parser.add_argument('foo', type=int, choices=range(10))
>>> parser.parse_args('7'.split())
Namespace(foo=7)
>>>
>>> parser.parse_args('11'.split())
usage: PROG [-h] {5,6,7,8,9}
PROG: error: argument foo: invalid choice: 11 (choose from 5, 6, 7, 8, 9)
```
See the *choices* section for more details.

### 16.4.3.7. choices

Some command-line arguments should be selected from a restricted set of values. These can be handled by passing a container object as the *choices* keyword argument to `add_argument()`. When the command line is parsed, argument values will be checked, and an error message will be displayed if the argument was not one of the acceptable values:

```python
>>> parser = argparse.ArgumentParser(prog='game.py')
>>> parser.add_argument('move', choices=['rock', 'paper'])
>>> parser.parse_args(['rock'])
Namespace(move='rock')
>>> parser.parse_args(['fire'])
usage: game.py [-h] {rock,paper,scissors}
game.py: error: argument move: invalid choice: 'fire' (choose from 'rock', 'paper', 'scissors')
```

Note that inclusion in the *choices* container is checked after any *type* conversions have been performed, so the type of the objects in the *choices* container should match the *type* specified:

```python
>>> parser = argparse.ArgumentParser(prog='doors.py')
>>> parser.add_argument('door', type=int, choices=range(4))
>>> print(parser.parse_args(['3']))
Namespace(door=3)
>>> parser.parse_args(['4'])
usage: doors.py [-h] {1,2,3}
doors.py: error: argument door: invalid choice: 4 (choose from 1, 2, 3)
```
Any object that supports the `in` operator can be passed as the `choices` value, so `dict` objects, `set` objects, custom containers, etc. are all supported.

### 16.4.3.8. required

In general, the `argparse` module assumes that flags like `-f` and `--bar` indicate *optional* arguments, which can always be omitted at the command line. To make an option *required*, `True` can be specified for the `required=` keyword argument to `add_argument()`:

```python
>>> parser = argparse.ArgumentParser()
>>> parser.add_argument('--foo', required=True)
>>> parser.parse_args(['--foo', 'BAR'])
Namespace(foo='BAR')
>>> parser.parse_args([])
usage: argparse.py [-h] [--foo FOO]
argparse.py: error: option --foo is required
```

As the example shows, if an option is marked as *required*, `parse_args()` will report an error if that option is not present at the command line.

**Note:** Required options are generally considered bad form because users expect *options* to be *optional*, and thus they should be avoided when possible.

### 16.4.3.9. help

The `help` value is a string containing a brief description of the argument. When a user requests help (usually by using `-h` or `--help` at the command line), these `help` descriptions will be displayed with
each argument:

```python
>>> parser = argparse.ArgumentParser(prog='frobble')
>>> parser.add_argument('--foo', action='store_true',
...    help='foo the bars before fribbling')
>>> parser.add_argument('bar', nargs='+',
...    help='one of the bars to be fribbled')
>>> parser.parse_args('-h'.split())
usage: frobble [-h] [--foo] bar [bar ...]

positional arguments:
  bar     one of the bars to be fribbled

optional arguments:
  -h, --help  show this help message and exit
  --foo      foo the bars before fribbling
```

The `help` strings can include various format specifiers to avoid repetition of things like the program name or the argument `default`. The available specifiers include the program name, `%(prog)s` and most keyword arguments to `add_argument()`, e.g. `%(default)s`, `%(type)s`, etc.:

```python
>>> parser = argparse.ArgumentParser(prog='frobble')
>>> parser.add_argument('bar', nargs='?',
...    help='the bar to %(prog)s (default: %(default)s')
>>> parser.print_help()
usage: frobble [-h] [bar]

positional arguments:
  bar     the bar to fribble (default: 42)

optional arguments:
  -h, --help  show this help message and exit
```
As the help string supports %-formatting, if you want a literal % to appear in the help string, you must escape it as %%.

argparse supports silencing the help entry for certain options, by setting the help value to argparse.SUPPRESS:

```python
>>> parser = argparse.ArgumentParser(prog='frobble')
>>> parser.add_argument('--foo', help=argparse.SUPPRESS)
>>> parser.print_help()
usage: frobble [-h]
optional arguments:
  -h, --help    show this help message and exit
```

### 16.4.3.10. metavar

When `ArgumentParser` generates help messages, it needs some way to refer to each expected argument. By default, `ArgumentParser` objects use the `dest` value as the “name” of each object. By default, for positional argument actions, the `dest` value is used directly, and for optional argument actions, the `dest` value is uppercased. So, a single positional argument with `dest='bar'` will be referred to as `bar`. A single optional argument `--foo` that should be followed by a single command-line argument will be referred to as `FOO`. An example:

```python
>>> parser = argparse.ArgumentParser()
>>> parser.add_argument('--foo')
>>> parser.add_argument('bar')
>>> parser.parse_args('X --foo Y'.split())
Namespace(bar='X', foo='Y')
>>> parser.print_help()
usage: [-h] [-foo FOO] bar
```
An alternative name can be specified with `metavar`:

```python
>>> parser = argparse.ArgumentParser()
>>> parser.add_argument('--foo', metavar='YYY')
>>> parser.add_argument('bar', metavar='XXX')
>>> parser.parse_args('X --foo Y'.split())
Namespace(bar='X', foo='Y')
```

```python
>>> parser.print_help()
usage: [-h] [--foo YYY] XXX
```

Note that `metavar` only changes the displayed name - the name of the attribute on the `parse_args()` object is still determined by the `dest` value.

Different values of `nargs` may cause the metavar to be used multiple times. Providing a tuple to `metavar` specifies a different display for each of the arguments:

```python
>>> parser = argparse.ArgumentParser(prog='PROG')
>>> parser.add_argument('-x', nargs=2)
>>> parser.add_argument('--foo', nargs=2, metavar=('bar', 'bar')
```
16.4.3.11. dest

Most ArgumentParser actions add some value as an attribute of the object returned by parse_args(). The name of this attribute is determined by the dest keyword argument of add_argument(). For positional argument actions, dest is normally supplied as the first argument to add_argument:

```python
>>> parser = argparse.ArgumentParser()
>>> parser.add_argument('-f', '--foo-bar', '--foo')
>>> parser.parse_args('XXX'.split())
Namespace(bar='XXX')
```

For optional argument actions, the value of dest is normally inferred from the option strings. ArgumentParser generates the value of dest by taking the first long option string and stripping away the initial -- string. If no long option strings were supplied, dest will be derived from the first short option string by stripping the initial - character. Any internal - characters will be converted to _ characters to make sure the string is a valid attribute name. The examples below illustrate this behavior:

```python
>>> parser = argparse.ArgumentParser()
>>> parser.add_argument('-f', '--foo-bar', '--foo')
```
>>> parser.add_argument('-x', '-y')
>>> parser.parse_args('-f 1 -x 2'.split())
Namespace(foo_bar='1', x='2')

>>> parser.parse_args('--foo 1 -y 2'.split())
Namespace(foo_bar='1', x='2')

`dest` allows a custom attribute name to be provided:

```python
>>> parser = argparse.ArgumentParser()
>>> parser.add_argument('--foo', dest='bar')
>>> parser.parse_args('--foo XXX'.split())
Namespace(bar='XXX')
```
16.4.4. The parse_args() method

`ArgumentParser.parse_args(args=None, namespace=None)`

Convert argument strings to objects and assign them as attributes of the namespace. Return the populated namespace.

Previous calls to `add_argument()` determine exactly what objects are created and how they are assigned. See the documentation for `add_argument()` for details.

By default, the argument strings are taken from `sys.argv`, and a new empty `Namespace` object is created for the attributes.

16.4.4.1. Option value syntax

The `parse_args()` method supports several ways of specifying the value of an option (if it takes one). In the simplest case, the option and its value are passed as two separate arguments:

```python
>>> parser = argparse.ArgumentParser(prog='PROG')
>>> parser.add_argument('-x')
>>> parser.add_argument('--foo')
>>> parser.parse_args('-x X'.split())
Namespace(x='X')
>>> parser.parse_args('--foo=FOO'.split())
Namespace(foo='FOO', x=None)
```

For long options (options with names longer than a single character), the option and value can also be passed as a single command-line argument, using `=` to separate them:

```python
>>> parser.parse_args('--foo=FOO'.split())
```
Namespace(foo='FOO', x=None)

For short options (options only one character long), the option and its value can be concatenated:

```python
>>> parser.parse_args('-xX'.split())
Namespace(foo=None, x='X')
```

Several short options can be joined together, using only a single - prefix, as long as only the last option (or none of them) requires a value:

```python
>>> parser = argparse.ArgumentParser(prog='PROG')
>>> parser.add_argument('-x', action='store_true')
>>> parser.add_argument('-y', action='store_true')
>>> parser.add_argument('-z')
>>> parser.parse_args('-xyzZ'.split())
Namespace(x=True, y=True, z='Z')
```

16.4.4.2. Invalid arguments

While parsing the command line, `parse_args()` checks for a variety of errors, including ambiguous options, invalid types, invalid options, wrong number of positional arguments, etc. When it encounters such an error, it exits and prints the error along with a usage message:

```python
>>> parser = argparse.ArgumentParser(prog='PROG')
>>> parser.add_argument('--foo', type=int)
>>> parser.add_argument('bar', nargs='?')

>>> # invalid type
>>> parser.parse_args(['--foo', 'spam'])
usage: PROG [-h] [--foo FOO] [bar]
PROG: error: argument --foo: invalid int value: 'spam'
```
16.4.4.3. Arguments containing `-`

The `parse_args()` method attempts to give errors whenever the user has clearly made a mistake, but some situations are inherently ambiguous. For example, the command-line argument `-1` could either be an attempt to specify an option or an attempt to provide a positional argument. The `parse_args()` method is cautious here: positional arguments may only begin with `-` if they look like negative numbers and there are no options in the parser that look like negative numbers:

```python
>>> parser = argparse.ArgumentParser(prog='PROG')
>>> parser.add_argument('-x')
>>> parser.add_argument('foo', nargs='?')

>>> # no negative number options, so -1 is a position
>>> parser.parse_args(['-x', '-1'])
Namespace(foo=None, x='-1')

>>> # no negative number options, so -1 and -5 are position
>>> parser.parse_args(['-x', '-1', '-5'])
Namespace(foo='-5', x='-1')

>>> parser = argparse.ArgumentParser(prog='PROG')
```
If you have positional arguments that must begin with `-` and don’t look like negative numbers, you can insert the pseudo-argument `--` which tells `parse_args()` that everything after that is a positional argument:

```python
>>> parser.parse_args(['--', '-f'])
Namespace(foo='-f', one=None)
```

16.4.4.4. Argument abbreviations (prefix matching)

The `parse_args()` method allows long options to be abbreviated to a prefix, if the abbreviation is unambiguous (the prefix matches a unique option):

```python
>>> parser = argparse.ArgumentParser(prog='PROG')
```
An error is produced for arguments that could produce more than one options.

16.4.4.5. Beyond sys.argv

Sometimes it may be useful to have an ArgumentParser parse arguments other than those of sys.argv. This can be accomplished by passing a list of strings to parse_args(). This is useful for testing at the interactive prompt:

16.4.4.6. The Namespace object
**class argparse.Namespace**

Simple class used by default by `parse_args()` to create an object holding attributes and return it.

This class is deliberately simple, just an `object` subclass with a readable string representation. If you prefer to have dict-like view of the attributes, you can use the standard Python idiom, `vars()`:

```python
>>> parser = argparse.ArgumentParser()
>>> parser.add_argument('--foo')
>>> args = parser.parse_args(['--foo', 'BAR'])
>>> vars(args)
{'foo': 'BAR'}
```

It may also be useful to have an `ArgumentParser` assign attributes to an already existing object, rather than a new `Namespace` object. This can be achieved by specifying the `namespace=` keyword argument:

```python
>>> class C:
...     pass
...
>>> c = C()
>>> parser = argparse.ArgumentParser()
>>> parser.add_argument('--foo')
>>> parser.parse_args(args=['--foo', 'BAR'], namespace=c)
>>> c.foo
'BAR'
```
16.4.5. Other utilities

16.4.5.1. Sub-commands

ArgumentParser.add_subparsers([title][, description][, prog]
[, parser_class][, action][, option_string][, dest][, help][, metavar])

Many programs split up their functionality into a number of sub-
commands, for example, the `svn` program can invoke sub-
commands like `svn checkout`, `svn update`, and `svn commit`. Splitting up functionality this way can be a particularly good idea when a program performs several different functions which require different kinds of command-line arguments. ArgumentParser supports the creation of such sub-commands with the add_subparsers() method. The add_subparsers() method is normally called with no arguments and returns a special action object. This object has a single method, add_parser(), which takes a command name and any ArgumentParser constructor arguments, and returns an ArgumentParser object that can be modified as usual.

Description of parameters:

- title - title for the sub-parser group in help output; by default “subcommands” if description is provided, otherwise uses title for positional arguments
- description - description for the sub-parser group in help output, by default None
- prog - usage information that will be displayed with sub-command help, by default the name of the program and any positional arguments before the subparser argument
- parser_class - class which will be used to create sub-parser
instances, by default the class of the current parser (e.g. ArgumentParser)
- dest - name of the attribute under which sub-command name will be stored; by default None and no value is stored
- help - help for sub-parser group in help output, by default None
- metavar - string presenting available sub-commands in help; by default it is None and presents sub-commands in form {cmd1, cmd2, ..}

Some example usage:

```python
>>> # create the top-level parser
>>> parser = argparse.ArgumentParser(prog='PROG')
>>> parser.add_argument('--foo', action='store_true')
>>> subparsers = parser.add_subparsers(help='sub-command help')

>>> # create the parser for the "a" command
>>> parser_a = subparsers.add_parser('a', help='a help')
>>> parser_a.add_argument('bar', type=int, help='bar help')

>>> # create the parser for the "b" command
>>> parser_b = subparsers.add_parser('b', help='b help')
>>> parser_b.add_argument('--baz', choices='XYZ', help='baz help')

>>> # parse some argument lists
>>> parser.parse_args(['a', '12'])
Namespace(bar=12, foo=False)
>>> parser.parse_args(['--foo', 'b', '--baz', 'Z'])
Namespace(baz='Z', foo=True)
```

Note that the object returned by `parse_args()` will only contain attributes for the main parser and the subparser that was selected by the command line (and not any other subparsers). So in the example above, when the `a` command is specified, only the `foo`
and bar attributes are present, and when the b command is specified, only the foo and baz attributes are present.

Similarly, when a help message is requested from a subparser, only the help for that particular parser will be printed. The help message will not include parent parser or sibling parser messages. (A help message for each subparser command, however, can be given by supplying the help= argument to add_parser() as above.)

```python
>>> parser.parse_args(['--help'])
usage: PROG [-h] [--foo] {{a,b} ...

positional arguments:
  {a,b}     sub-command help
    a     a help
    b     b help

optional arguments:
  -h, --help     show this help message and exit
  --foo     foo help
```

```python
>>> parser.parse_args(['a', '--help'])
usage: PROG a [-h] bar

positional arguments:
  bar     bar help

optional arguments:
  -h, --help     show this help message and exit
```

```python
>>> parser.parse_args(['b', '--help'])
usage: PROG b [-h] [--baz {X,Y,Z}]

optional arguments:
  -h, --help     show this help message and exit
```
--baz {X,Y,Z} baz help

The **add_subparsers()** method also supports **title** and **description** keyword arguments. When either is present, the subparser's commands will appear in their own group in the help output. For example:

```python
>>> parser = argparse.ArgumentParser()
>>> subparsers = parser.add_subparsers(title='sub
... description
... help='addi
... subparsers.add_parser('foo')
>>> subparsers.add_parser('bar')
>>> parser.parse_args(['-h'])
usage: [-h] {foo,bar} ...

optional arguments:
  -h, --help    show this help message and exit

subcommands:
  valid subcommands

  {foo,bar}    additional help
```

Furthermore, **add_parser** supports an additional **aliases** argument, which allows multiple strings to refer to the same subparser. This example, like **svn**, aliases **co** as a shorthand for **checkout**:

```python
>>> parser = argparse.ArgumentParser()
>>> subparsers = parser.add_subparsers()
>>> checkout = subparsers.add_parser('checkout',
>>> checkout.add_argument('foo')
>>> parser.parse_args(['co', 'bar'])
```
One particularly effective way of handling sub-commands is to combine the use of the `add_subparsers()` method with calls to `set_defaults()` so that each subparser knows which Python function it should execute. For example:

```python
>>> # sub-command functions
>>> def foo(args):
...   print(args.x * args.y)
...
>>> def bar(args):
...   print('((%s))' % args.z)
...
>>> # create the top-level parser
>>> parser = argparse.ArgumentParser()
>>> subparsers = parser.add_subparsers()
>>> # create the parser for the "foo" command
>>> parser_foo = subparsers.add_parser('foo')
>>> parser_foo.add_argument('-x', type=int, default=1)
>>> parser_foo.add_argument('y', type=float)
>>> parser_foo.set_defaults(func=foo)
>>> # create the parser for the "bar" command
>>> parser_bar = subparsers.add_parser('bar')
>>> parser_bar.add_argument('z')
>>> parser_bar.set_defaults(func=bar)
>>> # parse the args and call whatever function was selected
>>> args = parser.parse_args('foo 1 -x 2'.split())
>>> args.func(args)
2.0
>>> # parse the args and call whatever function was selected
```
This way, you can let `parse_args()` do the job of calling the appropriate function after argument parsing is complete. Associating functions with actions like this is typically the easiest way to handle the different actions for each of your subparsers. However, if it is necessary to check the name of the subparser that was invoked, the `dest` keyword argument to the `add_subparsers()` call will work:

```python
>>> parser = argparse.ArgumentParser()
>>> subparsers = parser.add_subparsers(dest='subparser_name')
>>> subparser1 = subparsers.add_parser('1')
>>> subparser1.add_argument('-x')
>>> subparser2 = subparsers.add_parser('2')
>>> subparser2.add_argument('y')
>>> parser.parse_args(['2', 'frobble'])
Namespace(subparser_name='2', y='frobble')
```

16.4.5.2. FileType objects

```python
class argparse.FileType(mode='r', bufsize=-1, encoding=None, errors=None)
```

The `FileType` factory creates objects that can be passed to the `type` argument of `ArgumentParser.add_argument()`. Arguments that have `FileType` objects as their type will open command-line arguments as files with the requested modes, buffer sizes, encodings and error handling (see the `open()` function for more details):
FileType objects understand the pseudo-argument `'-` and automatically convert this into `sys.stdin` for readable `FileType` objects and `sys.stdout` for writable `FileType` objects:

```python
>>> parser = argparse.ArgumentParser()
>>> parser.add_argument('infile', type=argparse.FileType)
>>> parser.parse_args(['-'])
Namespace(infile<_io.TextIOWrapper name='<stdin>' encoding='UTF-8'>)
```

*New in version 3.4:* The `encodings` and `errors` keyword arguments.

16.4.5.3. Argument groups

`argparse.ArgumentParser.add_argument_group(title=None, description=None)`

By default, `argparse.ArgumentParser` groups command-line arguments into “positional arguments” and “optional arguments” when displaying help messages. When there is a better conceptual grouping of arguments than this default one, appropriate groups can be created using the `add_argument_group()` method:

```python
>>> parser = argparse.ArgumentParser(prog='PROG',
>>> group = parser.add_argument_group('group')
>>> group.add_argument('--foo', help='foo help')
>>> group.add_argument('bar', help='bar help')
>>> parser.print_help()
```
usage: PROG [--foo FOO] bar

group:
   bar   bar help  
   --foo FOO  foo help

The `add_argument_group()` method returns an argument group object which has an `add_argument()` method just like a regular `ArgumentParser`. When an argument is added to the group, the parser treats it just like a normal argument, but displays the argument in a separate group for help messages. The `add_argument_group()` method accepts `title` and `description` arguments which can be used to customize this display:

```python
>>> parser = argparse.ArgumentParser(prog='PROG',
>>> group1 = parser.add_argument_group('group1',
>>> group1.add_argument('foo', help='foo help')
>>> group2 = parser.add_argument_group('group2',
>>> group2.add_argument('--bar', help='bar help')
>>> parser.print_help()
usage: PROG [--bar BAR] foo

  group1:
    group1 description
    
    foo   foo help

  group2:
    group2 description
    
    --bar BAR   bar help
```

Note that any arguments not in your user-defined groups will end up back in the usual “positional arguments” and “optional
arguments” sections.

16.4.5.4. Mutual exclusion

`ArgumentParser.add_mutually_exclusive_group(required=False)`

Create a mutually exclusive group. `argparse` will make sure that only one of the arguments in the mutually exclusive group was present on the command line:

```python
>>> parser = argparse.ArgumentParser(prog='PROG')
>>> group = parser.add_mutually_exclusive_group()
>>> group.add_argument('--foo', action='store_true')
>>> group.add_argument('--bar', action='store_false')
>>> parser.parse_args(['--foo'])
Namespace(bar=True, foo=True)
>>> parser.parse_args(['--bar'])
Namespace(bar=False, foo=False)
>>> parser.parse_args(['--foo', '--bar'])
usage: PROG [-h] [--foo | --bar]
PROG: error: argument --bar: not allowed with argument --foo
```

The `add_mutually_exclusive_group()` method also accepts a `required` argument, to indicate that at least one of the mutually exclusive arguments is required:

```python
>>> parser = argparse.ArgumentParser(prog='PROG')
>>> group = parser.add_mutually_exclusive_group(required=True)
>>> group.add_argument('--foo', action='store_true')
>>> group.add_argument('--bar', action='store_false')
>>> parser.parse_args([])
usage: PROG [-h] (--foo | --bar)
PROG: error: one of the arguments --foo --bar is required
```
Note that currently mutually exclusive argument groups do not support the *title* and *description* arguments of `add_argument_group()`.

### 16.4.5.5. Parser defaults

**ArgumentParser**. `set_defaults(**kwargs)`

Most of the time, the attributes of the object returned by `parse_args()` will be fully determined by inspecting the command-line arguments and the argument actions. `set_defaults()` allows some additional attributes that are determined without any inspection of the command line to be added:

```python
>>> parser = argparse.ArgumentParser()
>>> parser.add_argument('foo', type=int)
>>> parser.set_defaults(bar=42, baz='badger')
>>> parser.parse_args(['736'])
Namespace(bar=42, baz='badger', foo=736)
```

Note that parser-level defaults always override argument-level defaults:

```python
>>> parser = argparse.ArgumentParser()
>>> parser.add_argument('--foo', default='bar')
>>> parser.set_defaults(foo='spam')
>>> parser.parse_args([])
Namespace(foo='spam')
```

Parser-level defaults can be particularly useful when working with multiple parsers. See the `add_subparsers()` method for an example of this type.
ArgumentParser.get_default(dest)

Get the default value for a namespace attribute, as set by either add_argument() or by set_defaults():

```python
>>> parser = argparse.ArgumentParser()
>>> parser.add_argument('--foo', default='badger')
>>> parser.get_default('foo')
'badger'
```

16.4.5.6. Printing help

In most typical applications, parse_args() will take care of formatting and printing any usage or error messages. However, several formatting methods are available:

ArgumentParser.print_usage(file=None)

Print a brief description of how the ArgumentParser should be invoked on the command line. If file is None, sys.stdout is assumed.

ArgumentParser.print_help(file=None)

Print a help message, including the program usage and information about the arguments registered with the ArgumentParser. If file is None, sys.stdout is assumed.

There are also variants of these methods that simply return a string instead of printing it:

ArgumentParser.format_usage()

Return a string containing a brief description of how the ArgumentParser should be invoked on the command line.
ArgumentParser.format_help()

Return a string containing a help message, including the program usage and information about the arguments registered with the ArgumentParser.

16.4.5.7. Partial parsing

ArgumentParser.parse_known_args(args=None, namespace=None)

Sometimes a script may only parse a few of the command-line arguments, passing the remaining arguments on to another script or program. In these cases, the parse_known_args() method can be useful. It works much like parse_args() except that it does not produce an error when extra arguments are present. Instead, it returns a two item tuple containing the populated namespace and the list of remaining argument strings.

```python
>>> parser = argparse.ArgumentParser()
>>> parser.add_argument('--foo', action='store_true')
>>> parser.add_argument('bar')
>>> parser.parse_known_args(['--foo', '--badger', 'BAR'])
(Namespace(bar='BAR', foo=True), ['--badger', 'spam'])
```

**Warning:** Prefix matching rules apply to parse_known_args(). The parser may consume an option even if it's just a prefix of one of its known options, instead of leaving it in the remaining arguments list.

16.4.5.8. Customizing file parsing
ArgumentParser.\texttt{convert\_arg\_line\_to\_args}(\texttt{arg\_line})

Arguments that are read from a file (see the \texttt{fromfile\_prefix\_chars} keyword argument to the \texttt{ArgumentParser} constructor) are read one argument per line. \texttt{convert\_arg\_line\_to\_args()} can be overridden for fancier reading.

This method takes a single argument \texttt{arg\_line} which is a string read from the argument file. It returns a list of arguments parsed from this string. The method is called once per line read from the argument file, in order.

A useful override of this method is one that treats each space-separated word as an argument:

\begin{verbatim}
def convert_arg_line_to_args(self, arg_line):
    for arg in arg_line.split():
        if not arg.strip():
            continue
        yield arg
\end{verbatim}

16.4.5.9. Exiting methods

ArgumentParser.\texttt{exit}(\texttt{status}=0, \texttt{message}=None)

This method terminates the program, exiting with the specified \texttt{status} and, if given, it prints a \texttt{message} before that.

ArgumentParser.\texttt{error}(\texttt{message})

This method prints a usage message including the \texttt{message} to the standard error and terminates the program with a status code of 2.
16.4.6. Upgrading optparse code

Originally, the `argparse` module had attempted to maintain compatibility with `optparse`. However, `optparse` was difficult to extend transparently, particularly with the changes required to support the new `nargs=` specifiers and better usage messages. When most everything in `optparse` had either been copy-pasted over or monkey-patched, it no longer seemed practical to try to maintain the backwards compatibility.

A partial upgrade path from `optparse` to `argparse`:

- Replace all `optparse.OptionParser.add_option()` calls with `ArgumentParser.add_argument()` calls.
- Replace `(options, args) = parser.parse_args()` with `args = parser.parse_args()` and add additional `ArgumentParser.add_argument()` calls for the positional arguments. Keep in mind that what was previously called `options`, now in `argparse` context is called `args`.
- Replace callback actions and the `callback_*` keyword arguments with `type` or `action` arguments.
- Replace string names for type keyword arguments with the corresponding type objects (e.g. `int`, `float`, `complex`, etc).
- Replace strings with implicit arguments such as `%default` or `%prog` with the standard Python syntax to use dictionaries to format strings, that is, `%(default)s` and `%(prog)s`.
- Replace the `OptionParser` constructor `version` argument with a call to `parser.add_argument('--version',`
16.5. optparse — Parser for command line options

Deprecation Notice: The `optparse` module is deprecated and will not be developed further; development will continue with the `argparse` module.

Source code: `Lib/optparse.py`

`optparse` is a more convenient, flexible, and powerful library for parsing command-line options than the old `getopt` module. `optparse` uses a more declarative style of command-line parsing: you create an instance of `OptionParser`, populate it with options, and parse the command line. `optparse` allows users to specify options in the conventional GNU/POSIX syntax, and additionally generates usage and help messages for you.

Here's an example of using `optparse` in a simple script:

```python
from optparse import OptionParser

parser = OptionParser()
parser.add_option("-f", "--file", dest="filename",
    help="write report to FILE", metavar="FILE")
parser.add_option("-q", "--quiet",
    action="store_false", dest="verbose",
    help="don't print status messages")

(options, args) = parser.parse_args()
```
With these few lines of code, users of your script can now do the “usual thing” on the command-line, for example:

```bash
<yourscript> --file=outfile -q
```

As it parses the command line, `optparse` sets attributes of the `options` object returned by `parse_args()` based on user-supplied command-line values. When `parse_args()` returns from parsing this command line, `options.filename` will be "outfile" and `options.verbose` will be False. `optparse` supports both long and short options, allows short options to be merged together, and allows options to be associated with their arguments in a variety of ways. Thus, the following command lines are all equivalent to the above example:

```bash
<yourscript> -f outfile --quiet
<yourscript> --quiet --file outfile
<yourscript> -q -f outfile
<yourscript> -qf outfile
```

Additionally, users can run one of

```bash
<yourscript> -h
<yourscript> --help
```

and `optparse` will print out a brief summary of your script's options:

```
Usage: <yourscript> [options]

Options:
  -h, --help              show this help message and exit
  -f FILE, --file=FILE    write report to FILE
  -q, --quiet             don't print status messages
```
where the value of *yourscript* is determined at runtime (normally from `sys.argv[0]`).
16.5.1. Background

`optparse` was explicitly designed to encourage the creation of programs with straightforward, conventional command-line interfaces. To that end, it supports only the most common command-line syntax and semantics conventionally used under Unix. If you are unfamiliar with these conventions, read this section to acquaint yourself with them.

16.5.1.1. Terminology

**argument**

A string entered on the command-line, and passed by the shell to `exec1()` or `execv()`. In Python, arguments are elements of `sys.argv[1:]` (`sys.argv[0]` is the name of the program being executed). Unix shells also use the term “word”.

It is occasionally desirable to substitute an argument list other than `sys.argv[1:]`, so you should read “argument” as “an element of `sys.argv[1:]`, or of some other list provided as a substitute for `sys.argv[1:]`”.

**option**

An argument used to supply extra information to guide or customize the execution of a program. There are many different syntaxes for options; the traditional Unix syntax is a hyphen (“-”) followed by a single letter, e.g. `-x` or `-F`. Also, traditional Unix syntax allows multiple options to be merged into a single argument, e.g. `-x -F` is equivalent to `-xF`. The GNU project introduced `--` followed by a series of hyphen-separated words, e.g. `--file` or `- -dry-run`. These are the only two option syntaxes provided by
Some other option syntaxes that the world has seen include:

- a hyphen followed by a few letters, e.g. `-pf` (this is *not* the same as multiple options merged into a single argument)
- a hyphen followed by a whole word, e.g. `-file` (this is technically equivalent to the previous syntax, but they aren’t usually seen in the same program)
- a plus sign followed by a single letter, or a few letters, or a word, e.g. `+f`, `+rgb`
- a slash followed by a letter, or a few letters, or a word, e.g. `/f`, `/file`

These option syntaxes are not supported by `optparse`, and they never will be. This is deliberate: the first three are non-standard on any environment, and the last only makes sense if you’re exclusively targeting VMS, MS-DOS, and/or Windows.

**Option argument**

An argument that follows an option, is closely associated with that option, and is consumed from the argument list when that option is. With `optparse`, option arguments may either be in a separate argument from their option:

```
-f foo
--file foo
```

or included in the same argument:

```
-ffoo
--file=foo
```

Typically, a given option either takes an argument or it doesn’t. Lots
of people want an “optional option arguments” feature, meaning that some options will take an argument if they see it, and won't if they don't. This is somewhat controversial, because it makes parsing ambiguous: if -a takes an optional argument and -b is another option entirely, how do we interpret -ab? Because of this ambiguity, optparse does not support this feature.

positional argument
something leftover in the argument list after options have been parsed, i.e. after options and their arguments have been parsed and removed from the argument list.

required option
an option that must be supplied on the command-line; note that the phrase “required option” is self-contradictory in English. optparse doesn’t prevent you from implementing required options, but doesn’t give you much help at it either.

For example, consider this hypothetical command-line:

```
prog -v --report report.txt foo bar
```

-v and --report are both options. Assuming that --report takes one argument, report.txt is an option argument. foo and bar are positional arguments.

16.5.1.2. What are options for?

Options are used to provide extra information to tune or customize the execution of a program. In case it wasn’t clear, options are usually optional. A program should be able to run just fine with no options whatsoever. (Pick a random program from the Unix or GNU toolsets. Can it run without any options at all and still make sense? The main
exceptions are `find`, `tar`, and `dd`—all of which are mutant oddballs that have been rightly criticized for their non-standard syntax and confusing interfaces.)

Lots of people want their programs to have “required options”. Think about it. If it’s required, then it’s *not optional*! If there is a piece of information that your program absolutely requires in order to run successfully, that’s what positional arguments are for.

As an example of good command-line interface design, consider the humble `cp` utility, for copying files. It doesn’t make much sense to try to copy files without supplying a destination and at least one source. Hence, `cp` fails if you run it with no arguments. However, it has a flexible, useful syntax that does not require any options at all:

```bash
cp SOURCE DEST
```

```bash
cp SOURCE ... DEST-DIR
```

You can get pretty far with just that. Most `cp` implementations provide a bunch of options to tweak exactly how the files are copied: you can preserve mode and modification time, avoid following symlinks, ask before clobbering existing files, etc. But none of this distracts from the core mission of `cp`, which is to copy either one file to another, or several files to another directory.

### 16.5.1.3. What are positional arguments for?

Positional arguments are for those pieces of information that your program absolutely, positively requires to run.

A good user interface should have as few absolute requirements as possible. If your program requires 17 distinct pieces of information in
order to run successfully, it doesn't much matter how you get that information from the user—most people will give up and walk away before they successfully run the program. This applies whether the user interface is a command-line, a configuration file, or a GUI: if you make that many demands on your users, most of them will simply give up.

In short, try to minimize the amount of information that users are absolutely required to supply—use sensible defaults whenever possible. Of course, you also want to make your programs reasonably flexible. That's what options are for. Again, it doesn't matter if they are entries in a config file, widgets in the “Preferences” dialog of a GUI, or command-line options—the more options you implement, the more flexible your program is, and the more complicated its implementation becomes. Too much flexibility has drawbacks as well, of course; too many options can overwhelm users and make your code much harder to maintain.
16.5.2. Tutorial

While **optparse** is quite flexible and powerful, it's also straightforward to use in most cases. This section covers the code patterns that are common to any **optparse**-based program.

First, you need to import the OptionParser class; then, early in the main program, create an OptionParser instance:

```python
from optparse import OptionParser
[...]
parser = OptionParser()
```

Then you can start defining options. The basic syntax is:

```python
parser.add_option(opt_str, ..., attr=value, ...)
```

Each option has one or more option strings, such as `-f` or `--file`, and several option attributes that tell **optparse** what to expect and what to do when it encounters that option on the command line.

Typically, each option will have one short option string and one long option string, e.g.:

```python
parser.add_option("-f", "--file", ...)
```

You're free to define as many short option strings and as many long option strings as you like (including zero), as long as there is at least one option string overall.

The option strings passed to `OptionParser.add_option()` are effectively labels for the option defined by that call. For brevity, we will
frequently refer to *encountering an option* on the command line; in reality, *optparse* encounters *option strings* and looks up options from them.

Once all of your options are defined, instruct *optparse* to parse your program's command line:

```python
(options, args) = parser.parse_args()
```

(If you like, you can pass a custom argument list to *parse_args()*, but that's rarely necessary: by default it uses `sys.argv[1:]`.)

*parse_args()* returns two values:

- **options**, an object containing values for all of your options—e.g. if *--file* takes a single string argument, then *options.file* will be the filename supplied by the user, or *None* if the user did not supply that option
- **args**, the list of positional arguments leftover after parsing options

This tutorial section only covers the four most important option attributes: *action*, *type*, *dest* (destination), and *help*. Of these, *action* is the most fundamental.

### 16.5.2.1. Understanding option actions

Actions tell *optparse* what to do when it encounters an option on the command line. There is a fixed set of actions hard-coded into *optparse*; adding new actions is an advanced topic covered in section *Extending optparse*. Most actions tell *optparse* to store a value in some variable—for example, take a string from the command
line and store it in an attribute of `options`.

If you don’t specify an option action, `optparse` defaults to `store`.

### 16.5.2.2. The store action

The most common option action is `store`, which tells `optparse` to take the next argument (or the remainder of the current argument), ensure that it is of the correct type, and store it to your chosen destination.

For example:

```python
parser.add_option("-f", "--file",
    action="store", type="string", dest="filename")
```

Now let’s make up a fake command line and ask `optparse` to parse it:

```python
args = ["-f", "foo.txt"]
(options, args) = parser.parse_args(args)
```

When `optparse` sees the option string `-f`, it consumes the next argument, `foo.txt`, and stores it in `options.filename`. So, after this call to `parse_args()`, `options.filename` is "foo.txt".

Some other option types supported by `optparse` are `int` and `float`. Here’s an option that expects an integer argument:

```python
parser.add_option("-n", type="int", dest="num")
```

Note that this option has no long option string, which is perfectly
acceptable. Also, there's no explicit action, since the default is store.

Let's parse another fake command-line. This time, we'll jam the option argument right up against the option: since -n42 (one argument) is equivalent to -n 42 (two arguments), the code

```python
(options, args) = parser.parse_args(['-n42'])
print(options.num)
```

will print 42.

If you don't specify a type, optparse assumes string. Combined with the fact that the default action is store, that means our first example can be a lot shorter:

```python
parser.add_option('-f', '--file', dest='filename')
```

If you don't supply a destination, optparse figures out a sensible default from the option strings: if the first long option string is --foo-bar, then the default destination is foo_bar. If there are no long option strings, optparse looks at the first short option string: the default destination for -f is f.

optparse also includes the built-in complex type. Adding types is covered in section Extending optparse.

### 16.5.2.3. Handling boolean (flag) options

Flag options—set a variable to true or false when a particular option is seen—are quite common. optparse supports them with two separate actions, store_true and store_false. For example, you might have a verbose flag that is turned on with -v and off with -q:
Here we have two different options with the same destination, which is perfectly OK. (It just means you have to be a bit careful when setting default values—see below.)

When `optparse` encounters `-v` on the command line, it sets `options.verbose` to `True`; when it encounters `-q`, `options.verbose` is set to `False`.

16.5.2.4. Other actions

Some other actions supported by `optparse` are:

"store_const"
  store a constant value
"append"
  append this option’s argument to a list
"count"
  increment a counter by one
"callback"
  call a specified function

These are covered in section `Reference Guide`, Reference Guide and section `Option Callbacks`.

16.5.2.5. Default values

All of the above examples involve setting some variable (the “destination”) when certain command-line options are seen. What
happens if those options are never seen? Since we didn’t supply any defaults, they are all set to None. This is usually fine, but sometimes you want more control. optparse lets you supply a default value for each destination, which is assigned before the command line is parsed.

First, consider the verbose/quiet example. If we want optparse to set verbose to True unless -q is seen, then we can do this:

```python
parser.add_option("-v", action="store_true", dest="verbose")
parser.add_option("-q", action="store_false", dest="verbose")
```

Since default values apply to the destination rather than to any particular option, and these two options happen to have the same destination, this is exactly equivalent:

```python
parser.add_option("-v", action="store_true", dest="verbose")
parser.add_option("-q", action="store_false", dest="verbose")
```

Consider this:

```python
parser.add_option("-v", action="store_true", dest="verbose")
parser.add_option("-q", action="store_false", dest="verbose")
```

Again, the default value for verbose will be True: the last default value supplied for any particular destination is the one that counts.

A clearer way to specify default values is the set_defaults() method of OptionParser, which you can call at any time before calling parse_args():

```python
parser.set_defaults(verbosetrue)
```
As before, the last value specified for a given option destination is the one that counts. For clarity, try to use one method or the other of setting default values, not both.

16.5.2.6. Generating help

`optparse`'s ability to generate help and usage text automatically is useful for creating user-friendly command-line interfaces. All you have to do is supply a `help` value for each option, and optionally a short usage message for your whole program. Here's an OptionParser populated with user-friendly (documented) options:

```python
usage = "usage: %prog [options] arg1 arg2"
parser = OptionParser(usage=usage)
parser.add_option("-v", "--verbose",
                 action="store_true", dest="verbose",
                 help="make lots of noise [default]"
parser.add_option("-q", "--quiet",
                 action="store_false", dest="verbose",
                 help="be vewwy quiet (I'm hunting"
parser.add_option("-f", "--filename",
                 metavar="FILE", help="write output"
parser.add_option("-m", "--mode",
                 default="intermediate",
                 help="interaction mode: novice, intermediate, or expert [default: %default"
```

If `optparse` encounters either `-h` or `--help` on the command-line, or if you just call `parser.print_help()`, it prints the following to standard output:
Usage: <yourscript> [options] arg1 arg2

Options:
- `h, --help`       show this help message and exit
- `v, --verbose`    make lots of noise [default]
- `q, --quiet`      be vewwy quiet (I'm hunting)
- `f FILE, --filename=FILE` write output to FILE
- `m MODE, --mode=MODE` interaction mode: novice, intermediate, or expert [default: intermediate]

(If the help output is triggered by a help option, `optparse` exits after printing the help text.)

There's a lot going on here to help `optparse` generate the best possible help message:

- the script defines its own usage message:

  ```python
  usage = "usage: %prog [options] arg1 arg2"
  ```

  `optparse` expands `%prog` in the usage string to the name of the current program, i.e. `os.path.basename(sys.argv[0])`. The expanded string is then printed before the detailed option help.

  If you don't supply a usage string, `optparse` uses a bland but sensible default: "Usage: %prog [options]", which is fine if your script doesn't take any positional arguments.

- every option defines a help string, and doesn't worry about line-wrapping— `optparse` takes care of wrapping lines and making the help output look good.

- options that take a value indicate this fact in their automatically-
generated help message, e.g. for the “mode” option:

-\texttt{m MODE, --mode=MODE}

Here, “MODE” is called the meta-variable: it stands for the argument that the user is expected to supply to -\texttt{m}/-\texttt{--mode}. By default, \texttt{optparse} converts the destination variable name to uppercase and uses that for the meta-variable. Sometimes, that’s not what you want—for example, the \texttt{--filename} option explicitly sets \texttt{metavar=\"FILE\"}, resulting in this automatically-generated option description:

\texttt{-f FILE, --filename=FILE}

This is important for more than just saving space, though: the manually written help text uses the meta-variable \texttt{FILE} to clue the user in that there’s a connection between the semi-formal syntax \texttt{-f FILE} and the informal semantic description “write output to FILE”. This is a simple but effective way to make your help text a lot clearer and more useful for end users.

- options that have a default value can include \texttt{\%default} in the help string—\texttt{optparse} will replace it with \texttt{str()} of the option’s default value. If an option has no default value (or the default value is \texttt{None}), \texttt{\%default} expands to \texttt{none}.

16.5.2.6.1. Grouping Options

When dealing with many options, it is convenient to group these options for better help output. An \texttt{OptionParser} can contain several option groups, each of which can contain several options.
An option group is obtained using the class `OptionGroup`:

class optparse.**OptionGroup**(parser, title, description=None)

where

- parser is the `OptionParser` instance the group will be inserted into
- title is the group title
- description, optional, is a long description of the group

`OptionGroup` inherits from `OptionContainer` (like `OptionParser`) and so the `add_option()` method can be used to add an option to the group.

Once all the options are declared, using the `OptionParser` method `add_option_group()` the group is added to the previously defined parser.

Continuing with the parser defined in the previous section, adding an `OptionGroup` to a parser is easy:

```python
group = OptionGroup(parser, "Dangerous Options", "Caution: use these options at your own risk. It is believed that some of them bite.
parser.add_option("-g", action="store_true", help="Group option.
group.add_option_group(group)
```

This would result in the following help output:

```
Usage: <yourscript> [options] arg1 arg2

Options:
  -h, --help            show this help message and exit
  -v, --verbose         make lots of noise [default]
```
-q, --quiet be vewwy quiet (I'm hunting
-f FILE, --filename=FILE write output to FILE
-m MODE, --mode=MODE interaction mode: novice, inter-
expert [default: intermediate]

Dangerous Options:
Caution: use these options at your own risk. It of-
them bite.
-g Group option.

A bit more complete example might involve using more than one
group: still extending the previous example:

group = OptionGroup(parser, "Dangerous Options",
"Caution: use these options at your own risk. It of-
them bite.

parser.add_option_group(group)

group = OptionGroup(parser, "Debug Options")
group.add_option("-d", "--debug", action="store_true", help="Print debug information")
group.add_option("-s", "--sql", action="store_true", help="Print all SQL statements executed")
group.add_option("-e", action="store_true", help="Print all actions done")

parser.add_option_group(group)

that results in the following output:

Usage: <yourscript> [options] arg1 arg2

Options:
-h, --help show this help message and exit
-v, --verbose make lots of noise [default]
-q, --quiet be vewwy quiet (I'm hunting
-f FILE, --filename=FILE write output to FILE
-m MODE, --mode=MODE interaction mode: novice, in
     [default: intermediate]

Dangerous Options:
Caution: use these options at your own risk. It
     of them bite.

-g Group option.

Debug Options:
-d, --debug Print debug information
-s, --sql Print all SQL statements exe
-e Print every action done

Another interesting method, in particular when working
programmatically with option groups is:

OptionParser. **get_option_group**(opt_str)
   Return the OptionGroup to which the short or long option string
   opt_str (e.g. '-o' or '--option') belongs. If there's no such
   OptionGroup, return None.

16.5.2.7. Printing a version string

Similar to the brief usage string, optparse can also print a version
string for your program. You have to supply the string as the version
argument to OptionParser:

parser = OptionParser(usage="%prog [-f] [-q]", versi
%prog is expanded just like it is in usage. Apart from that, version can contain anything you like. When you supply it, optparse automatically adds a --version option to your parser. If it encounters this option on the command line, it expands your version string (by replacing %prog), prints it to stdout, and exits.

For example, if your script is called /usr/bin/foo:

```
$ /usr/bin/foo --version
foo 1.0
```

The following two methods can be used to print and get the version string:

**OptionParser.get_version()**

Same as print_version() but returns the version string instead of printing it.

**OptionParser.print_version(file=None)**

Print the version message for the current program (self.version) to file (default stdout). As with print_usage(), any occurrence of %prog in self.version is replaced with the name of the current program. Does nothing if self.version is empty or undefined.

**16.5.2.8. How optparse handles errors**

There are two broad classes of errors that optparse has to worry about: programmer errors and user errors. Programmer errors are usually erroneous calls to OptionParser.add_option(), e.g. invalid option strings, unknown option attributes, missing option
attributes, etc. These are dealt with in the usual way: raise an exception (either optparse.OptionError or TypeError) and let the program crash.

Handling user errors is much more important, since they are guaranteed to happen no matter how stable your code is. optparse can automatically detect some user errors, such as bad option arguments (passing \texttt{-n 4x} where \texttt{-n} takes an integer argument), missing arguments (\texttt{-n} at the end of the command line, where \texttt{-n} takes an argument of any type). Also, you can call OptionParser.error() to signal an application-defined error condition:

```python
(options, args) = parser.parse_args()
[...
if options.a and options.b:
    parser.error("options -a and -b are mutually exclusive")
```

In either case, optparse handles the error the same way: it prints the program's usage message and an error message to standard error and exits with error status 2.

Consider the first example above, where the user passes \texttt{4x} to an option that takes an integer:

```bash
$ /usr/bin/foo -n 4x
Usage: foo [options]
foo: error: option -n: invalid integer value: '4x'
```

Or, where the user fails to pass a value at all:

```bash
$ /usr/bin/foo -n
```
Usage: foo [options]

foo: error: -n option requires an argument

`optparse`-generated error messages take care always to mention the option involved in the error; be sure to do the same when calling `OptionParser.error()` from your application code.

If `optparse`'s default error-handling behaviour does not suit your needs, you'll need to subclass `OptionParser` and override its `exit()` and/or `error()` methods.

### 16.5.2.9. Putting it all together

Here's what `optparse`-based scripts usually look like:

```python
from optparse import OptionParser

def main():
    usage = "usage: %prog [options] arg"
    parser = OptionParser(usage)
    parser.add_option("-f", "--file", dest="filename",
                      help="read data from FILENAME")
    parser.add_option("-v", "--verbose",
                      action="store_true", dest="verbose")
    parser.add_option("-q", "--quiet",
                      action="store_false", dest="verbose")

    (options, args) = parser.parse_args()
    if len(args) != 1:
        parser.error("incorrect number of arguments")
    if options.verbose:
        print("reading %s..." % options.filename)
```

if __name__ == "__main__":
    main()
16.5.3. Reference Guide

16.5.3.1. Creating the parser

The first step in using `optparse` is to create an OptionParser instance.

```python
class optparse.OptionParser(...)
```

The OptionParser constructor has no required arguments, but a number of optional keyword arguments. You should always pass them as keyword arguments, i.e. do not rely on the order in which the arguments are declared.

**usage** (default: "%prog [options]")

The usage summary to print when your program is run incorrectly or with a help option. When `optparse` prints the usage string, it expands `%prog` to `os.path.basename(sys.argv[0])` (or to `prog` if you passed that keyword argument). To suppress a usage message, pass the special value `optparse.SUPPRESS_USAGE`.

**option_list** (default: `[]`)

A list of Option objects to populate the parser with. The options in `option_list` are added after any options in `standard_option_list` (a class attribute that may be set by OptionParser subclasses), but before any version or help options. Deprecated; use `add_option()` after creating the parser instead.

**option_class** (default: `optparse.Option`)

Class to use when adding options to the parser in `add_option()`.
version (default: None)
A version string to print when the user supplies a version option. If you supply a true value for version, optparse automatically adds a version option with the single option string --version. The substring %prog is expanded the same as for usage.

conflict_handler (default: "error")
Specifies what to do when options with conflicting option strings are added to the parser; see section Conflicts between options.

description (default: None)
A paragraph of text giving a brief overview of your program. optparse reformats this paragraph to fit the current terminal width and prints it when the user requests help (after usage, but before the list of options).

formatter (default: a new IndentedHelpFormatter)
An instance of optparse.HelpFormatter that will be used for printing help text. optparse provides two concrete classes for this purpose: IndentedHelpFormatter and TitledHelpFormatter.

add_help_option (default: True)
If true, optparse will add a help option (with option strings -h and --help) to the parser.

prog
The string to use when expanding %prog in usage and version instead of os.path.basename(sys.argv[0]).

epilog (default: None)
A paragraph of help text to print after the option help.

16.5.3.2. Populating the parser
There are several ways to populate the parser with options. The preferred way is by using `OptionParser.add_option()`, as shown in section *Tutorial*. `add_option()` can be called in one of two ways:

- pass it an Option instance (as returned by `make_option()`)
- pass it any combination of positional and keyword arguments that are acceptable to `make_option()` (i.e., to the Option constructor), and it will create the Option instance for you

The other alternative is to pass a list of pre-constructed Option instances to the OptionParser constructor, as in:

```python
option_list = [  
    make_option("-f", "--filename",  
                action="store", type="string", dest=  
    make_option("-q", "--quiet",  
                action="store_false", dest="verbose"  

parser = OptionParser(option_list=option_list)
```

`make_option()` is a factory function for creating Option instances; currently it is an alias for the Option constructor. A future version of `optparse` may split Option into several classes, and `make_option()` will pick the right class to instantiate. Do not instantiate Option directly.)

**16.5.3.3. Defining options**

Each Option instance represents a set of synonymous command-line option strings, e.g. `-f` and `--file`. You can specify any number of short or long option strings, but you must specify at least one overall option string.
The canonical way to create an Option instance is with the `add_option()` method of `OptionParser`.

`OptionParser.add_option(option)`

`OptionParser.add_option(*opt_str, attr=value, ...)`

To define an option with only a short option string:

```
parser.add_option("-f", attr=value, ...)
```

And to define an option with only a long option string:

```
parser.add_option("--foo", attr=value, ...)
```

The keyword arguments define attributes of the new Option object. The most important option attribute is `action`, and it largely determines which other attributes are relevant or required. If you pass irrelevant option attributes, or fail to pass required ones, `optparse` raises an `OptionError` exception explaining your mistake.

An option's `action` determines what `optparse` does when it encounters this option on the command-line. The standard option actions hard-coded into `optparse` are:

- "store"
  - store this option's argument (default)
- "store_const"
  - store a constant value
- "store_true"
  - store a true value
- "store_false"
  - store a false value
"append"
append this option's argument to a list

"append_const"
append a constant value to a list

"count"
increment a counter by one

"callback"
call a specified function

"help"
print a usage message including all options and the documentation for them

(If you don't supply an action, the default is "store". For this action, you may also supply type and dest option attributes; see Standard option actions.)

As you can see, most actions involve storing or updating a value somewhere. optparse always creates a special object for this, conventionally called options (it happens to be an instance of optparse.Values). Option arguments (and various other values) are stored as attributes of this object, according to the dest (destination) option attribute.

For example, when you call

```
parser.parse_args()
```

one of the first things optparse does is create the options object:

```
options = Values()
```

If one of the options in this parser is defined with
and the command-line being parsed includes any of the following:

- `--file` = `foo`
  - `--file foo`
  - `--file=foo`
  - `--file foo`

then **optparse**, on seeing this option, will do the equivalent of

```python
options.filename = "foo"
```

The **type** and **dest** option attributes are almost as important as **action**, but **action** is the only one that makes sense for all options.

### 16.5.3.4. Option attributes

The following option attributes may be passed as keyword arguments to **OptionParser.add_option()**. If you pass an option attribute that is not relevant to a particular option, or fail to pass a required option attribute, **optparse** raises **OptionError**.

**Option.** **action**

(default: "store")

Determines **optparse**'s behaviour when this option is seen on the command line; the available options are documented [here](#).

**Option.** **type**

(default: "string")
The argument type expected by this option (e.g., "string" or "int"); the available option types are documented here.

**Option. dest**  
(default: derived from option strings)

If the option's action implies writing or modifying a value somewhere, this tells optparse where to write it: dest names an attribute of the options object that optparse builds as it parses the command line.

**Option. default**  
The value to use for this option's destination if the option is not seen on the command line. See also OptionParser.set_defaults().

**Option. nargs**  
(default: 1)

How many arguments of type type should be consumed when this option is seen. If > 1, optparse will store a tuple of values to dest.

**Option. const**  
For actions that store a constant value, the constant value to store.

**Option. choices**  
For options of type "choice", the list of strings the user may choose from.

**Option. callback**  
For options with action "callback", the callable to call when this option is seen. See section Option Callbacks for detail on the
arguments passed to the callable.

Option. `callback_args`
Option. `callback_kwargs`

Additional positional and keyword arguments to pass to `callback` after the four standard callback arguments.

Option. `help`

Help text to print for this option when listing all available options after the user supplies a `help` option (such as `--help`). If no help text is supplied, the option will be listed without help text. To hide this option, use the special value `optparse.SUPPRESS_HELP`.

Option. `metavar`

(default: derived from option strings)

Stand-in for the option argument(s) to use when printing help text. See section `Tutorial` for an example.

16.5.3.5. Standard option actions

The various option actions all have slightly different requirements and effects. Most actions have several relevant option attributes which you may specify to guide `optparse`'s behaviour; a few have required attributes, which you must specify for any option using that action.

- "store" [relevant: `type`, `dest`, `nargs`, `choices`]

  The option must be followed by an argument, which is converted to a value according to `type` and stored in `dest`. If `nargs` > 1, multiple arguments will be consumed from the command line; all will be converted according to `type` and stored to `dest` as a
tuple. See the *Standard option types* section.

If *choices* is supplied (a list or tuple of strings), the type defaults to "choice".

If *type* is not supplied, it defaults to "string".

If *dest* is not supplied, *optparse* derives a destination from the first long option string (e.g., --foo-bar implies foo_bar). If there are no long option strings, *optparse* derives a destination from the first short option string (e.g., -f implies f).

Example:

```python
parser.add_option("-f")
parser.add_option("-p", type="float", nargs=3, dest="point")
```

As it parses the command line

```
-f foo.txt -p 1 -3.5 4 -fbar.txt
```

*optparse* will set

```python
options.f = "foo.txt"
options.point = (1.0, -3.5, 4.0)
options.f = "bar.txt"
```

- "store_const" [required: *const*; relevant: *dest*]

  The value *const* is stored in *dest*.

Example:

```python
parser.add_option("-q", "--quiet",
```
If `--noisy` is seen, `optparse` will set

```python
options.verbose = 2
```

- **"store_true"** [relevant: `dest`]
  
  A special case of "store_const" that stores a true value to `dest`.

- **"store_false"** [relevant: `dest`]
  
  Like "store_true", but stores a false value.

  Example:

```python
parser.add_option("--clobber", action="store_true")
parser.add_option("--no-clobber", action="store_true")
```

- **"append"** [relevant: `type, dest, nargs, choices`]
  
  The option must be followed by an argument, which is appended to the list in `dest`. If no default value for `dest` is supplied, an empty list is automatically created when `optparse` first encounters this option on the command-line. If `nargs > 1`, multiple arguments are consumed, and a tuple of length `nargs` is appended to `dest`. 
The defaults for type and dest are the same as for the "store" action.

Example:

```python
parser.add_option("-t", "--tracks", action="append")
```

If -t3 is seen on the command-line, optparse does the equivalent of:

```python
options.tracks = []
options.tracks.append(int("3"))
```

If, a little later on, --tracks=4 is seen, it does:

```python
options.tracks.append(int("4"))
```

The append action calls the append method on the current value of the option. This means that any default value specified must have an append method. It also means that if the default value is non-empty, the default elements will be present in the parsed value for the option, with any values from the command line appended after those default values:

```python
>>> parser.add_option("--files", action="append")
>>> opts, args = parser.parse_args(['--files', ''])
>>> opts.files
["~/mypkg/defaults", 'overrides.mypkg']
```

- "append_const" [required: const; relevant: dest]

  Like "store_const", but the value const is appended to
**dest**: as with "append", dest defaults to None, and an empty list is automatically created the first time the option is encountered.

- "count" [relevant: dest]

  Increment the integer stored at dest. If no default value is supplied, dest is set to zero before being incremented the first time.

  Example:

  ```python
  parser.add_option('-v', action='count', dest='verbosity',)
  ```

  The first time -v is seen on the command line, optparse does the equivalent of:

  ```python
  options.verbosity = 0
  options.verbosity += 1
  ```

  Every subsequent occurrence of -v results in

  ```python
  options.verbosity += 1
  ```

- "callback" [required: callback; relevant: type, nargs, callback_args, callback_kwargs]

  Call the function specified by callback, which is called as

  ```python
  func(option, opt_str, value, parser, *args, **kwargs)
  ```

  See section Option Callbacks for more detail.
"help"

Prints a complete help message for all the options in the current option parser. The help message is constructed from the usage string passed to OptionParser’s constructor and the help string passed to every option.

If no help string is supplied for an option, it will still be listed in the help message. To omit an option entirely, use the special value optparse.SUPPRESS_HELP.

optparse automatically adds a help option to all OptionParsers, so you do not normally need to create one.

Example:

```python
from optparse import OptionParser, SUPPRESS_HELP

# usually, a help option is added automatically, 
# be suppressed using the add_help_option argument
parser = OptionParser(add_help_option=False)

parser.add_option("-h", "--help", action="help")
parser.add_option("-v", action="store_true", dest=help="Be moderately verbose")
parser.add_option("--file", dest="filename", 
   help="Input file to read data from")
parser.add_option("--secret", help=SUPPRESS_HELP)
```

If optparse sees either -h or --help on the command line, it will print something like the following help message to stdout (assuming sys.argv[0] is "foo.py"):

```
Usage: foo.py [options]
```
Options:
- h, --help    Show this help message and exit
- v            Be moderately verbose
--file=FILENAME Input file to read data from

After printing the help message, optparse terminates your process with sys.exit(0).

- "version"

Prints the version number supplied to the OptionParser to stdout and exits. The version number is actually formatted and printed by the print_version() method of OptionParser. Generally only relevant if the version argument is supplied to the OptionParser constructor. As with help options, you will rarely create version options, since optparse automatically adds them when needed.

16.5.3.6. Standard option types

optparse has five built-in option types: "string", "int", "choice", "float" and "complex". If you need to add new option types, see section Extending optparse.

Arguments to string options are not checked or converted in any way: the text on the command line is stored in the destination (or passed to the callback) as-is.

Integer arguments (type "int") are parsed as follows:

- if the number starts with 0x, it is parsed as a hexadecimal number
- if the number starts with 0, it is parsed as an octal number
- if the number starts with `0b`, it is parsed as a binary number
- otherwise, the number is parsed as a decimal number

The conversion is done by calling `int()` with the appropriate base (2, 8, 10, or 16). If this fails, so will `optparse`, although with a more useful error message.

"float" and "complex" option arguments are converted directly with `float()` and `complex()`, with similar error-handling.

"choice" options are a subtype of "string" options. The `choices` option attribute (a sequence of strings) defines the set of allowed option arguments. `optparse.check_choice()` compares user-supplied option arguments against this master list and raises `OptionValueError` if an invalid string is given.

### 16.5.3.7. Parsing arguments

The whole point of creating and populating an OptionParser is to call its `parse_args()` method:

```python
(options, args) = parser.parse_args(args=None, values=optparse.Values())
```

where the input parameters are

- `args`  
  the list of arguments to process (default: `sys.argv[1:]`)  
- `values`  
  a `optparse.Values` object to store option arguments in (default: a new instance of `Values`) – if you give an existing object, the option defaults will not be initialized on it
and the return values are

**options**
the same object that was passed in as `values`, or the optparse.Values instance created by `optparse`

**args**
the leftover positional arguments after all options have been processed

The most common usage is to supply neither keyword argument. If you supply `values`, it will be modified with repeated `setattr()` calls (roughly one for every option argument stored to an option destination) and returned by `parse_args()`.

If `parse_args()` encounters any errors in the argument list, it calls the OptionParser's `error()` method with an appropriate end-user error message. This ultimately terminates your process with an exit status of 2 (the traditional Unix exit status for command-line errors).

### 16.5.3.8. Querying and manipulating your option parser

The default behavior of the option parser can be customized slightly, and you can also poke around your option parser and see what's there. OptionParser provides several methods to help you out:

**OptionParser**. `disable_interspersed_args()`
Set parsing to stop on the first non-option. For example, if `-a` and `-b` are both simple options that take no arguments, `optparse` normally accepts this syntax:

```
prog -a arg1 -b arg2
```
and treats it as equivalent to

```
prog -a -b arg1 arg2
```

To disable this feature, call `disable_interspersed_args()`. This restores traditional Unix syntax, where option parsing stops with the first non-option argument.

Use this if you have a command processor which runs another command which has options of its own and you want to make sure these options don’t get confused. For example, each command might have a different set of options.

OptionParser.**enable_interspersed_args()**

Set parsing to not stop on the first non-option, allowing interspersing switches with command arguments. This is the default behavior.

OptionParser.**get_option(opt_str)**

Returns the Option instance with the option string `opt_str`, or None if no options have that option string.

OptionParser.**has_option(opt_str)**

Return true if the OptionParser has an option with option string `opt_str` (e.g., `-q` or `--verbose`).

OptionParser.**remove_option(opt_str)**

If the OptionParser has an option corresponding to `opt_str`, that option is removed. If that option provided any other option strings, all of those option strings become invalid. If `opt_str` does not occur in any option belonging to this OptionParser, raises ValueError.
16.5.3.9. Conflicts between options

If you're not careful, it's easy to define options with conflicting option strings:

```python
parser.add_option("-n", "--dry-run", ...)  
[...]  
parser.add_option("-n", "--noisy", ...)  
```

(This is particularly true if you've defined your own OptionParser subclass with some standard options.)

Every time you add an option, `optparse` checks for conflicts with existing options. If it finds any, it invokes the current conflict-handling mechanism. You can set the conflict-handling mechanism either in the constructor:

```python
parser = OptionParser(..., conflict_handler=handler)  
```

or with a separate call:

```python
parser.set_conflict_handler(handler)  
```

The available conflict handlers are:

"error" (default)

- assume option conflicts are a programming error and raise `OptionConflictError`

"resolve"

- resolve option conflicts intelligently (see below)

As an example, let's define an `OptionParser` that resolves conflicts intelligently and add conflicting options to it:
At this point, `optparse` detects that a previously-added option is already using the `-n` option string. Since `conflict_handler` is "resolve", it resolves the situation by removing `-n` from the earlier option's list of option strings. Now `--dry-run` is the only way for the user to activate that option. If the user asks for help, the help message will reflect that:

```
Options:
  -dry-run       do no harm
  [...]          
  -n, --noisy   be noisy
```

It's possible to whittle away the option strings for a previously-added option until there are none left, and the user has no way of invoking that option from the command-line. In that case, `optparse` removes that option completely, so it doesn't show up in help text or anywhere else. Carrying on with our existing OptionParser:

```
parser.add_option("--dry-run", ..., help="new dry-run option")
```

At this point, the original `-n/--dry-run` option is no longer accessible, so `optparse` removes it, leaving this help text:

```
Options:
  [...]          
  -n, --noisy   be noisy
  --dry-run     new dry-run option
```
16.5.3.10. Cleanup

OptionParser instances have several cyclic references. This should not be a problem for Python's garbage collector, but you may wish to break the cyclic references explicitly by calling `destroy()` on your OptionParser once you are done with it. This is particularly useful in long-running applications where large object graphs are reachable from your OptionParser.

16.5.3.11. Other methods

OptionParser supports several other public methods:

**OptionParser**. `set_usage(usage)`

Set the usage string according to the rules described above for the `usage` constructor keyword argument. Passing `None` sets the default usage string; use `optparse.SUPPRESS_USAGE` to suppress a usage message.

**OptionParser**. `print_usage(file=None)`

Print the usage message for the current program (`self.usage`) to `file` (default stdout). Any occurrence of the string `%prog` in `self.usage` is replaced with the name of the current program. Does nothing if `self.usage` is empty or not defined.

**OptionParser**. `get_usage()`

Same as `print_usage()` but returns the usage string instead of printing it.

**OptionParser**. `set_defaults(dest=value, ...)`

Set default values for several option destinations at once. Using
`set_defaults()` is the preferred way to set default values for options, since multiple options can share the same destination. For example, if several “mode” options all set the same destination, any one of them can set the default, and the last one wins:

```python
defaults()
set_defaults()
is	the	preferred	way	to	set
default	values	for
options,	since	multiple	options
can	share	the	same
destination.

For
e.g.,	if
everal	"mode"	options
tt	set	the	same
destination,
any
tne			can	set	the
default, 
and
the
last
one
wins:

```python
parser.add_option("--advanced", action="store_const",
                dest="mode", const="advanced",
default="novice")  # override
```

parser.add_option("--novice", action="store_const",
                dest="mode", const="novice",
default="advanced")  # override

To avoid this confusion, use `set_defaults()`:

```python
parser.set_defaults(mode="advanced")
parser.add_option("--advanced", action="store_const",
                dest="mode", const="advanced")
parser.add_option("--novice", action="store_const",
                dest="mode", const="novice")
```
16.5.4. Option Callbacks

When `optparse`'s built-in actions and types aren't quite enough for your needs, you have two choices: extend `optparse` or define a callback option. Extending `optparse` is more general, but overkill for a lot of simple cases. Quite often a simple callback is all you need.

There are two steps to defining a callback option:

- define the option itself using the "callback" action
- write the callback; this is a function (or method) that takes at least four arguments, as described below

16.5.4.1. Defining a callback option

As always, the easiest way to define a callback option is by using the `OptionParser.add_option()` method. Apart from `action`, the only option attribute you must specify is `callback`, the function to call:

```python
parser.add_option("-c", action="callback", callback=callback)
```

callback is a function (or other callable object), so you must have already defined `my_callback()` when you create this callback option. In this simple case, `optparse` doesn't even know if `-c` takes any arguments, which usually means that the option takes no arguments—the mere presence of `-c` on the command-line is all it needs to know. In some circumstances, though, you might want your callback to consume an arbitrary number of command-line arguments. This is where writing callbacks gets tricky; it's covered later in this
optparse always passes four particular arguments to your callback, and it will only pass additional arguments if you specify them via callback_args and callback_kwargs. Thus, the minimal callback function signature is:

```python
def my_callback(option, opt, value, parser):
```

The four arguments to a callback are described below.

There are several other option attributes that you can supply when you define a callback option:

- **type**
  has its usual meaning: as with the "store" or "append" actions, it instructs optparse to consume one argument and convert it to type. Rather than storing the converted value(s) anywhere, though, optparse passes it to your callback function.

- **nargs**
  also has its usual meaning: if it is supplied and > 1, optparse will consume nargs arguments, each of which must be convertible to type. It then passes a tuple of converted values to your callback.

- **callback_args**
  a tuple of extra positional arguments to pass to the callback

- **callback_kwargs**
  a dictionary of extra keyword arguments to pass to the callback

### 16.5.4.2. How callbacks are called

All callbacks are called as follows:
func(option, opt_str, value, parser, *args, **kwargs)

where

**option**

is the Option instance that's calling the callback

**opt_str**

is the option string seen on the command-line that's triggering the callback. (If an abbreviated long option was used, **opt_str** will be the full, canonical option string—e.g. if the user puts --foo on the command-line as an abbreviation for --foobar, then **opt_str** will be "--foobar").

**value**

is the argument to this option seen on the command-line. **optparse** will only expect an argument if **type** is set; the type of **value** will be the type implied by the option's type. If **type** for this option is None (no argument expected), then **value** will be None. If **nargs** > 1, **value** will be a tuple of values of the appropriate type.

**parser**

is the OptionParser instance driving the whole thing, mainly useful because you can access some other interesting data through its instance attributes:

**parser.largs**

the current list of leftover arguments, ie. arguments that have been consumed but are neither options nor option arguments. Feel free to modify **parser.largs**, e.g. by adding more arguments to it. (This list will become **args**, the second return value of **parse_args()**.)

**parser.rargs**
the current list of remaining arguments, ie. with `opt_str` and `value` (if applicable) removed, and only the arguments following them still there. Feel free to modify `parser.rargs`, e.g. by consuming more arguments.

`parser.values`

the object where option values are by default stored (an instance of `optparse.OptionValues`). This lets callbacks use the same mechanism as the rest of `optparse` for storing option values; you don’t need to mess around with globals or closures. You can also access or modify the value(s) of any options already encountered on the command-line.

`args`

is a tuple of arbitrary positional arguments supplied via the `callback_args` option attribute.

`kwargs`

is a dictionary of arbitrary keyword arguments supplied via `callback_kwargs`.

16.5.4.3. Raising errors in a callback

The callback function should raise `OptionValueError` if there are any problems with the option or its argument(s). `optparse` catches this and terminates the program, printing the error message you supply to stderr. Your message should be clear, concise, accurate, and mention the option at fault. Otherwise, the user will have a hard time figuring out what he did wrong.

16.5.4.4. Callback example 1: trivial callback

Here’s an example of a callback option that takes no arguments, and simply records that the option was seen:
def record_foo_seen(option, opt_str, value, parser):
    parser.values.saw_foo = True
    parser.add_option("--foo", action="callback", callback=)

Of course, you could do that with the "store_true" action.

16.5.4.5. Callback example 2: check option order

Here's a slightly more interesting example: record the fact that -a is seen, but blow up if it comes after -b in the command-line.

def check_order(option, opt_str, value, parser):
    if parser.values.b:
        raise OptionValueError("can't use -a after -b")
    parser.values.a = 1
    [...]
    parser.add_option("-a", action="callback", callback=)
    parser.add_option("-b", action="store_true", dest="b")

16.5.4.6. Callback example 3: check option order (generalized)

If you want to re-use this callback for several similar options (set a flag, but blow up if -b has already been seen), it needs a bit of work: the error message and the flag that it sets must be generalized.

def check_order(option, opt_str, value, parser):
    if parser.values.b:
        raise OptionValueError("can't use %s after -b")
    setattr(parser.values, option.dest, 1)
    [...]

16.5.4.7. Callback example 4: check arbitrary condition

Of course, you could put any condition in there—you're not limited to checking the values of already-defined options. For example, if you have options that should not be called when the moon is full, all you have to do is this:

```python
def check_moon(option, opt_str, value, parser):
    if is_moon_full():
        raise OptionValueError("%s option invalid when moon is full" % opt_str)
    setattr(parser.values, option.dest, 1)
parser.add_option("--foo",
    action="callback", callback=check_moon)
```

(The definition of `is_moon_full()` is left as an exercise for the reader.)

16.5.4.8. Callback example 5: fixed arguments

Things get slightly more interesting when you define callback options that take a fixed number of arguments. Specifying that a callback option takes arguments is similar to defining a "store" or "append" option: if you define `type`, then the option takes one argument that must be convertible to that type; if you further define `nargs`, then the
option takes \texttt{nargs} arguments.

Here’s an example that just emulates the standard "store" action:

```python
def store_value(option, opt_str, value, parser):
   setattr(parser.values, option.dest, value)

parser.add_option("--foo",
    action="callback", callback=store_value,
    type="int", nargs=3, dest="foo")
```

Note that \texttt{optparse} takes care of consuming 3 arguments and converting them to integers for you; all you have to do is store them. (Or whatever; obviously you don’t need a callback for this example.)

16.5.4.9. Callback example 6: variable arguments

Things get hairy when you want an option to take a variable number of arguments. For this case, you must write a callback, as \texttt{optparse} doesn’t provide any built-in capabilities for it. And you have to deal with certain intricacies of conventional Unix command-line parsing that \texttt{optparse} normally handles for you. In particular, callbacks should implement the conventional rules for bare -- and - arguments:

- either -- or - can be option arguments
- bare -- (if not the argument to some option): halt command-line processing and discard the --
- bare - (if not the argument to some option): halt command-line processing but keep the - (append it to \texttt{parser.largs})

If you want an option that takes a variable number of arguments, there are several subtle, tricky issues to worry about. The exact
implementation you choose will be based on which trade-offs you’re willing to make for your application (which is why `optparse` doesn’t support this sort of thing directly).

Nevertheless, here’s a stab at a callback for an option with variable arguments:

```python
def vararg_callback(option, opt_str, value, parser):
    assert value is None
    value = []

def floatable(str):
    try:
        float(str)
        return True
    except ValueError:
        return False

for arg in parser.rargs:
    # stop on --foo like options
    if arg[:2] == "--" and len(arg) > 2:
        break
    # stop on -a, but not on -3 or -3.0
    if arg[:1] == "-" and len(arg) > 1 and not
        break
    value.append(arg)

del parser.rargs[:len(value)]
setattr(parser.values, option.dest, value)

[...] parser.add_option("-c", "--callback", dest="vararg_attr"
         action="callback", callback=vararg_callback)
```
16.5.5. Extending optparse

Since the two major controlling factors in how optparse interprets command-line options are the action and type of each option, the most likely direction of extension is to add new actions and new types.

16.5.5.1. Adding new types

To add new types, you need to define your own subclass of optparse's Option class. This class has a couple of attributes that define optparse's types: TYPES and TYPE_CHECKER.

Option. TYPES

A tuple of type names; in your subclass, simply define a new tuple TYPES that builds on the standard one.

Option. TYPE_CHECKER

A dictionary mapping type names to type-checking functions. A type-checking function has the following signature:

```python
def check_mytype(option, opt, value)
```

where option is an Option instance, opt is an option string (e.g., -f), and value is the string from the command line that must be checked and converted to your desired type. check_mytype() should return an object of the hypothetical type mytype. The value returned by a type-checking function will wind up in the OptionValues instance returned by OptionParser.parse_args(), or be passed to a callback as the value parameter.
Your type-checking function should raise OptionValueError if it encounters any problems. OptionValueError takes a single string argument, which is passed as-is to OptionParser's error() method, which in turn prepends the program name and the string "error:" and prints everything to stderr before terminating the process.

Here's a silly example that demonstrates adding a "complex" option type to parse Python-style complex numbers on the command line. (This is even sillier than it used to be, because optparse 1.3 added built-in support for complex numbers, but never mind.)

First, the necessary imports:

```python
from copy import copy
from optparse import Option, OptionValueError
```

You need to define your type-checker first, since it's referred to later (in the TYPE_CHECKER class attribute of your Option subclass):

```python
def check_complex(option, opt, value):
    try:
        return complex(value)
    except ValueError:
        raise OptionValueError("option %s: invalid complex value: %r" %
                         (opt, value),)
```

Finally, the Option subclass:

```python
class MyOption (Option):
    TYPES = Option.TYPES + ("complex",)
    TYPE_CHECKER = copy(Option.TYPE_CHECKER)
    TYPE_CHECKER["complex"] = check_complex
```
(If we didn’t make a copy() of `Option.TYPE_CHECKER`, we would end up modifying the `TYPE_CHECKER` attribute of `optparse`'s Option class. This being Python, nothing stops you from doing that except good manners and common sense.)

That’s it! Now you can write a script that uses the new option type just like any other `optparse`-based script, except you have to instruct your OptionParser to use MyOption instead of Option:

```python
generator = OptionParser(option_class=MyOption)  
generator.add_option("-c", type="complex")
```

Alternately, you can build your own option list and pass it to OptionParser; if you don’t use `add_option()` in the above way, you don’t need to tell OptionParser which option class to use:

```python
option_list = [MyOption("-c", action="store", type='complex')]
generator = OptionParser(option_list=option_list)
```

### 16.5.5.2. Adding new actions

Adding new actions is a bit trickier, because you have to understand that `optparse` has a couple of classifications for actions:

**“store” actions**

actions that result in `optparse` storing a value to an attribute of the current `OptionValues` instance; these options require a `dest` attribute to be supplied to the Option constructor.

**“typed” actions**

actions that take a value from the command line and expect it to be of a certain type; or rather, a string that can be converted to a certain type. These options require a `type` attribute to the Option constructor.
constructor.

These are overlapping sets: some default “store” actions are "store", "store_const", "append", and "count", while the default “typed” actions are "store", "append", and "callback".

When you add an action, you need to categorize it by listing it in at least one of the following class attributes of Option (all are lists of strings):

Option. ACTIONS
All actions must be listed in ACTIONS.

Option. STORE_ACTIONS
“store” actions are additionally listed here.

Option. TYPED_ACTIONS
“typed” actions are additionally listed here.

Option. ALWAYS_TYPED_ACTIONS
Actions that always take a type (i.e. whose options always take a value) are additionally listed here. The only effect of this is that optparse assigns the default type, "string", to options with no explicit type whose action is listed in ALWAYS_TYPED_ACTIONS.

In order to actually implement your new action, you must override Option's take_action() method and add a case that recognizes your action.

For example, let’s add an "extend" action. This is similar to the standard "append" action, but instead of taking a single value from the command-line and appending it to an existing list, "extend" will take multiple values in a single comma-delimited string, and extend an
existing list with them. That is, if `--names` is an "extend" option of type "string", the command line

```
--names=foo,bar --names blah --names ding,dong
```

would result in a list

```
["foo", "bar", "blah", "ding", "dong"]
```

Again we define a subclass of Option:

```python
class MyOption(Option):

    ACTIONS = Option.ACTIONS + ("extend",)
    STORE_ACTIONS = Option.STORE_ACTIONS + ("extend")
    TYPED_ACTIONS = Option.TYPED_ACTIONS + ("extend")
    ALWAYS_TYPED_ACTIONS = Option.ALWAYS_TYPED_ACTIONS

    def take_action(self, action, dest, opt, value, lvalue = value.split(",")
        values.ensure_value(dest, []).extend(lvalue)
    else:
        Option.take_action( self, action, dest, opt, value, value
```

Features of note:

- "extend" both expects a value on the command-line and stores that value somewhere, so it goes in both `STORE_ACTIONS` and `TYPED_ACTIONS`.

- to ensure that `optparse` assigns the default type of "string" to "extend" actions, we put the "extend" action in
**ALWAYS_TYPED_ACTIONS** as well.

- MyOption.take_action() implements just this one new action, and passes control back to Option.take_action() for the standard *optparse* actions.

- *values* is an instance of the *optparse_parser.Values* class, which provides the very useful *ensure_value()* method. *ensure_value()* is essentially *getattr()* with a safety valve; it is called as

  ```python
  values.ensure_value(attr, value)
  ```

  If the *attr* attribute of *values* doesn't exist or is None, then *ensure_value()* first sets it to *value*, and then returns `value`. This is very handy for actions like "extend", "append", and "count", all of which accumulate data in a variable and expect that variable to be of a certain type (a list for the first two, an integer for the latter). Using *ensure_value()* means that scripts using your action don't have to worry about setting a default value for the option destinations in question; they can just leave the default as None and *ensure_value()* will take care of getting it right when it's needed.
16.6. getopt — C-style parser for command line options

Source code: Lib/getopt.py

Note: The getopt module is a parser for command line options whose API is designed to be familiar to users of the C getopt() function. Users who are unfamiliar with the C getopt() function or who would like to write less code and get better help and error messages should consider using the argparse module instead.

This module helps scripts to parse the command line arguments in sys.argv. It supports the same conventions as the Unix getopt() function (including the special meanings of arguments of the form ‘-‘ and ‘--‘). Long options similar to those supported by GNU software may be used as well via an optional third argument.

This module provides two functions and an exception:

getopt.getopt(args, shortopts, longopts=[])  

 Parses command line options and parameter list. args is the argument list to be parsed, without the leading reference to the running program. Typically, this means sys.argv[1:]. shortopts is the string of option letters that the script wants to recognize, with options that require an argument followed by a colon (':'); i.e., the same format that Unix getopt() uses.

Note: Unlike GNU getopt(), after a non-option argument, all further arguments are considered also non-options. This is similar
to the way non-GNU Unix systems work.

`longopts`, if specified, must be a list of strings with the names of the long options which should be supported. The leading `--` characters should not be included in the option name. Long options which require an argument should be followed by an equal sign (`='). Optional arguments are not supported. To accept only long options, `shortopts` should be an empty string. Long options on the command line can be recognized so long as they provide a prefix of the option name that matches exactly one of the accepted options. For example, if `longopts` is `['foo', 'frob']`, the option `--fo` will match as `--foo`, but `--f` will not match uniquely, so `GetoptError` will be raised.

The return value consists of two elements: the first is a list of `(option, value)` pairs; the second is the list of program arguments left after the option list was stripped (this is a trailing slice of `args`). Each option-and-value pair returned has the option as its first element, prefixed with a hyphen for short options (e.g., `-x`) or two hyphens for long options (e.g., `--long-option`), and the option argument as its second element, or an empty string if the option has no argument. The options occur in the list in the same order in which they were found, thus allowing multiple occurrences. Long and short options may be mixed.

```
getopt. gnu_getopt(args, shortopts, longopts=[])  
```

This function works like `getopt()`, except that GNU style scanning mode is used by default. This means that option and non-option arguments may be intermixed. The `getopt()` function stops processing options as soon as a non-option argument is encountered.
If the first character of the option string is `+' or if the environment variable POSIXLY_CORRECT is set, then option processing stops as soon as a non-option argument is encountered.

`exception getopt.GetoptError`

This is raised when an unrecognized option is found in the argument list or when an option requiring an argument is given none. The argument to the exception is a string indicating the cause of the error. For long options, an argument given to an option which does not require one will also cause this exception to be raised. The attributes msg and opt give the error message and related option; if there is no specific option to which the exception relates, opt is an empty string.

`exception getopt.error`

Alias for `GetoptError`; for backward compatibility.

An example using only Unix style options:

```python
>>> import getopt
>>> args = '-a -b -cfoo -d bar a1 a2'.split()
>>> args
['-a', '-b', '-cfoo', '-d', 'bar', 'a1', 'a2']
>>> optlist, args = getopt.getopt(args, 'abc:d:')
>>> optlist
[('-a', ''), ('-b', ''), ('-c', 'foo'), ('-d', 'bar')]
>>> args
['a1', 'a2']
```

Using long option names is equally easy:

```python
>>> s = '--condition=foo --testing --output-file abc
default'
```
In a script, typical usage is something like this:

```python
import getopt, sys

def main():
    try:
        opts, args = getopt.getopt(sys.argv[1:], "hp:v")
    except getopt.GetoptError as err:
        # print help information and exit:
        print(err) # will print something like "option -a not recognized"
        usage()
        sys.exit(2)
        output = None
        verbose = False
    for o, a in opts:
        if o == "-v":
            verbose = True
        elif o in ("-h", "--help"):
            usage()
            sys.exit()
        elif o in ("-o", "--output"):
            output = a
        else:
            assert False, "unhandled option"

    # ...
```
if __name__ == "__main__":
    main()

Note that an equivalent command line interface could be produced with less code and more informative help and error messages by using the `argparse` module:

```python
import argparse

if __name__ == '__main__':
    parser = argparse.ArgumentParser()
    parser.add_argument('-o', '--output')
    parser.add_argument('-v', dest='verbose', action='store_true')
    args = parser.parse_args()
    # ... do something with args.output ...
    # ... do something with args.verbose ..
```

Module `argparse`

Alternative command line option and argument parsing library.
16.7. **logging** — Logging facility for Python

**Source code:** [Lib/logging/__init__.py](Lib/logging/__init__.py)

This module defines functions and classes which implement a flexible event logging system for applications and libraries.

The key benefit of having the logging API provided by a standard library module is that all Python modules can participate in logging, so your application log can include your own messages integrated with messages from third-party modules.

The module provides a lot of functionality and flexibility. If you are unfamiliar with logging, the best way to get to grips with it is to see the tutorials (see the links on the right).

The basic classes defined by the module, together with their functions, are listed below.

- Loggers expose the interface that application code directly uses.
- Handlers send the log records (created by loggers) to the appropriate destination.
- Filters provide a finer grained facility for determining which log records to output.
- Formatters specify the layout of log records in the final output.
16.7.1. Logger Objects

Loggers have the following attributes and methods. Note that Loggers are never instantiated directly, but always through the module-level function `logging.getLogger(name)`. Multiple calls to `getLogger()` with the same name will always return a reference to the same Logger object.

The name is potentially a period-separated hierarchical value, like `foo.bar.baz` (though it could also be just plain `foo`, for example). Loggers that are further down in the hierarchical list are children of loggers higher up in the list. For example, given a logger with a name of `foo`, loggers with names of `foo.bar`, `foo.bar.baz`, and `foo.bam` are all descendants of `foo`. The logger name hierarchy is analogous to the Python package hierarchy, and identical to it if you organise your loggers on a per-module basis using the recommended construction `logging.getLogger(__name__)`. That’s because in a module, `__name__` is the module’s name in the Python package namespace.

```python
class logging.Logger
```

**Logger**. `propagate`

If this evaluates to true, events logged to this logger will be passed to the handlers of higher level (ancestor) loggers, in addition to any handlers attached to this logger. Messages are passed directly to the ancestor loggers’ handlers - neither the level nor filters of the ancestor loggers in question are considered.

If this evaluates to false, logging messages are not passed to the handlers of ancestor loggers.
The constructor sets this attribute to True.

**Note:** If you attach a handler to a logger *and* one or more of its ancestors, it may emit the same record multiple times. In general, you should not need to attach a handler to more than one logger - if you just attach it to the appropriate logger which is highest in the logger hierarchy, then it will see all events logged by all descendant loggers, provided that their propagate setting is left set to True. A common scenario is to attach handlers only to the root logger, and to let propagation take care of the rest.

Logger. `setLevel(lvl)`

Sets the threshold for this logger to `lvl`. Logging messages which are less severe than `lvl` will be ignored. When a logger is created, the level is set to `NOTSET` (which causes all messages to be processed when the logger is the root logger, or delegation to the parent when the logger is a non-root logger). Note that the root logger is created with level `WARNING`.

The term ‘delegation to the parent’ means that if a logger has a level of `NOTSET`, its chain of ancestor loggers is traversed until either an ancestor with a level other than `NOTSET` is found, or the root is reached.

If an ancestor is found with a level other than `NOTSET`, then that ancestor’s level is treated as the effective level of the logger where the ancestor search began, and is used to determine how a logging event is handled.

If the root is reached, and it has a level of `NOTSET`, then all messages will be processed. Otherwise, the root’s level will be used as the effective level.
See *Logging Levels* for a list of levels.

*Changed in version 3.2:* The *lvl* parameter now accepts a string representation of the level such as ‘INFO’ as an alternative to the integer constants such as INFO.

**Logger**. `isEnabledFor(lvl)`

Indicates if a message of severity *lvl* would be processed by this logger. This method checks first the module-level level set by `logging.disable(lvl)` and then the logger’s effective level as determined by `getEffectiveLevel()`.

**Logger**. `getEffectiveLevel()`

Indicates the effective level for this logger. If a value other than NOTSET has been set using `setLevel()`, it is returned. Otherwise, the hierarchy is traversed towards the root until a value other than NOTSET is found, and that value is returned.

**Logger**. `getChild(suffix)`

Returns a logger which is a descendant to this logger, as determined by the `suffix`. Thus, `logging.getLogger('abc').getChild('def.ghi')` would return the same logger as would be returned by `logging.getLogger('abc.def.ghi')`. This is a convenience method, useful when the parent logger is named using e.g. `__name__` rather than a literal string.

*New in version 3.2.*

**Logger**. `debug(msg, *args, **kwargs)`

Logs a message with level DEBUG on this logger. The *msg* is the message format string, and the *args* are the arguments which are
merged into *msg* using the string formatting operator. (Note that this means that you can use keywords in the format string, together with a single dictionary argument.)

There are three keyword arguments in *kwargs* which are inspected: *exc_info* which, if it does not evaluate as false, causes exception information to be added to the logging message. If an exception tuple (in the format returned by *sys.exc_info()* is provided, it is used; otherwise, *sys.exc_info()* is called to get the exception information.

The second optional keyword argument is *stack_info*, which defaults to *False*. If true, stack information is added to the logging message, including the actual logging call. Note that this is not the same stack information as that displayed through specifying *exc_info*: The former is stack frames from the bottom of the stack up to the logging call in the current thread, whereas the latter is information about stack frames which have been unwound, following an exception, while searching for exception handlers.

You can specify *stack_info* independently of *exc_info*, e.g. to just show how you got to a certain point in your code, even when no exceptions were raised. The stack frames are printed following a header line which says:

```
Stack (most recent call last):
```

This mimics the Traceback *(most recent call last)*: which is used when displaying exception frames.

The third keyword argument is *extra* which can be used to pass a dictionary which is used to populate the __dict__ of the LogRecord created for the logging event with user-defined attributes. These
custom attributes can then be used as you like. For example, they could be incorporated into logged messages. For example:

```python
FORMAT = '%(asctime)-15s %(clientip)s %(user)-8s %(message)s'
logging.basicConfig(format=FORMAT)
d = {'clientip': '192.168.0.1', 'user': 'fbloggs'}
logger = logging.getLogger('tcpserver')
logger.warning('Protocol problem: %s', 'connection reset')
```

would print something like

```
2006-02-08 22:20:02,165 192.168.0.1 fbloggs Protocol problem: connection reset
```

The keys in the dictionary passed in `extra` should not clash with the keys used by the logging system. (See the `Formatter` documentation for more information on which keys are used by the logging system.)

If you choose to use these attributes in logged messages, you need to exercise some care. In the above example, for instance, the `Formatter` has been set up with a format string which expects ‘clientip’ and ‘user’ in the attribute dictionary of the LogRecord. If these are missing, the message will not be logged because a string formatting exception will occur. So in this case, you always need to pass the `extra` dictionary with these keys.

While this might be annoying, this feature is intended for use in specialized circumstances, such as multi-threaded servers where the same code executes in many contexts, and interesting conditions which arise are dependent on this context (such as remote client IP address and authenticated user name, in the above example). In such circumstances, it is likely that specialized
Formatter would be used with particular Handlers.

New in version 3.2: The stack_info parameter was added.

Logger . info (msg, *args, **kwargs)
Logs a message with level INFO on this logger. The arguments are interpreted as for debug().

Logger . warning (msg, *args, **kwargs)
Logs a message with level WARNING on this logger. The arguments are interpreted as for debug().

Note: There is an obsolete method warn which is functionally identical to warning. As warn is deprecated, please do not use it - use warning instead.

Logger . error (msg, *args, **kwargs)
Logs a message with level ERROR on this logger. The arguments are interpreted as for debug().

Logger . critical (msg, *args, **kwargs)
Logs a message with level CRITICAL on this logger. The arguments are interpreted as for debug().

Logger . log (lvl, msg, *args, **kwargs)
Logs a message with integer level lvl on this logger. The other arguments are interpreted as for debug().

Logger . exception (msg, *args)
Logs a message with level ERROR on this logger. The arguments are interpreted as for debug(). Exception info is added to the
logging message. This method should only be called from an exception handler.

Logger.addFilter(filt)
   Adds the specified filter filt to this logger.

Logger.removeFilter(filt)
   Removes the specified filter filt from this logger.

Logger.filter(record)
   Applies this logger’s filters to the record and returns a true value if the record is to be processed. The filters are consulted in turn, until one of them returns a false value. If none of them return a false value, the record will be processed (passed to handlers). If one returns a false value, no further processing of the record occurs.

Logger.addHandler(hdlr)
   Adds the specified handler hdlr to this logger.

Logger.removeHandler(hdlr)
   Removes the specified handler hdlr from this logger.

Logger.findCaller(stack_info=False)
   Finds the caller’s source filename and line number. Returns the filename, line number, function name and stack information as a 4-element tuple. The stack information is returned as None unless stack_info is True.

Logger.handle(record)
   Handles a record by passing it to all handlers associated with this logger and its ancestors (until a false value of propagate is found). This method is used for unpickled records received from a socket, as well as those created locally. Logger-level filtering is applied
using \texttt{filter()}.  

\texttt{Logger.makeRecord(name, lvl, fn, lno, msg, args, exc_info, func=None, extra=None, sinfo=None)}

This is a factory method which can be overridden in subclasses to create specialized \texttt{LogRecord} instances.

\texttt{Logger.hasHandlers()} 

Checks to see if this logger has any handlers configured. This is done by looking for handlers in this logger and its parents in the logger hierarchy. Returns \texttt{True} if a handler was found, else \texttt{False}. The method stops searching up the hierarchy whenever a logger with the `propagate` attribute set to False is found - that will be the last logger which is checked for the existence of handlers.

\textit{New in version 3.2.}
16.7.2. Logging Levels

The numeric values of logging levels are given in the following table. These are primarily of interest if you want to define your own levels, and need them to have specific values relative to the predefined levels. If you define a level with the same numeric value, it overwrites the predefined value; the predefined name is lost.

<table>
<thead>
<tr>
<th>Level</th>
<th>Numeric value</th>
</tr>
</thead>
<tbody>
<tr>
<td>CRITICAL</td>
<td>50</td>
</tr>
<tr>
<td>ERROR</td>
<td>40</td>
</tr>
<tr>
<td>WARNING</td>
<td>30</td>
</tr>
<tr>
<td>INFO</td>
<td>20</td>
</tr>
<tr>
<td>DEBUG</td>
<td>10</td>
</tr>
<tr>
<td>NOTSET</td>
<td>0</td>
</tr>
</tbody>
</table>
16.7.3. Handler Objects

Handlers have the following attributes and methods. Note that Handler is never instantiated directly; this class acts as a base for more useful subclasses. However, the `__init__()` method in subclasses needs to call `Handler.__init__()`.

**Handler.__init__(level=NOTSET)**

Initializes the Handler instance by setting its level, setting the list of filters to the empty list and creating a lock (using `createLock()`) for serializing access to an I/O mechanism.

**Handler.createLock()**

Initializes a thread lock which can be used to serialize access to underlying I/O functionality which may not be threadsafe.

**Handler.acquire()**

Acquires the thread lock created with `createLock()`.

**Handler.release()**

Releases the thread lock acquired with `acquire()`.

**Handler.setLevel(lvl)**

Sets the threshold for this handler to `lvl`. Logging messages which are less severe than `lvl` will be ignored. When a handler is created, the level is set to NOTSET (which causes all messages to be processed).

See *Logging Levels* for a list of levels.

*Changed in version 3.2:* The `lvl` parameter now accepts a string representation of the level such as ‘INFO’ as an alternative to the
integer constants such as INFO.

Handler. **setFormatter**(form)

Sets the **Formatter** for this handler to *form*.

Handler. **addFilter**(filt)

Adds the specified filter *filt* to this handler.

Handler. **removeFilter**(filt)

Removes the specified filter *filt* from this handler.

Handler. **filter**(record)

Applies this handler's filters to the record and returns a true value if the record is to be processed. The filters are consulted in turn, until one of them returns a false value. If none of them return a false value, the record will be emitted. If one returns a false value, the handler will not emit the record.

Handler. **flush**()

Ensure all logging output has been flushed. This version does nothing and is intended to be implemented by subclasses.

Handler. **close**()

Tidy up any resources used by the handler. This version does no output but removes the handler from an internal list of handlers which is closed when **shutdown**() is called. Subclasses should ensure that this gets called from overridden **close**() methods.

Handler. **handle**(record)

Conditionally emits the specified logging record, depending on filters which may have been added to the handler. Wraps the actual emission of the record with acquisition/release of the I/O thread
lock.

**Handler.handleError(record)**

This method should be called from handlers when an exception is encountered during an `emit()` call. If the module-level attribute `raiseExceptions` is `False`, exceptions get silently ignored. This is what is mostly wanted for a logging system - most users will not care about errors in the logging system, they are more interested in application errors. You could, however, replace this with a custom handler if you wish. The specified record is the one which was being processed when the exception occurred. (The default value of `raiseExceptions` is `True`, as that is more useful during development).

**Handler.format(record)**

Do formatting for a record - if a formatter is set, use it. Otherwise, use the default formatter for the module.

**Handler.emit(record)**

Do whatever it takes to actually log the specified logging record. This version is intended to be implemented by subclasses and so raises a `NotImplementedError`.

For a list of handlers included as standard, see `logging.handlers`. 
16.7.4. Formatter Objects

Formatter objects have the following attributes and methods. They are responsible for converting a LogRecord to (usually) a string which can be interpreted by either a human or an external system. The base Formatter allows a formatting string to be specified. If none is supplied, the default value of '%(message)s' is used.

A Formatter can be initialized with a format string which makes use of knowledge of the LogRecord attributes - such as the default value mentioned above making use of the fact that the user’s message and arguments are pre-formatted into a LogRecord’s message attribute. This format string contains standard Python %-style mapping keys. See section printf-style String Formatting for more information on string formatting.

The useful mapping keys in a LogRecord are given in the section on LogRecord attributes.

class logging.Formatter(fmt=None, datefmt=None, style='%')

Returns a new instance of the Formatter class. The instance is initialized with a format string for the message as a whole, as well as a format string for the date/time portion of a message. If no fmt is specified, '%(message)s' is used. If no datefmt is specified, the ISO8601 date format is used.

The style parameter can be one of '%', '{' or '$' and determines how the format string will be merged with its data: using one of %-formatting, str.format() or string.Template. See Using particular formatting styles throughout your application for more information on using %- and $-formatting for log messages.
Changed in version 3.2: The style parameter was added.

**format**(record)

The record’s attribute dictionary is used as the operand to a string formatting operation. Returns the resulting string. Before formatting the dictionary, a couple of preparatory steps are carried out. The message attribute of the record is computed using `msg % args`. If the formatting string contains `(asctime)`, `formatTime()` is called to format the event time. If there is exception information, it is formatted using `formatException()` and appended to the message. Note that the formatted exception information is cached in attribute `exc_text`. This is useful because the exception information can be pickled and sent across the wire, but you should be careful if you have more than one Formatter subclass which customizes the formatting of exception information. In this case, you will have to clear the cached value after a formatter has done its formatting, so that the next formatter to handle the event doesn’t use the cached value but recalculates it afresh.

If stack information is available, it’s appended after the exception information, using `formatStack()` to transform it if necessary.

**formatTime**(record, datefmt=None)

This method should be called from `format()` by a formatter which wants to make use of a formatted time. This method can be overridden in formatters to provide for any specific requirement, but the basic behavior is as follows: if `datefmt` (a string) is specified, it is used with `time.strftime()` to format the creation time of the record. Otherwise, the ISO8601 format is used. The resulting string is returned.
This function uses a user-configurable function to convert the creation time to a tuple. By default, \texttt{time.localtime()} is used; to change this for a particular formatter instance, set the \texttt{converter} attribute to a function with the same signature as \texttt{time.localtime()} or \texttt{time.gmtime()}. To change it for all formatters, for example if you want all logging times to be shown in GMT, set the \texttt{converter} attribute in the \texttt{Formatter} class.

\textit{Changed in version 3.3:} Previously, the default ISO 8601 format was hard-coded as in this example: \texttt{2010-09-06 22:38:15,292} where the part before the comma is handled by a \texttt{strptime} format string (\texttt{%Y-%m-%d %H:%M:%S}), and the part after the comma is a millisecond value. Because \texttt{strptime} does not have a format placeholder for milliseconds, the millisecond value is appended using another format string, \texttt{%s,%03d} – and both of these format strings have been hardcoded into this method. With the change, these strings are defined as class-level attributes which can be overridden at the instance level when desired. The names of the attributes are \texttt{default_time_format} (for the \texttt{strptime} format string) and \texttt{default_msec_format} (for appending the millisecond value).

\texttt{formatException(exc_info)}

Formats the specified exception information (a standard exception tuple as returned by \texttt{sys.exc_info()}) as a string. This default implementation just uses \texttt{traceback.print_exception()}. The resulting string is returned.
**formatStack**(*stack_info*)

Formats the specified stack information (a string as returned by `traceback.print_stack()`, but with the last newline removed) as a string. This default implementation just returns the input value.
16.7.5. Filter Objects

Filters can be used by Handlers and Loggers for more sophisticated filtering than is provided by levels. The base filter class only allows events which are below a certain point in the logger hierarchy. For example, a filter initialized with ‘A.B’ will allow events logged by loggers ‘A.B’, ‘A.B.C’, ‘A.B.C.D’, ‘A.B.D’ etc. but not ‘A.BB’, ‘B.A.B’ etc. If initialized with the empty string, all events are passed.

```python
class logging.Filter(name='')
    Returns an instance of the Filter class. If name is specified, it names a logger which, together with its children, will have its events allowed through the filter. If name is the empty string, allows every event.

    filter(record)
    Is the specified record to be logged? Returns zero for no, nonzero for yes. If deemed appropriate, the record may be modified in-place by this method.
```

Note that filters attached to handlers are consulted before an event is emitted by the handler, whereas filters attached to loggers are consulted whenever an event is logged (using debug(), info(), etc.), before sending an event to handlers. This means that events which have been generated by descendant loggers will not be filtered by a logger’s filter setting, unless the filter has also been applied to those descendant loggers.

You don’t actually need to subclass Filter: you can pass any instance which has a filter method with the same semantics.

*Changed in version 3.2:* You don’t need to create specialized Filter
classes, or use other classes with a filter method: you can use a function (or other callable) as a filter. The filtering logic will check to see if the filter object has a filter attribute: if it does, it’s assumed to be a Filter and its filter() method is called. Otherwise, it’s assumed to be a callable and called with the record as the single parameter. The returned value should conform to that returned by filter().

Although filters are used primarily to filter records based on more sophisticated criteria than levels, they get to see every record which is processed by the handler or logger they’re attached to: this can be useful if you want to do things like counting how many records were processed by a particular logger or handler, or adding, changing or removing attributes in the LogRecord being processed. Obviously changing the LogRecord needs to be done with some care, but it does allow the injection of contextual information into logs (see Using Filters to impart contextual information).
16.7.6. LogRecord Objects

LogRecord instances are created automatically by the Logger every time something is logged, and can be created manually via makeLogRecord() (for example, from a pickled event received over the wire).

class logging.LogRecord(name, level, pathname, lineno, msg, args, exc_info, func=None, sinfo=None)

Contains all the information pertinent to the event being logged.

The primary information is passed in msg and args, which are combined using msg % args to create the message field of the record.

- **name** – The name of the logger used to log the event represented by this LogRecord. Note that this name will always have this value, even though it may be emitted by a handler attached to a different (ancestor) logger.
- **level** – The numeric level of the logging event (one of DEBUG, INFO etc.) Note that this is converted to two attributes of the LogRecord: levelno for the numeric value andlevelname for the corresponding level name.
- **pathname** – The full pathname of the source file where the logging call was made.
- **lineno** – The line number in the source file where the logging call was made.
- **msg** – The event description message, possibly a format string with placeholders for variable data.
• **args** – Variable data to merge into the *msg* argument to obtain the event description.

• **exc_info** – An exception tuple with the current exception information, or *None* if no exception information is available.

• **func** – The name of the function or method from which the logging call was invoked.

• **sinfo** – A text string representing stack information from the base of the stack in the current thread, up to the logging call.

**getmessage()**

Returns the message for this LogRecord instance after merging any user-supplied arguments with the message. If the user-supplied message argument to the logging call is not a string, `str()` is called on it to convert it to a string. This allows use of user-defined classes as messages, whose `__str__` method can return the actual format string to be used.

*Changed in version 3.2:* The creation of a LogRecord has been made more configurable by providing a factory which is used to create the record. The factory can be set using `getLogRecordFactory()` and `setLogRecordFactory()` (see this for the factory's signature).

This functionality can be used to inject your own values into a LogRecord at creation time. You can use the following pattern:

```python
old_factory = logging.getLogRecordFactory()

def record_factory(*args, **kwargs):
    record = old_factory(*args, **kwargs)
    record.custom_attribute = 0xdecafbad
    return record
```
logging.setLogRecordFactory(record_factory)

With this pattern, multiple factories could be chained, and as long as they don’t overwrite each other’s attributes or unintentionally overwrite the standard attributes listed above, there should be no surprises.
16.7.7. LogRecord attributes

The LogRecord has a number of attributes, most of which are derived from the parameters to the constructor. (Note that the names do not always correspond exactly between the LogRecord constructor parameters and the LogRecord attributes.) These attributes can be used to merge data from the record into the format string. The following table lists (in alphabetical order) the attribute names, their meanings and the corresponding placeholder in a %-style format string.

If you are using {}-formatting (str.format()), you can use {attrname} as the placeholder in the format string. If you are using $-formatting (string.Template), use the form ${attrname}. In both cases, of course, replace attrname with the actual attribute name you want to use.

In the case of {}-formatting, you can specify formatting flags by placing them after the attribute name, separated from it with a colon. For example: a placeholder of {msecs:03d} would format a millisecond value of 4 as 004. Refer to the str.format() documentation for full details on the options available to you.

*Changed in version 3.1: `processName` was added.*
16.7.8. LoggerAdapter Objects

LoggerAdapter instances are used to conveniently pass contextual information into logging calls. For a usage example, see the section on *adding contextual information to your logging output*.

```python
class logging.LoggerAdapter(logger, extra)

Returns an instance of LoggerAdapter initialized with an underlying Logger instance and a dict-like object.

process(msg, kwargs)

Modifies the message and/or keyword arguments passed to a logging call in order to insert contextual information. This implementation takes the object passed as extra to the constructor and adds it to kwargs using key ‘extra’. The return value is a (msg, kwargs) tuple which has the (possibly modified) versions of the arguments passed in.
```

In addition to the above, LoggerAdapter supports the following methods of Logger: debug(), info(), warning(), error(), exception(), critical(), log(), isEnabledFor(), getEffectiveLevel(), setLevel() and hasHandlers(). These methods have the same signatures as their counterparts in Logger, so you can use the two types of instances interchangeably.

*Changed in version 3.2:* The isEnabledFor(), getEffectiveLevel(), setLevel() and hasHandlers() methods were added to LoggerAdapter. These methods delegate to the underlying logger.
16.7.9. Thread Safety

The logging module is intended to be thread-safe without any special work needing to be done by its clients. It achieves this though using threading locks; there is one lock to serialize access to the module's shared data, and each handler also creates a lock to serialize access to its underlying I/O.

If you are implementing asynchronous signal handlers using the signal module, you may not be able to use logging from within such handlers. This is because lock implementations in the threading module are not always re-entrant, and so cannot be invoked from such signal handlers.
16.7.10. Module-Level Functions

In addition to the classes described above, there are a number of module-level functions.

**logging.getLogger(name=None)**

Return a logger with the specified name or, if name is `None`, return a logger which is the root logger of the hierarchy. If specified, the name is typically a dot-separated hierarchical name like ‘a’, ‘a.b’ or ‘a.b.c.d’. Choice of these names is entirely up to the developer who is using logging.

All calls to this function with a given name return the same logger instance. This means that logger instances never need to be passed between different parts of an application.

**logging.getLoggerClass()**

Return either the standard `Logger` class, or the last class passed to `setLoggerClass()`. This function may be called from within a new class definition, to ensure that installing a customized `Logger` class will not undo customizations already applied by other code. For example:

```
class MyLogger(logging.getLoggerClass()):
    # ... override behaviour here
```

**logging.getLogRecordFactory()**

Return a callable which is used to create a `LogRecord`.

*New in version 3.2:* This function has been provided, along with `setLogRecordFactory()`, to allow developers more control
over how the LogRecord representing a logging event is constructed.

See setLogRecordFactory() for more information about the how the factory is called.

logging.debug(msg, *args, **kwargs)

Logs a message with level DEBUG on the root logger. The msg is the message format string, and the args are the arguments which are merged into msg using the string formatting operator. (Note that this means that you can use keywords in the format string, together with a single dictionary argument.)

There are three keyword arguments in kwargs which are inspected: exc_info which, if it does not evaluate as false, causes exception information to be added to the logging message. If an exception tuple (in the format returned by sys.exc_info()) is provided, it is used; otherwise, sys.exc_info() is called to get the exception information.

The second optional keyword argument is stack_info, which defaults to False. If true, stack information is added to the logging message, including the actual logging call. Note that this is not the same stack information as that displayed through specifying exc_info: The former is stack frames from the bottom of the stack up to the logging call in the current thread, whereas the latter is information about stack frames which have been unwound, following an exception, while searching for exception handlers.

You can specify stack_info independently of exc_info, e.g. to just show how you got to a certain point in your code, even when no exceptions were raised. The stack frames are printed following a header line which says:
Stack (most recent call last):

This mimics the Traceback (most recent call last): which is used when displaying exception frames.

The third optional keyword argument is extra which can be used to pass a dictionary which is used to populate the __dict__ of the LogRecord created for the logging event with user-defined attributes. These custom attributes can then be used as you like. For example, they could be incorporated into logged messages. For example:

```python
FORMAT = '%(asctime)-15s %(clientip)s %(user)-8s %(message)s'
logging.basicConfig(format=FORMAT)
d = {'clientip': '192.168.0.1', 'user': 'fbloggs'
logging.warning('Protocol problem: %s', 'connection reset')
```

would print something like:

```
2006-02-08 22:20:02,165 192.168.0.1 fbloggs Protocol 
```

The keys in the dictionary passed in extra should not clash with the keys used by the logging system. (See the Formatter documentation for more information on which keys are used by the logging system.)

If you choose to use these attributes in logged messages, you need to exercise some care. In the above example, for instance, the Formatter has been set up with a format string which expects ‘clientip’ and ‘user’ in the attribute dictionary of the LogRecord. If these are missing, the message will not be logged
because a string formatting exception will occur. So in this case, you always need to pass the extra dictionary with these keys.

While this might be annoying, this feature is intended for use in specialized circumstances, such as multi-threaded servers where the same code executes in many contexts, and interesting conditions which arise are dependent on this context (such as remote client IP address and authenticated user name, in the above example). In such circumstances, it is likely that specialized Formatters would be used with particular Handlers.

New in version 3.2: The stack_info parameter was added.

logging.info(msg, *args, **kwargs)
Logs a message with level INFO on the root logger. The arguments are interpreted as for debug().

logging.warning(msg, *args, **kwargs)
Logs a message with level WARNING on the root logger. The arguments are interpreted as for debug().

Note: There is an obsolete function warn which is functionally identical to warning. As warn is deprecated, please do not use it - use warning instead.

logging.error(msg, *args, **kwargs)
Logs a message with level ERROR on the root logger. The arguments are interpreted as for debug().

logging.critical(msg, *args, **kwargs)
Logs a message with level CRITICAL on the root logger. The arguments are interpreted as for debug().
logging \texttt{exception}(msg, *args)

Logs a message with level \texttt{ERROR} on the root logger. The arguments are interpreted as for \texttt{debug()}. Exception info is added to the logging message. This function should only be called from an exception handler.

logging \texttt{log}(level, msg, *args, **kwargs)

Logs a message with level \texttt{level} on the root logger. The other arguments are interpreted as for \texttt{debug()}.

\begin{quote}
\textbf{Note:} The above module-level convenience functions, which delegate to the root logger, call \texttt{basicConfig()} to ensure that at least one handler is available. Because of this, they should \textit{not} be used in threads, in versions of Python earlier than 2.7.1 and 3.2, unless at least one handler has been added to the root logger \textit{before} the threads are started. In earlier versions of Python, due to a thread safety shortcoming in \texttt{basicConfig()}, this can (under rare circumstances) lead to handlers being added multiple times to the root logger, which can in turn lead to multiple messages for the same event.
\end{quote}

logging \texttt{disable}(lvl)

Provides an overriding level \texttt{lvl} for all loggers which takes precedence over the logger’s own level. When the need arises to temporarily throttle logging output down across the whole application, this function can be useful. Its effect is to disable all logging calls of severity \texttt{lvl} and below, so that if you call it with a value of \texttt{INFO}, then all \texttt{INFO} and \texttt{DEBUG} events would be discarded, whereas those of severity \texttt{WARNING} and above would be processed according to the logger’s effective level. If \texttt{logging.disable(logging.NOTSET)} is called, it effectively
removes this overriding level, so that logging output again depends on the effective levels of individual loggers.

```
logging.addLevelName(lvl, levelName)
```

Associates level `lvl` with text `levelName` in an internal dictionary, which is used to map numeric levels to a textual representation, for example when a `Formatter` formats a message. This function can also be used to define your own levels. The only constraints are that all levels used must be registered using this function, levels should be positive integers and they should increase in increasing order of severity.

**Note:** If you are thinking of defining your own levels, please see the section on *Custom Levels*.

```
logging.getLevelName(lvl)
```

Returns the textual representation of logging level `lvl`. If the level is one of the predefined levels CRITICAL, ERROR, WARNING, INFO or DEBUG then you get the corresponding string. If you have associated levels with names using `addLevelName()` then the name you have associated with `lvl` is returned. If a numeric value corresponding to one of the defined levels is passed in, the corresponding string representation is returned. Otherwise, the string ‘Level %s’ % lvl is returned.

```
logging.makeLogRecord(attrdict)
```

Creates and returns a new `LogRecord` instance whose attributes are defined by `attrdict`. This function is useful for taking a pickled `LogRecord` attribute dictionary, sent over a socket, and reconstituting it as a `LogRecord` instance at the receiving end.

```
logging.basicConfig(**kwargs)
```
Does basic configuration for the logging system by creating a StreamHandler with a default Formatter and adding it to the root logger. The functions debug(), info(), warning(), error() and critical() will call basicConfig() automatically if no handlers are defined for the root logger.

This function does nothing if the root logger already has handlers configured for it.

**Note:** This function should be called from the main thread before other threads are started. In versions of Python prior to 2.7.1 and 3.2, if this function is called from multiple threads, it is possible (in rare circumstances) that a handler will be added to the root logger more than once, leading to unexpected results such as messages being duplicated in the log.

The following keyword arguments are supported.

<table>
<thead>
<tr>
<th>Format</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>filename</td>
<td>Specifies that a FileHandler be created, using the specified filename, rather than a StreamHandler.</td>
</tr>
<tr>
<td>filemode</td>
<td>Specifies the mode to open the file, if filename is specified (if filemode is unspecified, it defaults to ‘a’).</td>
</tr>
<tr>
<td>format</td>
<td>Use the specified format string for the handler.</td>
</tr>
<tr>
<td>datefmt</td>
<td>Use the specified date/time format.</td>
</tr>
<tr>
<td>style</td>
<td>If format is specified, use this style for the format string. One of ‘%’, ‘{’ or ‘$’ for %-formatting, str.format() or string.Template respectively, and defaulting to ‘%’ if not specified.</td>
</tr>
<tr>
<td><strong>level</strong></td>
<td>Set the root logger level to the specified level.</td>
</tr>
<tr>
<td>-----------</td>
<td>-------------------------------------------------</td>
</tr>
<tr>
<td><strong>stream</strong></td>
<td>Use the specified stream to initialize the StreamHandler. Note that this argument is incompatible with ‘filename’ - if both are present, a ValueError is raised.</td>
</tr>
<tr>
<td><strong>handlers</strong></td>
<td>If specified, this should be an iterable of already created handlers to add to the root logger. Any handlers which don’t already have a formatter set will be assigned the default formatter created in this function. Note that this argument is incompatible with ‘filename’ or ‘stream’ - if both are present, a ValueError is raised.</td>
</tr>
</tbody>
</table>

*Changed in version 3.2:* The `style` argument was added.

*Changed in version 3.3:* The `handlers` argument was added. Additional checks were added to catch situations where incompatible arguments are specified (e.g. `handlers` together with `stream` or `filename`, or `stream` together with `filename`).

**logging.shutdown()**

Informs the logging system to perform an orderly shutdown by flushing and closing all handlers. This should be called at application exit and no further use of the logging system should be made after this call.

**logging.getLoggerClass(klass)**

Tells the logging system to use the class `klass` when instantiating a logger. The class should define `__init__()` such that only a name argument is required, and the `__init__()` should call `Logger.__init__()`.

This function is typically called before any loggers are instantiated by applications which need to use custom logger behavior.
logging.setLogRecordFactory(factory)

Set a callable which is used to create a LogRecord.

**Parameters:**

| **factory** – The factory callable to be used to instantiate a log record. |

*New in version 3.2:* This function has been provided, along with `getLogRecordFactory()`, to allow developers more control over how the LogRecord representing a logging event is constructed.

The factory has the following signature:

```python
factory(name, level, fn, lno, msg, args, exc_info, func=None, sinfo=None, **kwargs)
```

- **name:** The logger name.
- **level:** The logging level (numeric).
- **fn:** The full pathname of the file where the logging call was made.
- **lno:** The line number in the file where the logging call was made.
- **msg:** The logging message.
- **args:** The arguments for the logging message.
- **exc_info:** An exception tuple, or None.
- **func:** The name of the function or method which invoked the logging call.
- **sinfo:** A stack traceback such as is provided by `traceback.print_stack()`, showing the call hierarchy.
- **kwargs:** Additional keyword arguments.
16.7.11. Module-Level Attributes

logging. **lastResort**

A “handler of last resort” is available through this attribute. This is a `StreamHandler` writing to `sys.stderr` with a level of `WARNING`, and is used to handle logging events in the absence of any logging configuration. The end result is to just print the message to `sys.stderr`. This replaces the earlier error message saying that “no handlers could be found for logger XYZ”. If you need the earlier behaviour for some reason, `lastResort` can be set to `None`.

*New in version 3.2.*
16.7.12. Integration with the warnings module

The `captureWarnings()` function can be used to integrate logging with the `warnings` module.

`logging.captureWarnings(capture)`

This function is used to turn the capture of warnings by logging on and off.

If `capture` is `True`, warnings issued by the `warnings` module will be redirected to the logging system. Specifically, a warning will be formatted using `warnings.formatwarning()` and the resulting string logged to a logger named `'py.warnings'` with a severity of `WARNING`.

If `capture` is `False`, the redirection of warnings to the logging system will stop, and warnings will be redirected to their original destinations (i.e. those in effect before `captureWarnings(True)` was called).

**Module `logging.config`**

Configuration API for the logging module.

**Module `logging.handlers`**

Useful handlers included with the logging module.

**PEP 282 - A Logging System**

The proposal which described this feature for inclusion in the Python standard library.
**Original Python logging package**

This is the original source for the `logging` package. The version of the package available from this site is suitable for use with Python 1.5.2, 2.1.x and 2.2.x, which do not include the `logging` package in the standard library.
This section describes the API for configuring the logging module.

**Source code:** Lib/logging/config.py

**Important**

This page contains only reference information. For tutorials, please see

- Basic Tutorial
- Advanced Tutorial
- Logging Cookbook
16.8.1. Configuration functions

The following functions configure the logging module. They are located in the `logging.config` module. Their use is optional — you can configure the logging module using these functions or by making calls to the main API (defined in `logging` itself) and defining handlers which are declared either in `logging` or `logging.handlers`.

`logging.config.dictConfig(config)`

Takes the logging configuration from a dictionary. The contents of this dictionary are described in *Configuration dictionary schema* below.

If an error is encountered during configuration, this function will raise a `ValueError`, `TypeError`, `AttributeError` or `ImportError` with a suitably descriptive message. The following is a (possibly incomplete) list of conditions which will raise an error:

- A `level` which is not a string or which is a string not corresponding to an actual logging level.
- A `propagate` value which is not a boolean.
- An id which does not have a corresponding destination.
- A non-existent handler id found during an incremental call.
- An invalid logger name.
- Inability to resolve to an internal or external object.

Parsing is performed by the DictConfigurator class, whose constructor is passed the dictionary used for configuration, and has a `configure()` method. The `logging.config` module has a callable attribute
dictConfigClass which is initially set to DictConfigurator. You can replace the value of dictConfigClass with a suitable implementation of your own.

dictConfig() calls dictConfigClass passing the specified dictionary, and then calls the configure() method on the returned object to put the configuration into effect:

```python
def dictConfig(config):
    dictConfigClass(config).configure()
```

For example, a subclass of DictConfigurator could call DictConfigurator.__init__() in its own __init__(), then set up custom prefixes which would be usable in the subsequent configure() call. dictConfigClass would be bound to this new subclass, and then dictConfig() could be called exactly as in the default, uncustomized state.

*New in version 3.2.*

logging.config.fileConfig(fname, defaults=None, disable_existing_loggers=True)

Reads the logging configuration from a configparser-format file. The format of the file should be as described in *Configuration file format*. This function can be called several times from an application, allowing an end user to select from various pre-canned configurations (if the developer provides a mechanism to present the choices and load the chosen configuration).

- **fname** – A filename, or a file-like object, or an instance derived from RawConfigParser. If
Parameters:

- a `RawConfigParser`-derived instance is passed, it is used as is. Otherwise, a `ConfigParser` is instantiated, and the configuration read by it from the object passed in `fname`. If that has a `readline()` method, it is assumed to be a file-like object and read using `read_file()`; otherwise, it is assumed to be a filename and passed to `read()`.
- **defaults** – Defaults to be passed to the `ConfigParser` can be specified in this argument.
- **disable_existing_loggers** – If specified as `False`, loggers which exist when this call is made are left alone. The default is `True` because this enables old behaviour in a backward-compatible way. This behaviour is to disable any existing loggers unless they or their ancestors are explicitly named in the logging configuration.

*Changed in version 3.4:* An instance of a subclass of `RawConfigParser` is now accepted as a value for `fname`. This facilitates:

- Use of a configuration file where logging configuration is just part of the overall application configuration.
- Use of a configuration read from a file, and then modified by the using application (e.g. based on command-line parameters or other aspects of the runtime environment) before being passed to `fileConfig`.

```python
logging.config.listen(port=DEFAULT_LOGGING_CONFIG_PORT, verify=None)
```

Starts up a socket server on the specified port, and listens for new
configurations. If no port is specified, the module's default
DEFAULT_LOGGING_CONFIG_PORT is used. Logging
configurations will be sent as a file suitable for processing by
fileConfig(). Returns a Thread instance on which you can
call start() to start the server, and which you can join() when
appropriate. To stop the server, call stopListening().

The verify argument, if specified, should be a callable which
should verify whether bytes received across the socket are valid
and should be processed. This could be done by encrypting and/or
signing what is sent across the socket, such that the verify
callable can perform signature verification and/or decryption. The
verify callable is called with a single argument - the bytes
received across the socket - and should return the bytes to be
processed, or None to indicate that the bytes should be discarded.
The returned bytes could be the same as the passed in bytes (e.g.
when only verification is done), or they could be completely
different (perhaps if decryption were performed).

To send a configuration to the socket, read in the configuration file
and send it to the socket as a string of bytes preceded by a four-
byte length string packed in binary using struct.pack(>'L',
n).

**Note:** Because portions of the configuration are passed through
eval(), use of this function may open its users to a security
risk. While the function only binds to a socket on localhost,
and so does not accept connections from remote machines, there
are scenarios where untrusted code could be run under the
account of the process which calls listen(). Specifically, if the
process calling listen() runs on a multi-user machine where
users cannot trust each other, then a malicious user could arrange to run essentially arbitrary code in a victim user’s process, simply by connecting to the victim’s `listen()` socket and sending a configuration which runs whatever code the attacker wants to have executed in the victim’s process. This is especially easy to do if the default port is used, but not hard even if a different port is used). To avoid the risk of this happening, use the verify argument to `listen()` to prevent unrecognised configurations from being applied.

*Changed in version 3.4.*: The `verify` argument was added.

`logging.config.stopListening()`

Stops the listening server which was created with a call to `listen()`. This is typically called before calling `join()` on the return value from `listen()`.
16.8.2. Configuration dictionary schema

Describing a logging configuration requires listing the various objects to create and the connections between them; for example, you may create a handler named ‘console’ and then say that the logger named ‘startup’ will send its messages to the ‘console’ handler. These objects aren’t limited to those provided by the `logging` module because you might write your own formatter or handler class. The parameters to these classes may also need to include external objects such as `sys.stderr`. The syntax for describing these objects and connections is defined in `Object connections` below.

16.8.2.1. Dictionary Schema Details

The dictionary passed to `dictConfig()` must contain the following keys:

- `version` - to be set to an integer value representing the schema version. The only valid value at present is 1, but having this key allows the schema to evolve while still preserving backwards compatibility.

All other keys are optional, but if present they will be interpreted as described below. In all cases below where a ‘configuring dict’ is mentioned, it will be checked for the special `()' key to see if a custom instantiation is required. If so, the mechanism described in `User-defined objects` below is used to create an instance; otherwise, the context is used to determine what to instantiate.

- `formatters` - the corresponding value will be a dict in which each key is a formatter id and each value is a dict describing how to
configure the corresponding **Formatter** instance.

The configuring dict is searched for keys `format` and `datefmt` (with defaults of `None`) and these are used to construct a **Formatter** instance.

- **filters** - the corresponding value will be a dict in which each key is a filter id and each value is a dict describing how to configure the corresponding Filter instance.

  The configuring dict is searched for the key `name` (defaulting to the empty string) and this is used to construct a **logging.Filter** instance.

- **handlers** - the corresponding value will be a dict in which each key is a handler id and each value is a dict describing how to configure the corresponding Handler instance.

  The configuring dict is searched for the following keys:

  - **class** (mandatory). This is the fully qualified name of the handler class.
  - **level** (optional). The level of the handler.
  - **formatter** (optional). The id of the formatter for this handler.
  - **filters** (optional). A list of ids of the filters for this handler.

  All other keys are passed through as keyword arguments to the handler's constructor. For example, given the snippet:

```python
handlers:
    console:
        class : logging.StreamHandler
        formatter: brief
```
the handler with id console is instantiated as a `logging.StreamHandler`, using `sys.stdout` as the underlying stream. The handler with id file is instantiated as a `logging.handlers.RotatingFileHandler` with the keyword arguments `filename='logconfig.log', maxBytes=1024, backupCount=3`.

- **loggers** - the corresponding value will be a dict in which each key is a logger name and each value is a dict describing how to configure the corresponding Logger instance.

The configuring dict is searched for the following keys:

- **level** (optional). The level of the logger.
- **propagate** (optional). The propagation setting of the logger.
- **filters** (optional). A list of ids of the filters for this logger.
- **handlers** (optional). A list of ids of the handlers for this logger.

The specified loggers will be configured according to the level, propagation, filters and handlers specified.

- **root** - this will be the configuration for the root logger. Processing of the configuration will be as for any logger, except that the
propagate setting will not be applicable.

- *incremental* - whether the configuration is to be interpreted as incremental to the existing configuration. This value defaults to False, which means that the specified configuration replaces the existing configuration with the same semantics as used by the existing `fileConfig()` API.

  If the specified value is True, the configuration is processed as described in the section on *Incremental Configuration*.

- *disable_existing_loggers* - whether any existing loggers are to be disabled. This setting mirrors the parameter of the same name in `fileConfig()`. If absent, this parameter defaults to True. This value is ignored if *incremental* is True.

16.8.2.2. Incremental Configuration

It is difficult to provide complete flexibility for incremental configuration. For example, because objects such as filters and formatters are anonymous, once a configuration is set up, it is not possible to refer to such anonymous objects when augmenting a configuration.

Furthermore, there is not a compelling case for arbitrarily altering the object graph of loggers, handlers, filters, formatters at run-time, once a configuration is set up; the verbosity of loggers and handlers can be controlled just by setting levels (and, in the case of loggers, propagation flags). Changing the object graph arbitrarily in a safe way is problematic in a multi-threaded environment; while not impossible, the benefits are not worth the complexity it adds to the implementation.

Thus, when the *incremental* key of a configuration dict is present
and is True, the system will completely ignore any formatters and filters entries, and process only the level settings in the handlers entries, and the level and propagate settings in the loggers and root entries.

Using a value in the configuration dict lets configurations to be sent over the wire as pickled dicts to a socket listener. Thus, the logging verbosity of a long-running application can be altered over time with no need to stop and restart the application.

16.8.2.3. Object connections

The schema describes a set of logging objects - loggers, handlers, formatters, filters - which are connected to each other in an object graph. Thus, the schema needs to represent connections between the objects. For example, say that, once configured, a particular logger has attached to it a particular handler. For the purposes of this discussion, we can say that the logger represents the source, and the handler the destination, of a connection between the two. Of course in the configured objects this is represented by the logger holding a reference to the handler. In the configuration dict, this is done by giving each destination object an id which identifies it unambiguously, and then using the id in the source object’s configuration to indicate that a connection exists between the source and the destination object with that id.

So, for example, consider the following YAML snippet:

```yaml
formatters:
    brief:
        # configuration for formatter with id 'brief'
    precise:
        # configuration for formatter with id 'precise'
```
handlers:
  h1: #This is an id
      # configuration of handler with id 'h1' goes here
      formatter: brief
  h2: #This is another id
      # configuration of handler with id 'h2' goes here
      formatter: precise
loggers:
  foo.bar.baz:
      # other configuration for logger 'foo.bar.baz'
      handlers: [h1, h2]

(Note: YAML used here because it’s a little more readable than the equivalent Python source form for the dictionary.)

The ids for loggers are the logger names which would be used programatically to obtain a reference to those loggers, e.g. foo.bar.baz. The ids for Formatters and Filters can be any string value (such as brief, precise above) and they are transient, in that they are only meaningful for processing the configuration dictionary and used to determine connections between objects, and are not persisted anywhere when the configuration call is complete.

The above snippet indicates that logger named foo.bar.baz should have two handlers attached to it, which are described by the handler ids h1 and h2. The formatter for h1 is that described by id brief, and the formatter for h2 is that described by id precise.

16.8.2.4. User-defined objects

The schema supports user-defined objects for handlers, filters and formatters. (Loggers do not need to have different types for different instances, so there is no support in this configuration schema for user-
defined logger classes.)

Objects to be configured are described by dictionaries which detail their configuration. In some places, the logging system will be able to infer from the context how an object is to be instantiated, but when a user-defined object is to be instantiated, the system will not know how to do this. In order to provide complete flexibility for user-defined object instantiation, the user needs to provide a ‘factory’ - a callable which is called with a configuration dictionary and which returns the instantiated object. This is signalled by an absolute import path to the factory being made available under the special key `()`. Here’s a concrete example:

```yaml
formatters:
    brief:
        format: '%(message)s'
    default:
        format: '%(asctime)s %(levelname)-8s %(name)-15s %(message)s'
        datefmt: '%Y-%m-%d %H:%M:%S'
    custom:
        (): my.package.customFormatterFactory
        bar: baz
        spam: 99.9
        answer: 42
```

The above YAML snippet defines three formatters. The first, with id `brief`, is a standard `logging.Formatter` instance with the specified format string. The second, with id `default`, has a longer format and also defines the time format explicitly, and will result in a `logging.Formatter` initialized with those two format strings. Shown in Python source form, the `brief` and `default` formatters have configuration sub-dictionaries:
and:

```python
{
    'format' : '%(asctime)s \t%(levelname)-8s \t%(name)-15s \t%(message)s'
    'datefmt' : '%Y-%m-%d \t%H:%M:%S'
}
```

respectively, and as these dictionaries do not contain the special key `()`, the instantiation is inferred from the context: as a result, standard `logging.Formatter` instances are created. The configuration sub-dictionary for the third formatter, with id `custom`, is:

```python
{
    '()' : 'my.package.customFormatterFactory',
    'bar' : 'baz',
    'spam' : 99.9,
    'answer' : 42
}
```

and this contains the special key `()`, which means that user-defined instantiation is wanted. In this case, the specified factory callable will be used. If it is an actual callable it will be used directly - otherwise, if you specify a string (as in the example) the actual callable will be located using normal import mechanisms. The callable will be called with the remaining items in the configuration sub-dictionary as keyword arguments. In the above example, the formatter with id `custom` will be assumed to be returned by the call:

```
my.package.customFormatterFactory(bar='baz', spam=99.9)
```
The key `()` has been used as the special key because it is not a valid keyword parameter name, and so will not clash with the names of the keyword arguments used in the call. The `()` also serves as a mnemonic that the corresponding value is a callable.

### 16.8.2.5. Access to external objects

There are times where a configuration needs to refer to objects external to the configuration, for example `sys.stderr`. If the configuration dict is constructed using Python code, this is straightforward, but a problem arises when the configuration is provided via a text file (e.g. JSON, YAML). In a text file, there is no standard way to distinguish `sys.stderr` from the literal string `'sys.stderr'`. To facilitate this distinction, the configuration system looks for certain special prefixes in string values and treat them specially. For example, if the literal string `'ext://sys.stderr'` is provided as a value in the configuration, then the `ext://` will be stripped off and the remainder of the value processed using normal import mechanisms.

The handling of such prefixes is done in a way analogous to protocol handling: there is a generic mechanism to look for prefixes which match the regular expression `^(?P<prefix>[a-z]+)://(?P<suffix>.*).*$` whereby, if the prefix is recognised, the suffix is processed in a prefix-dependent manner and the result of the processing replaces the string value. If the prefix is not recognised, then the string value will be left as-is.

### 16.8.2.6. Access to internal objects
As well as external objects, there is sometimes also a need to refer to objects in the configuration. This will be done implicitly by the configuration system for things that it knows about. For example, the string value 'DEBUG' for a level in a logger or handler will automatically be converted to the value `logging.DEBUG`, and the handlers, filters and formatter entries will take an object id and resolve to the appropriate destination object.

However, a more generic mechanism is needed for user-defined objects which are not known to the `logging` module. For example, consider `logging.handlers.MemoryHandler`, which takes a target argument which is another handler to delegate to. Since the system already knows about this class, then in the configuration, the given target just needs to be the object id of the relevant target handler, and the system will resolve to the handler from the id. If, however, a user defines a `my.package.MyHandler` which has an alternate handler, the configuration system would not know that the alternate referred to a handler. To cater for this, a generic resolution system allows the user to specify:

```
handlers:
  file:
    # configuration of file handler goes here

custom:
  (): my.package.MyHandler
  alternate: cfg://handlers.file
```

The literal string `'cfg://handlers.file'` will be resolved in an analogous way to strings with the `ext://` prefix, but looking in the configuration itself rather than the import namespace. The mechanism allows access by dot or by index, in a similar way to that provided by
str.format. Thus, given the following snippet:

```python
define handlers:  
    email:  
        class: logging.handlers.SMTPHandler  
        mailhost: localhost  
        fromaddr: my_app@domain.tld  
        toaddrs:  
            - support_team@domain.tld  
            - dev_team@domain.tld  
        subject: Houston, we have a problem.
```

in the configuration, the string `cfg://handlers` would resolve to the dict with key `handlers`, the string `cfg://handlers.email` would resolve to the dict with key `email` in the handlers dict, and so on. The string `cfg://handlers.email.toaddrs[1]` would resolve to `dev_team.domain.tld` and the string `cfg://handlers.email.toaddrs[0]` would resolve to the value `support_team@domain.tld`. The subject value could be accessed using either `cfg://handlers.email.subject` or, equivalently, `cfg://handlers.email[subject]`. The latter form only needs to be used if the key contains spaces or non-alphanumeric characters. If an index value consists only of decimal digits, access will be attempted using the corresponding integer value, falling back to the string value if needed.

Given a string `cfg://handlers.myhandler.mykey.123`, this will resolve to `config_dict['handlers']['myhandler']['mykey']['123']`. If the string is specified as `cfg://handlers.myhandler.mykey[123]`, the system will attempt to retrieve the value from `config_dict['handlers']['myhandler']['mykey'][123]`, and fall back to
config_dict['handlers']['myhandler']['mykey']['123']

if that fails.

16.8.2.7. Import resolution and custom importers

Import resolution, by default, uses the built-in `__import__()` function to do its importing. You may want to replace this with your own importing mechanism: if so, you can replace the importer attribute of the `DictConfigurator` or its superclass, the `BaseConfigurator` class. However, you need to be careful because of the way functions are accessed from classes via descriptors. If you are using a Python callable to do your imports, and you want to define it at class level rather than instance level, you need to wrap it with `staticmethod()`. For example:

```python
from importlib import import_module
from logging.config import BaseConfigurator

BaseConfigurator.importer = staticmethod(import_module)
```

You don't need to wrap with `staticmethod()` if you're setting the import callable on a configurator instance.
16.8.3. Configuration file format

The configuration file format understood by `fileConfig()` is based on `configparser` functionality. The file must contain sections called [loggers], [handlers] and [formatters] which identify by name the entities of each type which are defined in the file. For each such entity, there is a separate section which identifies how that entity is configured. Thus, for a logger named `log01` in the [loggers] section, the relevant configuration details are held in a section [logger_log01]. Similarly, a handler called `hand01` in the [handlers] section will have its configuration held in a section called [handler_hand01], while a formatter called `form01` in the [formatters] section will have its configuration specified in a section called [formatter_form01]. The root logger configuration must be specified in a section called [logger_root].

Examples of these sections in the file are given below.

```ini
[loggers]
keys=root,log02,log03,log04,log05,log06,log07

[handlers]
keys=hand01,hand02,hand03,hand04,hand05,hand06,hand07

[formatters]
keys=form01(form02,form03,form04,form05,form06,form07

The root logger must specify a level and a list of handlers. An example of a root logger section is given below.

```ini
[logger_root]
level=NOTSET
handlers=hand01

The `level` entry can be one of `DEBUG`, `INFO`, `WARNING`, `ERROR`, `CRITICAL` or `NOTSET`. For the root logger only, `NOTSET` means that all messages will be logged. Level values are `eval()`uated in the context of the logging package's namespace.

The `handlers` entry is a comma-separated list of handler names, which must appear in the `[handlers]` section. These names must appear in the `[handlers]` section and have corresponding sections in the configuration file.

For loggers other than the root logger, some additional information is required. This is illustrated by the following example.

```ini
[logger_parser]
level=DEBUG
handlers=hand01
propagate=1
qualname=compiler.parser
```

The `level` and `handlers` entries are interpreted as for the root logger, except that if a non-root logger's level is specified as `NOTSET`, the system consults loggers higher up the hierarchy to determine the effective level of the logger. The `propagate` entry is set to 1 to indicate that messages must propagate to handlers higher up the logger hierarchy from this logger, or 0 to indicate that messages are not propagated to handlers up the hierarchy. The `qualname` entry is the hierarchical channel name of the logger, that is to say the name used by the application to get the logger.

Sections which specify handler configuration are exemplified by the
The class entry indicates the handler's class (as determined by eval() in the logging package's namespace). The level is interpreted as for loggers, and NOTSET is taken to mean 'log everything'.

The formatter entry indicates the key name of the formatter for this handler. If blank, a default formatter (logging._defaultFormatter) is used. If a name is specified, it must appear in the [formatters] section and have a corresponding section in the configuration file.

The args entry, when eval()uated in the context of the logging package's namespace, is the list of arguments to the constructor for the handler class. Refer to the constructors for the relevant handlers, or to the examples below, to see how typical entries are constructed.
args=('localhost', handlers.DEFAULT_TCP_LOGGING_PORT)

[handler_hand04]
class=handlers.DatagramHandler
level=WARN
formatter=form04
args=('localhost', handlers.DEFAULT_UDP_LOGGING_PORT)

[handler_hand05]
class=handlers.SysLogHandler
level=ERROR
formatter=form05
args=(['localhost', handlers.SYSLOG_UDP_PORT], handlers)

[handler_hand06]
class=handlers.NTEventLogHandler
level=CRITICAL
formatter=form06
args=('Python Application', '', 'Application')

[handler_hand07]
class=handlers.SMTPHandler
level=WARN
formatter=form07
args=('localhost', 'from@abc', ['user1@abc', 'user2@xyz'])

[handler_hand08]
class=handlers.MemoryHandler
level=NOTSET
formatter=form08
target=
args=(10, ERROR)

[handler_hand09]
class=handlers.HTTPHandler
level=NOTSET
formatter=form09
Sections which specify formatter configuration are typified by the following.

```
[formatter_form01]
format=F1 %(asctime)s %(levelname)s %(message)s
datefmt=
class=logging.Formatter
```

The `format` entry is the overall format string, and the `datefmt` entry is the `strftime()`-compatible date/time format string. If empty, the package substitutes ISO8601 format date/times, which is almost equivalent to specifying the date format string `%Y-%m-%d %H:%M:%S`. The ISO8601 format also specifies milliseconds, which are appended to the result of using the above format string, with a comma separator. An example time in ISO8601 format is `2003-01-23 00:29:50,411`.

The `class` entry is optional. It indicates the name of the formatter's class (as a dotted module and class name.) This option is useful for instantiating a `Formatter` subclass. Subclasses of `Formatter` can present exception tracebacks in an expanded or condensed format.

**Note:** Due to the use of `eval()` as described above, there are potential security risks which result from using the `listen()` to send and receive configurations via sockets. The risks are limited to where multiple users with no mutual trust run code on the same machine; see the `listen()` documentation for more information.

**See also:**
Module **logging**
API reference for the logging module.

Module **logging.handlers**
Useful handlers included with the logging module.
The following useful handlers are provided in the package. Note that three of the handlers (StreamHandler, FileHandler and NullHandler) are actually defined in the logging module itself, but have been documented here along with the other handlers.
16.9.1. StreamHandler

The StreamHandler class, located in the core logging package, sends logging output to streams such as sys.stdout, sys.stderr or any file-like object (or, more precisely, any object which supports write() and flush() methods).

class logging.StreamHandler(stream=None)

    Returns a new instance of the StreamHandler class. If stream is specified, the instance will use it for logging output; otherwise, sys.stderr will be used.

    emit(record)

        If a formatter is specified, it is used to format the record. The record is then written to the stream with a terminator. If exception information is present, it is formatted using traceback.print_exception() and appended to the stream.

    flush()

        Flushes the stream by calling its flush() method. Note that the close() method is inherited from Handler and so does no output, so an explicit flush() call may be needed at times.

    Changed in version 3.2: The StreamHandler class now has a terminator attribute, default value '\n', which is used as the terminator when writing a formatted record to a stream. If you don't want this newline termination, you can set the handler instance's terminator attribute to the empty string. In earlier versions, the terminator was hardcoded as '\n'.
16.9.2. FileHandler

The `FileHandler` class, located in the core `logging` package, sends logging output to a disk file. It inherits the output functionality from `StreamHandler`.

```python
class logging.FileHandler(filename, mode='a', encoding=None, delay=False)
```

Returns a new instance of the `FileHandler` class. The specified file is opened and used as the stream for logging. If `mode` is not specified, 'a' is used. If `encoding` is not `None`, it is used to open the file with that encoding. If `delay` is true, then file opening is deferred until the first call to `emit()`. By default, the file grows indefinitely.

```python
close()
```

Closes the file.

```python
emit(record)
```

Outputs the record to the file.
16.9.3. NullHandler

New in version 3.1.

The NullHandler class, located in the core logging package, does not do any formatting or output. It is essentially a ‘no-op’ handler for use by library developers.

```python
class logging.NullHandler
    Returns a new instance of the NullHandler class.

    emit(record)
        This method does nothing.

    handle(record)
        This method does nothing.

    createLock()
        This method returns None for the lock, since there is no underlying I/O to which access needs to be serialized.
```

See Configuring Logging for a Library for more information on how to use NullHandler.
16.9.4. WatchedFileHandler

The WatchedFileHandler class, located in the logging.handlers module, is a FileHandler which watches the file it is logging to. If the file changes, it is closed and reopened using the file name.

A file change can happen because of usage of programs such as newsyslog and logrotate which perform log file rotation. This handler, intended for use under Unix/Linux, watches the file to see if it has changed since the last emit. (A file is deemed to have changed if its device or inode have changed.) If the file has changed, the old file stream is closed, and the file opened to get a new stream.

This handler is not appropriate for use under Windows, because under Windows open log files cannot be moved or renamed - logging opens the files with exclusive locks - and so there is no need for such a handler. Furthermore, ST_INO is not supported under Windows; stat() always returns zero for this value.

class logging.handlers.WatchedFileHandler(filename[, mode[, encoding[, delay]]])

Returns a new instance of the WatchedFileHandler class. The specified file is opened and used as the stream for logging. If mode is not specified, 'a' is used. If encoding is not None, it is used to open the file with that encoding. If delay is true, then file opening is deferred until the first call to emit(). By default, the file grows indefinitely.

emit(record)

Outputs the record to the file, but first checks to see if the file
has changed. If it has, the existing stream is flushed and closed and the file opened again, before outputting the record to the file.
16.9.5. BaseRotatingHandler

The `BaseRotatingHandler` class, located in the `logging.handlers` module, is the base class for the rotating file handlers, `RotatingFileHandler` and `TimedRotatingFileHandler`. You should not need to instantiate this class, but it has attributes and methods you may need to override.

```python
class logging.handlers.BaseRotatingHandler(filename, mode, encoding=None, delay=False)
```

The parameters are as for `FileHandler`. The attributes are:

**namer**

If this attribute is set to a callable, the `rotation_filename()` method delegates to this callable. The parameters passed to the callable are those passed to `rotation_filename()`.

**Note:** The namer function is called quite a few times during rollover, so it should be as simple and as fast as possible. It should also return the same output every time for a given input, otherwise the rollover behaviour may not work as expected.

*New in version 3.3.*

**rotator**

If this attribute is set to a callable, the `rotate()` method delegates to this callable. The parameters passed to the callable are those passed to `rotate()`.

*New in version 3.3.*
**rotation_filename**(*default_name*)

Modify the filename of a log file when rotating.

This is provided so that a custom filename can be provided.

The default implementation calls the ‘namer’ attribute of the handler, if it’s callable, passing the default name to it. If the attribute isn’t callable (the default is `None`), the name is returned unchanged.

| Parameters: | default_name – The default name for the log file. |

*New in version 3.3.*

**rotate**(*source, dest*)

When rotating, rotate the current log.

The default implementation calls the ‘rotator’ attribute of the handler, if it’s callable, passing the source and dest arguments to it. If the attribute isn’t callable (the default is `None`), the source is simply renamed to the destination.

| Parameters: | • source – The source filename. This is normally the base filename, e.g. ‘test.log’
• dest – The destination filename. This is normally what the source is rotated to, e.g. ‘test.log.1’ |

*New in version 3.3.*

The reason the attributes exist is to save you having to subclass - you can use the same callables for instances of RotatingFileHandler and TimedRotatingFileHandler. If either the namer or rotator
callable raises an exception, this will be handled in the same way as any other exception during an emit() call, i.e. via the handleError() method of the handler.

If you need to make more significant changes to rotation processing, you can override the methods.

For an example, see *Using a rotator and namer to customize log rotation processing*. 
16.9.6. RotatingFileHandler

The RotatingFileHandler class, located in the logging.handlers module, supports rotation of disk log files.

```python
class logging.handlers.RotatingFileHandler(filename,
mode='a', maxBytes=0, backupCount=0, encoding=None, delay=0)
```

Returns a new instance of the RotatingFileHandler class. The specified file is opened and used as the stream for logging. If mode is not specified, 'a' is used. If encoding is not None, it is used to open the file with that encoding. If delay is true, then file opening is deferred until the first call to emit(). By default, the file grows indefinitely.

You can use the maxBytes and backupCount values to allow the file to rollover at a predetermined size. When the size is about to be exceeded, the file is closed and a new file is silently opened for output. Rollover occurs whenever the current log file is nearly maxBytes in length; if maxBytes is zero, rollover never occurs. If backupCount is non-zero, the system will save old log files by appending the extensions '.1', '.2' etc., to the filename. For example, with a backupCount of 5 and a base file name of app.log, you would get app.log, app.log.1, app.log.2, up to app.log.5. The file being written to is always app.log. When this file is filled, it is closed and renamed to app.log.1, and if files app.log.1, app.log.2, etc. exist, then they are renamed to app.log.2, app.log.3 etc. respectively.

```python
doRollover()
```

Does a rollover, as described above.
emit(*record*)

Outputs the record to the file, catering for rollover as described previously.
16.9.7. TimedRotatingFileHandler

The `TimedRotatingFileHandler` class, located in the `logging.handlers` module, supports rotation of disk log files at certain timed intervals.

class
logging.handlers.TimedRotatingFileHandler(filename, when='h', interval=1, backupCount=0, encoding=None, delay=False, utc=False, atTime=None)

Returns a new instance of the TimedRotatingFileHandler class. The specified file is opened and used as the stream for logging. On rotating it also sets the filename suffix. Rotating happens based on the product of when and interval.

You can use the when to specify the type of interval. The list of possible values is below. Note that they are not case sensitive.

<table>
<thead>
<tr>
<th>Value</th>
<th>Type of interval</th>
</tr>
</thead>
<tbody>
<tr>
<td>'S'</td>
<td>Seconds</td>
</tr>
<tr>
<td>'M'</td>
<td>Minutes</td>
</tr>
<tr>
<td>'H'</td>
<td>Hours</td>
</tr>
<tr>
<td>'D'</td>
<td>Days</td>
</tr>
<tr>
<td>'W0'-'W6'</td>
<td>Weekday (0=Monday)</td>
</tr>
<tr>
<td>'midnight'</td>
<td>Roll over at midnight</td>
</tr>
</tbody>
</table>

When using weekday-based rotation, specify ‘W0’ for Monday, ‘W1’ for Tuesday, and so on up to ‘W6’ for Sunday. In this case, the value passed for interval isn’t used.
The system will save old log files by appending extensions to the filename. The extensions are date-and-time based, using the strftime format `%Y-%m-%d_%H-%M-%S` or a leading portion thereof, depending on the rollover interval.

When computing the next rollover time for the first time (when the handler is created), the last modification time of an existing log file, or else the current time, is used to compute when the next rotation will occur.

If the `utc` argument is true, times in UTC will be used; otherwise local time is used.

If `backupCount` is nonzero, at most `backupCount` files will be kept, and if more would be created when rollover occurs, the oldest one is deleted. The deletion logic uses the interval to determine which files to delete, so changing the interval may leave old files lying around.

If `delay` is true, then file opening is deferred until the first call to `emit()`.

If `atTime` is not None, it must be a `datetime.time` instance which specifies the time of day when rollover occurs, for the cases where rollover is set to happen “at midnight” or “on a particular weekday”.

*Changed in version 3.4: atTime parameter was added.*

**doRollover()**

Does a rollover, as described above.

**emit(record)**
Outputs the record to the file, catering for rollover as described above.
16.9.8. SocketHandler

The **SocketHandler** class, located in the `logging.handlers` module, sends logging output to a network socket. The base class uses a TCP socket.

```python
class logging.handlers.SocketHandler(host, port)
    Returns a new instance of the `SocketHandler` class intended to communicate with a remote machine whose address is given by `host` and `port`.

    Changed in version 3.4: If `port` is specified as `None`, a Unix domain socket is created using the value in `host` - otherwise, a TCP socket is created.

    close()
    Closes the socket.

    emit()
    Pickles the record's attribute dictionary and writes it to the socket in binary format. If there is an error with the socket, silently drops the packet. If the connection was previously lost, re-establishes the connection. To unpickle the record at the receiving end into a `LogRecord`, use the `makeLogRecord()` function.

    handleError()
    Handles an error which has occurred during `emit()`. The most likely cause is a lost connection. Closes the socket so that we can retry on the next event.

    makeSocket()
```
This is a factory method which allows subclasses to define the precise type of socket they want. The default implementation creates a TCP socket (`socket.SOCK_STREAM`).

**makePickle**(*record*)

Pickles the record's attribute dictionary in binary format with a length prefix, and returns it ready for transmission across the socket.

Note that pickles aren't completely secure. If you are concerned about security, you may want to override this method to implement a more secure mechanism. For example, you can sign pickles using HMAC and then verify them on the receiving end, or alternatively you can disable unpickling of global objects on the receiving end.

**send**(*packet*)

Send a pickled string *packet* to the socket. This function allows for partial sends which can happen when the network is busy.

**createSocket**()

Tries to create a socket; on failure, uses an exponential back-off algorithm. On intial failure, the handler will drop the message it was trying to send. When subsequent messages are handled by the same instance, it will not try connecting until some time has passed. The default parameters are such that the initial delay is one second, and if after that delay the connection still can't be made, the handler will double the delay each time up to a maximum of 30 seconds.

This behaviour is controlled by the following handler attributes:

- `retryStart` (initial delay, defaulting to 1.0 seconds).
retryFactor (multiplier, defaulting to 2.0).
retryMax (maximum delay, defaulting to 30.0 seconds).

This means that if the remote listener starts up after the handler has been used, you could lose messages (since the handler won’t even attempt a connection until the delay has elapsed, but just silently drop messages during the delay period).
16.9.9. DatagramHandler

The `DatagramHandler` class, located in the `logging.handlers` module, inherits from `SocketHandler` to support sending logging messages over UDP sockets.

```python
class logging.handlers.DatagramHandler(host, port)
```

Returns a new instance of the `DatagramHandler` class intended to communicate with a remote machine whose address is given by `host` and `port`.

*Changed in version 3.4:* If `port` is specified as `None`, a Unix domain socket is created using the value in `host` - otherwise, a TCP socket is created.

**emit()**

Pickles the record's attribute dictionary and writes it to the socket in binary format. If there is an error with the socket, silently drops the packet. To unpickle the record at the receiving end into a `LogRecord`, use the `makeLogRecord()` function.

**makeSocket()**

The factory method of `SocketHandler` is here overridden to create a UDP socket (`socket.SOCK_DGRAM`).

**send(s)**

Send a pickled string to a socket.
16.9.10. SysLogHandler

The `SysLogHandler` class, located in the `logging.handlers` module, supports sending logging messages to a remote or local Unix syslog.

```python
class logging.handlers.SysLogHandler(address=('localhost', SYSLOG_UDP_PORT), facility=LOG_USER, socktype=socket.SOCK_DGRAM)
```

Returns a new instance of the `SysLogHandler` class intended to communicate with a remote Unix machine whose address is given by `address` in the form of a `(host, port)` tuple. If `address` is not specified, `('localhost', 514)` is used. The address is used to open a socket. An alternative to providing a `(host, port)` tuple is providing an address as a string, for example `'/dev/log'`. In this case, a Unix domain socket is used to send the message to the syslog. If `facility` is not specified, `LOG_USER` is used. The type of socket opened depends on the `socktype` argument, which defaults to `socket.SOCK_DGRAM` and thus opens a UDP socket. To open a TCP socket (for use with the newer syslog daemons such as rsyslog), specify a value of `socket.SOCK_STREAM`.

Note that if your server is not listening on UDP port 514, `SysLogHandler` may appear not to work. In that case, check what address you should be using for a domain socket - it's system dependent. For example, on Linux it's usually `'/dev/log'` but on OS/X it's `'/var/run/syslog'`. You'll need to check your platform and use the appropriate address (you may need to do this check at runtime if your application needs to run on several platforms). On Windows, you pretty much have to use the UDP option.
Changed in version 3.2: socktype was added.

**close()**
Closes the socket to the remote host.

**emit(record)**
The record is formatted, and then sent to the syslog server. If exception information is present, it is *not* sent to the server.

*Changed in version 3.2.1:* (See: issue 12168.) In earlier versions, the message sent to the syslog daemons was always terminated with a NUL byte, because early versions of these daemons expected a NUL terminated message - even though it's not in the relevant specification (RF 5424). More recent versions of these daemons don’t expect the NUL byte but strip it off if it's there, and even more recent daemons (which adhere more closely to RFC 5424) pass the NUL byte on as part of the message.

To enable easier handling of syslog messages in the face of all these differing daemon behaviours, the appending of the NUL byte has been made configurable, through the use of a class-level attribute, `append_nul`. This defaults to `True` (preserving the existing behaviour) but can be set to `False` on a `SysLogHandler` instance in order for that instance to *not* append the NUL terminator.

*Changed in version 3.3:* (See: issue 12419.) In earlier versions, there was no facility for an “ident” or “tag” prefix to identify the source of the message. This can now be specified using a class-level attribute, defaulting to `""` to preserve existing behaviour, but which can be overridden on a `SysLogHandler`
instance in order for that instance to prepend the ident to every message handled. Note that the provided ident must be text, not bytes, and is prepended to the message exactly as is.

**encodePriority**(*facility, priority*)

Encodes the facility and priority into an integer. You can pass in strings or integers - if strings are passed, internal mapping dictionaries are used to convert them to integers.

The symbolic LOG_value}s are defined in `SysLogHandler` and mirror the values defined in the `sys/syslog.h` header file.

### Priorities

<table>
<thead>
<tr>
<th>Name (string)</th>
<th>Symbolic value</th>
</tr>
</thead>
<tbody>
<tr>
<td>alert</td>
<td>LOG_ALERT</td>
</tr>
<tr>
<td>crit or critical</td>

<td>LOG_AUTH</td>
</tr>
<tr>
<td>authpriv</td>
<td>LOG_AUTHPRIV</td>
</tr>
<tr>
<td>cron</td>
<td>LOG_CRON</td>
</tr>
</tbody>
</table>
### mapPriority(levelname)

Maps a logging level name to a syslog priority name. You may need to override this if you are using custom levels, or if the default algorithm is not suitable for your needs. The default algorithm maps `DEBUG`, `INFO`, `WARNING`, `ERROR` and `CRITICAL` to the equivalent syslog names, and all other level names to 'warning'.

<table>

</table>
16.9.11. NTEventLogHandler

The **NTEventLogHandler** class, located in the `logging.handlers` module, supports sending logging messages to a local Windows NT, Windows 2000 or Windows XP event log. Before you can use it, you need Mark Hammond’s Win32 extensions for Python installed.

```python
class logging.handlers.NTEventLogHandler(appname, dllname=None, logtype='Application')
```

Returns a new instance of the `NTEventLogHandler` class. The `appname` is used to define the application name as it appears in the event log. An appropriate registry entry is created using this name. The `dllname` should give the fully qualified pathname of a .dll or .exe which contains message definitions to hold in the log (if not specified, `win32service.pyd` is used - this is installed with the Win32 extensions and contains some basic placeholder message definitions. Note that use of these placeholders will make your event logs big, as the entire message source is held in the log. If you want slimmer logs, you have to pass in the name of your own .dll or .exe which contains the message definitions you want to use in the event log). The `logtype` is one of `'Application'`, `'System'` or `'Security'`, and defaults to `'Application'`.

```python
close()
```

At this point, you can remove the application name from the registry as a source of event log entries. However, if you do this, you will not be able to see the events as you intended in the Event Log Viewer - it needs to be able to access the registry to get the .dll name. The current version does not do this.
**emit**(record)
   Determines the message ID, event category and event type, and then logs the message in the NT event log.

**getEventCategory**(record)
   Returns the event category for the record. Override this if you want to specify your own categories. This version returns 0.

**getEventType**(record)
   Returns the event type for the record. Override this if you want to specify your own types. This version does a mapping using the handler’s typemap attribute, which is set up in __init__( ) to a dictionary which contains mappings for DEBUG, INFO, WARNING, ERROR and CRITICAL. If you are using your own levels, you will either need to override this method or place a suitable dictionary in the handler’s typemap attribute.

**getMessageID**(record)
   Returns the message ID for the record. If you are using your own messages, you could do this by having the msg passed to the logger being an ID rather than a format string. Then, in here, you could use a dictionary lookup to get the message ID. This version returns 1, which is the base message ID in win32service.pyd.
16.9.12. SMTPHandler

The **SMTPHandler** class, located in the `logging.handlers` module, supports sending logging messages to an email address via SMTP.

```python
class logging.handlers.SMTPHandler(mailhost, fromaddr, toaddrs, subject, credentials=None, secure=None, timeout=1.0)
```

Returns a new instance of the **SMTPHandler** class. The instance is initialized with the from and to addresses and subject line of the email. The `toaddrs` should be a list of strings. To specify a non-standard SMTP port, use the (host, port) tuple format for the `mailhost` argument. If you use a string, the standard SMTP port is used. If your SMTP server requires authentication, you can specify a (username, password) tuple for the `credentials` argument.

To specify the use of a secure protocol (TLS), pass in a tuple to the `secure` argument. This will only be used when authentication credentials are supplied. The tuple should be either an empty tuple, or a single-value tuple with the name of a keyfile, or a 2-value tuple with the names of the keyfile and certificate file. (This tuple is passed to the `smtplib.SMTP.starttls()` method.)

A timeout can be specified for communication with the SMTP server using the `timeout` argument.

*New in version 3.3:* The `timeout` argument was added.

```python
emit(record)
```

Formats the record and sends it to the specified addressees.

```python
getSubject(record)
```
If you want to specify a subject line which is record-dependent, override this method.
16.9.13. MemoryHandler

The **MemoryHandler** class, located in the `logging.handlers` module, supports buffering of logging records in memory, periodically flushing them to a *target* handler. Flushing occurs whenever the buffer is full, or when an event of a certain severity or greater is seen.

**MemoryHandler** is a subclass of the more general **BufferingHandler**, which is an abstract class. This buffers logging records in memory. Whenever each record is added to the buffer, a check is made by calling `shouldFlush()` to see if the buffer should be flushed. If it should, then `flush()` is expected to do the flushing.

```python
class logging.handlers.BufferingHandler(capacity):
    Initializes the handler with a buffer of the specified capacity.

    emit(record)
    Appends the record to the buffer. If `shouldFlush()` returns true, calls `flush()` to process the buffer.

    flush()
    You can override this to implement custom flushing behavior. This version just zaps the buffer to empty.

    shouldFlush(record)
    Returns true if the buffer is up to capacity. This method can be overridden to implement custom flushing strategies.
```

```python
class logging.handlers.MemoryHandler(capacity, flushLevel=ERROR, target=None):
    Returns a new instance of the MemoryHandler class. The
instance is initialized with a buffer size of capacity. If flushLevel is not specified, ERROR is used. If no target is specified, the target will need to be set using setTarget() before this handler does anything useful.

**close()**
Calls flush(), sets the target to None and clears the buffer.

**flush()**
For a MemoryHandler, flushing means just sending the buffered records to the target, if there is one. The buffer is also cleared when this happens. Override if you want different behavior.

**setTarget(target)**
Sets the target handler for this handler.

**shouldFlush(record)**
Checks for buffer full or a record at the flushLevel or higher.
16.9.14. HTTPHandler

The HTTPHandler class, located in the logging.handlers module, supports sending logging messages to a Web server, using either GET or POST semantics.

class logging.handlers.HTTPHandler(host, url, method='GET', secure=False, credentials=None)

Returns a new instance of the HTTPHandler class. The host can be of the form host:port, should you need to use a specific port number. If no method is specified, GET is used. If secure is true, an HTTPS connection will be used. If credentials is specified, it should be a 2-tuple consisting of userid and password, which will be placed in an HTTP ‘Authorization’ header using Basic authentication. If you specify credentials, you should also specify secure=True so that your userid and password are not passed in cleartext across the wire.

emit(record)

Sends the record to the Web server as a percent-encoded dictionary.
16.9.15. QueueHandler

New in version 3.2.

The QueueHandler class, located in the logging.handlers module, supports sending logging messages to a queue, such as those implemented in the queue or multiprocessing modules.

Along with the QueueListener class, QueueHandler can be used to let handlers do their work on a separate thread from the one which does the logging. This is important in Web applications and also other service applications where threads servicing clients need to respond as quickly as possible, while any potentially slow operations (such as sending an email via SMTPHandler) are done on a separate thread.

class logging.handlers.QueueHandler(queue)

Returns a new instance of the QueueHandler class. The instance is initialized with the queue to send messages to. The queue can be any queue-like object; it's used as-is by the enqueue() method, which needs to know how to send messages to it.

emit(record)

Enqueues the result of preparing the LogRecord.

prepare(record)

Prepares a record for queuing. The object returned by this method is enqueued.

The base implementation formats the record to merge the message and arguments, and removes unpickleable items from the record in-place.
You might want to override this method if you want to convert
the record to a dict or JSON string, or send a modified copy of
the record while leaving the original intact.

enqueue(record)

Enqueues the record on the queue using put_nowait(); you
may want to override this if you want to use blocking behaviour,
or a timeout, or a customized queue implementation.
16.9.16. QueueListener

New in version 3.2.

The QueueListener class, located in the logging.handlers module, supports receiving logging messages from a queue, such as those implemented in the queue or multiprocessing modules. The messages are received from a queue in an internal thread and passed, on the same thread, to one or more handlers for processing. While QueueListener is not itself a handler, it is documented here because it works hand-in-hand with QueueHandler.

Along with the QueueHandler class, QueueListener can be used to let handlers do their work on a separate thread from the one which does the logging. This is important in Web applications and also other service applications where threads servicing clients need to respond as quickly as possible, while any potentially slow operations (such as sending an email via SMTPHandler) are done on a separate thread.

class logging.handlers.QueueListener(queue, *handlers)
    Returns a new instance of the QueueListener class. The instance is initialized with the queue to send messages to and a list of handlers which will handle entries placed on the queue. The queue can be any queue-like object; it’s passed as-is to the dequeue() method, which needs to know how to get messages from it.

dqueue(block)
    Dequeues a record and return it, optionally blocking.

    The base implementation uses get(). You may want to
override this method if you want to use timeouts or work with custom queue implementations.

**prepare**(\textit{record})
Prepare a record for handling.

This implementation just returns the passed-in record. You may want to override this method if you need to do any custom marshalling or manipulation of the record before passing it to the handlers.

**handle**(\textit{record})
Handle a record.

This just loops through the handlers offering them the record to handle. The actual object passed to the handlers is that which is returned from \textit{prepare}().

**start()**
Starts the listener.

This starts up a background thread to monitor the queue for LogRecords to process.

**stop()**
Stops the listener.

This asks the thread to terminate, and then waits for it to do so. Note that if you don’t call this before your application exits, there may be some records still left on the queue, which won’t be processed.

**enqueue_sentinel()**
Writes a sentinel to the queue to tell the listener to quit. This implementation uses `put_nowait()`. You may want to override this method if you want to use timeouts or work with custom queue implementations.

*New in version 3.3.*

**Module** `logging.config`

Configuration API for the logging module.
16.10. `getpass` — Portable password input

The `getpass` module provides two functions:

`getpass.getpass(prompt='Password: ', stream=None)`

Prompt the user for a password without echoing. The user is prompted using the string `prompt`, which defaults to `'Password: '`. On Unix, the prompt is written to the file-like object `stream`. `stream` defaults to the controlling terminal (`/dev/tty`) or if that is unavailable to `sys.stderr` (this argument is ignored on Windows).

If echo free input is unavailable `getpass()` falls back to printing a warning message to `stream` and reading from `sys.stdin` and issuing a `GetPassWarning`.

Availability: Macintosh, Unix, Windows.

**Note:** If you call `getpass` from within IDLE, the input may be done in the terminal you launched IDLE from rather than the idle window itself.

`exception getpass.GetPassWarning`

A `UserWarning` subclass issued when password input may be echoed.

`getpass.getuser()`

Return the “login name” of the user. Availability: Unix, Windows.
This function checks the environment variables LOGNAME, USER, LNAME and USERNAME, in order, and returns the value of the first one which is set to a non-empty string. If none are set, the login name from the password database is returned on systems which support the `pwd` module, otherwise, an exception is raised.
16. Generic Operating System Services
16.11. **curses** — Terminal handling for character-cell displays

The `curses` module provides an interface to the curses library, the de-facto standard for portable advanced terminal handling.

While curses is most widely used in the Unix environment, versions are available for Windows, DOS, and possibly other systems as well. This extension module is designed to match the API of ncurses, an open-source curses library hosted on Linux and the BSD variants of Unix.

**Note:** Since version 5.4, the ncurses library decides how to interpret non-ASCII data using the `nl_langinfo` function. That means that you have to call `locale.setlocale()` in the application and encode Unicode strings using one of the system’s available encodings. This example uses the system’s default encoding:

```python
import locale
locale.setlocale(locale.LC_ALL, '')
code = locale.getpreferredencoding()
```

Then use `code` as the encoding for `str.encode()` calls.

**Curses Programming with Python**

Tutorial material on using curses with Python, by Andrew Kuchling and Eric Raymond.

The **Tools/demo/** directory in the Python source distribution contains some example programs using the curses bindings provided by this module.
16.11.1. Functions

The module `curses` defines the following exception:

```
exception curses.error
```

Exception raised when a curses library function returns an error.

**Note:** Whenever `x` or `y` arguments to a function or a method are optional, they default to the current cursor location. Whenever `attr` is optional, it defaults to `A_NORMAL`.

The module `curses` defines the following functions:

**curses.baudrate()**

Return the output speed of the terminal in bits per second. On software terminal emulators it will have a fixed high value. Included for historical reasons; in former times, it was used to write output loops for time delays and occasionally to change interfaces depending on the line speed.

**curses.beep()**

Emit a short attention sound.

**curses.can_change_color()**

Return `True` or `False`, depending on whether the programmer can change the colors displayed by the terminal.

**curses.cbreak()**

Enter cbreak mode. In cbreak mode (sometimes called “rare” mode) normal tty line buffering is turned off and characters are available to be read one by one. However, unlike raw mode,
special characters (interrupt, quit, suspend, and flow control) retain their effects on the tty driver and calling program. Calling first `raw()` then `cbreak()` leaves the terminal in cbreak mode.

curses.**color_content**(color_number)
Return the intensity of the red, green, and blue (RGB) components in the color color_number, which must be between 0 and COLORS. A 3-tuple is returned, containing the R,G,B values for the given color, which will be between 0 (no component) and 1000 (maximum amount of component).

curses.**color_pair**(color_number)
Return the attribute value for displaying text in the specified color. This attribute value can be combined with A_STANDOUT, A_REVERSE, and the other A_* attributes. `pair_number()` is the counterpart to this function.

curses.**curs_set**(visibility)
Set the cursor state. visibility can be set to 0, 1, or 2, for invisible, normal, or very visible. If the terminal supports the visibility requested, the previous cursor state is returned; otherwise, an exception is raised. On many terminals, the “visible” mode is an underline cursor and the “very visible” mode is a block cursor.

curses.**def_prog_mode**( )
Save the current terminal mode as the “program” mode, the mode when the running program is using curses. (Its counterpart is the “shell” mode, for when the program is not in curses.) Subsequent calls to `reset_prog_mode()` will restore this mode.

curses.**def_shell_mode**( )
Save the current terminal mode as the “shell” mode, the mode
when the running program is not using curses. (Its counterpart is the “program” mode, when the program is using curses capabilities.) Subsequent calls to `reset_shell_mode()` will restore this mode.

curses.`delay_output(ms)`
Insert an $ms$ millisecond pause in output.

curses.`doupdate()`
Update the physical screen. The curses library keeps two data structures, one representing the current physical screen contents and a virtual screen representing the desired next state. The `doupdate()` ground updates the physical screen to match the virtual screen.

The virtual screen may be updated by a `noutrefresh()` call after write operations such as `addstr()` have been performed on a window. The normal `refresh()` call is simply `noutrefresh()` followed by `doupdate()`; if you have to update multiple windows, you can speed performance and perhaps reduce screen flicker by issuing `noutrefresh()` calls on all windows, followed by a single `doupdate()`.

curses.`echo()`
Enter echo mode. In echo mode, each character input is echoed to the screen as it is entered.

curses.`endwin()`
De-initialize the library, and return terminal to normal status.

curses.`erasechar()`
Return the user’s current erase character. Under Unix operating
systems this is a property of the controlling tty of the curses program, and is not set by the curses library itself.

**curses.filter()**

The `filter()` routine, if used, must be called before `initscr()` is called. The effect is that, during those calls, LINES is set to 1; the capabilities clear, cup, cud, cud1, cuu1, cuu, vpa are disabled; and the home string is set to the value of cr. The effect is that the cursor is confined to the current line, and so are screen updates. This may be used for enabling character-at-a-time line editing without touching the rest of the screen.

**curses.flash()**

Flash the screen. That is, change it to reverse-video and then change it back in a short interval. Some people prefer such as ‘visible bell’ to the audible attention signal produced by `beep()`.

**curses.flushinp()**

Flush all input buffers. This throws away any typeahead that has been typed by the user and has not yet been processed by the program.

**curses.getmouse()**

After `getch()` returns `KEY_MOUSE` to signal a mouse event, this method should be call to retrieve the queued mouse event, represented as a 5-tuple `(id, x, y, z, bstate)`. `id` is an ID value used to distinguish multiple devices, and `x, y, z` are the event’s coordinates. (z is currently unused.) `bstate` is an integer value whose bits will be set to indicate the type of event, and will be the bitwise OR of one or more of the following constants, where `n` is the button number from 1 to 4: BUTTONn_PRESSED, BUTTONn_RELEASED, BUTTONn_CLICKED,
curses.getsyx()
Return the current coordinates of the virtual screen cursor in y and x. If leaveok is currently true, then -1,-1 is returned.

curses.getwin(file)
Read window related data stored in the file by an earlier putwin() call. The routine then creates and initializes a new window using that data, returning the new window object.

curses.has_colors()
Return True if the terminal can display colors; otherwise, return False.

curses.has_ic()
Return True if the terminal has insert- and delete-character capabilities. This function is included for historical reasons only, as all modern software terminal emulators have such capabilities.

curses.has_il()
Return True if the terminal has insert- and delete-line capabilities, or can simulate them using scrolling regions. This function is included for historical reasons only, as all modern software terminal emulators have such capabilities.

curses.has_key(ch)
Take a key value ch, and return True if the current terminal type recognizes a key with that value.

curses.halfdelay(tenths)
Used for half-delay mode, which is similar to `cbreak` mode in that characters typed by the user are immediately available to the program. However, after blocking for `tenths` tenths of seconds, an exception is raised if nothing has been typed. The value of `tenths` must be a number between 1 and 255. Use `nocbreak()` to leave half-delay mode.

`curses.init_color(color_number, r, g, b)`

Change the definition of a color, taking the number of the color to be changed followed by three RGB values (for the amounts of red, green, and blue components). The value of `color_number` must be between 0 and `COLORS`. Each of `r`, `g`, `b`, must be a value between 0 and 1000. When `init_color()` is used, all occurrences of that color on the screen immediately change to the new definition. This function is a no-op on most terminals; it is active only if `can_change_color()` returns 1.

`curses.init_pair(pair_number, fg, bg)`

Change the definition of a color-pair. It takes three arguments: the number of the color-pair to be changed, the foreground color number, and the background color number. The value of `pair_number` must be between 1 and `COLOR_PAIRS - 1` (the 0 color pair is wired to white on black and cannot be changed). The value of `fg` and `bg` arguments must be between 0 and `COLORS`. If the color-pair was previously initialized, the screen is refreshed and all occurrences of that color-pair are changed to the new definition.

`curses.initscr()`

Initialize the library. Return a `WindowObject` which represents the whole screen.

**Note:** If there is an error opening the terminal, the underlying
curses library may cause the interpreter to exit.

curses.\texttt{is\_term\_resized}(nlines, ncols)

Return \texttt{True} if \texttt{resize\_term()} would modify the window structure, \texttt{False} otherwise.

curses.\texttt{is\_end\_win()}

Return \texttt{True} if \texttt{end\_win()} has been called (that is, the curses library has been deinitialized).

curses.\texttt{key\_name}(k)

Return the name of the key numbered \( k \). The name of a key generating printable ASCII character is the key's character. The name of a control-key combination is a two-character string consisting of a caret followed by the corresponding printable ASCII character. The name of an alt-key combination (128-255) is a string consisting of the prefix ‘M-’ followed by the name of the corresponding ASCII character.

curses.\texttt{kill\_char()}

Return the user’s current line kill character. Under Unix operating systems this is a property of the controlling tty of the curses program, and is not set by the curses library itself.

curses.\texttt{long\_name()}

Return a string containing the terminfo long name field describing the current terminal. The maximum length of a verbose description is 128 characters. It is defined only after the call to \texttt{initscr()}.

curses.\texttt{meta}(yes)

If \texttt{yes} is 1, allow 8-bit characters to be input. If \texttt{yes} is 0, allow only 7-bit chars.
curses. mouseinterval(interval)
Set the maximum time in milliseconds that can elapse between press and release events in order for them to be recognized as a click, and return the previous interval value. The default value is 200 msec, or one fifth of a second.

curses. mousemask(mousemask)
Set the mouse events to be reported, and return a tuple (availmask, oldmask). availmask indicates which of the specified mouse events can be reported; on complete failure it returns 0. oldmask is the previous value of the given window's mouse event mask. If this function is never called, no mouse events are ever reported.

curses. napms(ms)
Sleep for ms milliseconds.

curses. newpad(nlines, ncols)
Create and return a pointer to a new pad data structure with the given number of lines and columns. A pad is returned as a window object.

A pad is like a window, except that it is not restricted by the screen size, and is not necessarily associated with a particular part of the screen. Pads can be used when a large window is needed, and only a part of the window will be on the screen at one time. Automatic refreshes of pads (such as from scrolling or echoing of input) do not occur. The refresh() and noutrefresh() methods of a pad require 6 arguments to specify the part of the pad to be displayed and the location on the screen to be used for the display. The arguments are pminrow, pmincol, sminrow, smincol, smaxrow, smaxcol; the p arguments refer to the upper left
corner of the pad region to be displayed and the s arguments
define a clipping box on the screen within which the pad region is
to be displayed.

curses.\texttt{newwin}(nlines, ncols)
curses.\texttt{newwin}(nlines, ncols, begin\_y, begin\_x)

Return a new window, whose left-upper corner is at (begin\_y, begin\_x), and whose height/width is \texttt{nlines/ncols}.

By default, the window will extend from the specified position to the
lower right corner of the screen.

curses.\texttt{nl}()

Enter newline mode. This mode translates the return key into
newline on input, and translates newline into return and line-feed
on output. Newline mode is initially on.

curses.\texttt{nocbreak}()

Leave cbreak mode. Return to normal “cooked” mode with line
buffering.

curses.\texttt{noecho}()

Leave echo mode. Echoing of input characters is turned off.

curses.\texttt{nonl}()

Leave newline mode. Disable translation of return into newline on
input, and disable low-level translation of newline into
newline/return on output (but this does not change the behavior of
\texttt{addch(’\n’)}, which always does the equivalent of return and
line feed on the virtual screen). With translation off, curses can
sometimes speed up vertical motion a little; also, it will be able to
detect the return key on input.
curses.noqiflush()
When the noqiflush() routine is used, normal flush of input and output queues associated with the INTR, QUIT and SUSP characters will not be done. You may want to call noqiflush() in a signal handler if you want output to continue as though the interrupt had not occurred, after the handler exits.

curses.noraw()
Leave raw mode. Return to normal “cooked” mode with line buffering.

curses.pair_content(pair_number)
Return a tuple (fg, bg) containing the colors for the requested color pair. The value of pair_number must be between 1 and COLOR_PAIRS - 1.

curses.pair_number(attr)
Return the number of the color-pair set by the attribute value attr. color_pair() is the counterpart to this function.

curses.putp(string)
Equivalent to tputs(str, 1, putchar); emit the value of a specified terminfo capability for the current terminal. Note that the output of putp() always goes to standard output.

curses.qiflush([flag])
If flag is False, the effect is the same as calling noqiflush(). If flag is True, or no argument is provided, the queues will be flushed when these control characters are read.

curses.raw()
Enter raw mode. In raw mode, normal line buffering and processing of interrupt, quit, suspend, and flow control keys are turned off; characters are presented to curses input functions one by one.

curses.\texttt{reset\_prog\_mode()}\hfill
\begin{quote}
Restore the terminal to “program” mode, as previously saved by \texttt{def\_prog\_mode()}.
\end{quote}

curses.\texttt{reset\_shell\_mode()}\hfill
\begin{quote}
Restore the terminal to “shell” mode, as previously saved by \texttt{def\_shell\_mode()}.
\end{quote}

curses.\texttt{resetty()}\hfill
\begin{quote}
Restore the state of the terminal modes to what it was at the last call to \texttt{savetty()}.
\end{quote}

curses.\texttt{resize\_term(nlines, ncols)}\hfill
\begin{quote}
Backend function used by \texttt{resizeterm()}, performing most of the work; when resizing the windows, \texttt{resize\_term()} blank-fills the areas that are extended. The calling application should fill in these areas with appropriate data. The \texttt{resize\_term()} function attempts to resize all windows. However, due to the calling convention of pads, it is not possible to resize these without additional interaction with the application.
\end{quote}

curses.\texttt{resizeterm(nlines, ncols)}\hfill
\begin{quote}
Resize the standard and current windows to the specified dimensions, and adjusts other bookkeeping data used by the curses library that record the window dimensions (in particular the \texttt{SIGWINCH} handler).
\end{quote}

curses.\texttt{savetty()}
Save the current state of the terminal modes in a buffer, usable by `resetty()`.

`curses.setsyx(y, x)`
Set the virtual screen cursor to \( y, x \). If \( y \) and \( x \) are both -1, then `leaveok` is set.

`curses.setupterm([termstr, fd])`
Initialize the terminal. `termstr` is a string giving the terminal name; if omitted, the value of the `TERM` environment variable will be used. `fd` is the file descriptor to which any initialization sequences will be sent; if not supplied, the file descriptor for `sys.stdout` will be used.

`curses.start_color()`
Must be called if the programmer wants to use colors, and before any other color manipulation routine is called. It is good practice to call this routine right after `initscr()`.

`start_color()` initializes eight basic colors (black, red, green, yellow, blue, magenta, cyan, and white), and two global variables in the `curses` module, `COLORS` and `COLOR_PAIRS`, containing the maximum number of colors and color-pairs the terminal can support. It also restores the colors on the terminal to the values they had when the terminal was just turned on.

`curses.termattrs()`
Return a logical OR of all video attributes supported by the terminal. This information is useful when a `curses` program needs complete control over the appearance of the screen.

`curses.termname()`
Return the value of the environment variable TERM, truncated to 14 characters.

curses.\texttt{tigetflag}(\textit{capname})

Return the value of the Boolean capability corresponding to the terminfo capability name \textit{capname}. The value $\text{-1}$ is returned if \textit{capname} is not a Boolean capability, or $\text{0}$ if it is canceled or absent from the terminal description.

curses.\texttt{tigetnum}(\textit{capname})

Return the value of the numeric capability corresponding to the terminfo capability name \textit{capname}. The value $\text{-2}$ is returned if \textit{capname} is not a numeric capability, or $\text{-1}$ if it is canceled or absent from the terminal description.

curses.\texttt{tigetstr}(\textit{capname})

Return the value of the string capability corresponding to the terminfo capability name \textit{capname}. \texttt{None} is returned if \textit{capname} is not a string capability, or is canceled or absent from the terminal description.

curses.\texttt{tparm}(\textit{str}, [...])

Instantiate the string \textit{str} with the supplied parameters, where \textit{str} should be a parameterized string obtained from the terminfo database. E.g. \texttt{tparm(tigetstr("cup"), 5, 3)} could result in \texttt{b'\033[6;4H'}, the exact result depending on terminal type.

curses.\texttt{typeahead}(\textit{fd})

Specify that the file descriptor \textit{fd} be used for typeahead checking. If \textit{fd} is $\text{-1}$, then no typeahead checking is done.

The curses library does “line-breakout optimization” by looking for
typeahead periodically while updating the screen. If input is found, and it is coming from a tty, the current update is postponed until refresh or doupdate is called again, allowing faster response to commands typed in advance. This function allows specifying a different file descriptor for typeahead checking.

**curses.unctr1**(ch)

Return a string which is a printable representation of the character `ch`. Control characters are displayed as a caret followed by the character, for example as `^C`. Printing characters are left as they are.

**curses.ungetch**(ch)

Push `ch` so the next `getch()` will return it.

**Note:** Only one `ch` can be pushed before `getch()` is called.

**curses.unget_wch**(ch)

Push `ch` so the next `get_wch()` will return it.

**Note:** Only one `ch` can be pushed before `get_wch()` is called.

*New in version 3.3.*

**curses.ungetmouse**(id, x, y, z, bstate)

Push a KEY_MOUSE event onto the input queue, associating the given state data with it.

**curses.use_env**(flag)

If used, this function should be called before `initscr()` or `newterm` are called. When `flag` is `False`, the values of lines and columns specified in the terminfo database will be used, even if
environment variables LINES and COLUMNS (used by default) are set, or if curses is running in a window (in which case default behavior would be to use the window size if LINES and COLUMNS are not set).

curses.\texttt{use\_default\_colors()}

Allow use of default values for colors on terminals supporting this feature. Use this to support transparency in your application. The default color is assigned to the color number -1. After calling this function, \texttt{init\_pair(x, curses.COLOR\_RED, -1)} initializes, for instance, color pair \(x\) to a red foreground color on the default background.

curses.\texttt{wrapper(func, ...)}

Initialize curses and call another callable object, \texttt{func}, which should be the rest of your curses-using application. If the application raises an exception, this function will restore the terminal to a sane state before re-raising the exception and generating a traceback. The callable object \texttt{func} is then passed the main window ‘stdscr’ as its first argument, followed by any other arguments passed to \texttt{wrapper()}. Before calling \texttt{func}, \texttt{wrapper()} turns on cbreak mode, turns off echo, enables the terminal keypad, and initializes colors if the terminal has color support. On exit (whether normally or by exception) it restores cooked mode, turns on echo, and disables the terminal keypad.
Window objects, as returned by `initscr()` and `newwin()` above, have the following methods and attributes:

```python
window.addch(ch[, attr])
window.addch(y, x, ch[, attr])
```

**Note:** A character means a C character (an ASCII code), rather than a Python character (a string of length 1). (This note is true whenever the documentation mentions a character.) The built-in `ord()` is handy for conveying strings to codes.

Paint character `ch` at `(y, x)` with attributes `attr`, overwriting any character previously painter at that location. By default, the character position and attributes are the current settings for the window object.

```python
window.addnstr(str[, n[, attr]])
window.addnstr(y, x, str[, n[, attr]])
```

Paint at most `n` characters of the string `str` at `(y, x)` with attributes `attr`, overwriting anything previously on the display.

```python
window.addstr(str[, attr])
window.addstr(y, x, str[, attr])
```

Paint the string `str` at `(y, x)` with attributes `attr`, overwriting anything previously on the display.

```python
window.attroff(attr)
```

Remove attribute `attr` from the “background” set applied to all writes to the current window.
window.\texttt{attron}(\textit{attr})

Add attribute \textit{attr} from the “background” set applied to all writes to the current window.

window.\texttt{attrset}(\textit{attr})

Set the “background” set of attributes to \textit{attr}. This set is initially 0 (no attributes).

window.\texttt{bkgd}(\textit{ch}[, \textit{attr}])

Set the background property of the window to the character \textit{ch}, with attributes \textit{attr}. The change is then applied to every character position in that window:

- The attribute of every character in the window is changed to the new background attribute.
- Wherever the former background character appears, it is changed to the new background character.

window.\texttt{bkgdset}(\textit{ch}[, \textit{attr}])

Set the window's background. A window's background consists of a character and any combination of attributes. The attribute part of the background is combined (OR’ed) with all non-blank characters that are written into the window. Both the character and attribute parts of the background are combined with the blank characters. The background becomes a property of the character and moves with the character through any scrolling and insert/delete line/character operations.

window.\texttt{border}([\textit{ls}[\textit{rs}], \textit{ts}[\textit{bs}], \textit{tl}[\textit{tr}], \textit{bl}[\textit{br}]]])

Draw a border around the edges of the window. Each parameter specifies the character to use for a specific part of the border; see the table below for more details. The characters can be specified
as integers or as one-character strings.

**Note:** A 0 value for any parameter will cause the default character to be used for that parameter. Keyword parameters can *not* be used. The defaults are listed in this table:

<table>
<thead>
<tr>
<th>Parameter</th>
<th>Description</th>
<th>Default value</th>
</tr>
</thead>
<tbody>
<tr>
<td><strong>ls</strong></td>
<td>Left side</td>
<td>ACS_VLINE</td>
</tr>
<tr>
<td><strong>rs</strong></td>
<td>Right side</td>
<td>ACS_VLINE</td>
</tr>
<tr>
<td><strong>ts</strong></td>
<td>Top</td>
<td>ACS_HLINE</td>
</tr>
<tr>
<td><strong>bs</strong></td>
<td>Bottom</td>
<td>ACS_HLINE</td>
</tr>
<tr>
<td><strong>tl</strong></td>
<td>Upper-left corner</td>
<td>ACS_ULCORNER</td>
</tr>
<tr>
<td><strong>tr</strong></td>
<td>Upper-right corner</td>
<td>ACS_URCORNER</td>
</tr>
<tr>
<td><strong>bl</strong></td>
<td>Bottom-left corner</td>
<td>ACS_LLCORNER</td>
</tr>
<tr>
<td><strong>br</strong></td>
<td>Bottom-right corner</td>
<td>ACS_LRCORNER</td>
</tr>
</tbody>
</table>

`window.box([vertch, horch])`

Similar to `border()`, but both `ls` and `rs` are `vertch` and both `ts` and `bs` are `horch`. The default corner characters are always used by this function.

`window.chgat(attr)`

`window.chgat(num, attr)`

`window.chgat(y, x, attr)`

`window.chgat(y, x, num, attr)`

Set the attributes of `num` characters at the current cursor position, or at position `(y, x)` if supplied. If no value of `num` is given or `num = -1`, the attribute will be set on all the characters to the end of the line. This function does not move the cursor. The changed line
will be touched using the `touchline()` method so that the contents will be redisplayed by the next window refresh.

```plaintext
window.clear()
Like `erase()`, but also cause the whole window to be repainted upon next call to `refresh()`.

window.clearok(yes)
If yes is 1, the next call to `refresh()` will clear the window completely.

window.clrtobot()
Erase from cursor to the end of the window: all lines below the cursor are deleted, and then the equivalent of `clrtoeol()` is performed.

window.clrtoeol()
Erase from cursor to the end of the line.

window.cursyncup()
Update the current cursor position of all the ancestors of the window to reflect the current cursor position of the window.

window.delch([y, x])
Delete any character at (y, x).

window.deleteln()
Delete the line under the cursor. All following lines are moved up by one line.

window.derwin(begin_y, begin_x)
window.derwin(nlines, ncols, begin_y, begin_x)`
An abbreviation for “derive window”, **derwin()** is the same as calling **subwin()**, except that **begin_y** and **begin_x** are relative to the origin of the window, rather than relative to the entire screen. Return a window object for the derived window.

**window.echochar(ch[, attr])**

Add character **ch** with attribute **attr**, and immediately call **refresh()** on the window.

**window.enclose(y, x)**

Test whether the given pair of screen-relative character-cell coordinates are enclosed by the given window, returning **True** or **False**. It is useful for determining what subset of the screen windows enclose the location of a mouse event.

**window.encoding**

Encoding used to encode method arguments (Unicode strings and characters). The encoding attribute is inherited from the parent window when a subwindow is created, for example with **window.subwin()**. By default, the locale encoding is used (see **locale.getpreferredencoding()**).

*New in version 3.3.*

**window.erase()**

Clear the window.

**window.getbegyx()**

Return a tuple **(y, x)** of co-ordinates of upper-left corner.

**window.getbkgd()**

Return the given window’s current background character/attribute
window. **getch**([y, x])

Get a character. Note that the integer returned does *not* have to be in ASCII range: function keys, keypad keys and so on return numbers higher than 256. In no-delay mode, -1 is returned if there is no input, else `getch()` waits until a key is pressed.

window. **get_wch**([y, x])

Get a wide character. Return a character for most keys, or an integer for function keys, keypad keys, and other special keys.

*New in version 3.3.*

window. **getkey**([y, x])

Get a character, returning a string instead of an integer, as `getch()` does. Function keys, keypad keys and other special keys return a multibyte string containing the key name. In no-delay mode, an exception is raised if there is no input.

window. **getmaxyx**()

Return a tuple (y, x) of the height and width of the window.

window. **getpaxyx**()

Return the beginning coordinates of this window relative to its parent window into two integer variables y and x. Return -1, -1 if this window has no parent.

window. **getstr**([y, x])

Read a string from the user, with primitive line editing capacity.

window. **getyx**()
Return a tuple \((y, x)\) of current cursor position relative to the window's upper-left corner.

\[
\text{window.} \quad \text{hline}(ch, n) \\
\text{window.} \quad \text{hline}(y, x, ch, n)
\]

Display a horizontal line starting at \((y, x)\) with length \(n\) consisting of the character \(ch\).

\[
\text{window.} \quad \text{idcok}(flag)
\]

If \(flag\) is \text{False}, curses no longer considers using the hardware insert/delete character feature of the terminal; if \(flag\) is \text{True}, use of character insertion and deletion is enabled. When curses is first initialized, use of character insert/delete is enabled by default.

\[
\text{window.} \quad \text{idlok}(yes)
\]

If called with \(yes\) equal to 1, \text{curses} will try and use hardware line editing facilities. Otherwise, line insertion/deletion are disabled.

\[
\text{window.} \quad \text{immedok}(flag)
\]

If \(flag\) is \text{True}, any change in the window image automatically causes the window to be refreshed; you no longer have to call \text{refresh()}\) yourself. However, it may degrade performance considerably, due to repeated calls to \text{wrefresh}. This option is disabled by default.

\[
\text{window.} \quad \text{inch}([y, x])
\]

Return the character at the given position in the window. The bottom 8 bits are the character proper, and upper bits are the attributes.

\[
\text{window.} \quad \text{insch}(ch[, attr]) \\
\text{window.} \quad \text{insch}(y, x, ch[, attr])
\]
Paint character \( ch \) at \((y, x)\) with attributes \( attr \), moving the line from position \( x \) right by one character.

**window.** **insdelln**(\( nlines \))

Insert \( nlines \) lines into the specified window above the current line. The \( nlines \) bottom lines are lost. For negative \( nlines \), delete \( nlines \) lines starting with the one under the cursor, and move the remaining lines up. The bottom \( nlines \) lines are cleared. The current cursor position remains the same.

**window.** **insertln**()

Insert a blank line under the cursor. All following lines are moved down by one line.

**window.** **insnstr**(\( str, n[, attr] \))

**window.** **insnstr**(\( y, x, str[, attr] \))

Insert a character string (as many characters as will fit on the line) before the character under the cursor, up to \( n \) characters. If \( n \) is zero or negative, the entire string is inserted. All characters to the right of the cursor are shifted right, with the rightmost characters on the line being lost. The cursor position does not change (after moving to \( y, x \), if specified).

**window.** **insstr**(\( str[, attr] \))

**window.** **insstr**(\( y, x, str[, attr] \))

Insert a character string (as many characters as will fit on the line) before the character under the cursor. All characters to the right of the cursor are shifted right, with the rightmost characters on the line being lost. The cursor position does not change (after moving to \( y, x \), if specified).
window.instr([n])

window.instr(y, x[, n])

Return a string of characters, extracted from the window starting at the current cursor position, or at y, x if specified. Attributes are stripped from the characters. If n is specified, instr() returns a string at most n characters long (exclusive of the trailing NUL).

window.is_linetouched(line)

Return True if the specified line was modified since the last call to refresh(); otherwise return False. Raise a curses.error exception if line is not valid for the given window.

window.is_wintouched()

Return True if the specified window was modified since the last call to refresh(); otherwise return False.

window.keypad(yes)

If yes is 1, escape sequences generated by some keys (keypad, function keys) will be interpreted by curses. If yes is 0, escape sequences will be left as is in the input stream.

window.leaveok(yes)

If yes is 1, cursor is left where it is on update, instead of being at “cursor position.” This reduces cursor movement where possible. If possible the cursor will be made invisible.

If yes is 0, cursor will always be at “cursor position” after an update.

window.move(new_y, new_x)

Move cursor to (new_y, new_x).

window.mvderwin(y, x)
Move the window inside its parent window. The screen-relative parameters of the window are not changed. This routine is used to display different parts of the parent window at the same physical position on the screen.

```c
window.mvwin(new_y, new_x)
```
Move the window so its upper-left corner is at \((\text{new}\_y, \text{new}\_x)\).

```c
window.nodelay(yes)
```
If \(\text{yes}\) is \(1\), \text{getch()} will be non-blocking.

```c
window.notimeout(yes)
```
If \(\text{yes}\) is \(1\), escape sequences will not be timed out.

If \(\text{yes}\) is \(0\), after a few milliseconds, an escape sequence will not be interpreted, and will be left in the input stream as is.

```c
window.noutrefresh()
```
Mark for refresh but wait. This function updates the data structure representing the desired state of the window, but does not force an update of the physical screen. To accomplish that, call \text{doupdate()}.

```c
window.overlay(destwin[, sminrow, smincol, dminrow, dmincol, dmaxrow, dmaxcol])
```
Overlay the window on top of \text{destwin}. The windows need not be the same size, only the overlapping region is copied. This copy is non-destructive, which means that the current background character does not overwrite the old contents of \text{destwin}.

To get fine-grained control over the copied region, the second form of \text{overlay()} can be used. \text{sminrow} and \text{smincol} are the upper-
left coordinates of the source window, and the other variables mark a rectangle in the destination window.

```plaintext
window overwrite(destwin[, sminrow, smincol, dminrow, dmincol, dmaxrow, dmaxcol])
```

Overwrite the window on top of `destwin`. The windows need not be the same size, in which case only the overlapping region is copied. This copy is destructive, which means that the current background character overwrites the old contents of `destwin`.

To get fine-grained control over the copied region, the second form of `overwrite()` can be used. `sminrow` and `smincol` are the upper-left coordinates of the source window, the other variables mark a rectangle in the destination window.

```plaintext
window putwin(file)
```

Write all data associated with the window into the provided file object. This information can be later retrieved using the `getwin()` function.

```plaintext
window redrawln(beg, num)
```

Indicate that the `num` screen lines, starting at line `beg`, are corrupted and should be completely redrawn on the next `refresh()` call.

```plaintext
window redrawwin()
```

Touch the entire window, causing it to be completely redrawn on the next `refresh()` call.

```plaintext
window refresh([pminrow, pmincol, sminrow, smincol, smaxrow, smaxcol])
```

Update the display immediately (sync actual screen with previous
The 6 optional arguments can only be specified when the window is a pad created with `newpad()`. The additional parameters are needed to indicate what part of the pad and screen are involved. `pminrow` and `pmincol` specify the upper left-hand corner of the rectangle to be displayed in the pad. `sminrow`, `smincol`, `smaxrow`, and `smaxcol` specify the edges of the rectangle to be displayed on the screen. The lower right-hand corner of the rectangle to be displayed in the pad is calculated from the screen coordinates, since the rectangles must be the same size. Both rectangles must be entirely contained within their respective structures. Negative values of `pminrow`, `pmincol`, `sminrow`, or `smincol` are treated as if they were zero.

`window.resize(nlines, ncols)`

Reallocate storage for a curses window to adjust its dimensions to the specified values. If either dimension is larger than the current values, the window's data is filled with blanks that have the current background rendition (as set by `bkgdset()`) merged into them.

`window.scroll([lines=1])`

Scroll the screen or scrolling region upward by `lines` lines.

`window.scrollOk(flag)`

Control what happens when the cursor of a window is moved off the edge of the window or scrolling region, either as a result of a newline action on the bottom line, or typing the last character of the last line. If `flag` is false, the cursor is left on the bottom line. If `flag` is true, the window is scrolled up one line. Note that in order to get the physical scrolling effect on the terminal, it is also necessary to call `idlok()`.
window.setscrreg(top, bottom)

Set the scrolling region from line top to line bottom. All scrolling actions will take place in this region.

window.standend()

Turn off the standout attribute. On some terminals this has the side effect of turning off all attributes.

window.standout()

Turn on attribute A_STANDOUT.

window.subpad(begin_y, begin_x)

window.subpad(nlines, ncols, begin_y, begin_x)

Return a sub-window, whose upper-left corner is at (begin_y, begin_x), and whose width/height is ncols/nlines.

window.subwin(begin_y, begin_x)

window.subwin(nlines, ncols, begin_y, begin_x)

Return a sub-window, whose upper-left corner is at (begin_y, begin_x), and whose width/height is ncols/nlines.

By default, the sub-window will extend from the specified position to the lower right corner of the window.

window.syncdown()

Touch each location in the window that has been touched in any of its ancestor windows. This routine is called by refresh(), so it should almost never be necessary to call it manually.

window.syncok(flag)

If called with flag set to True, then syncup() is called automatically whenever there is a change in the window.
window. **syncup()**

Touch all locations in ancestors of the window that have been changed in the window.

window. **timeout**(delay)

Set blocking or non-blocking read behavior for the window. If *delay* is negative, blocking read is used (which will wait indefinitely for input). If *delay* is zero, then non-blocking read is used, and -1 will be returned by `getch()` if no input is waiting. If *delay* is positive, then `getch()` will block for *delay* milliseconds, and return -1 if there is still no input at the end of that time.

window. **touchline**(start, count[, changed])

Pretend *count* lines have been changed, starting with line *start*. If *changed* is supplied, it specifies whether the affected lines are marked as having been changed (*changed*=1) or unchanged (*changed*=0).

window. **touchwin()**

Pretend the whole window has been changed, for purposes of drawing optimizations.

window. **untouchwin()**

Mark all lines in the window as unchanged since the last call to `refresh()`.

window. **vline**(ch, n)

window. **vline**(y, x, ch, n)

Display a vertical line starting at (y, x) with length *n* consisting of the character *ch*. 
16.11.3. Constants

The `curses` module defines the following data members:

**curses.**`ERR`

Some curses routines that return an integer, such as `getch()`, return `ERR` upon failure.

**curses.**`OK`

Some curses routines that return an integer, such as `napms()`, return `OK` upon success.

**curses.**`version`

A string representing the current version of the module. Also available as `__version__`.

Several constants are available to specify character cell attributes:

<table>
<thead>
<tr>
<th>Attribute</th>
<th>Meaning</th>
</tr>
</thead>
<tbody>
<tr>
<td><code>A_ALTCHARSET</code></td>
<td>Alternate character set mode.</td>
</tr>
<tr>
<td><code>A_BLINK</code></td>
<td>Blink mode.</td>
</tr>
<tr>
<td><code>A_BOLD</code></td>
<td>Bold mode.</td>
</tr>
<tr>
<td><code>A_DIM</code></td>
<td>Dim mode.</td>
</tr>
<tr>

</tbody>
</table>

On VT100s and their software emulations, such as X terminal emulators, there are normally at least four function keys (KEY_F1,
KEY_F2, KEY_F3, KEY_F4) available, and the arrow keys mapped to
KEY_UP, KEY_DOWN, KEY_LEFT and KEY_RIGHT in the obvious way.
If your machine has a PC keyboard, it is safe to expect arrow keys and
twelve function keys (older PC keyboards may have only ten function
keys); also, the following keypad mappings are standard:

<table>
<thead>
<tr>
<th>Keycap</th>
<th>Constant</th>
</tr>
</thead>
<tbody>
<tr>
<td>Insert</td>
<td>KEY_IC</td>
</tr>
<tr>
<td>Delete</td>
<td>KEY_DC</td>
</tr>
<tr>
<td>Home</td>
<td>KEY_HOME</td>
</tr>
<tr>
<td>End</td>
<td>KEY_END</td>
</tr>
<tr>
<td>Page Up</td>
<td>KEY_NPAGE</td>
</tr>
<tr>
<td>Page Down</td>
<td>KEY_PPAGE</td>
</tr>
</tbody>
</table>

The following table lists characters from the alternate character set.
These are inherited from the VT100 terminal, and will generally be
available on software emulations such as X terminals. When there is
no graphic available, curses falls back on a crude printable ASCII
approximation.

**Note:** These are available only after `initscr()` has been called.

</tbody>
</table>
16.12. **curses.textpad** — Text input widget for curses programs

The **curses.textpad** module provides a **Textbox** class that handles elementary text editing in a curses window, supporting a set of keybindings resembling those of Emacs (thus, also of Netscape Navigator, BBedit 6.x, FrameMaker, and many other programs). The module also provides a rectangle-drawing function useful for framing text boxes or for other purposes.

The module **curses.textpad** defines the following function:

```python
curses.textpad.rectangle(win, uly, ulx, lry, lrx)
```

Draw a rectangle. The first argument must be a window object; the remaining arguments are coordinates relative to that window. The second and third arguments are the y and x coordinates of the upper left hand corner of the rectangle to be drawn; the fourth and fifth arguments are the y and x coordinates of the lower right hand corner. The rectangle will be drawn using VT100/IBM PC forms characters on terminals that make this possible (including xterm and most other software terminal emulators). Otherwise it will be drawn with ASCII dashes, vertical bars, and plus signs.
16.12.1. Textbox objects

You can instantiate a `Textbox` object as follows:

```python
class curses.textpad.Textbox(win)
```

Return a textbox widget object. The `win` argument should be a `curses.WindowObject` in which the textbox is to be contained. The edit cursor of the textbox is initially located at the upper left hand corner of the containing window, with coordinates `(0, 0)`. The instance's `stripspaces` flag is initially on.

`Textbox` objects have the following methods:

`edit([validator])`

This is the entry point you will normally use. It accepts editing keystrokes until one of the termination keystrokes is entered. If `validator` is supplied, it must be a function. It will be called for each keystroke entered with the keystroke as a parameter; command dispatch is done on the result. This method returns the window contents as a string; whether blanks in the window are included is affected by the `stripspaces` attribute.

`do_command(ch)`

Process a single command keystroke. Here are the supported special keystrokes:

<table>
<thead>
<tr>
<th>Keystroke</th>
<th>Action</th>
</tr>
</thead>
<tbody>
<tr>
<td>Control-A</td>
<td>Go to left edge of window.</td>
</tr>
<tr>
<td>Control-B</td>
<td>Cursor left, wrapping to previous line if appropriate.</td>
</tr>
<tr>
<td>Keystroke</td>
<td>Description</td>
</tr>
<tr>
<td>--------------</td>
<td>-----------------------------------------------------------------------------</td>
</tr>
<tr>
<td>Control-D</td>
<td>Delete character under cursor.</td>
</tr>
<tr>
<td>Control-E</td>
<td>Go to right edge (stripspaces off) or end of line (stripspaces on).</td>
</tr>
<tr>
<td>Control-F</td>
<td>Cursor right, wrapping to next line when appropriate.</td>
</tr>
<tr>
<td>Control-G</td>
<td>Terminate, returning the window contents.</td>
</tr>
<tr>
<td>Control-H</td>
<td>Delete character backward.</td>
</tr>
<tr>
<td>Control-J</td>
<td>Terminate if the window is 1 line, otherwise insert newline.</td>
</tr>
<tr>
<td>Control-K</td>
<td>If line is blank, delete it, otherwise clear to end of line.</td>
</tr>
<tr>
<td>Control-L</td>
<td>Refresh screen.</td>
</tr>
<tr>
<td>Control-N</td>
<td>Cursor down; move down one line.</td>
</tr>
<tr>
<td>Control-O</td>
<td>Insert a blank line at cursor location.</td>
</tr>
<tr>
<td>Control-P</td>
<td>Cursor up; move up one line.</td>
</tr>
</tbody>
</table>

Move operations do nothing if the cursor is at an edge where the movement is not possible. The following synonyms are supported where possible:

<table>
<thead>
<tr>
<th>Constant</th>
<th>Keystroke</th>
</tr>
</thead>
<tbody>
<tr>
<td>KEY_LEFT</td>
<td>Control-B</td>
</tr>
<tr>
<td>KEY_RIGHT</td>
<td>Control-F</td>
</tr>
<tr>
<td>KEY_UP</td>
<td>Control-P</td>
</tr>
<tr>
<td>KEY_DOWN</td>
<td>Control-N</td>
</tr>
<tr>
<td>KEY_BACKSPACE</td>
<td>Control-h</td>
</tr>
</tbody>
</table>

All other keystrokes are treated as a command to insert the given character and move right (with line wrapping).
gather()

Return the window contents as a string; whether blanks in the window are included is affected by the `stripspaces` member.

stripspaces

This attribute is a flag which controls the interpretation of blanks in the window. When it is on, trailing blanks on each line are ignored; any cursor motion that would land the cursor on a trailing blank goes to the end of that line instead, and trailing blanks are stripped when the window contents are gathered.
16.13. **curses.ascii** — Utilities for ASCII characters

The *curses.ascii* module supplies name constants for ASCII characters and functions to test membership in various ASCII character classes. The constants supplied are names for control characters as follows:

<table>
<thead>
<tr>
<th>Name</th>
<th>Meaning</th>
</tr>
</thead>
<tbody>
<tr>
<td>NUL</td>
<td>Start of heading, console interrupt</td>
</tr>
<tr>
<td>S0H</td>
<td>Start of text</td>
</tr>
<tr>
<td>STX</td>
<td>End of text</td>
</tr>
<tr>
<td>ETX</td>
<td>End of transmission</td>
</tr>
<tr>
<td>EOT</td>
<td>End of transmission</td>
</tr>
<tr>
<td>ENQ</td>
<td>Enquiry, goes with ACK flow control</td>
</tr>
<tr>
<td>ACK</td>
<td>Acknowledgement</td>
</tr>
<tr>
<td>BEL</td>
<td>Bell</td>
</tr>
<tr>

<td>Backspace</td>
</tr>
<tr>
<td>TAB</td>
<td>Tab</td>
</tr>
<tr>
<td>HT</td>
<td>Alias for TAB: “Horizontal tab”</td>
</tr>
<tr>
<td>LF</td>
<td>Line feed</td>
</tr>
<tr>
<td>NL</td>
<td>Alias for LF: “New line”</td>
</tr>
<tr>
<td>VT</td>
<td>Vertical tab</td>
</tr>
<tr>
<td>FF</td>
<td>Form feed</td>
</tr>
<tr>
<td>CR</td>
<td>Carriage return</td>
</tr>
<tr>
<td>Code</td>
<td>Description</td>
</tr>
<tr>
<td>------</td>
<td>-------------</td>
</tr>
<tr>
<td>S0</td>
<td>Shift-out, begin alternate character set</td>
</tr>
<tr>
<td>SI</td>
<td>Shift-in, resume default character set</td>
</tr>
<tr>
<td>DLE</td>
<td>Data-link escape</td>
</tr>
<tr>
<td>DC1</td>
<td>XON, for flow control</td>
</tr>
<tr>
<td>DC2</td>
<td>Device control 2, block-mode flow control</td>
</tr>
<tr>
<td>DC3</td>
<td>XOFF, for flow control</td>
</tr>
<tr>
<td>DC4</td>
<td>Device control 4</td>
</tr>
<tr>
<td>NAK</td>
<td>Negative acknowledgement</td>
</tr>
<tr>
<td>SYN</td>
<td>Synchronous idle</td>
</tr>
<tr>
<td>ETB</td>
<td>End transmission block</td>
</tr>
<tr>
<td>CAN</td>
<td>Cancel</td>
</tr>
<tr>
<td>EM</td>
<td>End of medium</td>
</tr>
<tr>
<td>SUB</td>
<td>Substitute</td>
</tr>
<tr>
<td>ESC</td>
<td>Escape</td>
</tr>
<tr>
<td>FS</td>
<td>File separator</td>
</tr>
<tr>
<td>GS</td>
<td>Group separator</td>
</tr>
<tr>
<td>RS</td>
<td>Record separator, block-mode terminator</td>
</tr>
<tr>
<td>US</td>
<td>Unit separator</td>
</tr>
<tr>
<td>SP</td>
<td>Space</td>
</tr>
<tr>
<td>DEL</td>
<td>Delete</td>
</tr>
</tbody>
</table>

Note that many of these have little practical significance in modern usage. The mnemonics derive from teleprinter conventions that predate digital computers.

The module supplies the following functions, patterned on those in the
standard C library:

curses.ascii.**isalnum**(c)
Checks for an ASCII alphanumeric character; it is equivalent to `isalpha(c)` or `isdigit(c)`.

curses.ascii.**isalpha**(c)
Checks for an ASCII alphabetic character; it is equivalent to `isupper(c)` or `islower(c)`.

curses.ascii.**isascii**(c)
Checks for a character value that fits in the 7-bit ASCII set.

curses.ascii.**isblank**(c)
Checks for an ASCII whitespace character.

curses.ascii.**iscntrl**(c)
Checks for an ASCII control character (in the range 0x00 to 0x1f).

curses.ascii.**isdigit**(c)
Checks for an ASCII decimal digit, '0' through '9'. This is equivalent to `c in string.digits`.

curses.ascii.**isgraph**(c)
Checks for ASCII any printable character except space.

curses.ascii.**islower**(c)
Checks for an ASCII lower-case character.

curses.ascii.**isprint**(c)
Checks for any ASCII printable character including space.

curses.ascii.**ispunct**(c)
Checks for any printable ASCII character which is not a space or an alphanumeric character.

`curses.ascii.isspace(c)`
Checks for ASCII white-space characters; space, line feed, carriage return, form feed, horizontal tab, vertical tab.

`curses.ascii.isupper(c)`
Checks for an ASCII uppercase letter.

`curses.ascii.isxdigit(c)`
Checks for an ASCII hexadecimal digit. This is equivalent to `c in string.hexdigits`.

`curses.ascii.isctrl(c)`
Checks for an ASCII control character (ordinal values 0 to 31).

`curses.ascii.ismeta(c)`
Checks for a non-ASCII character (ordinal values 0x80 and above).

These functions accept either integers or strings; when the argument is a string, it is first converted using the built-in function `ord()`.

Note that all these functions check ordinal bit values derived from the first character of the string you pass in; they do not actually know anything about the host machine's character encoding. For functions that know about the character encoding (and handle internationalization properly) see the `string` module.

The following two functions take either a single-character string or integer byte value; they return a value of the same type.

`curses.ascii.ascii(c)`
Return the ASCII value corresponding to the low 7 bits of \( c \).

```
curses.ascii.ctrl(c)
```

Return the control character corresponding to the given character (the character bit value is bitwise-anded with 0x1f).

```
curses.ascii.alt(c)
```

Return the 8-bit character corresponding to the given ASCII character (the character bit value is bitwise-ored with 0x80).

The following function takes either a single-character string or integer value; it returns a string.

```
curses.ascii.unctrl(c)
```

Return a string representation of the ASCII character \( c \). If \( c \) is printable, this string is the character itself. If the character is a control character (0x00-0x1f) the string consists of a caret ('\^') followed by the corresponding uppercase letter. If the character is an ASCII delete (0x7f) the string is '\^?'. If the character has its meta bit (0x80) set, the meta bit is stripped, the preceding rules applied, and '!\!' prepended to the result.

```
curses.ascii.controlnames
```

A 33-element string array that contains the ASCII mnemonics for the thirty-two ASCII control characters from 0 (NUL) to 0x1f (US), in order, plus the mnemonic SP for the space character.

Panels are windows with the added feature of depth, so they can be stacked on top of each other, and only the visible portions of each window will be displayed. Panels can be added, moved up or down in the stack, and removed.
16.14.1. Functions

The module `curses.panel` defines the following functions:

`curses.panel.bottom_panel()`
- Returns the bottom panel in the panel stack.

`curses.panel.new_panel(win)`
- Returns a panel object, associating it with the given window `win`. Be aware that you need to keep the returned panel object referenced explicitly. If you don’t, the panel object is garbage collected and removed from the panel stack.

`curses.panel.top_panel()`
- Returns the top panel in the panel stack.

`curses.panel.update_panels()`
- Updates the virtual screen after changes in the panel stack. This does not call `curses.doupdate()`, so you’ll have to do this yourself.
16.14.2. Panel Objects

Panel objects, as returned by `new_panel()` above, are windows with a stacking order. There’s always a window associated with a panel which determines the content, while the panel methods are responsible for the window’s depth in the panel stack.

Panel objects have the following methods:

Panel. **above()**
- Returns the panel above the current panel.

Panel. **below()**
- Returns the panel below the current panel.

Panel. **bottom()**
- Push the panel to the bottom of the stack.

Panel. **hidden()**
- Returns true if the panel is hidden (not visible), false otherwise.

Panel. **hide()**
- Hide the panel. This does not delete the object, it just makes the window on screen invisible.

Panel. **move(y, x)**
- Move the panel to the screen coordinates \((y, x)\).

Panel. **replace(win)**
- Change the window associated with the panel to the window `win`.

Panel. **set_userptr(obj)**
Set the panel's user pointer to `obj`. This is used to associate an arbitrary piece of data with the panel, and can be any Python object.

```python
Panel.show()
```
Display the panel (which might have been hidden).

```python
Panel.top()
```
Push panel to the top of the stack.

```python
Panel.userptr()
```
Returns the user pointer for the panel. This might be any Python object.

```python
Panel.window()
```
Returns the window object associated with the panel.
16.15. **platform** — Access to underlying platform’s identifying data

**Source code:** Lib/platform.py

**Note:** Specific platforms listed alphabetically, with Linux included in the Unix section.
16.15.1. Cross Platform

platform.\texttt{architecture}(\texttt{executable=\texttt{sys.executable}}, \texttt{bits=``}, \texttt{linkage=``})

Queries the given executable (defaults to the Python interpreter binary) for various architecture information.

Returns a tuple \texttt{(bits, linkage)} which contain information about the bit architecture and the linkage format used for the executable. Both values are returned as strings.

Values that cannot be determined are returned as given by the parameter presets. If \texttt{bits} is given as '', the \texttt{sizeof(pointer)} (or \texttt{sizeof(long)} on Python version < 1.5.2) is used as indicator for the supported pointer size.

The function relies on the system's \texttt{file} command to do the actual work. This is available on most if not all Unix platforms and some non-Unix platforms and then only if the executable points to the Python interpreter. Reasonable defaults are used when the above needs are not met.

\textbf{Note:} On Mac OS X (and perhaps other platforms), executable files may be universal files containing multiple architectures. To get at the “64-bitness” of the current interpreter, it is more reliable to query the \texttt{sys.maxsize} attribute:

\texttt{is\_64bits = sys.maxsize > 2**32}

platform.\texttt{machine}()

Returns the machine type, e.g. \texttt{'i386'}. An empty string is
returned if the value cannot be determined.

platform.node()
Returns the computer’s network name (may not be fully qualified!). An empty string is returned if the value cannot be determined.

platform.platform(aliased=0, terse=0)
Returns a single string identifying the underlying platform with as much useful information as possible.

The output is intended to be *human readable* rather than machine parseable. It may look different on different platforms and this is intended.

If `aliased` is true, the function will use aliases for various platforms that report system names which differ from their common names, for example SunOS will be reported as Solaris. The `system_alias()` function is used to implement this.

Setting `terse` to true causes the function to return only the absolute minimum information needed to identify the platform.

platform.processor()
Returns the (real) processor name, e.g. 'amdk6'.

An empty string is returned if the value cannot be determined. Note that many platforms do not provide this information or simply return the same value as for `machine()`. NetBSD does this.

platform.python_build()
Returns a tuple `(buildno, builddate)` stating the Python build number and date as strings.
platform.python_compiler()
    Returns a string identifying the compiler used for compiling Python.

platform.python_branch()
    Returns a string identifying the Python implementation SCM branch.

platform.python_implementation()

platform.python_revision()
    Returns a string identifying the Python implementation SCM revision.

platform.python_version()
    Returns the Python version as string 'major.minor.patchlevel'
    
    Note that unlike the Python sys.version, the returned value will always include the patchlevel (it defaults to 0).

platform.python_version_tuple()
    Returns the Python version as tuple (major, minor, patchlevel) of strings.
    
    Note that unlike the Python sys.version, the returned value will always include the patchlevel (it defaults to '0').

platform.release()
    Returns the system’s release, e.g. '2.2.0' or 'NT' An empty string is returned if the value cannot be determined.
platform.system()
Returns the system/OS name, e.g. 'Linux', 'Windows', or 'Java'. An empty string is returned if the value cannot be determined.

platform.system_alias(system, release, version)
Returns (system, release, version) aliased to common marketing names used for some systems. It also does some reordering of the information in some cases where it would otherwise cause confusion.

platform.version()
Returns the system's release version, e.g. '#3 on degas'. An empty string is returned if the value cannot be determined.

platform.uname()
Fairly portable uname interface. Returns a namedtuple() containing six attributes: system, node, release, version, machine, and processor.

Note that this adds a sixth attribute (processor) not present in the os.uname() result. Also, the attribute names are different for the first two attributes; os.uname() names them sysname and nodename.

Entries which cannot be determined are set to ''.

Changed in version 3.3: Result changed from a tuple to a namedtuple.
16.15.2. Java Platform

platform.\texttt{java\_ver}(release='', vendor='', vminfo=('', '', ''), osinfo=('','', '))

Version interface for Jython.

Returns a tuple \((release, vendor, vminfo, osinfo)\) with \(vminfo\) being a tuple \((vm\_name, vm\_release, vm\_vendor)\) and \(osinfo\) being a tuple \((os\_name, os\_version, os\_arch)\). Values which cannot be determined are set to the defaults given as parameters (which all default to '').
16.15.3. Windows Platform

platform.**win32_ver**(release='', version='', csd='', ptype='')

Get additional version information from the Windows Registry and return a tuple \((\text{release}, \text{version}, \text{csd}, \text{ptype})\) referring to OS release, version number, CSD level (service pack) and OS type (multi/single processor).

As a hint: \textit{ptype} is 'Uniprocessor Free' on single processor NT machines and 'Multiprocessor Free' on multi processor machines. The 'Free' refers to the OS version being free of debugging code. It could also state 'Checked' which means the OS version uses debugging code, i.e. code that checks arguments, ranges, etc.

**Note:** This function works best with Mark Hammond's win32all package installed, but also on Python 2.3 and later (support for this was added in Python 2.6). It obviously only runs on Win32 compatible platforms.

16.15.3.1. Win95/98 specific

platform.**popen**(cmd, mode='r', bufsize=-1)

Portable \textit{popen()} interface. Find a working popen implementation preferring win32pipe.popen(). On Windows NT, win32pipe.popen() should work; on Windows 9x it hangs due to bugs in the MS C library.

*Deprecated since version 3.3:* This function is obsolete. Use the \texttt{subprocess} module. Check especially the \textit{Replacing Older}
Functions with the subprocess Module section.
16.15.4. Mac OS Platform

platform.\texttt{mac\_ver}(release='', versioninfo=('','',''), machine='')

Get Mac OS version information and return it as tuple (release, versioninfo, machine) with versioninfo being a tuple (version, dev\_stage, non\_release\_version).

Entries which cannot be determined are set to ''. All tuple entries are strings.
16.15.5. Unix Platforms

platform.dist(distname='', version='', id='', supported_dists=('SuSE', 'debian', 'redhat', 'mandrake', ...))

This is another name for linux_distribution().

platform.linux_distribution(distname='', version='', id='', supported_dists=('SuSE', 'debian', 'redhat', 'mandrake', ...), full_distribution_name=1)

Tries to determine the name of the Linux OS distribution name.

supported_dists may be given to define the set of Linux distributions to look for. It defaults to a list of currently supported Linux distributions identified by their release file name.

If full_distribution_name is true (default), the full distribution read from the OS is returned. Otherwise the short name taken from supported_dists is used.

Returns a tuple (distname, version, id) which defaults to the args given as parameters. id is the item in parentheses after the version number. It is usually the version codename.

platform.libc_ver(executable=sys.executable, lib='', version='', chunksize=2048)

Tries to determine the libc version against which the file executable (defaults to the Python interpreter) is linked. Returns a tuple of strings (lib, version) which default to the given parameters in case the lookup fails.

Note that this function has intimate knowledge of how different libc versions add symbols to the executable is probably only usable for
executables compiled using gcc.

The file is read and scanned in chunks of chunksize bytes.
16.16. **errno** — Standard errno system symbols

This module makes available standard **errno** system symbols. The value of each symbol is the corresponding integer value. The names and descriptions are borrowed from `linux/include/errno.h`, which should be pretty all-inclusive.

**errno.errorcode**

Dictionary providing a mapping from the errno value to the string name in the underlying system. For instance, `errno.errorcode[errno.EPERM]` maps to 'EPERM'.

To translate a numeric error code to an error message, use `os.strerror()`.

Of the following list, symbols that are not used on the current platform are not defined by the module. The specific list of defined symbols is available as `errno.errorcode.keys()`. Symbols available can include:

**errno.EPERM**

Operation not permitted

**errno.ENOENT**

No such file or directory

**errno.ESRCH**

No such process

**errno.EINTR**
Interrupted system call

errno. **EIO**  
I/O error

errno. **ENXIO**  
No such device or address

errno. **E2BIG**  
Arg list too long

errno. **ENOEXEC**  
Exec format error

errno. **EBADF**  
Bad file number

errno. **ECHILD**  
No child processes

errno. **EAGAIN**  
Try again

errno. **ENOMEM**  
Out of memory

errno. **EACCES**  
Permission denied

errno. **EFAULT**  
Bad address

errno. **ENOTBLK**  
Block device required
errno. **EBUSY**
Device or resource busy

errno. **EEXIST**
File exists

errno. **EXDEV**
Cross-device link

errno. **ENODEV**
No such device

errno. **ENOTDIR**
Not a directory

errno. **EISDIR**
Is a directory

errno. **EINVAL**
Invalid argument

errno. **ENFILE**
File table overflow

errno. **EMFILE**
Too many open files

errno. **ENOTTY**
Not a typewriter

errno. **ETXTBSY**
Text file busy

errno. **EFBIG**
File too large

errno. **ENOSPC**
No space left on device

errno. **ESPIPE**
Illegal seek

errno. **EROF S**
Read-only file system

errno. **EMLINK**
Too many links

errno. **EPIPE**
Broken pipe

errno. **EDOM**
Math argument out of domain of func

errno. **ERANGE**
Math result not representable

errno. **EDEADLK**
Resource deadlock would occur

errno. **ENAMETOOLONG**
File name too long

errno. **ENOLCK**
No record locks available

errno. **ENOSYS**
Function not implemented
errno. **ENOTEMPTY**
   Directory not empty

errno. **ELOOP**
   Too many symbolic links encountered

errno. **EWOULDBLOCK**
   Operation would block

errno. **ENOMSG**
   No message of desired type

errno. **EIDRM**
   Identifier removed

errno. **ECHRNG**
   Channel number out of range

errno. **EL2NSYNC**
   Level 2 not synchronized

errno. **EL3HLT**
   Level 3 halted

errno. **EL3RST**
   Level 3 reset

errno. **ELNRNG**
   Link number out of range

errno. **EUNATCH**
   Protocol driver not attached

errno. **ENOCSI**
No CSI structure available

`errno.EL2HLT`
Level 2 halted

`errno.EBADE`
Invalid exchange

`errno.EBADR`
Invalid request descriptor

`errno.EXFULL`
Exchange full

`errno.ENOANO`
No anode

`errno.EBADRQC`
Invalid request code

`errno.EBADSLT`
Invalid slot

`errno.EDEADLOCK`
File locking deadlock error

`errno.EBFONT`
Bad font file format

`errno.ENOSTR`
Device not a stream

`errno.ENODATA`
No data available
errno. **ETIME**  
    Timer expired

errno. **ENOSR**  
    Out of streams resources

errno. **ENONET**  
    Machine is not on the network

errno. **ENOPKG**  
    Package not installed

errno. **EREMOTE**  
    Object is remote

errno. **ENOLINK**  
    Link has been severed

errno. **EADV**  
    Advertise error

errno. **ESRMNT**  
    Srmount error

errno. **ECOMM**  
    Communication error on send

errno. **EPROTO**  
    Protocol error

errno. **EMULTIHOP**  
    Multihop attempted

errno. **EDOTDOT**
RFS specific error

**errno. EBADMSG**
Not a data message

**errno. EOVERFLOW**
Value too large for defined data type

**errno. ENOTUNIQ**
Name not unique on network

**errno. EBADFD**
File descriptor in bad state

**errno. EREMCHG**
Remote address changed

**errno. ELIBACC**
Can not access a needed shared library

**errno. ELIBBAD**
Accessing a corrupted shared library

**errno. ELIBSCN**
.lib section in a.out corrupted

**errno. ELIBMAX**
Attempting to link in too many shared libraries

**errno. ELIBEXEC**
Cannot exec a shared library directly

**errno. EILSEQ**
Illegal byte sequence
errno. **ERESTART**
   Interrupted system call should be restarted

erro. **ESTRPIPE**
   Streams pipe error

errno. **EUSERS**
   Too many users

errno. **ENOTSOCK**
   Socket operation on non-socket

errno. **EDESTADDRREQ**
   Destination address required

errno. **EMSGSIZE**
   Message too long

errno. **EPROTOTYPE**
   Protocol wrong type for socket

errno. **ENOPROTOOPT**
   Protocol not available

errno. **EPROTONOSUPPORT**
   Protocol not supported

errno. **ESOCKTNOSUPPORT**
   Socket type not supported

errno. **EOPNOTSUPP**
   Operation not supported on transport endpoint

errno. **EPFNOSUPPORT**
Protocol family not supported

**errno. EAFNOSUPPORT**
Address family not supported by protocol

**errno. EADDRINUSE**
Address already in use

**errno. EADDRNOTAVAIL**
Cannot assign requested address

**errno. ENETDOWN**
Network is down

**errno. ENETUNREACH**
Network is unreachable

**errno. ENETRESET**
Network dropped connection because of reset

**errno. ECONNABORTED**
Software caused connection abort

**errno. ECONNRESET**
Connection reset by peer

**errno. ENOBUFFS**
No buffer space available

**errno. EISCONN**
Transport endpoint is already connected

**errno. ENOTCONN**
Transport endpoint is not connected
errno. **ESHUTDOWN**
  Cannot send after transport endpoint shutdown

errno. **ETOOMANYREFS**
  Too many references: cannot splice

errno. **ETIMEDOUT**
  Connection timed out

errno. **ECONNREFUSED**
  Connection refused

errno. **EHOSTDOWN**
  Host is down

errno. **EHOSTUNREACH**
  No route to host

errno. **EALREADY**
  Operation already in progress

errno. **EINPROGRESS**
  Operation now in progress

errno. **ESTALE**
  Stale NFS file handle

errno. **EUCLEAN**
  Structure needs cleaning

errno. **ENOTNAM**
  Not a XENIX named type file

errno. **ENAVAIL**
No XENIX semaphores available

errno. **EISNAM**
Is a named type file

errno. **EREMOTEIO**
Remote I/O error

errno. **EDQUOT**
Quota exceeded
16.17. **ctypes — A foreign function library for Python**

dtypes is a foreign function library for Python. It provides C compatible data types, and allows calling functions in DLLs or shared libraries. It can be used to wrap these libraries in pure Python.
16.17.1. ctypes tutorial

Note: The code samples in this tutorial use doctest to make sure that they actually work. Since some code samples behave differently under Linux, Windows, or Mac OS X, they contain doctest directives in comments.

Note: Some code samples reference the ctypes c_int type. This type is an alias for the c_long type on 32-bit systems. So, you should not be confused if c_long is printed if you would expect c_int — they are actually the same type.

16.17.1.1. Loading dynamic link libraries

cypes exports the cdll, and on Windows windll and oledll objects, for loading dynamic link libraries.

You load libraries by accessing them as attributes of these objects. cdll loads libraries which export functions using the standard cdecl calling convention, while windll libraries call functions using the stdcall calling convention. oledll also uses the stdcall calling convention, and assumes the functions return a Windows HRESULT error code. The error code is used to automatically raise a OSError exception when the function call fails.

*Changed in version 3.3:* Windows errors used to raise WindowsError, which is now an alias of OSError.

Here are some examples for Windows. Note that msvcr is the MS standard C library containing most standard C functions, and uses the cdecl calling convention:
Windows appends the usual `.dll` file suffix automatically.

On Linux, it is required to specify the filename including the extension to load a library, so attribute access can not be used to load libraries. Either the `LoadLibrary()` method of the dll loaders should be used, or you should load the library by creating an instance of `CDLL` by calling the constructor:

```
>>> cdll.LoadLibrary("libc.so.6")
<CDLL 'libc.so.6', handle ... at ...>
>>> libc = CDLL("libc.so.6")
>>> libc
<CDLL 'libc.so.6', handle ... at ...>
```
File "<stdin>", line 1, in ?
File "ctypes.py", line 239, in __getattr__
    func = _StdcallFuncPtr(name, self)
AttributeError: function 'MyOwnFunction' not found

Note that win32 system dlls like kernel32 and user32 often export ANSI as well as UNICODE versions of a function. The UNICODE version is exported with an W appended to the name, while the ANSI version is exported with an A appended to the name. The win32 GetModuleHandle function, which returns a module handle for a given module name, has the following C prototype, and a macro is used to expose one of them as GetModuleHandle depending on whether UNICODE is defined or not:

```c
/* ANSI version */
HMODULE GetModuleHandleA(LPCSTR lpModuleName);
/* UNICODE version */
HMODULE GetModuleHandleW(LPCWSTR lpModuleName);
```

`windll` does not try to select one of them by magic, you must access the version you need by specifying GetModuleHandleA or GetModuleHandleW explicitly, and then call it with bytes or string objects respectively.

Sometimes, dlls export functions with names which aren't valid Python identifiers, like "??2@YAPAXI@Z". In this case you have to use `getattr()` to retrieve the function:

```python
>>> getattr(cdll.msvcr, "??2@YAPAXI@Z")
<_FuncPtr object at 0x...>  
```
On Windows, some dlls export functions not by name but by ordinal. These functions can be accessed by indexing the dll object with the ordinal number:

```python
>>> cdll.kernel32[1]
<_FuncPtr object at 0x...>
>>> cdll.kernel32[0]
Traceback (most recent call last):
  File "<stdin>", line 1, in 
  File "ctypes.py", line 310, in __getitem__
    func = __stdcallFuncPtr(name, self)
AttributeError: function ordinal 0 not found
>>> 
```

16.17.1.3. Calling functions

You can call these functions like any other Python callable. This example uses the `time()` function, which returns system time in seconds since the Unix epoch, and the `GetModuleHandleA()` function, which returns a win32 module handle.

This example calls both functions with a NULL pointer (None should be used as the NULL pointer):

```python
>>> print(libc.time(None))
1150640792
>>> print(hex(windll.kernel32.GetModuleHandleA(None))
0x1d000000
>>> 
```

`ctypes` tries to protect you from calling functions with the wrong number of arguments or the wrong calling convention. Unfortunately this only works on Windows. It does this by examining the stack after
the function returns, so although an error is raised the function has been called:

```python
>>> windll.kernel32.GetModuleHandleA()
Traceback (most recent call last):
  File "<stdin>", line 1, in ?
ValueError: Procedure probably called with not enough arguments (4 bytes missing)
```

The same exception is raised when you call an `stdcall` function with the `cdecl` calling convention, or vice versa:

```python
>>> cdll.kernel32.GetModuleHandleA(None)
Traceback (most recent call last):
  File "<stdin>", line 1, in ?
ValueError: Procedure probably called with not enough arguments
```

```python
>>> windll.msvcrtp.printf(b"spam")
Traceback (most recent call last):
  File "<stdin>", line 1, in ?
ValueError: Procedure probably called with too many arguments
```

To find out the correct calling convention you have to look into the C header file or the documentation for the function you want to call.

On Windows, `ctypes` uses win32 structured exception handling to prevent crashes from general protection faults when functions are called with invalid argument values:
There are, however, enough ways to crash Python with \texttt{ctypes}, so you should be careful anyway. The \texttt{faulthandler} module can be helpful in debugging crashes (e.g. from segmentation faults produced by erroneous C library calls).

None, integers, bytes objects and (unicode) strings are the only native Python objects that can directly be used as parameters in these function calls. \texttt{None} is passed as a C \texttt{NULL} pointer, bytes objects and strings are passed as pointer to the memory block that contains their data (\texttt{char *} or \texttt{wchar_t *}). Python integers are passed as the platforms default C \texttt{int} type, their value is masked to fit into the C type.

Before we move on calling functions with other parameter types, we have to learn more about \texttt{ctypes} data types.

\textbf{16.17.1.4. Fundamental data types}

\texttt{ctypes} defines a number of primitive C compatible data types:

\begin{center}
\begin{tabular}{|c|c|c|}
\hline
\textbf{ctypes type} & \textbf{C type} & \textbf{Python type} \\
\hline
\texttt{c\_bool} & \_Bool & \texttt{bool (1)} \\
\hline
\texttt{c\_char} & \texttt{char} & \texttt{1-character bytes object} \\
\hline
\texttt{c\_wchar} & \texttt{wchar\_t} & \texttt{1-character string} \\
\hline
\end{tabular}
\end{center}
<p>| | | |</p>
<table>
<thead>
<tr>
<th></th>
<th></th>
<th></th>
</tr>
</thead>
<tbody>
<tr>
<td>c_byte</td>
<td>char</td>
<td>int</td>
</tr>
<tr>
<td>c_ubyte</td>
<td>unsigned char</td>
<td>int</td>
</tr>
<tr>
<td>c_short</td>

<td>int</td>
</tr>
<tr>
<td>c_ssize_t</td>
<td>ssize_t or Py_ssize_t</td>
<td>int</td>
</tr>
<tr>
<td>c_float</td>
<td>float</td>
<td>float</td>
</tr>
<tr>
<td>c_double</td>
<td>double</td>
<td>float</td>
</tr>
<tr>
<td>c_longdouble</td>
<td>long double</td>
<td>float</td>
</tr>
<tr>
<td>c_char_p</td>
<td>char * (NUL terminated)</td>
<td>bytes object or None</td>
</tr>
<tr>
<td>c_wchar_p</td>
<td>wchar_t * (NUL terminated)</td>
<td>string or None</td>
</tr>
<tr>
<td>c_void_p</td>
<td>void *</td>
<td>int or None</td>
</tr>
</tbody>
</table>

1. The constructor accepts any object with a truth value.

All these types can be created by calling them with an optional initializer of the correct type and value:

```python
>>> c_int()
```
Since these types are mutable, their value can also be changed afterwards:

```
>>> i = c_int(42)
>>> print(i)
c_long(42)
>>> print(i.value)
42
>>> i.value = -99
>>> print(i.value)
-99
```  

Assigning a new value to instances of the pointer types `c_char_p`, `c_wchar_p`, and `c_void_p` changes the memory location they point to, *not the contents* of the memory block (of course not, because Python bytes objects are immutable):

```
>>> s = "Hello, World"
>>> c_s = c_wchar_p(s)
>>> print(c_s)
c_wchar_p('Hello, World')
>>> c_s.value = "Hi, there"
>>> print(c_s)
c_wchar_p('Hi, there')
>>> print(s)  # first object is unchanged
Hello, World
```
You should be careful, however, not to pass them to functions expecting pointers to mutable memory. If you need mutable memory blocks, ctypes has a `create_string_buffer()` function which creates these in various ways. The current memory block contents can be accessed (or changed) with the `raw` property; if you want to access it as NUL terminated string, use the `value` property:

```python
>>> from ctypes import *
>>> p = create_string_buffer(3)  # create
3 b'\x00\x00\x00'
>>> p = create_string_buffer(b"Hello")  # create
6 b'Hello\x00'
>>> print(repr(p.value))
b'Hello'
>>> p = create_string_buffer(b"Hello", 10)  # create
10 b'Hello\x00\x00\x00\x00\x00\x00\x00\x00\x00'
>>> p.value = b"Hi"
>>> print(repr(p.value))
10 b'Hi\x00lo\x00\x00\x00\x00\x00\x00\x00\x00'
```
sys.stdout, so these examples will only work at the console prompt, not from within IDLE or PythonWin:

```python
>>> printf = libc.printf
>>> printf(b"Hello, %s\n", b"World!")
Hello, World!
14
>>> printf(b"Hello, %S\n", "World!")
Hello, World!
14
>>> printf(b"%d bottles of beer\n", 42)
42 bottles of beer
19
>>> printf(b"%f bottles of beer\n", 42.5)
Traceback (most recent call last):
  File "<stdin>", line 1, in ?
ArgumentError: argument 2: exceptions.TypeError: Don
```

As has been mentioned before, all Python types except integers, strings, and bytes objects have to be wrapped in their corresponding ctypes type, so that they can be converted to the required C data type:

```python
>>> printf(b"An int %d, a double %f\n", 1234, c_double(3.140000))
An int 1234, a double 3.140000
31
```

16.17.1.6. Calling functions with your own custom data types

You can also customize ctypes argument conversion to allow
instances of your own classes be used as function arguments. ctypes looks for an _as_parameter_ attribute and uses this as the function argument. Of course, it must be one of integer, string, or bytes:

```python
>>> class Bottles:
...     def __init__(self, number):
...         self._as_parameter_ = number

>>> bottles = Bottles(42)
>>> printf(b"%d bottles of beer\n", bottles)
42 bottles of beer
```

If you don't want to store the instance's data in the _as_parameter_ instance variable, you could define a property which makes the attribute available on request.

16.17.1.7. Specifying the required argument types (function prototypes)

It is possible to specify the required argument types of functions exported from DLLs by setting the argtypes attribute.

argtypes must be a sequence of C data types (the printf function is probably not a good example here, because it takes a variable number and different types of parameters depending on the format string, on the other hand this is quite handy to experiment with this feature):

```python
>>> printf.argtypes = [c_char_p, c_char_p, c_int, c_
>>> printf(b"String '%s', Int %d, Double %f\n", b"Hi"
Specifying a format protects against incompatible argument types (just as a prototype for a C function), and tries to convert the arguments to valid types:

```python
>>> printf(b"%d %d %d", 1, 2, 3)
Traceback (most recent call last):
  File "<stdin>", line 1, in ?
ArgumentError: argument 2: exceptions.TypeError: wrong type
```

```python
>>> printf(b"%s %d %f\n", b"X", 2, 3)
X 2 3.000000
```

If you have defined your own classes which you pass to function calls, you have to implement a `from_param()` class method for them to be able to use them in the `argtypes` sequence. The `from_param()` class method receives the Python object passed to the function call, it should do a typecheck or whatever is needed to make sure this object is acceptable, and then return the object itself, its `_as_parameter_` attribute, or whatever you want to pass as the C function argument in this case. Again, the result should be an integer, string, bytes, a `ctypes` instance, or an object with an `_as_parameter_` attribute.

### 16.17.1.8. Return types

By default functions are assumed to return the C `int` type. Other return types can be specified by setting the `restype` attribute of the function object.
Here is a more advanced example, it uses the `strchr` function, which expects a string pointer and a char, and returns a pointer to a string:

```python
>>> strchr = libc.strchr
>>> strchr(b"abcdef", ord("d"))
8059983
```

```python
>>> strchr.retype = c_char_p  # c_char_p is a pointer to a string
>>> strchr(b"abcdef", ord("d"))
'b'def'
```

```python
>>> print(strchr(b"abcdef", ord("x")))
None
```

If you want to avoid the `ord("x")` calls above, you can set the `argtypes` attribute, and the second argument will be converted from a single character Python bytes object into a C char:

```python
>>> strchr.retype = c_char_p
>>> strchr.argtypes = [c_char_p, c_char]
>>> strchr(b"abcdef", b"d")
'def'
```

```python
>>> strchr(b"abcdef", b"def")
Traceback (most recent call last):
 File "<stdin>", line 1, in ?
 ArgumentError: argument 2: exceptions.TypeError: one
```

```python
>>> print(strchr(b"abcdef", b"x"))
None
```

```python
>>> strchr(b"abcdef", b"d")
'def'
```

You can also use a callable Python object (a function or a class for example) as the `retype` attribute, if the foreign function returns an integer. The callable will be called with the `integer` the C function
returns, and the result of this call will be used as the result of your function call. This is useful to check for error return values and automatically raise an exception:

```python
>>> GetModuleHandle = windll.kernel32.GetModuleHandle
>>> def ValidHandle(value):
...     if value == 0:
...         raise WinError()
...     return value
...
>>> GetModuleHandle().restype = ValidHandle
>>> GetModuleHandle(2)
486539264
>>> GetModuleHandle("something silly")
Traceback (most recent call last):
  File "<stdin>", line 1, in ?
  File "<stdin>", line 3, in ValidHandle
OSError: [Errno 126] The specified module could not

WinError is a function which will call Windows FormatMessage() api to get the string representation of an error code, and returns an exception. WinError takes an optional error code parameter, if no one is used, it calls GetLastError() to retrieve it.

Please note that a much more powerful error checking mechanism is available through the errcheck attribute; see the reference manual for details.

16.17.1.9. Passing pointers (or: passing parameters by reference)
Sometimes a C api function expects a pointer to a data type as parameter, probably to write into the corresponding location, or if the data is too large to be passed by value. This is also known as passing parameters by reference.

ctypes exports the byref() function which is used to pass parameters by reference. The same effect can be achieved with the pointer() function, although pointer() does a lot more work since it constructs a real pointer object, so it is faster to use byref() if you don’t need the pointer object in Python itself:

```python
>>> i = c_int()
>>> f = c_float()
>>> s = create_string_buffer(b'\000' * 32)
>>> print(i.value, f.value, repr(s.value))
0 0.0 b''
>>> libc sscanf(b'1 3.14 Hello', b'%d %f %s', ... byref(i), byref(f), s)
3
>>> print(i.value, f.value, repr(s.value))
1 3.1400001049 b'Hello'
>>>
```

### 16.17.1.10. Structures and unions

Structures and unions must derive from the Structure and Union base classes which are defined in the ctypes module. Each subclass must define a _fields_ attribute. _fields_ must be a list of 2-tuples, containing a field name and a field type.

The field type must be a ctypes type like c_int, or any other derived ctypes type: structure, union, array, pointer.
Here is a simple example of a POINT structure, which contains two integers named \(x\) and \(y\), and also shows how to initialize a structure in the constructor:

```python
>>> from ctypes import *
>>> class POINT(Structure):
...   _fields_ = [('x', c_int),
...               ('y', c_int)]
...
>>> point = POINT(10, 20)
>>> print(point.x, point.y)
10 20
>>> point = POINT(y=5)
>>> print(point.x, point.y)
0 5
>>> POINT(1, 2, 3)
Traceback (most recent call last):
  File "<stdin>", line 1, in ?
ValueError: too many initializers
```

You can, however, build much more complicated structures. A structure can itself contain other structures by using a structure as a field type.

Here is a RECT structure which contains two POINTs named `upperleft` and `lowerright`:

```python
>>> class RECT(Structure):
...   _fields_ = [('upperleft', POINT),
...               ('lowerright', POINT)]
...
>>> rc = RECT(point)
>>> print(rc.upperleft.x, rc.upperleft.y)
0 5
>>> print(rc.lowerright.x, rc.lowerright.y)
```
Nested structures can also be initialized in the constructor in several ways:

```python
>>> r = RECT(POINT(1, 2), POINT(3, 4))
>>> r = RECT((1, 2), (3, 4))
```

Field descriptors can be retrieved from the class, they are useful for debugging because they can provide useful information:

```python
>>> print(POINT.x)
<Field type=c_long, ofs=0, size=4>
>>> print(POINT.y)
<Field type=c_long, ofs=4, size=4>
```

**Warning:** *ctypes* does not support passing unions or structures with bit-fields to functions by value. While this may work on 32-bit x86, it's not guaranteed by the library to work in the general case. Unions and structures with bit-fields should always be passed to functions by pointer.

### 16.17.1.11. Structure/union alignment and byte order

By default, Structure and Union fields are aligned in the same way the C compiler does it. It is possible to override this behavior by specifying a `_pack_` class attribute in the subclass definition. This must be set to a positive integer and specifies the maximum alignment for the fields. This is what `#pragma pack(n)` also does in MSVC.
**ctypes** uses the native byte order for Structures and Unions. To build structures with non-native byte order, you can use one of the `BigEndianStructure`, `LittleEndianStructure`, `BigEndianUnion`, and `LittleEndianUnion` base classes. These classes cannot contain pointer fields.

### 16.17.1.12. Bit fields in structures and unions

It is possible to create structures and unions containing bit fields. Bit fields are only possible for integer fields, the bit width is specified as the third item in the `_fields_` tuples:

```python
>>> class Int(Structure):
...     _fields_ = ["first_16", c_int, 16],
...     ("second_16", c_int, 16)]
... >>> print(Int.first_16)
<Field type=c_long, ofs=0:0, bits=16>
>>> print(Int.second_16)
<Field type=c_long, ofs=0:16, bits=16>
```

### 16.17.1.13. Arrays

Arrays are sequences, containing a fixed number of instances of the same type.

The recommended way to create array types is by multiplying a data type with a positive integer:

```python
TenPointsArrayType = POINT * 10
```

Here is an example of an somewhat artificial data type, a structure
containing 4 POINTs among other stuff:

```python
>>> from ctypes import *
>>> class POINT(Structure):
...     _fields_ = ("x", c_int), ("y", c_int)
... >>>
>>> class MyStruct(Structure):
...     _fields_ = [("a", c_int),
...                 ("b", c_float),
...                 ("point_array", POINT * 4)]
>>> >>>
>>> print(len(MyStruct().point_array))
4
>>>```

Instances are created in the usual way, by calling the class:

```python
arr = TenPointsArrayType()
for pt in arr:
    print(pt.x, pt.y)
```

The above code print a series of 0 0 lines, because the array contents is initialized to zeros.

Initializers of the correct type can also be specified:

```python
>>> from ctypes import *
>>> TenIntegers = c_int * 10
>>> ii = TenIntegers(1, 2, 3, 4, 5, 6, 7, 8, 9, 10)
>>> print(ii)
<c_long_Array_10 object at 0x...>
>>> for i in ii: print(i, end=" ")
...
1 2 3 4 5 6 7 8 9 10
>>>```

Pointer instances are created by calling the `pointer()` function on a `ctypes` type:

```python
>>> from ctypes import *
>>> i = c_int(42)
>>> pi = pointer(i)

>>> pi
```

Pointer instances have a `contents` attribute which returns the object to which the pointer points, the `i` object above:

```python
>>> pi.contents
```

Note that `ctypes` does not have OOR (original object return), it constructs a new, equivalent object each time you retrieve an attribute:

```python
>>> pi.contents is i
False
>>> pi.contents is pi.contents
False
```

Assigning another `c_int` instance to the pointer’s contents attribute would cause the pointer to point to the memory location where this is stored:

```python
>>> i = c_int(99)
>>> pi.contents = i
>>> pi.contents
```

Pointer instances can also be indexed with integers:

```python
>>> pi[0]
99
>>> 
```

Assigning to an integer index changes the pointed to value:

```python
>>> print(i)
c_long(99)
>>> pi[0] = 22
>>> print(i)
c_long(22)
>>> 
```

It is also possible to use indexes different from 0, but you must know what you're doing, just as in C: You can access or change arbitrary memory locations. Generally you only use this feature if you receive a pointer from a C function, and you know that the pointer actually points to an array instead of a single item.

Behind the scenes, the `pointer()` function does more than simply create pointer instances, it has to create pointer types first. This is done with the `POINTER()` function, which accepts any `ctypes` type, and returns a new type:

```python
>>> PI = POINTER(c_int)
>>> PI
<class 'ctypes.LP_c_long'>
>>> PI(42)
Traceback (most recent call last):
  File "<stdin>", line 1, in ?
TypeError: expected c_long instead of int
```
Calling the pointer type without an argument creates a `NULL` pointer. `NULL` pointers have a `False` boolean value:

```python
>>> null_ptr = POINTER(c_int)()
>>> print(bool(null_ptr))
False
```

cytypen checks for `NULL` when dereferencing pointers (but dereferencing invalid non-`NULL` pointers would crash Python):

```python
>>> null_ptr[0]
Traceback (most recent call last):
  ....
ValueError: NULL pointer access

>>> null_ptr[0] = 1234
>>> null_ptr[0] = 1234
Traceback (most recent call last):
  ....
ValueError: NULL pointer access
```

16.17.1.15. Type conversions

Usually, ctypes does strict type checking. This means, if you have `POINTER(c_int)` in the `argtypes` list of a function or as the type of a member field in a structure definition, only instances of exactly the same type are accepted. There are some exceptions to this rule, where ctypes accepts other objects. For example, you can pass
compatible array instances instead of pointer types. So, for `POINTER(c_int)`, ctypes accepts an array of `c_int`:

```python
class Bar(Structure):
    _fields_ = ["count", c_int], ("values", POINTER(c_int))

bar = Bar()
bar.values = (c_int * 3)(1, 2, 3)
bar.count = 3
for i in range(bar.count):
    print(bar.values[i])
```

In addition, if a function argument is explicitly declared to be a pointer type (such as `POINTER(c_int)`) in `argtypes`, an object of the pointed type (`c_int` in this case) can be passed to the function. ctypes will apply the required `byref()` conversion in this case automatically.

To set a `POINTER` type field to `NULL`, you can assign `None`:

```python
bar.values = None
```

Sometimes you have instances of incompatible types. In C, you can cast one type into another type. ctypes provides a `cast()` function which can be used in the same way. The `Bar` structure defined above accepts `POINTER(c_int)` pointers or `c_int` arrays for its `values` field, but not instances of other types:
For these cases, the `cast()` function is handy.

The `cast()` function can be used to cast a ctypes instance into a pointer to a different ctypes data type. `cast()` takes two parameters, a ctypes object that is or can be converted to a pointer of some kind, and a ctypes pointer type. It returns an instance of the second argument, which references the same memory block as the first argument:

```python
>>> a = (c_byte * 4)()
>>> cast(a, POINTER(c_int))
<ctypes.LP_c_long object at ...>
```

So, `cast()` can be used to assign to the `values` field of `Bar` the structure:

```python
>>> bar = Bar()
>>> bar.values = cast((c_byte * 4)(), POINTER(c_int))
>>> print(bar.values[0])
0
```

16.17.1.16. Incomplete Types

*Incomplete Types* are structures, unions or arrays whose members are
not yet specified. In C, they are specified by forward declarations, which are defined later:

```c
struct cell; /* forward declaration */
struct cell {
    char *name;
    struct cell *next;
};
```

The straightforward translation into ctypes code would be this, but it does not work:

```python
>>> class cell(Structure):
...     _fields_ = ["name", c_char_p],
...                 ("next", POINTER(cell))]
... Traceback (most recent call last):
  File "<stdin>" line 1 in ?
  File "<stdin>" line 2 in cell
NameError: name 'cell' is not defined

>>> because the new class cell is not available in the class statement itself. In ctypes, we can define the cell class and set the _fields_ attribute later, after the class statement:

```python
>>> from ctypes import *
>>> class cell(Structure):
...     pass
... >>> cell._fields_ = ["name", c_char_p],
...                 ("next", POINTER(cell))]
```
Lets try it. We create two instances of `cell`, and let them point to each other, and finally follow the pointer chain a few times:

```python
>>> c1 = cell()
>>> c1.name = "foo"
>>> c2 = cell()
>>> c2.name = "bar"
>>> c1.next = pointer(c2)
>>> c2.next = pointer(c1)
>>> p = c1
>>> for i in range(8):
...     print(p.name, end=" ")
...     p = p.next[0]
...
foo bar foo bar foo bar foo bar
```

### 16.17.1.17. Callback functions

c`types` allows to create C callable function pointers from Python callables. These are sometimes called *callback functions*.

First, you must create a class for the callback function. The class knows the calling convention, the return type, and the number and types of arguments this function will receive.

The `CFUNCTYPE()` factory function creates types for callback functions using the `cdecl` calling convention. On Windows, the `WINFUNCTYPE()` factory function creates types for callback functions using the `stdcall` calling convention.

Both of these factory functions are called with the result type as first argument, and the callback functions expected argument types as the remaining arguments.
I will present an example here which uses the standard C library’s `qsort()` function, that is used to sort items with the help of a callback function. `qsort()` will be used to sort an array of integers:

```python
>>> IntArray5 = c_int * 5
>>> ia = IntArray5(5, 1, 7, 33, 99)
>>> qsort = libc.qsort
>>> qsort.restype = None
>>> qsort()
```

`qsort()` must be called with a pointer to the data to sort, the number of items in the data array, the size of one item, and a pointer to the comparison function, the callback. The callback will then be called with two pointers to items, and it must return a negative integer if the first item is smaller than the second, a zero if they are equal, and a positive integer otherwise.

So our callback function receives pointers to integers, and must return an integer. First we create the type for the callback function:

```python
>>> CMPFUNC = CFUNCTYPE(c_int, POINTER(c_int), POINTER(c_int))
>>> def py_cmp_func(a, b):
...     print("py_cmp_func", a[0], b[0])
...     return 0
...
>>> cmp_func = CMPFUNC(py_cmp_func)
```
The result:

```python
>>> qsort(ia, len(ia), sizeof(c_int), cmp_func)
py_cmp_func 5 1
py_cmp_func 33 99
py_cmp_func 7 33
py_cmp_func 5 7
py_cmp_func 1 7
>>> 
```

Now we can actually compare the two items and return a useful result:

```python
>>> def py_cmp_func(a, b):
...     print("py_cmp_func", a[0], b[0])
...     return a[0] - b[0]
...
>>> qsort(ia, len(ia), sizeof(c_int), CMPFUNC(py_cmp_func))
py_cmp_func 5 1
py_cmp_func 33 99
py_cmp_func 7 33
py_cmp_func 1 7
py_cmp_func 5 7
```  

As we can easily check, our array is sorted now:

```python
>>> for i in ia: print(i, end=" ")
...
1 5 7 33 99
```  

**Note:** Make sure you keep references to `CFUNCTYPE()` objects as long as they are used from C code. `ctypes` doesn’t, and if you
don't, they may be garbage collected, crashing your program when a callback is made.

Also, note that if the callback function is called in a thread created outside of Python's control (e.g. by the foreign code that calls the callback), ctypes creates a new dummy Python thread on every invocation. This behavior is correct for most purposes, but it means that values stored with `threading.local` will not survive across different callbacks, even when those calls are made from the same C thread.

16.17.1.18. Accessing values exported from dlls

Some shared libraries not only export functions, they also export variables. An example in the Python library itself is the Py_OptimizeFlag, an integer set to 0, 1, or 2, depending on the `-O` or `-OO` flag given on startup.

`ctypes` can access values like this with the `in_dll()` class methods of the type. `pythonapi` is a predefined symbol giving access to the Python C api:

```python
>>> opt_flag = c_int.in_dll(pythonapi, "Py_OptimizeFlag")
>>> print(opt_flag)
c_long(0)
```

If the interpreter would have been started with `-O`, the sample would have printed `c_long(1)`, or `c_long(2)` if `-OO` would have been specified.

An extended example which also demonstrates the use of pointers
accesses the `PyImport_FrozenModules` pointer exported by Python.

Quoting the docs for that value:

```
This pointer is initialized to point to an array of struct _frozen records, terminated by one whose members are all NULL or zero. When a frozen module is imported, it is searched in this table. Third-party code could play tricks with this to provide a dynamically created collection of frozen modules.
```

So manipulating this pointer could even prove useful. To restrict the example size, we show only how this table can be read with `ctypes`:

```python
>>> from ctypes import *
>>> class struct_frozen(Structure):
...     _fields_ = ["name", c_char_p],
...     ("code", POINTER(c_ubyte)),
...     ("size", c_int)]
```

We have defined the `struct _frozen` data type, so we can get the pointer to the table:

```python
>>> FrozenTable = POINTER(struct_frozen)
>>> table = FrozenTable.in_dll(pythonapi, "PyImport_"
```

Since `table` is a pointer to the array of `struct_frozen` records, we can iterate over it, but we just have to make sure that our loop terminates, because pointers have no size. Sooner or later it would probably crash with an access violation or whatever, so it's better to
break out of the loop when we hit the NULL entry:

```python
>>> for item in table:
...    print(item.name, item.size)
...    if item.name is None:
...        break
...__hello__ 104
__phello__ -104
__phello__.spam 104
None 0
```

The fact that standard Python has a frozen module and a frozen package (indicated by the negative size member) is not well known, it is only used for testing. Try it out with `import __hello__` for example.

**16.17.1.19. Surprises**

There are some edges in `ctypes` where you might expect something other than what actually happens.

Consider the following example:

```python
>>> from ctypes import *
>>> class POINT(Structure):
...    _fields_ = ("x", c_int), ("y", c_int)
...>>> class RECT(Structure):
...    _fields_ = ("a", POINT), ("b", POINT)
...>>> p1 = POINT(1, 2)
>>> p2 = POINT(3, 4)
>>> rc = RECT(p1, p2)
```
Hm. We certainly expected the last statement to print 3 4 1 2. What happened? Here are the steps of the \texttt{rc.a, rc.b = rc.b, rc.a} line above:

```
>>> temp0, temp1 = rc.b, rc.a
>>> rc.a = temp0
>>> rc.b = temp1
```  

Note that \texttt{temp0} and \texttt{temp1} are objects still using the internal buffer of the \texttt{rc} object above. So executing \texttt{rc.a = temp0} copies the buffer contents of \texttt{temp0} into \texttt{rc}'s buffer. This, in turn, changes the contents of \texttt{temp1}. So, the last assignment \texttt{rc.b = temp1}, doesn't have the expected effect.

Keep in mind that retrieving sub-objects from Structure, Unions, and Arrays doesn't \textit{copy} the sub-object, instead it retrieves a wrapper object accessing the root-object's underlying buffer.

Another example that may behave different from what one would expect is this:

```
>>> s = c_char_p()
>>> s.value = "abc def ghi"
>>> s.value
'abc def ghi'
```
Why is it printing `False`? ctypes instances are objects containing a memory block plus some `descriptor` accessing the contents of the memory. Storing a Python object in the memory block does not store the object itself, instead the contents of the object is stored. Accessing the contents again constructs a new Python object each time!

16.17.1.20. Variable-sized data types

c`types` provides some support for variable-sized arrays and structures.

The `resize()` function can be used to resize the memory buffer of an existing ctypes object. The function takes the object as first argument, and the requested size in bytes as the second argument. The memory block cannot be made smaller than the natural memory block specified by the objects type, a `ValueError` is raised if this is tried:

```python
>>> short_array = (c_short * 4)()
>>> print(sizeof(short_array))
8
>>> resize(short_array, 4)
Traceback (most recent call last):
  ... ValueError: minimum size is 8
>>> resize(short_array, 32)
>>> sizeof(short_array)
32
>>> sizeof(type(short_array))
```
This is nice and fine, but how would one access the additional elements contained in this array? Since the type still only knows about 4 elements, we get errors accessing other elements:

```python
>>> short_array[:]
[0, 0, 0, 0]
>>> short_array[7]
Traceback (most recent call last):
  ...  
IndexError: invalid index
```

Another way to use variable-sized data types with `ctypes` is to use the dynamic nature of Python, and (re-)define the data type after the required size is already known, on a case by case basis.
16.17.2. ctypes reference

16.17.2.1. Finding shared libraries

When programming in a compiled language, shared libraries are accessed when compiling/linking a program, and when the program is run.

The purpose of the `find_library()` function is to locate a library in a way similar to what the compiler does (on platforms with several versions of a shared library the most recent should be loaded), while the ctypes library loaders act like when a program is run, and call the runtime loader directly.

The `ctypes.util` module provides a function which can help to determine the library to load.

`ctypes.util.find_library(name)`

Try to find a library and return a pathname. `name` is the library name without any prefix like `lib`, suffix like `.so, .dylib` or version number (this is the form used for the posix linker option `-l`). If no library can be found, returns `None`.

The exact functionality is system dependent.

On Linux, `find_library()` tries to run external programs (`/sbin/ldconfig, gcc, and objdump`) to find the library file. It returns the filename of the library file. Here are some examples:

```python
>>> from ctypes.util import find_library
>>> find_library("m")
'libm.so.6'
>>> find_library("c")
```
On OS X, find_library() tries several predefined naming schemes and paths to locate the library, and returns a full pathname if successful:

```python
>>> from ctypes.util import find_library
>>> find_library("c")
'/usr/lib/libc.dylib'
>>> find_library("m")
'/usr/lib/libm.dylib'
>>> find_library("bz2")
'/usr/lib/libbz2.dylib'
>>> find_library("AGL")
'/System/Library/Frameworks/AGL.framework/AGL'
```

On Windows, find_library() searches along the system search path, and returns the full pathname, but since there is no predefined naming scheme a call like `find_library("c")` will fail and return `None`.

If wrapping a shared library with `ctypes`, it may be better to determine the shared library name at development time, and hardcode that into the wrapper module instead of using `find_library()` to locate the library at runtime.

**16.17.2.2. Loading shared libraries**

There are several ways to loaded shared libraries into the Python process. One way is to instantiate one of the following classes:
class ctypes.**CDLL**(*name*, *mode=DEFAULT_MODE*, *handle=None*, *use_errno=False*, *
use_last_error=False*)

Instances of this class represent loaded shared libraries. Functions in
these libraries use the standard C calling convention, and are assumed to return int.

class ctypes.**OleDLL**(*name*, *mode=DEFAULT_MODE*,
*handle=None*, *use_errno=False*, *use_last_error=False*)

Windows only: Instances of this class represent loaded shared libraries, functions in these libraries use the *stdcall* calling convention, and are assumed to return the windows specific **HRESULT** code. **HRESULT** values contain information specifying whether the function call failed or succeeded, together with additional error code. If the return value signals a failure, an **OSError** is automatically raised.

*Changed in version 3.3:* **WindowsError** used to be raised.

class ctypes.**WinDLL**(*name*, *mode=DEFAULT_MODE*,
*handle=None*, *use_errno=False*, *use_last_error=False*)

Windows only: Instances of this class represent loaded shared libraries, functions in these libraries use the *stdcall* calling convention, and are assumed to return int by default.

On Windows CE only the standard calling convention is used, for convenience the **WinDLL** and **OleDLL** use the standard calling convention on this platform.

The Python **global interpreter lock** is released before calling any function exported by these libraries, and reacquired afterwards.

class ctypes.**PyDLL**(*name*, *mode=DEFAULT_MODE*,
*handle=None*, *use_errno=False*, *use_last_error=False*)

Windows only: Instances of this class represent loaded shared libraries, functions in these libraries use the *stdcall* calling convention, and are assumed to return int by default.

On Windows CE only the standard calling convention is used, for convenience the **WinDLL** and **OleDLL** use the standard calling convention on this platform.

The Python **global interpreter lock** is released before calling any function exported by these libraries, and reacquired afterwards.
Instances of this class behave like CDLL instances, except that the Python GIL is not released during the function call, and after the function execution the Python error flag is checked. If the error flag is set, a Python exception is raised.

Thus, this is only useful to call Python C api functions directly.

All these classes can be instantiated by calling them with at least one argument, the pathname of the shared library. If you have an existing handle to an already loaded shared library, it can be passed as the handle named parameter, otherwise the underlying platforms `dlopen` or `LoadLibrary` function is used to load the library into the process, and to get a handle to it.

The mode parameter can be used to specify how the library is loaded. For details, consult the `dlopen(3)` manpage, on Windows, mode is ignored.

The use_errno parameter, when set to True, enables a ctypes mechanism that allows to access the system errno error number in a safe way. ctypes maintains a thread-local copy of the systems errno variable; if you call foreign functions created with use_errno=True then the errno value before the function call is swapped with the ctypes private copy, the same happens immediately after the function call.

The function ctypes.get_errno() returns the value of the ctypes private copy, and the function ctypes.set_errno() changes the ctypes private copy to a new value and returns the former value.

The use_last_error parameter, when set to True, enables the same mechanism for the Windows error code which is managed by the
GetLastError() and SetLastError() Windows API functions; ctypes.get_last_error() and ctypes.set_last_error() are used to request and change the ctypes private copy of the windows error code.

ctypes.RTLD_GLOBAL
Flag to use as mode parameter. On platforms where this flag is not available, it is defined as the integer zero.

ctypes.RTLD_LOCAL
Flag to use as mode parameter. On platforms where this is not available, it is the same as RTLD_GLOBAL.

ctypes.DEFAULT_MODE
The default mode which is used to load shared libraries. On OSX 10.3, this is RTLD_GLOBAL, otherwise it is the same as RTLD_LOCAL.

Instances of these classes have no public methods, however __getattr__() and __getitem__() have special behavior: functions exported by the shared library can be accessed as attributes of by index. Please note that both __getattr__() and __getitem__() cache their result, so calling them repeatedly returns the same object each time.

The following public attributes are available, their name starts with an underscore to not clash with exported function names:

PyDLL._handle
The system handle used to access the library.

PyDLL._name
The name of the library passed in the constructor.
Shared libraries can also be loaded by using one of the prefabricated objects, which are instances of the `LibraryLoader` class, either by calling the `LoadLibrary()` method, or by retrieving the library as attribute of the loader instance.

```python
class ctypes.LibraryLoader(dlltype):
    Class which loads shared libraries. `dlltype` should be one of the CDLL, PyDLL, WinDLL, or OleDLL types.

    __getattr__() has special behavior: It allows to load a shared library by accessing it as attribute of a library loader instance. The result is cached, so repeated attribute accesses return the same library each time.

    LoadLibrary(name)
    Load a shared library into the process and return it. This method always returns a new instance of the library.
```

These prefabricated library loaders are available:

- `ctypes.cdll`: Creates CDLL instances.
- `ctypes.windll`: Windows only: Creates WinDLL instances.
- `ctypes.oledll`: Windows only: Creates OleDLL instances.
- `ctypes.pydll`: Creates PyDLL instances.

For accessing the C Python api directly, a ready-to-use Python shared
library object is available:

```
ctypes.pythonapi
```

An instance of `PyDLL` that exposes Python C API functions as attributes. Note that all these functions are assumed to return C `int`, which is of course not always the truth, so you have to assign the correct `restype` attribute to use these functions.

### 16.17.2.3. Foreign functions

As explained in the previous section, foreign functions can be accessed as attributes of loaded shared libraries. The function objects created in this way by default accept any number of arguments, accept any ctypes data instances as arguments, and return the default result type specified by the library loader. They are instances of a private class:

```
class ctypes._FuncPtr
```

Base class for C callable foreign functions.

Instances of foreign functions are also C compatible data types; they represent C function pointers.

This behavior can be customized by assigning to special attributes of the foreign function object.

```
restype
```

Assign a ctypes type to specify the result type of the foreign function. Use `None` for `void`, a function not returning anything.

It is possible to assign a callable Python object that is not a ctypes type, in this case the function is assumed to return a C `int`, and the callable will be called with this integer, allowing to
do further processing or error checking. Using this is deprecated, for more flexible post processing or error checking use a ctypes data type as `restype` and assign a callable to the `errcheck` attribute.

### argtypes
Assign a tuple of ctypes types to specify the argument types that the function accepts. Functions using the `stdcall` calling convention can only be called with the same number of arguments as the length of this tuple; functions using the C calling convention accept additional, unspecified arguments as well.

When a foreign function is called, each actual argument is passed to the `from_param()` class method of the items in the `argtypes` tuple, this method allows to adapt the actual argument to an object that the foreign function accepts. For example, a `c_char_p` item in the `argtypes` tuple will convert a string passed as argument into a bytes object using ctypes conversion rules.

New: It is now possible to put items in argtypes which are not ctypes types, but each item must have a `from_param()` method which returns a value usable as argument (integer, string, ctypes instance). This allows to define adapters that can adapt custom objects as function parameters.

### errcheck
Assign a Python function or another callable to this attribute. The callable will be called with three or more arguments:

```python
callable(result, func, arguments)
```
result is what the foreign function returns, as specified by the restype attribute.

func is the foreign function object itself, this allows to reuse the same callable object to check or post process the results of several functions.

arguments is a tuple containing the parameters originally passed to the function call, this allows to specialize the behavior on the arguments used.

The object that this function returns will be returned from the foreign function call, but it can also check the result value and raise an exception if the foreign function call failed.

exception ctypes. ArgumentError
   This exception is raised when a foreign function call cannot convert one of the passed arguments.

16.17.2.4. Function prototypes

Foreign functions can also be created by instantiating function prototypes. Function prototypes are similar to function prototypes in C; they describe a function (return type, argument types, calling convention) without defining an implementation. The factory functions must be called with the desired result type and the argument types of the function.

ctypes.CFUNCTYPE(restype, *argtypes, use_errno=False, use_last_error=False)
   The returned function prototype creates functions that use the standard C calling convention. The function will release the GIL during the call. If use_errno is set to True, the ctypes private copy
of the system `errno` variable is exchanged with the real `errno` value before and after the call; `use_last_error` does the same for the Windows error code.

```python
ctypes.WINFUNCTYPE(restype, *argtypes, use_errno=False, use_last_error=False)
```

Windows only: The returned function prototype creates functions that use the **stdcall** calling convention, except on Windows CE where `WINFUNCTYPE()` is the same as `CFUNCTYPE()`. The function will release the GIL during the call. `use_errno` and `use_last_error` have the same meaning as above.

```python
ctypes.PYFUNCTYPE(restype, *argtypes)
```

The returned function prototype creates functions that use the Python calling convention. The function will **not** release the GIL during the call.

Function prototypes created by these factory functions can be instantiated in different ways, depending on the type and number of the parameters in the call:

```python
prototype(address)
```

Returns a foreign function at the specified address which must be an integer.

```python
prototype(callable)
```

Create a C callable function (a callback function) from a Python callable.

```python
prototype(func_spec[, paramflags])
```

Returns a foreign function exported by a shared library. `func_spec` must be a 2-tuple (name_or_ordinal,
library). The first item is the name of the exported function as string, or the ordinal of the exported function as small integer. The second item is the shared library instance.

**prototype**(vtbl\_index, name[, paramflags[, iid]])

Returns a foreign function that will call a COM method. *vtbl\_index* is the index into the virtual function table, a small non-negative integer. *name* is name of the COM method. *iid* is an optional pointer to the interface identifier which is used in extended error reporting.

COM methods use a special calling convention: They require a pointer to the COM interface as first argument, in addition to those parameters that are specified in the arg\_types tuple.

The optional *paramflags* parameter creates foreign function wrappers with much more functionality than the features described above.

*paramflags* must be a tuple of the same length as arg\_types.

Each item in this tuple contains further information about a parameter, it must be a tuple containing one, two, or three items.

The first item is an integer containing a combination of direction flags for the parameter:

1

Specifies an input parameter to the function.

2

Output parameter. The foreign function fills in a value.

4

Input parameter which defaults to the integer zero.
The optional second item is the parameter name as string. If this is specified, the foreign function can be called with named parameters.

The optional third item is the default value for this parameter.

This example demonstrates how to wrap the Windows MessageBoxA function so that it supports default parameters and named arguments. The C declaration from the windows header file is this:

```
WINUSERAPI int WINAPI MessageBoxA(
    HWND hWnd,
    LPCSTR lpText,
    LPCSTR lpCaption,
    UINT uType);
```

Here is the wrapping with ctypes:

```python
>>> from ctypes import c_int, WINFUNCTYPE, windll
>>> from ctypes.wintypes import HWND, LPCSTR, UINT
>>> prototype = WINFUNCTYPE(c_int, HWND, LPCSTR, LPCSTR, UINT)
>>> paramflags = (1, "hwnd", 0), (1, "text", "Hi"),
>>> MessageBox = prototype(\"MessageBoxA\", windll.user32)
```

The MessageBox foreign function can now be called in these ways:

```python
>>> MessageBox()
>>> MessageBox(text="Spam, spam, spam")
>>> MessageBox(flags=2, text="foo bar")
```

A second example demonstrates output parameters. The win32
GetWindowRect function retrieves the dimensions of a specified window by copying them into RECT structure that the caller has to supply. Here is the C declaration:

```
WINUSERAPI BOOL WINAPI GetWindowRect(  
    HWND hWnd,  
    LPRECT lpRect);
```

Here is the wrapping with ctypes:

```python
>>> from ctypes import POINTER, WINFUNCTYPE, windll,  
>>> from ctypes.wintypes import BOOL, HWND, RECT  
>>> prototype = WINFUNCTYPE(BOOL, HWND, POINTER(RECT)  
>>> paramflags = (1, "hwnd"), (2, "lprect")  
>>> GetWindowRect = prototype("GetWindowRect", windl  
```

Functions with output parameters will automatically return the output parameter value if there is a single one, or a tuple containing the output parameter values when there are more than one, so the GetWindowRect function now returns a RECT instance, when called.

Output parameters can be combined with the errcheck protocol to do further output processing and error checking. The win32 GetWindowRect api function returns a BOOL to signal success or failure, so this function could do the error checking, and raises an exception when the api call failed:

```python
>>> def errcheck(result, func, args):  
    ...    if not result:  
    ...        raise WinError()  
    ...    return args
```
GetWindowRect.errcheck = errcheck

If the errcheck function returns the argument tuple it receives unchanged, ctypes continues the normal processing it does on the output parameters. If you want to return a tuple of window coordinates instead of a RECT instance, you can retrieve the fields in the function and return them instead, the normal processing will no longer take place:

```python
>>> def errcheck(result, func, args):
...     if not result:
...         raise WinError()
...     rc = args[1]
...     return rc.left, rc.top, rc.bottom, rc.right
...
>>> GetWindowRect.errcheck = errcheck
```

16.17.2.5. Utility functions

ctypes.**addressof**(obj)

Returns the address of the memory buffer as integer. *obj* must be an instance of a ctypes type.

ctypes.**alignment**(obj_or_type)

Returns the alignment requirements of a ctypes type. *obj_or_type* must be a ctypes type or instance.

ctypes.**byref**(obj[, offset])

Returns a light-weight pointer to *obj*, which must be an instance of a ctypes type. *offset* defaults to zero, and must be an integer that will be added to the internal pointer value.
byref(obj, offset) corresponds to this C code:

```c
(((char *)&obj) + offset)
```

The returned object can only be used as a foreign function call parameter. It behaves similar to `pointer(obj)`, but the construction is a lot faster.

```python
cast(obj, type)
```

This function is similar to the cast operator in C. It returns a new instance of `type` which points to the same memory block as `obj`. `type` must be a pointer type, and `obj` must be an object that can be interpreted as a pointer.

```python
create_string_buffer(init_or_size, size=None)
```

This function creates a mutable character buffer. The returned object is a ctypes array of `c_char`.

`init_or_size` must be an integer which specifies the size of the array, or a bytes object which will be used to initialize the array items.

If a bytes object is specified as first argument, the buffer is made one item larger than its length so that the last element in the array is a NUL termination character. An integer can be passed as second argument which allows to specify the size of the array if the length of the bytes should not be used.

```python
create_unicode_buffer(init_or_size, size=None)
```

This function creates a mutable unicode character buffer. The returned object is a ctypes array of `c_wchar`.

`init_or_size` must be an integer which specifies the size of the
array, or a string which will be used to initialize the array items.

If a string is specified as first argument, the buffer is made one item larger than the length of the string so that the last element in the array is a NUL termination character. An integer can be passed as second argument which allows to specify the size of the array if the length of the string should not be used.

ctypes.DllCanUnloadNow()
Windows only: This function is a hook which allows to implement in-process COM servers with ctypes. It is called from the DllCanUnloadNow function that the _ctypes extension dll exports.

ctypes.DllGetClassObject()
Windows only: This function is a hook which allows to implement in-process COM servers with ctypes. It is called from the DllGetClassObject function that the _ctypes extension dll exports.

ctypes.util.find_library(name)
Try to find a library and return a pathname. name is the library name without any prefix like lib, suffix like .so, .dylib or version number (this is the form used for the posix linker option -l). If no library can be found, returns None.

The exact functionality is system dependent.

ctypes.util.find_msvcrt()
Windows only: return the filename of the VC runtype library used by Python, and by the extension modules. If the name of the library cannot be determined, None is returned.

If you need to free memory, for example, allocated by an extension module with a call to the free(void *), it is important that you
use the function in the same library that allocated the memory.

`ctypes.FormatError([code])`
Windows only: Returns a textual description of the error code `code`. If no error code is specified, the last error code is used by calling the Windows api function `GetLastError`.

`ctypes.GetLastError()`
Windows only: Returns the last error code set by Windows in the calling thread. This function calls the Windows `GetLastError()` function directly, it does not return the ctypes-private copy of the error code.

`ctypes.get_errno()`
Returns the current value of the ctypes-private copy of the system `errno` variable in the calling thread.

`ctypes.get_last_error()`
Windows only: returns the current value of the ctypes-private copy of the system `LastError` variable in the calling thread.

`ctypes.memmove(dst, src, count)`
Same as the standard C memmove library function: copies `count` bytes from `src` to `dst`. `dst` and `src` must be integers or ctypes instances that can be converted to pointers.

`ctypes.memset(dst, c, count)`
Same as the standard C memset library function: fills the memory block at address `dst` with `count` bytes of value `c`. `dst` must be an integer specifying an address, or a ctypes instance.

`ctypes.POINTER(type)`
This factory function creates and returns a new ctypes pointer type. Pointer types are cached and reused internally, so calling this function repeatedly is cheap. type must be a ctypes type.

`ctypes.pointer(obj)`

This function creates a new pointer instance, pointing to obj. The returned object is of the type \texttt{POINTER(type(obj))}.

Note: If you just want to pass a pointer to an object to a foreign function call, you should use \texttt{byref(obj)} which is much faster.

`ctypes.resize(obj, size)`

This function resizes the internal memory buffer of obj, which must be an instance of a ctypes type. It is not possible to make the buffer smaller than the native size of the objects type, as given by \texttt{sizeof(type(obj))}, but it is possible to enlarge the buffer.

`ctypes.set_errno(value)`

Set the current value of the ctypes-private copy of the system \texttt{errno} variable in the calling thread to \texttt{value} and return the previous value.

`ctypes.set_last_error(value)`

Windows only: set the current value of the ctypes-private copy of the system \texttt{LastError} variable in the calling thread to \texttt{value} and return the previous value.

`ctypes.sizeof(obj_or_type)`

Returns the size in bytes of a ctypes type or instance memory buffer. Does the same as the C \texttt{sizeof} operator.

`ctypes.string_at(address, size=-1)`
This function returns the C string starting at memory address `address` as a bytes object. If size is specified, it is used as size, otherwise the string is assumed to be zero-terminated.

```python
ctypes.WinError(code=None, descr=None)
```

Windows only: this function is probably the worst-named thing in ctypes. It creates an instance of OSError. If `code` is not specified, `GetLastError` is called to determine the error code. If `descr` is not specified, `FormatError()` is called to get a textual description of the error.

*Changed in version 3.3:* An instance of `WindowsError` used to be created.

```python
ctypes.wstring_at(address, size=-1)
```

This function returns the wide character string starting at memory address `address` as a string. If `size` is specified, it is used as the number of characters of the string, otherwise the string is assumed to be zero-terminated.

### 16.17.2.6. Data types

```python
class ctypes._CData
```

This non-public class is the common base class of all ctypes data types. Among other things, all ctypes type instances contain a memory block that hold C compatible data; the address of the memory block is returned by the `addressof()` helper function. Another instance variable is exposed as `_objects`; this contains other Python objects that need to be kept alive in case the memory block contains pointers.

Common methods of ctypes data types, these are all class
methods (to be exact, they are methods of the `metaclass`):

`from_buffer(source[, offset])`
This method returns a ctypes instance that shares the buffer of the `source` object. The `source` object must support the writeable buffer interface. The optional `offset` parameter specifies an offset into the source buffer in bytes; the default is zero. If the source buffer is not large enough a `ValueError` is raised.

`from_buffer_copy(source[, offset])`
This method creates a ctypes instance, copying the buffer from the `source` object buffer which must be readable. The optional `offset` parameter specifies an offset into the source buffer in bytes; the default is zero. If the source buffer is not large enough a `ValueError` is raised.

`from_address(address)`
This method returns a ctypes type instance using the memory specified by `address` which must be an integer.

`from_param(obj)`
This method adapts `obj` to a ctypes type. It is called with the actual object used in a foreign function call when the type is present in the foreign function’s `argtypes` tuple; it must return an object that can be used as a function call parameter.

All ctypes data types have a default implementation of this classmethod that normally returns `obj` if that is an instance of the type. Some types accept other objects as well.

`in_dll(library, name)`
This method returns a ctypes type instance exported by a
shared library. *name* is the name of the symbol that exports the data, *library* is the loaded shared library.

Common instance variables of ctypes data types:

**_b_base_**
Sometimes ctypes data instances do not own the memory block they contain, instead they share part of the memory block of a base object. The **_b_base_** read-only member is the root ctypes object that owns the memory block.

**_b_needsfree_**
This read-only variable is true when the ctypes data instance has allocated the memory block itself, false otherwise.

**_objects_**
This member is either `None` or a dictionary containing Python objects that need to be kept alive so that the memory block contents is kept valid. This object is only exposed for debugging; never modify the contents of this dictionary.

### 16.17.2.7. Fundamental data types

**class** ctypes.*_SimpleCData*
This non-public class is the base class of all fundamental ctypes data types. It is mentioned here because it contains the common attributes of the fundamental ctypes data types. **_SimpleCData** is a subclass of **_CData**, so it inherits their methods and attributes. ctypes data types that are not and do not contain pointers can now be pickled.

Instances have a single attribute:
value

This attribute contains the actual value of the instance. For integer and pointer types, it is an integer, for character types, it is a single character bytes object or string, for character pointer types it is a Python bytes object or string.

When the `value` attribute is retrieved from a ctypes instance, usually a new object is returned each time. `ctypes` does not implement original object return, always a new object is constructed. The same is true for all other ctypes object instances.

Fundamental data types, when returned as foreign function call results, or, for example, by retrieving structure field members or array items, are transparently converted to native Python types. In other words, if a foreign function has a restype of `c_char_p`, you will always receive a Python bytes object, *not* a `c_char_p` instance.

Subclasses of fundamental data types do *not* inherit this behavior. So, if a foreign functions restype is a subclass of `c_void_p`, you will receive an instance of this subclass from the function call. Of course, you can get the value of the pointer by accessing the `value` attribute.

These are the fundamental ctypes data types:

```python
class ctypes.c_byte
    Represents the C signed char datatype, and interprets the value as small integer. The constructor accepts an optional integer initializer; no overflow checking is done.
```

```python
class ctypes.c_char
    Represents the C char datatype, and interprets the value as a single character. The constructor accepts an optional string
```
initializer, the length of the string must be exactly one character.

```python
class ctypes.c_char_p

    Represents the C char * datatype when it points to a zero-terminated string. For a general character pointer that may also point to binary data, POINTER(c_char) must be used. The constructor accepts an integer address, or a bytes object.

class ctypes.c_double

    Represents the C double datatype. The constructor accepts an optional float initializer.

class ctypes.c_longdouble

    Represents the C long double datatype. The constructor accepts an optional float initializer. On platforms where sizeof(long double) == sizeof(double) it is an alias to c_double.

class ctypes.c_float

    Represents the C float datatype. The constructor accepts an optional float initializer.

class ctypes.c_int

    Represents the C signed int datatype. The constructor accepts an optional integer initializer; no overflow checking is done. On platforms where sizeof(int) == sizeof(long) it is an alias to c_long.

class ctypes.c_int8

    Represents the C 8-bit signed int datatype. Usually an alias for c_byte.
```
class ctypes.c_int16
    Represents the C 16-bit signed int datatype. Usually an alias for c_short.

class ctypes.c_int32
    Represents the C 32-bit signed int datatype. Usually an alias for c_int.

class ctypes.c_int64
    Represents the C 64-bit signed int datatype. Usually an alias for c_longlong.

class ctypes.c_long
    Represents the C signed long datatype. The constructor accepts an optional integer initializer; no overflow checking is done.

class ctypes.c_longlong
    Represents the C signed long long datatype. The constructor accepts an optional integer initializer; no overflow checking is done.

class ctypes.c_short
    Represents the C signed short datatype. The constructor accepts an optional integer initializer; no overflow checking is done.

class ctypes.c_size_t
    Represents the C size_t datatype.

class ctypes.c_ssize_t
    Represents the C ssize_t datatype.

    New in version 3.2.

class ctypes.c_ubyte
Represents the C unsigned char datatype, it interprets the value as small integer. The constructor accepts an optional integer initializer; no overflow checking is done.

`class ctypes.c_uint`

Represents the C unsigned int datatype. The constructor accepts an optional integer initializer; no overflow checking is done. On platforms where `sizeof(int) == sizeof(long)` it is an alias for `c_ulong`.

`class ctypes.c_uint8`

Represents the C 8-bit unsigned int datatype. Usually an alias for `c_ubyte`.

`class ctypes.c_uint16`

Represents the C 16-bit unsigned int datatype. Usually an alias for `c_ushort`.

`class ctypes.c_uint32`

Represents the C 32-bit unsigned int datatype. Usually an alias for `c_uint`.

`class ctypes.c_uint64`

Represents the C 64-bit unsigned int datatype. Usually an alias for `c_ulonglong`.

`class ctypes.c_ulong`

Represents the C unsigned long datatype. The constructor accepts an optional integer initializer; no overflow checking is done.

`class ctypes.c_ulonglong`

Represents the C unsigned long long datatype. The
constructor accepts an optional integer initializer; no overflow checking is done.

`class ctypes.c_ushort`
    Represents the C unsigned short datatype. The constructor accepts an optional integer initializer; no overflow checking is done.

`class ctypes.c_void_p`
    Represents the C void * type. The value is represented as integer. The constructor accepts an optional integer initializer.

`class ctypes.c_wchar`
    Represents the C wchar_t datatype, and interprets the value as a single character unicode string. The constructor accepts an optional string initializer, the length of the string must be exactly one character.

`class ctypes.c_wchar_p`
    Represents the C wchar_t * datatype, which must be a pointer to a zero-terminated wide character string. The constructor accepts an integer address, or a string.

`class ctypes.c_bool`
    Represent the C bool datatype (more accurately, _Bool from C99). Its value can be `True` or `False`, and the constructor accepts any object that has a truth value.

`class ctypes.HRESULT`
    Windows only: Represents a HRESULT value, which contains success or error information for a function or method call.

`class ctypes.py_object`
    Represents the C PyObject * datatype. Calling this without an
argument creates a NULL PyObject * pointer.

The ctypes.wintypes module provides quite some other Windows specific data types, for example HWND, WPARAM, or DWORD. Some useful structures like MSG or RECT are also defined.

16.17.2.8. Structured data types

class ctypes.Union(*args, **kw)
    Abstract base class for unions in native byte order.

class ctypes.BigEndianStructure(*args, **kw)
    Abstract base class for structures in big endian byte order.

class ctypes.LittleEndianStructure(*args, **kw)
    Abstract base class for structures in little endian byte order.

Structures with non-native byte order cannot contain pointer type fields, or any other data types containing pointer type fields.

class ctypes.Structure(*args, **kw)
    Abstract base class for structures in native byte order.

Concrete structure and union types must be created by subclassing one of these types, and at least define a _fields_ class variable. ctypes will create descriptors which allow reading and writing the fields by direct attribute accesses. These are the _fields_

    A sequence defining the structure fields. The items must be 2-tuples or 3-tuples. The first item is the name of the field, the second item specifies the type of the field; it can be any ctypes
data type.

For integer type fields like `c_int`, a third optional item can be given. It must be a small positive integer defining the bit width of the field.

Field names must be unique within one structure or union. This is not checked, only one field can be accessed when names are repeated.

It is possible to define the `_fields_` class variable after the class statement that defines the Structure subclass, this allows to create data types that directly or indirectly reference themselves:

```python
class List(Structure):
    pass
List._fields_ = [('pnext', POINTER(List)),
                 ...
]
```

The `_fields_` class variable must, however, be defined before the type is first used (an instance is created, `sizeof()` is called on it, and so on). Later assignments to the `_fields_` class variable will raise an AttributeError.

Structure and union subclass constructors accept both positional and named arguments. Positional arguments are used to initialize the fields in the same order as they appear in the `_fields_` definition, named arguments are used to initialize the fields with the corresponding name.

It is possible to defined sub-subclasses of structure types, they
inherit the fields of the base class plus the _fields_ defined in the sub-subclass, if any.

__pack__
An optional small integer that allows to override the alignment of structure fields in the instance. __pack__ must already be defined when _fields_ is assigned, otherwise it will have no effect.

__anonymous__
An optional sequence that lists the names of unnamed (anonymous) fields. __anonymous__ must be already defined when _fields_ is assigned, otherwise it will have no effect.

The fields listed in this variable must be structure or union type fields. ctypes will create descriptors in the structure type that allows to access the nested fields directly, without the need to create the structure or union field.

Here is an example type (Windows):

```python
class _U(Union):
    _fields_ = [("lptdesc", POINTER(TYPEDESC)),
                ("lpadesc", POINTER(ARRAYDESC))
                ("hreftype", HREFTYPE)]

class TYPEDESC(Structure):
    _anonymous_ = ("u",)
    _fields_ = [("u", _U),
                ("vt", VARTYPE)]
```

The TYPEDESC structure describes a COM data type, the vt field specifies which one of the union fields is valid. Since the u
field is defined as anonymous field, it is now possible to access the members directly off the TYPEDESC instance. td.lptdesc and td.u.lptdesc are equivalent, but the former is faster since it does not need to create a temporary union instance:

```python
td = TYPEDESC()
td.vt = VT_PTR
td.lptdesc = POINTER(some_type)
td.u.lptdesc = POINTER(some_type)
```

It is possible to defined sub-subclasses of structures, they inherit the fields of the base class. If the subclass definition has a separate `_fields_` variable, the fields specified in this are appended to the fields of the base class.

Structure and union constructors accept both positional and keyword arguments. Positional arguments are used to initialize member fields in the same order as they appear in `_fields_`. Keyword arguments in the constructor are interpreted as attribute assignments, so they will initialize `_fields_` with the same name, or create new attributes for names not present in `_fields_`.

### 16.17.2.9. Arrays and pointers

Not yet written - please see the sections **Pointers** and section **Arrays** in the tutorial.
17. Concurrent Execution

The modules described in this chapter provide support for concurrent execution of code. The appropriate choice of tool will depend on the task to be executed (CPU bound vs IO bound) and preferred style of development (event driven cooperative multitasking vs preemptive multitasking). Here’s an overview:

• **17.1. threading — Thread-based parallelism**
  - 17.1.1. Thread-Local Data
  - 17.1.2. Thread Objects
  - 17.1.3. Lock Objects
  - 17.1.4. RLock Objects
  - 17.1.5. Condition Objects
  - 17.1.6. Semaphore Objects
    - 17.1.6.1. Semaphore Example
  - 17.1.7. Event Objects
  - 17.1.8. Timer Objects
  - 17.1.9. Barrier Objects
  - 17.1.10. Using locks, conditions, and semaphores in the with statement

• **17.2. multiprocessing — Process-based parallelism**
  - 17.2.1. Introduction
    - 17.2.1.1. The Process class
    - 17.2.1.2. Contexts and start methods
    - 17.2.1.3. Exchanging objects between processes
    - 17.2.1.4. Synchronization between processes
    - 17.2.1.5. Sharing state between processes
    - 17.2.1.6. Using a pool of workers
  - 17.2.2. Reference
    - 17.2.2.1. Process and exceptions
    - 17.2.2.2. Pipes and Queues
- 17.2.2.3. Miscellaneous
- 17.2.2.4. Connection Objects
- 17.2.2.5. Synchronization primitives
- 17.2.2.6. Shared ctypes Objects
  - 17.2.2.6.1. The multiprocessing.sharedctypes module
- 17.2.2.7. Managers
  - 17.2.2.7.1. Namespace objects
  - 17.2.2.7.2. Customized managers
  - 17.2.2.7.3. Using a remote manager
- 17.2.2.8. Proxy Objects
  - 17.2.2.8.1. Cleanup
- 17.2.2.9. Process Pools

The following are support modules for some of the above services:

- 17.8. dummy_threading — Drop-in replacement for the threading module
- 17.9. _thread — Low-level threading API
- 17.10. _dummy_thread — Drop-in replacement for the _thread module
17.1. **threading** — Thread-based parallelism

**Source code:** Lib/threading.py

This module constructs higher-level threading interfaces on top of the lower level `_thread` module. See also the `queue` module.

The `dummy_threading` module is provided for situations where `threading` cannot be used because `_thread` is missing.

**Note:** While they are not listed below, the camelCase names used for some methods and functions in this module in the Python 2.x series are still supported by this module.

This module defines the following functions:

**threading.active_count()**

Return the number of Thread objects currently alive. The returned count is equal to the length of the list returned by `enumerate()`.

**threading.current_thread()**

Return the current Thread object, corresponding to the caller’s thread of control. If the caller’s thread of control was not created through the `threading` module, a dummy thread object with limited functionality is returned.

**threading.get_ident()**

Return the ‘thread identifier’ of the current thread. This is a nonzero
integer. Its value has no direct meaning; it is intended as a magic cookie to be used e.g. to index a dictionary of thread-specific data. Thread identifiers may be recycled when a thread exits and another thread is created.

*New in version 3.3.*

**threading.enumerate()**

Return a list of all *Thread* objects currently alive. The list includes daemonic threads, dummy thread objects created by `current_thread()`, and the main thread. It excludes terminated threads and threads that have not yet been started.

**threading.main_thread()**

Return the main *Thread* object. In normal conditions, the main thread is the thread from which the Python interpreter was started.

*New in version 3.4.*

**threading.settrace(func)**

Set a trace function for all threads started from the *threading* module. The `func` will be passed to `sys.settrace()` for each thread, before its `run()` method is called.

**threading.setprofile(func)**

Set a profile function for all threads started from the *threading* module. The `func` will be passed to `sys.setprofile()` for each thread, before its `run()` method is called.

**threading.stack_size([size])**

Return the thread stack size used when creating new threads. The optional `size` argument specifies the stack size to be used for
subsequently created threads, and must be 0 (use platform or configured default) or a positive integer value of at least 32,768 (32 KiB). If changing the thread stack size is unsupported, a RuntimeError is raised. If the specified stack size is invalid, a ValueError is raised and the stack size is unmodified. 32 KiB is currently the minimum supported stack size value to guarantee sufficient stack space for the interpreter itself. Note that some platforms may have particular restrictions on values for the stack size, such as requiring a minimum stack size > 32 KiB or requiring allocation in multiples of the system memory page size - platform documentation should be referred to for more information (4 KiB pages are common; using multiples of 4096 for the stack size is the suggested approach in the absence of more specific information). Availability: Windows, systems with POSIX threads.

This module also defines the following constant:

```
threading.TIMOUT_MAX
```

The maximum value allowed for the `timeout` parameter of blocking functions (Lock.acquire(), RLock.acquire(), Condition.wait(), etc.). Specifying a timeout greater than this value will raise an OverflowError.

*New in version 3.2.*

This module defines a number of classes, which are detailed in the sections below.

The design of this module is loosely based on Java's threading model. However, where Java makes locks and condition variables basic behavior of every object, they are separate objects in Python. Python's `Thread` class supports a subset of the behavior of Java's Thread class; currently, there are no priorities, no thread groups, and threads
cannot be destroyed, stopped, suspended, resumed, or interrupted. The static methods of Java's Thread class, when implemented, are mapped to module-level functions.

All of the methods described below are executed atomically.
17.1.1. Thread-Local Data

Thread-local data is data whose values are thread specific. To manage thread-local data, just create an instance of `local` (or a subclass) and store attributes on it:

```python
mydata = threading.local()
mydata.x = 1
```

The instance's values will be different for separate threads.

`class threading. local`  
A class that represents thread-local data.

For more details and extensive examples, see the documentation string of the `_threading_local` module.
17.1.2. Thread Objects

The `Thread` class represents an activity that is run in a separate thread of control. There are two ways to specify the activity: by passing a callable object to the constructor, or by overriding the `run()` method in a subclass. No other methods (except for the constructor) should be overridden in a subclass. In other words, only override the `__init__()` and `run()` methods of this class.

Once a thread object is created, its activity must be started by calling the thread's `start()` method. This invokes the `run()` method in a separate thread of control.

Once the thread's activity is started, the thread is considered 'alive'. It stops being alive when its `run()` method terminates – either normally, or by raising an unhandled exception. The `is_alive()` method tests whether the thread is alive.

Other threads can call a thread's `join()` method. This blocks the calling thread until the thread whose `join()` method is called is terminated.

A thread has a name. The name can be passed to the constructor, and read or changed through the `name` attribute.

A thread can be flagged as a “daemon thread”. The significance of this flag is that the entire Python program exits when only daemon threads are left. The initial value is inherited from the creating thread. The flag can be set through the `daemon` property or the `daemon` constructor argument.

**Note:** Daemon threads are abruptly stopped at shutdown. Their
resources (such as open files, database transactions, etc.) may not be released properly. If you want your threads to stop gracefully, make them non-daemonic and use a suitable signalling mechanism such as an Event.

There is a “main thread” object; this corresponds to the initial thread of control in the Python program. It is not a daemon thread.

There is the possibility that “dummy thread objects” are created. These are thread objects corresponding to “alien threads”, which are threads of control started outside the threading module, such as directly from C code. Dummy thread objects have limited functionality; they are always considered alive and daemonic, and cannot be join()ed. They are never deleted, since it is impossible to detect the termination of alien threads.

class threading.Thread(group=None, target=None, name=None, args=(), kwargs={}, *, daemon=None)

This constructor should always be called with keyword arguments. Arguments are:

* group should be None; reserved for future extension when a ThreadGroup class is implemented.

* target is the callable object to be invoked by the run() method. Defaults to None, meaning nothing is called.

* name is the thread name. By default, a unique name is constructed of the form “Thread-N” where N is a small decimal number.

* args is the argument tuple for the target invocation. Defaults to ().

* kwargs is a dictionary of keyword arguments for the target
invocation. Defaults to `{}`.

If not None, daemon explicitly sets whether the thread is daemonic. If None (the default), the daemonic property is inherited from the current thread.

If the subclass overrides the constructor, it must make sure to invoke the base class constructor (Thread.__init__()) before doing anything else to the thread.

*Changed in version 3.3:* Added the daemon argument.

**start()**

Start the thread's activity.

It must be called at most once per thread object. It arranges for the object's `run()` method to be invoked in a separate thread of control.

This method will raise a `RuntimeError` if called more than once on the same thread object.

**run()**

Method representing the thread's activity.

You may override this method in a subclass. The standard `run()` method invokes the callable object passed to the object's constructor as the target argument, if any, with sequential and keyword arguments taken from the *args and **kwargs arguments, respectively.

**join(timeout=None)**

Wait until the thread terminates. This blocks the calling thread
until the thread whose `join()` method is called terminates – either normally or through an unhandled exception –, or until the optional timeout occurs.

When the `timeout` argument is present and not `None`, it should be a floating point number specifying a timeout for the operation in seconds (or fractions thereof). As `join()` always returns `None`, you must call `is_alive()` after `join()` to decide whether a timeout happened – if the thread is still alive, the `join()` call timed out.

When the `timeout` argument is not present or `None`, the operation will block until the thread terminates.

A thread can be `join()`ed many times.

`join()` raises a `RuntimeError` if an attempt is made to join the current thread as that would cause a deadlock. It is also an error to `join()` a thread before it has been started and attempts to do so raise the same exception.

**name**

A string used for identification purposes only. It has no semantics. Multiple threads may be given the same name. The initial name is set by the constructor.

**getName()**
**setName()**

Old getter/setter API for `name`; use it directly as a property instead.

**ident**

The ‘thread identifier’ of this thread or `None` if the thread has
not been started. This is a nonzero integer. See the 
_thread.get_ident() function. Thread identifiers may be
recycled when a thread exits and another thread is created. The
identifier is available even after the thread has exited.

**is_alive()**

Return whether the thread is alive.

This method returns True just before the run() method starts
until just after the run() method terminates. The module
function enumerate() returns a list of all alive threads.

**daemon**

A boolean value indicating whether this thread is a daemon
thread (True) or not (False). This must be set before start() is
called, otherwise RuntimeError is raised. Its initial value is
inherited from the creating thread; the main thread is not a
daemon thread and therefore all threads created in the main
thread default to daemon = False.

The entire Python program exits when no alive non-daemon
threads are left.

**isDaemon()**

**setDaemon()**

Old getter/setter API for daemon; use it directly as a property
instead.

**CPython implementation detail:** In CPython, due to the Global
Interpreter Lock, only one thread can execute Python code at once
(even though certain performance-oriented libraries might overcome
this limitation). If you want your application to make better use of the
computational resources of multi-core machines, you are advised to use multiprocessing or concurrent.futures.ProcessPoolExecutor. However, threading is still an appropriate model if you want to run multiple I/O-bound tasks simultaneously.
17.1.3. Lock Objects

A primitive lock is a synchronization primitive that is not owned by a particular thread when locked. In Python, it is currently the lowest level synchronization primitive available, implemented directly by the _thread extension module.

A primitive lock is in one of two states, “locked” or “unlocked”. It is created in the unlocked state. It has two basic methods, acquire() and release(). When the state is unlocked, acquire() changes the state to locked and returns immediately. When the state is locked, acquire() blocks until a call to release() in another thread changes it to unlocked, then the acquire() call resets it to locked and returns. The release() method should only be called in the locked state; it changes the state to unlocked and returns immediately. If an attempt is made to release an unlocked lock, a RuntimeError will be raised.

Locks also support the context manager protocol.

When more than one thread is blocked in acquire() waiting for the state to turn to unlocked, only one thread proceeds when a release() call resets the state to unlocked; which one of the waiting threads proceeds is not defined, and may vary across implementations.

All methods are executed atomically.

class threading.Lock

The class implementing primitive lock objects. Once a thread has acquired a lock, subsequent attempts to acquire it block, until it is released; any thread may release it.
**Changed in version 3.3:** Changed from a factory function to a class.

**acquire**(blocking=True, timeout=-1)

Acquire a lock, blocking or non-blocking.

When invoked with the `blocking` argument set to True (the default), block until the lock is unlocked, then set it to locked and return True.

When invoked with the `blocking` argument set to False, do not block. If a call with `blocking` set to True would block, return False immediately; otherwise, set the lock to locked and return True.

When invoked with the floating-point `timeout` argument set to a positive value, block for at most the number of seconds specified by `timeout` and as long as the lock cannot be acquired. A `timeout` argument of -1 specifies an unbounded wait. It is forbidden to specify a `timeout` when `blocking` is false.

The return value is True if the lock is acquired successfully, False if not (for example if the `timeout` expired).

**Changed in version 3.2:** The `timeout` parameter is new.

**Changed in version 3.2:** Lock acquires can now be interrupted by signals on POSIX.

**release()**

Release a lock. This can be called from any thread, not only the thread which has acquired the lock.
When the lock is locked, reset it to unlocked, and return. If any other threads are blocked waiting for the lock to become unlocked, allow exactly one of them to proceed.

When invoked on an unlocked lock, a `RuntimeError` is raised.

There is no return value.
17.1.4. RLock Objects

A reentrant lock is a synchronization primitive that may be acquired multiple times by the same thread. Internally, it uses the concepts of “owning thread” and “recursion level” in addition to the locked/unlocked state used by primitive locks. In the locked state, some thread owns the lock; in the unlocked state, no thread owns it.

To lock the lock, a thread calls its `acquire()` method; this returns once the thread owns the lock. To unlock the lock, a thread calls its `release()` method. `acquire()]/release()` call pairs may be nested; only the final `release()` (the `release()` of the outermost pair) resets the lock to unlocked and allows another thread blocked in `acquire()` to proceed.

Reentrant locks also support the *context manager protocol*.

```
class threading.RLock
    This class implements reentrant lock objects. A reentrant lock must be released by the thread that acquired it. Once a thread has acquired a reentrant lock, the same thread may acquire it again without blocking; the thread must release it once for each time it has acquired it.

    Note that RLock is actually a factory function which returns an instance of the most efficient version of the concrete RLock class that is supported by the platform.

    `acquire(blocking=True, timeout=-1)`
        Acquire a lock, blocking or non-blocking.

        When invoked without arguments: if this thread already owns
the lock, increment the recursion level by one, and return immediately. Otherwise, if another thread owns the lock, block until the lock is unlocked. Once the lock is unlocked (not owned by any thread), then grab ownership, set the recursion level to one, and return. If more than one thread is blocked waiting until the lock is unlocked, only one at a time will be able to grab ownership of the lock. There is no return value in this case.

When invoked with the `blocking` argument set to true, do the same thing as when called without arguments, and return true.

When invoked with the `blocking` argument set to false, do not block. If a call without an argument would block, return false immediately; otherwise, do the same thing as when called without arguments, and return true.

When invoked with the floating-point `timeout` argument set to a positive value, block for at most the number of seconds specified by `timeout` and as long as the lock cannot be acquired. Return true if the lock has been acquired, false if the timeout has elapsed.

*Changed in version 3.2:* The `timeout` parameter is new.

**release()**

Release a lock, decrementing the recursion level. If after the decrement it is zero, reset the lock to unlocked (not owned by any thread), and if any other threads are blocked waiting for the lock to become unlocked, allow exactly one of them to proceed. If after the decrement the recursion level is still nonzero, the lock remains locked and owned by the calling thread.

Only call this method when the calling thread owns the lock. A
RuntimeError is raised if this method is called when the lock is unlocked.

There is no return value.
17.1.5. Condition Objects

A condition variable is always associated with some kind of lock; this can be passed in or one will be created by default. Passing one in is useful when several condition variables must share the same lock. The lock is part of the condition object: you don’t have to track it separately.

A condition variable obeys the context manager protocol: using the with statement acquires the associated lock for the duration of the enclosed block. The acquire() and release() methods also call the corresponding methods of the associated lock.

Other methods must be called with the associated lock held. The wait() method releases the lock, and then blocks until another thread awakens it by calling notify() or notify_all(). Once awakened, wait() re-acquires the lock and returns. It is also possible to specify a timeout.

The notify() method wakes up one of the threads waiting for the condition variable, if any are waiting. The notify_all() method wakes up all threads waiting for the condition variable.

Note: the notify() and notify_all() methods don’t release the lock; this means that the thread or threads awakened will not return from their wait() call immediately, but only when the thread that called notify() or notify_all() finally relinquishes ownership of the lock.

The typical programming style using condition variables uses the lock to synchronize access to some shared state; threads that are
interested in a particular change of state call \texttt{wait()} repeatedly until they see the desired state, while threads that modify the state call \texttt{notify()} or \texttt{notify\_all()} when they change the state in such a way that it could possibly be a desired state for one of the waiters. For example, the following code is a generic producer-consumer situation with unlimited buffer capacity:

```
# Consume one item
with cv:
    while not an\_item\_is\_available():
        cv.wait()
        get\_an\_available\_item()

# Produce one item
with cv:
    make\_an\_item\_available()
    cv.notify()
```

The while loop checking for the application's condition is necessary because \texttt{wait()} can return after an arbitrary long time, and the condition which prompted the \texttt{notify()} call may no longer hold true. This is inherent to multi-threaded programming. The \texttt{wait\_for()} method can be used to automate the condition checking, and eases the computation of timeouts:

```
# Consume an item
with cv:
    cv.wait\_for(an\_item\_is\_available)
    get\_an\_available\_item()
```

To choose between \texttt{notify()} and \texttt{notify\_all()}, consider whether one state change can be interesting for only one or several waiting threads. E.g. in a typical producer-consumer situation, adding
one item to the buffer only needs to wake up one consumer thread.

```python
class threading.Condition(lock=None)
```

This class implements condition variable objects. A condition variable allows one or more threads to wait until they are notified by another thread.

If the `lock` argument is given and not `None`, it must be a `Lock` or `RLock` object, and it is used as the underlying lock. Otherwise, a new `RLock` object is created and used as the underlying lock.

*Changed in version 3.3:* changed from a factory function to a class.

**acquire(**args**)**

Acquire the underlying lock. This method calls the corresponding method on the underlying lock; the return value is whatever that method returns.

**release()**

Release the underlying lock. This method calls the corresponding method on the underlying lock; there is no return value.

**wait(**timeout=None**)**

Wait until notified or until a timeout occurs. If the calling thread has not acquired the lock when this method is called, a `RuntimeError` is raised.

This method releases the underlying lock, and then blocks until it is awakened by a `notify()` or `notify_all()` call for the same condition variable in another thread, or until the optional timeout occurs. Once awakened or timed out, it re-acquires the lock and returns.
When the `timeout` argument is present and not `None`, it should be a floating point number specifying a timeout for the operation in seconds (or fractions thereof).

When the underlying lock is an `RLock`, it is not released using its `release()` method, since this may not actually unlock the lock when it was acquired multiple times recursively. Instead, an internal interface of the `RLock` class is used, which really unlocks it even when it has been recursively acquired several times. Another internal interface is then used to restore the recursion level when the lock is reacquired.

The return value is `True` unless a given `timeout` expired, in which case it is `False`.

*Changed in version 3.2:* Previously, the method always returned `None`.

**`wait_for(predicate, timeout=None)`**

Wait until a condition evaluates to True. `predicate` should be a callable which result will be interpreted as a boolean value. A `timeout` may be provided giving the maximum time to wait.

This utility method may call `wait()` repeatedly until the predicate is satisfied, or until a timeout occurs. The return value is the last return value of the predicate and will evaluate to `False` if the method timed out.

Ignoring the timeout feature, calling this method is roughly equivalent to writing:

```python
while not predicate():
    cv.wait()
```
Therefore, the same rules apply as with \texttt{wait()}: The lock must be held when called and is re-acquired on return. The predicate is evaluated with the lock held.

\textit{New in version 3.2.}

\textbf{notify}(n=1)

By default, wake up one thread waiting on this condition, if any. If the calling thread has not acquired the lock when this method is called, a \texttt{RuntimeError} is raised.

This method wakes up at most $n$ of the threads waiting for the condition variable; it is a no-op if no threads are waiting.

The current implementation wakes up exactly $n$ threads, if at least $n$ threads are waiting. However, it's not safe to rely on this behavior. A future, optimized implementation may occasionally wake up more than $n$ threads.

Note: an awakened thread does not actually return from its \texttt{wait()} call until it can reacquire the lock. Since \texttt{notify()} does not release the lock, its caller should.

\textbf{notify\_all()}

Wake up all threads waiting on this condition. This method acts like \texttt{notify()}, but wakes up all waiting threads instead of one. If the calling thread has not acquired the lock when this method is called, a \texttt{RuntimeError} is raised.
17.1.6. Semaphore Objects

This is one of the oldest synchronization primitives in the history of computer science, invented by the early Dutch computer scientist Edsger W. Dijkstra (he used the names \texttt{P()} and \texttt{V()} instead of \texttt{acquire()} and \texttt{release()}).

A semaphore manages an internal counter which is decremented by each \texttt{acquire()} call and incremented by each \texttt{release()} call. The counter can never go below zero; when \texttt{acquire()} finds that it is zero, it blocks, waiting until some other thread calls \texttt{release()}.

Semaphores also support the \textit{context manager protocol}.

\begin{verbatim}
class threading.Semaphore(value=1)

    This class implements semaphore objects. A semaphore manages a counter representing the number of \texttt{release()} calls minus the number of \texttt{acquire()} calls, plus an initial value. The \texttt{acquire()} method blocks if necessary until it can return without making the counter negative. If not given, \texttt{value} defaults to 1.

    The optional argument gives the initial \texttt{value} for the internal counter; it defaults to 1. If the \texttt{value} given is less than 0, \texttt{ValueError} is raised.

    \textit{Changed in version 3.3:} changed from a factory function to a class.

    \texttt{acquire(blocking=True, timeout=None)}

    Acquire a semaphore.

    When invoked without arguments: if the internal counter is larger than zero on entry, decrement it by one and return
\end{verbatim}
immediately. If it is zero on entry, block, waiting until some other thread has called `release()` to make it larger than zero. This is done with proper interlocking so that if multiple `acquire()` calls are blocked, `release()` will wake exactly one of them up. The implementation may pick one at random, so the order in which blocked threads are awakened should not be relied on. Returns true (or blocks indefinitely).

When invoked with `blocking` set to false, do not block. If a call without an argument would block, return false immediately; otherwise, do the same thing as when called without arguments, and return true.

When invoked with a `timeout` other than None, it will block for at most `timeout` seconds. If `acquire` does not complete successfully in that interval, return false. Return true otherwise.

*Changed in version 3.2:* The `timeout` parameter is new.

**`release()`**

Release a semaphore, incrementing the internal counter by one. When it was zero on entry and another thread is waiting for it to become larger than zero again, wake up that thread.

**class threading.BoundedSemaphore(value=1)**

Class implementing bounded semaphore objects. A bounded semaphore checks to make sure its current value doesn’t exceed its initial value. If it does, `ValueError` is raised. In most situations semaphores are used to guard resources with limited capacity. If the semaphore is released too many times it’s a sign of a bug. If not given, `value` defaults to 1.

*Changed in version 3.3:* changed from a factory function to a class.
17.1.6.1. **Semaphore Example**

Semaphores are often used to guard resources with limited capacity, for example, a database server. In any situation where the size of the resource is fixed, you should use a bounded semaphore. Before spawning any worker threads, your main thread would initialize the semaphore:

```python
maxconnections = 5
# ...
pool_sema = BoundedSemaphore(value=maxconnections)
```

Once spawned, worker threads call the semaphore’s acquire and release methods when they need to connect to the server:

```python
with pool_sema:
    conn = connectdb()
    try:
        # ... use connection ...
    finally:
        conn.close()
```

The use of a bounded semaphore reduces the chance that a programming error which causes the semaphore to be released more than it’s acquired will go undetected.
17.1.7. Event Objects

This is one of the simplest mechanisms for communication between threads: one thread signals an event and other threads wait for it.

An event object manages an internal flag that can be set to true with the `set()` method and reset to false with the `clear()` method. The `wait()` method blocks until the flag is true.

```python
class threading.Event
    Class implementing event objects. An event manages a flag that can be set to true with the `set()` method and reset to false with the `clear()` method. The `wait()` method blocks until the flag is true. The flag is initially false.

Changed in version 3.3: changed from a factory function to a class.
```

```python
is_set()
    Return true if and only if the internal flag is true.

set()
    Set the internal flag to true. All threads waiting for it to become true are awakened. Threads that call `wait()` once the flag is true will not block at all.

clear()
    Reset the internal flag to false. Subsequently, threads calling `wait()` will block until `set()` is called to set the internal flag to true again.

wait(timeout=None)
    Block until the internal flag is true. If the internal flag is true on
entry, return immediately. Otherwise, block until another thread calls \texttt{set()} to set the flag to true, or until the optional timeout occurs.

When the timeout argument is present and not \texttt{None}, it should be a floating point number specifying a timeout for the operation in seconds (or fractions thereof).

This method returns true if and only if the internal flag has been set to true, either before the wait call or after the wait starts, so it will always return \texttt{True} except if a timeout is given and the operation times out.

\textit{Changed in version 3.1:} Previously, the method always returned \texttt{None}. 

17.1.8. Timer Objects

This class represents an action that should be run only after a certain amount of time has passed — a timer. Timer is a subclass of Thread and as such also functions as an example of creating custom threads.

Timers are started, as with threads, by calling their start() method. The timer can be stopped (before its action has begun) by calling the cancel() method. The interval the timer will wait before executing its action may not be exactly the same as the interval specified by the user.

For example:

```python
def hello():
    print("hello, world")

t = Timer(30.0, hello)
t.start()  # after 30 seconds, "hello, world" will be printed
```

```python
class threading.Timer(interval, function, args=None, kwargs=None)
```

Create a timer that will run function with arguments args and keyword arguments kwargs, after interval seconds have passed. If args is None (the default) then an empty list will be used. If kwargs is None (the default) then an empty dict will be used.

*Changed in version 3.3:* changed from a factory function to a class.

```python
cancel()
```

Stop the timer, and cancel the execution of the timer’s action. This will only work if the timer is still in its waiting stage.
17.1.9. Barrier Objects

*New in version 3.2.*

This class provides a simple synchronization primitive for use by a fixed number of threads that need to wait for each other. Each of the threads tries to pass the barrier by calling the `wait()` method and will block until all of the threads have made the call. At this points, the threads are released simultaneously.

The barrier can be reused any number of times for the same number of threads.

As an example, here is a simple way to synchronize a client and server thread:

```python
b = Barrier(2, timeout=5)

def server():
    start_server()
    b.wait()
    while True:
        connection = accept_connection()
        process_server_connection(connection)

def client():
    b.wait()
    while True:
        connection = make_connection()
        process_client_connection(connection)
```

```python
class threading.Barrier(parties, action=None, timeout=None)
```

Create a barrier object for `parties` number of threads. An `action`, when provided, is a callable to be called by one of the threads.
when they are released. *timeout* is the default timeout value if none is specified for the `wait()` method.

**wait**(timeout=None)

Pass the barrier. When all the threads party to the barrier have called this function, they are all released simultaneously. If a *timeout* is provided, it is used in preference to any that was supplied to the class constructor.

The return value is an integer in the range 0 to *parties* – 1, different for each thread. This can be used to select a thread to do some special housekeeping, e.g.:

```python
i = barrier.wait()
if i == 0:
    # Only one thread needs to print this
    print("passed the barrier")
```

If an *action* was provided to the constructor, one of the threads will have called it prior to being released. Should this call raise an error, the barrier is put into the broken state.

If the call times out, the barrier is put into the broken state.

This method may raise a `BrokenBarrierError` exception if the barrier is broken or reset while a thread is waiting.

**reset()**

Return the barrier to the default, empty state. Any threads waiting on it will receive the `BrokenBarrierError` exception.

Note that using this function may can require some external synchronization if there are other threads whose state is unknown. If a barrier is broken it may be better to just leave it
and create a new one.

**abort()**

Put the barrier into a broken state. This causes any active or future calls to `wait()` to fail with the `BrokenBarrierError`. Use this for example if one of the needs to abort, to avoid deadlocking the application.

It may be preferable to simply create the barrier with a sensible `timeout` value to automatically guard against one of the threads going awry.

**parties**

The number of threads required to pass the barrier.

**n_waiting**

The number of threads currently waiting in the barrier.

**broken**

A boolean that is `True` if the barrier is in the broken state.

**exception** threading. `BrokenBarrierError`

This exception, a subclass of `RuntimeError`, is raised when the `Barrier` object is reset or broken.
17.1.10. Using locks, conditions, and semaphores in the `with` statement

All of the objects provided by this module that have `acquire()` and `release()` methods can be used as context managers for a `with` statement. The `acquire()` method will be called when the block is entered, and `release()` will be called when the block is exited. Hence, the following snippet:

```python
with some_lock:
    # do something...
```

is equivalent to:

```python
some_lock.acquire()
try:
    # do something...
finally:
    some_lock.release()
```

Currently, `Lock`, `RLock`, `Condition`, `Semaphore`, and `BoundedSemaphore` objects may be used as `with` statement context managers.
17.2. multiprocessing — Process-based parallelism
17.2.1. Introduction

`multiprocessing` is a package that supports spawning processes using an API similar to the `threading` module. The `multiprocessing` package offers both local and remote concurrency, effectively side-stepping the `Global Interpreter Lock` by using subprocesses instead of threads. Due to this, the `multiprocessing` module allows the programmer to fully leverage multiple processors on a given machine. It runs on both Unix and Windows.

**Note:** Some of this package's functionality requires a functioning shared semaphore implementation on the host operating system. Without one, the `multiprocessing.synchronize` module will be disabled, and attempts to import it will result in an `ImportError`. See issue 3770 for additional information.

**Note:** Functionality within this package requires that the `__main__` module be importable by the children. This is covered in the `Programming guidelines` however it is worth pointing out here. This means that some examples, such as the `multiprocessing.pool.Pool` examples will not work in the interactive interpreter. For example:

```python
>>> from multiprocessing import Pool
>>> p = Pool(5)
>>> def f(x):
...     return x*x
... >>> p.map(f, [1,2,3])
Process PoolWorker-1:
Process PoolWorker-2:
```
(If you try this it will actually output three full tracebacks interleaved in a semi-random fashion, and then you may have to stop the master process somehow.)

17.2.1.1. The Process class

In multiprocessing, processes are spawned by creating a Process object and then calling its start() method. Process follows the API of threading.Thread. A trivial example of a multiprocess program is

```
from multiprocessing import Process

def f(name):
    print('hello', name)

if __name__ == '__main__':
    p = Process(target=f, args=('bob',))
    p.start()
    p.join()
```

To show the individual process IDs involved, here is an expanded example:

```
from multiprocessing import Process
import os
```
def info(title):
    print(title)
    print('module name:', __name__)
    if hasattr(os, 'getppid'):  # only available on Unix
        print('parent process:', os.getppid())
    print('process id:', os.getpid())

def f(name):
    info('function f')
    print('hello', name)

if __name__ == '__main__':
    info('main line')
    p = Process(target=f, args=('bob',))
    p.start()
    p.join()

For an explanation of why the if __name__ == '__main__' part is necessary, see *Programming guidelines*.

### 17.2.1.2. Contexts and start methods

Depending on the platform, multiprocessing supports three ways to start a process. These *start methods* are

*spawn*

The parent process starts a fresh python interpreter process. The child process will only inherit those resources necessary to run the process objects *run()* method. In particular, unnecessary file descriptors and handles from the parent process will not be inherited. Starting a process using this method is rather slow compared to using *fork* or *forkserver*.

Available on Unix and Windows. The default on Windows.
**fork**

The parent process uses `os.fork()` to fork the Python interpreter. The child process, when it begins, is effectively identical to the parent process. All resources of the parent are inherited by the child process. Note that safely forking a multithreaded process is problematic.

Available on Unix only. The default on Unix.

**forkserver**

When the program starts and selects the *forkserver* start method, a server process is started. From then on, whenever a new process is needed, the parent process connects to the server and requests that it fork a new process. The fork server process is single threaded so it is safe for it to use `os.fork()`. No unnecessary resources are inherited.

Available on Unix platforms which support passing file descriptors over Unix pipes.

_Changed in version 3.4:_ *spawn* added on all unix platforms, and *forkserver* added for some unix platforms. Child processes no longer inherit all of the parents inheritable handles on Windows.

On Unix using the *spawn* or *forkserver* start methods will also start a *semaphore tracker* process which tracks the unlinked named semaphores created by processes of the program. When all processes have exited the semaphore tracker unlinks any remaining semaphores. Usually there should be none, but if a process was killed by a signal there may some “leaked” semaphores. (Unlinking the named semaphores is a serious matter since the system allows only a limited number, and they will not be automatically unlinked until the next reboot.)
To select a start method you use the `set_start_method()` in the `if __name__ == '__main__'` clause of the main module. For example:

```python
import multiprocessing as mp

def foo(q):
    q.put('hello')

if __name__ == '__main__':
    mp.set_start_method('spawn')
    q = mp.Queue()
    p = mp.Process(target=foo, args=(q,))
    p.start()
    print(q.get())
    p.join()
```

`set_start_method()` should not be used more than once in the program.

Alternatively, you can use `get_context()` to obtain a context object. Context objects have the same API as the multiprocessing module, and allow one to use multiple start methods in the same program.

```python
import multiprocessing as mp

def foo(q):
    q.put('hello')

if __name__ == '__main__':
    ctx = mp.get_context('spawn')
    q = ctx.Queue()
    p = ctx.Process(target=foo, args=(q,))
    p.start()
    print(q.get())
```
Note that objects related to one context may not be compatible with processes for a different context. In particular, locks created using the fork context cannot be passed to a processes started using the spawn or forkserver start methods.

A library which wants to use a particular start method should probably use get_context() to avoid interfering with the choice of the library user.

17.2.1.3. Exchanging objects between processes

multiprocessing supports two types of communication channel between processes:

Queues

The Queue class is a near clone of queue.Queue. For example:

```python
from multiprocessing import Process, Queue
def f(q):
    q.put([42, None, 'hello'])

if __name__ == '__main__':
    q = Queue()
    p = Process(target=f, args=(q,))
    p.start()
    print(q.get())  # prints '[42, None, 'hello']
p.join()
```

Queues are thread and process safe.
Pipes

The `Pipe()` function returns a pair of connection objects connected by a pipe which by default is duplex (two-way). For example:

```python
from multiprocessing import Process, Pipe

def f(conn):
    conn.send([42, None, 'hello'])
    conn.close()

if __name__ == '__main__':
    parent_conn, child_conn = Pipe()
    p = Process(target=f, args=(child_conn,))
    p.start()
    print(parent_conn.recv())  # prints "[42, None, 'hello']"
    p.join()
```

The two connection objects returned by `Pipe()` represent the two ends of the pipe. Each connection object has `send()` and `recv()` methods (among others). Note that data in a pipe may become corrupted if two processes (or threads) try to read from or write to the same end of the pipe at the same time. Of course there is no risk of corruption from processes using different ends of the pipe at the same time.

17.2.1.4. Synchronization between processes

`multiprocessing` contains equivalents of all the synchronization primitives from `threading`. For instance one can use a lock to ensure that only one process prints to standard output at a time:
from multiprocessing import Process, Lock

def f(l, i):
    l.acquire()
    print('hello world', i)
    l.release()

if __name__ == '__main__':
    lock = Lock()

    for num in range(10):
        Process(target=f, args=(lock, num)).start()

Without using the lock output from the different processes is liable to get all mixed up.

17.2.1.5. Sharing state between processes

As mentioned above, when doing concurrent programming it is usually best to avoid using shared state as far as possible. This is particularly true when using multiple processes.

However, if you really do need to use some shared data then multiprocessing provides a couple of ways of doing so.

Shared memory

Data can be stored in a shared memory map using Value or Array. For example, the following code

from multiprocessing import Process, Value, Array

def f(n, a):
    n.value = 3.1415927
```python
for i in range(len(a)):
    a[i] = -a[i]

if __name__ == '__main__':
    num = Value('d', 0.0)
    arr = Array('i', range(10))

    p = Process(target=f, args=(num, arr))
    p.start()
    p.join()

    print(num.value)
    print(arr[:])
```

will print

```
3.1415927
[0, -1, -2, -3, -4, -5, -6, -7, -8, -9]
```

The 'd' and 'i' arguments used when creating `num` and `arr` are typecodes of the kind used by the `array` module: 'd' indicates a double precision float and 'i' indicates a signed integer. These shared objects will be process and thread-safe.

For more flexibility in using shared memory one can use the `multiprocessing.sharedctypes` module which supports the creation of arbitrary ctypes objects allocated from shared memory.

**Server process**

A manager object returned by `Manager()` controls a server process which holds Python objects and allows other processes to manipulate them using proxies.
A manager returned by Manager() will support types list, dict, Namespace, Lock, RLock, Semaphore, BoundedSemaphore, Condition, Event, Barrier, Queue, Value and Array. For example,

```python
from multiprocessing import Process, Manager

def f(d, l):
    d[1] = '1'
    d[2] = 2
    d[0.25] = None
l.reverse()

if __name__ == '__main__':
    with Manager() as manager:
        d = manager.dict()
        l = manager.list(range(10))

        p = Process(target=f, args=(d, l))
        p.start()
        p.join()

        print(d)
        print(l)
```

will print

```
{0.25: None, 1: '1', '2': 2}
[9, 8, 7, 6, 5, 4, 3, 2, 1, 0]
```

Server process managers are more flexible than using shared memory objects because they can be made to support arbitrary object types. Also, a single manager can be shared by processes on different computers over a network. They are, however, slower than using shared memory.
17.2.1.6. Using a pool of workers

The **Pool** class represents a pool of worker processes. It has methods which allows tasks to be offloaded to the worker processes in a few different ways.

For example:

```python
from multiprocessing import Pool
from time import sleep

def f(x):
    return x**x

if __name__ == '__main__':
    # start 4 worker processes
    with Pool(processes=4) as pool:
        # print "[0, 1, 4,..., 81]"
        print(pool.map(f, range(10)))

        # print same numbers in arbitrary order
        for i in pool.imap_unordered(f, range(10)):
            print(i)

        # evaluate "f(10)" asynchronously
        res = pool.apply_async(f, [10])
        print(res.get(timeout=1))  # print

        # make worker sleep for 10 secs
        res = pool.apply_async(sleep, 10)
        print(res.get(timeout=1))  # raise

        # exiting the 'with'-block has stopped the pool
```
Note that the methods of a pool should only ever be used by the process which created it.
17.2.2. Reference

The multiprocessing package mostly replicates the API of the threading module.

17.2.2.1. Process and exceptions

```python
class multiprocessing.Process(group=None, target=None, name=None, args=(), kwargs={}, *, daemon=None)
```

Process objects represent activity that is run in a separate process. The Process class has equivalents of all the methods of threading.Thread.

The constructor should always be called with keyword arguments. group should always be None; it exists solely for compatibility with threading.Thread. target is the callable object to be invoked by the run() method. It defaults to None, meaning nothing is called. name is the process name (see name for more details). args is the argument tuple for the target invocation. kwargs is a dictionary of keyword arguments for the target invocation. If provided, the keyword-only daemon argument sets the process daemon flag to True or False. If None (the default), this flag will be inherited from the creating process.

By default, no arguments are passed to target.

If a subclass overrides the constructor, it must make sure it invokes the base class constructor (Process.__init__()) before doing anything else to the process.

*Changed in version 3.3:* Added the daemon argument.
**run()**
Method representing the process’s activity.

You may override this method in a subclass. The standard `run()` method invokes the callable object passed to the object’s constructor as the target argument, if any, with sequential and keyword arguments taken from the `args` and `kwargs` arguments, respectively.

**start()**
Start the process’s activity.

This must be called at most once per process object. It arranges for the object’s `run()` method to be invoked in a separate process.

**join([timeout])**
If the optional argument `timeout` is None (the default), the method blocks until the process whose `join()` method is called terminates. If `timeout` is a positive number, it blocks at most `timeout` seconds.

A process can be joined many times.

A process cannot join itself because this would cause a deadlock. It is an error to attempt to join a process before it has been started.

**name**
The process’s name. The name is a string used for identification purposes only. It has no semantics. Multiple processes may be given the same name.
The initial name is set by the constructor. If no explicit name is provided to the constructor, a name of the form ‘Process-N_1:N_2:...:N_k’ is constructed, where each N_k is the N-th child of its parent.

**is_alive()**

Return whether the process is alive.

Roughly, a process object is alive from the moment the **start()** method returns until the child process terminates.

**daemon**

The process’s daemon flag, a Boolean value. This must be set before **start()** is called.

The initial value is inherited from the creating process.

When a process exits, it attempts to terminate all of its daemonic child processes.

Note that a daemonic process is not allowed to create child processes. Otherwise a daemonic process would leave its children orphaned if it gets terminated when its parent process exits. Additionally, these are **not** Unix daemons or services, they are normal processes that will be terminated (and not joined) if non-daemonic processes have exited.

In addition to the **threading.Thread** API, **Process** objects also support the following attributes and methods:

**pid**

Return the process ID. Before the process is spawned, this will be None.
**exitcode**

The child’s exit code. This will be `None` if the process has not yet terminated. A negative value `-N` indicates that the child was terminated by signal `N`.

**authkey**

The process’s authentication key (a byte string).

When `multiprocessing` is initialized the main process is assigned a random string using `os.urandom()`.

When a `Process` object is created, it will inherit the authentication key of its parent process, although this may be changed by setting `authkey` to another byte string.

See *Authentication keys*.

**sentinel**

A numeric handle of a system object which will become “ready” when the process ends.

You can use this value if you want to wait on several events at once using `multiprocessing.connection.wait()`. Otherwise calling `join()` is simpler.

On Windows, this is an OS handle usable with the `WaitForSingleObject` and `WaitForMultipleObjects` family of API calls. On Unix, this is a file descriptor usable with primitives from the `select` module.

*New in version 3.3.*

**terminate()**
Terminate the process. On Unix this is done using the `SIGTERM` signal; on Windows `TerminateProcess()` is used. Note that exit handlers and finally clauses, etc., will not be executed.

Note that descendant processes of the process will *not* be terminated – they will simply become orphaned.

**Warning:** If this method is used when the associated process is using a pipe or queue then the pipe or queue is liable to become corrupted and may become unusable by other process. Similarly, if the process has acquired a lock or semaphore etc. then terminating it is liable to cause other processes to deadlock.

Note that the `start()`, `join()`, `is_alive()`, `terminate()` and `exitcode` methods should only be called by the process that created the process object.

Example usage of some of the methods of `Process`:

```python
>>> import multiprocessing, time, signal
>>> p = multiprocessing.Process(target=time.sleep)
>>> print(p, p.is_alive())
<Process(Process-1, initial)> False
>>> p.start()
>>> print(p, p.is_alive())
<Process(Process-1, started)> True
>>> p.terminate()
>>> time.sleep(0.1)
>>> print(p, p.is_alive())
<Process(Process-1, stopped[SIGTERM])> False
>>> p.exitcode == -signal.SIGTERM
True
```
exception multiprocessing.ProcessError

The base class of all multiprocessing exceptions.

exception multiprocessing.BufferTooShort

Exception raised by Connection.recv_bytes_into() when the supplied buffer object is too small for the message read.

If e is an instance of BufferTooShort then e.args[0] will give the message as a byte string.

exception multiprocessing.AuthenticationError

Raised when there is an authentication error.

exception multiprocessing.TimeoutError

Raised by methods with a timeout when the timeout expires.

17.2.2.2. Pipes and Queues

When using multiple processes, one generally uses message passing for communication between processes and avoids having to use any synchronization primitives like locks.

For passing messages one can use Pipe() (for a connection between two processes) or a queue (which allows multiple producers and consumers).

The Queue, SimpleQueue and JoinableQueue types are multi-producer, multi-consumer FIFO queues modelled on the queue.Queue class in the standard library. They differ in that Queue lacks the task_done() and join() methods introduced into Python 2.5's queue.Queue class.

If you use JoinableQueue then you must call
JoinableQueue.task_done() for each task removed from the queue or else the semaphore used to count the number of unfinished tasks may eventually overflow, raising an exception.

Note that one can also create a shared queue by using a manager object – see Managers.

**Note:** multiprocessing uses the usual queue.Empty and queue.Full exceptions to signal a timeout. They are not available in the multiprocessing namespace so you need to import them from queue.

**Note:** When an object is put on a queue, the object is pickled and a background thread later flushes the pickled data to an underlying pipe. This has some consequences which are a little surprising, but should not cause any practical difficulties – if they really bother you then you can instead use a queue created with a manager.

1. After putting an object on an empty queue there may be an infinitesimal delay before the queue’s empty() method returns False and get_nowait() can return without raising queue.Empty.
2. If multiple processes are enqueuing objects, it is possible for the objects to be received at the other end out-of-order. However, objects enqueued by the same process will always be in the expected order with respect to each other.

**Warning:** If a process is killed using Process.terminate() or os.kill() while it is trying to use a Queue, then the data in the queue is likely to become corrupted. This may cause any other process to get an exception when it tries to use the queue later on.
Warning: As mentioned above, if a child process has put items on a queue (and it has not used `JoinableQueue.cancel_join_thread`), then that process will not terminate until all buffered items have been flushed to the pipe.

This means that if you try joining that process you may get a deadlock unless you are sure that all items which have been put on the queue have been consumed. Similarly, if the child process is non-daemonic then the parent process may hang on exit when it tries to join all its non-daemonic children.

Note that a queue created using a manager does not have this issue. See Programming guidelines.

For an example of the usage of queues for interprocess communication see Examples.

```python
multiprocessing.Pipe([duplex])
```
Returns a pair `(conn1, conn2)` of `Connection` objects representing the ends of a pipe.

If `duplex` is True (the default) then the pipe is bidirectional. If `duplex` is False then the pipe is unidirectional: `conn1` can only be used for receiving messages and `conn2` can only be used for sending messages.

```python
class multiprocessing.Queue([maxsize])
```
Returns a process shared queue implemented using a pipe and a few locks/semaphores. When a process first puts an item on the queue a feeder thread is started which transfers objects from a buffer into the pipe.
The usual `queue.Empty` and `queue.Full` exceptions from the standard library's `queue` module are raised to signal timeouts.

`Queue` implements all the methods of `queue.Queue` except for `task_done()` and `join()`.

`qsize()`
Return the approximate size of the queue. Because of multithreading/multiprocessing semantics, this number is not reliable.

Note that this may raise `NotImplementedError` on Unix platforms like Mac OS X where `sem_getvalue()` is not implemented.

`empty()`
Return `True` if the queue is empty, `False` otherwise. Because of multithreading/multiprocessing semantics, this is not reliable.

`full()`
Return `True` if the queue is full, `False` otherwise. Because of multithreading/multiprocessing semantics, this is not reliable.

`put(obj[, block[, timeout]])`
Put `obj` into the queue. If the optional argument `block` is `True` (the default) and `timeout` is `None` (the default), block if necessary until a free slot is available. If `timeout` is a positive number, it blocks at most `timeout` seconds and raises the `queue.Full` exception if no free slot was available within that time. Otherwise (`block` is `False`), put an item on the queue if a free slot is immediately available, else raise the `queue.Full` exception (`timeout` is ignored in that case).
put_nowait(obj)
Equivalent to put(obj, False).

get([block[, timeout]])
Remove and return an item from the queue. If optional args
block is True (the default) and timeout is None (the default),
block if necessary until an item is available. If timeout is a
positive number, it blocks at most timeout seconds and raises
the queue.Empty exception if no item was available within that
time. Otherwise (block is False), return an item if one is
immediately available, else raise the queue.Empty exception
(timeout is ignored in that case).

get_nowait()
Equivalent to get(False).

multiprocessing.Queue has a few additional methods not
found in queue.Queue. These methods are usually unnecessary
for most code:

close()
Indicate that no more data will be put on this queue by the
current process. The background thread will quit once it has
flushed all buffered data to the pipe. This is called automatically
when the queue is garbage collected.

join_thread()
Join the background thread. This can only be used after
close() has been called. It blocks until the background thread
exits, ensuring that all data in the buffer has been flushed to the
pipe.
By default if a process is not the creator of the queue then on exit it will attempt to join the queue's background thread. The process can call `cancel_join_thread()` to make `join_thread()` do nothing.

`cancel_join_thread()`
Prevent `join_thread()` from blocking. In particular, this prevents the background thread from being joined automatically when the process exits – see `join_thread()`.

A better name for this method might be `allow_exit_without_flush()`. It is likely to cause enqueued data to be lost, and you almost certainly will not need to use it. It is really only there if you need the current process to exit immediately without waiting to flush enqueued data to the underlying pipe, and you don’t care about lost data.

`class multiprocessing.SimpleQueue`
It is a simplified `Queue` type, very close to a locked `Pipe`.

`empty()`
Return `True` if the queue is empty, `False` otherwise.

`get()`
Remove and return an item from the queue.

`put(item)`
Put `item` into the queue.

`class multiprocessing.JoinableQueue([maxsize])`
`JoinableQueue`, a `Queue` subclass, is a queue which additionally has `task_done()` and `join()` methods.
**task_done()**

Indicate that a formerly enqueued task is complete. Used by queue consumers. For each `get()` used to fetch a task, a subsequent call to `task_done()` tells the queue that the processing on the task is complete.

If a `join()` is currently blocking, it will resume when all items have been processed (meaning that a `task_done()` call was received for every item that had been `put()` into the queue).

Raises a `ValueError` if called more times than there were items placed in the queue.

**join()**

Block until all items in the queue have been gotten and processed.

The count of unfinished tasks goes up whenever an item is added to the queue. The count goes down whenever a consumer calls `task_done()` to indicate that the item was retrieved and all work on it is complete. When the count of unfinished tasks drops to zero, `join()` unblocks.

17.2.2.3. Miscellaneous

**multiprocessing.**`active_children()`

Return list of all live children of the current process.

Calling this has the side affect of “joining” any processes which have already finished.

**multiprocessing.**`cpu_count()`
Return the number of CPUs in the system. May raise `NotImplementedError`.

**See also:** `os.cpu_count()`

`multiprocessing.current_process()`  
Return the `Process` object corresponding to the current process.

An analogue of `threading.current_thread()`.

`multiprocessing.freeze_support()`  
Add support for when a program which uses `multiprocessing` has been frozen to produce a Windows executable. (Has been tested with `py2exe`, `PyInstaller` and `cx_Freeze`.)

One needs to call this function straight after the `if __name__ == '__main__'` line of the main module. For example:

```python
from multiprocessing import Process, freeze_support

def f():
    print('hello world!')

if __name__ == '__main__':
    freeze_support()
    Process(target=f).start()
```

If the `freeze_support()` line is omitted then trying to run the frozen executable will raise `RuntimeError`.

If the module is being run normally by the Python interpreter then `freeze_support()` has no effect.
multiprocessing.get_all_start_methods()

Returns a list of the supported start methods, the first of which is the default. The possible start methods are 'fork', 'spawn' and 'forkserver'. On Windows only 'spawn' is available. On Unix 'fork' and 'spawn' are always supported, with 'fork' being the default.

*New in version 3.4.*

multiprocessing.get_context(method=None)

Return a context object which has the same attributes as the multiprocessing module.

If method is None then the default context is returned. Otherwise method should be 'fork', 'spawn', 'forkserver'. ValueError is raised if the specified start method is not available.

*New in version 3.4.*

multiprocessing.get_start_method(allow_none=False)

Return the name of start method used for starting processes.

If the start method has not been fixed and allow_none is false, then the start method is fixed to the default and the name is returned. If the start method has not been fixed and allow_none is true then None is returned.

The return value can be 'fork', 'spawn', 'forkserver' or None. 'fork' is the default on Unix, while 'spawn' is the default on Windows.

*New in version 3.4.*
multiprocessing.set_executable()

Sets the path of the Python interpreter to use when starting a child process. (By default `sys.executable` is used). Embedders will probably need to do some thing like

```python
set_executable(os.path.join(sys.exec_prefix, 'pythonw.exe'))
```

before they can create child processes.

*Changed in version 3.4:* Now supported on Unix when the 'spawn' start method is used.

multiprocessing.set_start_method(method)

Set the method which should be used to start child processes. `method` can be 'fork', 'spawn' or 'forkserver'.

Note that this should be called at most once, and it should be protected inside the `if __name__ == '__main__'` clause of the main module.

*New in version 3.4.*

**Note:** `multiprocessing` contains no analogues of `threading.active_count()`, `threading.enumerate()`, `threading.settrace()`, `threading.setprofile()`, `threading.Timer`, or `threading.local`.

17.2.2.4. Connection Objects

Connection objects allow the sending and receiving of picklable objects or strings. They can be thought of as message oriented connected sockets.
Connection objects are usually created using \texttt{Pipe()} – see also \textit{Listeners and Clients}.

\texttt{class multiprocessing.Connection}

\texttt{send(obj)}

Send an object to the other end of the connection which should be read using \texttt{recv()}.

The object must be picklable. Very large pickles (approximately 32 MB+ though it depends on the OS) may raise a \texttt{ValueError} exception.

\texttt{recv()}

Return an object sent from the other end of the connection using \texttt{send()}. Blocks until there is something to receive. Raises \texttt{EOFError} if there is nothing left to receive and the other end was closed.

\texttt{fileno()}

Return the file descriptor or handle used by the connection.

\texttt{close()}

Close the connection.

This is called automatically when the connection is garbage collected.

\texttt{poll([timeout])}

Return whether there is any data available to be read.

If \texttt{timeout} is not specified then it will return immediately. If \texttt{timeout} is a number then this specifies the maximum time in
seconds to block. If `timeout` is `None` then an infinite timeout is used.

Note that multiple connection objects may be polled at once by using `multiprocessing.connection.wait()`.

**send_bytes**(`buffer[, offset[, size]]`)  
Send byte data from a `bytes-like object` as a complete message.

If `offset` is given then data is read from that position in `buffer`. If `size` is given then that many bytes will be read from `buffer`. Very large buffers (approximately 32 MB+, though it depends on the OS) may raise a `ValueError` exception.

**recv_bytes**(`[maxlength]`)  
Return a complete message of byte data sent from the other end of the connection as a string. Blocks until there is something to receive. Raises `EOFError` if there is nothing left to receive and the other end has closed.

If `maxlength` is specified and the message is longer than `maxlength` then `OSError` is raised and the connection will no longer be readable.

*Changed in version 3.3:* This function used to raise a `IOError`, which is now an alias of `OSError`.

**recv_bytes_into**(`buffer[, offset]`)  
Read into `buffer` a complete message of byte data sent from the other end of the connection and return the number of bytes in the message. Blocks until there is something to receive. Raises
**E0FError** if there is nothing left to receive and the other end was closed.

*buffer* must be a writable *bytes-like object*. If *offset* is given then the message will be written into the buffer from that position. Offset must be a non-negative integer less than the length of *buffer* (in bytes).

If the buffer is too short then a **BufferTooShort** exception is raised and the complete message is available as `e.args[0]` where `e` is the exception instance.

*Changed in version 3.3:* Connection objects themselves can now be transferred between processes using `Connection.send()` and `Connection.recv()`.

*New in version 3.3:* Connection objects now support the context manager protocol – see *Context Manager Types*. `__enter__()` returns the connection object, and `__exit__()` calls `close()`.

For example:

```python
>>> from multiprocessing import Pipe
>>> a, b = Pipe()
>>> a.send([1, 'hello', None])
>>> b.recv()
[1, 'hello', None]
>>> b.send_bytes(b'thank you')
>>> a.recv_bytes()
b'thank you'
>>> import array
>>> arr1 = array.array('i', range(5))
>>> arr2 = array.array('i', [0] * 10)
>>> a.send_bytes(arr1)
```
Warning: The `Connection.recv()` method automatically unpickles the data it receives, which can be a security risk unless you can trust the process which sent the message.

Therefore, unless the connection object was produced using `Pipe()` you should only use the `recv()` and `send()` methods after performing some sort of authentication. See `Authentication keys`.

Warning: If a process is killed while it is trying to read or write to a pipe then the data in the pipe is likely to become corrupted, because it may become impossible to be sure where the message boundaries lie.

17.2.2.5. Synchronization primitives

Generally synchronization primitives are not as necessary in a multiprocess program as they are in a multithreaded program. See the documentation for `threading` module.

Note that one can also create synchronization primitives by using a manager object – see `Managers`.

```python
class multiprocessing.Barrier(parties[, action[, timeout]])
A barrier object: a clone of `threading.Barrier`.

New in version 3.3.
```
**class multiprocessing.**\texttt{BoundedSemaphore}([\texttt{value}])
A bounded semaphore object: a clone of \texttt{threading.BoundedSemaphore}.

(On Mac OS X, this is indistinguishable from \texttt{Semaphore} because \texttt{sem_getvalue()} is not implemented on that platform).

**class multiprocessing.**\texttt{Condition}([\texttt{lock}])
A condition variable: an alias for \texttt{threading.Condition}.

If \texttt{lock} is specified then it should be a \texttt{Lock} or \texttt{RLock} object from \texttt{multiprocessing}.

*Changed in version 3.3*: The \texttt{wait_for()} method was added.

**class multiprocessing.**\texttt{Event}
A clone of \texttt{threading.Event}.

**class multiprocessing.**\texttt{Lock}
A non-recursive lock object: a clone of \texttt{threading.Lock}.

**class multiprocessing.**\texttt{RLock}
A recursive lock object: a clone of \texttt{threading.RLock}.

**class multiprocessing.**\texttt{Semaphore}([\texttt{value}])
A semaphore object: a clone of \texttt{threading.Semaphore}.

**Note:** The acquire() and wait() methods of each of these types treat negative timeouts as zero timeouts. This differs from \texttt{threading} where, since version 3.2, the equivalent acquire() methods treat negative timeouts as infinite timeouts.
On Mac OS X, `sem_timedwait` is unsupported, so calling `acquire()` with a timeout will emulate that function's behavior using a sleeping loop.

**Note:** If the SIGINT signal generated by Ctrl-C arrives while the main thread is blocked by a call to
`BoundedSemaphore.acquire()`, `Lock.acquire()`,
`RLock.acquire()`, `Semaphore.acquire()`,
`Condition.acquire()` or `Condition.wait()` then the call will be immediately interrupted and `KeyboardInterrupt` will be raised.

This differs from the behaviour of `threading` where SIGINT will be ignored while the equivalent blocking calls are in progress.

### 17.2.2.6. Shared ctypes Objects

It is possible to create shared objects using shared memory which can be inherited by child processes.

```
import multiprocessing

Value(typecode_or_type, *args, lock=True)
```

Return a `ctypes` object allocated from shared memory. By default the return value is actually a synchronized wrapper for the object. The object itself can be accessed via the `value` attribute of a `Value`.

`typecode_or_type` determines the type of the returned object: it is either a `ctypes` type or a one character `typecode` of the kind used by the `array` module. `*args` is passed on to the constructor for the type.
If `lock` is `True` (the default) then a new recursive lock object is created to synchronize access to the value. If `lock` is a `Lock` or `RLock` object then that will be used to synchronize access to the value. If `lock` is `False` then access to the returned object will not be automatically protected by a lock, so it will not necessarily be “process-safe”.

Operations like `+=` which involve a read and write are not atomic. So if, for instance, you want to atomically increment a shared value it is insufficient to just do

```python
counter.value += 1
```

Assuming the associated lock is recursive (which it is by default) you can instead do

```python
with counter.get_lock():
    counter.value += 1
```

Note that `lock` is a keyword-only argument.

`multiprocessing.Array(typecode_or_type, size_or_initializer, *, lock=True)`

Return a ctypes array allocated from shared memory. By default the return value is actually a synchronized wrapper for the array.

`typecode_or_type` determines the type of the elements of the returned array: it is either a ctypes type or a one character typecode of the kind used by the `array` module. If `size_or_initializer` is an integer, then it determines the length of the array, and the array will be initially zeroed. Otherwise, `size_or_initializer` is a sequence which is used to initialize the array and whose length determines the length of the array.
If `lock` is `True` (the default) then a new lock object is created to synchronize access to the value. If `lock` is a `Lock` or `RLock` object then that will be used to synchronize access to the value. If `lock` is `False` then access to the returned object will not be automatically protected by a lock, so it will not necessarily be “process-safe”.

Note that `lock` is a keyword only argument.

Note that an array of `ctypes.c_char` has `value` and `raw` attributes which allow one to use it to store and retrieve strings.

17.2.2.6.1. The `multiprocessing.sharedctypes` module

The `multiprocessing.sharedctypes` module provides functions for allocating `ctypes` objects from shared memory which can be inherited by child processes.

**Note:** Although it is possible to store a pointer in shared memory remember that this will refer to a location in the address space of a specific process. However, the pointer is quite likely to be invalid in the context of a second process and trying to dereference the pointer from the second process may cause a crash.

`multiprocessing.sharedctypes.RawArray(typecode_or_type, size_or_initializer)`

Return a ctypes array allocated from shared memory.

`typecode_or_type` determines the type of the elements of the returned array: it is either a ctypes type or a one character typecode of the kind used by the `array` module. If `size_or_initializer` is an integer then it determines the length of the
array, and the array will be initially zeroed. Otherwise size_or_initializer is a sequence which is used to initialize the array and whose length determines the length of the array.

Note that setting and getting an element is potentially non-atomic – use Array() instead to make sure that access is automatically synchronized using a lock.

multiprocessing.sharedctypes.RawValue(typecode_or_type *args)

Return a ctypes object allocated from shared memory.

typecode_or_type determines the type of the returned object: it is either a ctypes type or a one character typecode of the kind used by the array module. *args is passed on to the constructor for the type.

Note that setting and getting the value is potentially non-atomic – use Value() instead to make sure that access is automatically synchronized using a lock.

Note that an array of ctypes.c_char has value and raw attributes which allow one to use it to store and retrieve strings – see documentation for ctypes.

multiprocessing.sharedctypes.Array(typecode_or_type, size_or_initializer, *, lock=True)

The same as RawArray() except that depending on the value of lock a process-safe synchronization wrapper may be returned instead of a raw ctypes array.

If lock is True (the default) then a new lock object is created to synchronize access to the value. If lock is a Lock or RLock object
then that will be used to synchronize access to the value. If \textit{lock} is \texttt{False} then access to the returned object will not be automatically protected by a lock, so it will not necessarily be “process-safe”.

Note that \textit{lock} is a keyword-only argument.

\begin{verbatim}
multiprocessing.sharedctypes.Value(typecode_or_type, *args, lock=True)
\end{verbatim}

The same as \texttt{RawValue()} except that depending on the value of \textit{lock} a process-safe synchronization wrapper may be returned instead of a raw ctypes object.

If \textit{lock} is \texttt{True} (the default) then a new lock object is created to synchronize access to the value. If \textit{lock} is a \texttt{Lock} or \texttt{RLock} object then that will be used to synchronize access to the value. If \textit{lock} is \texttt{False} then access to the returned object will not be automatically protected by a lock, so it will not necessarily be “process-safe”.

Note that \textit{lock} is a keyword-only argument.

\begin{verbatim}
multiprocessing.sharedctypes.copy(obj)
\end{verbatim}

Return a ctypes object allocated from shared memory which is a copy of the ctypes object \texttt{obj}.

\begin{verbatim}
multiprocessing.sharedctypes.synchronized(obj[, lock])
\end{verbatim}

Return a process-safe wrapper object for a ctypes object which uses \textit{lock} to synchronize access. If \textit{lock} is \texttt{None} (the default) then a \texttt{multiprocessing.RLock} object is created automatically.

A synchronized wrapper will have two methods in addition to those of the object it wraps: \texttt{get_obj()} returns the wrapped object and \texttt{get_lock()} returns the lock object used for synchronization.
Note that accessing the ctypes object through the wrapper can be a lot slower than accessing the raw ctypes object.

The table below compares the syntax for creating shared ctypes objects from shared memory with the normal ctypes syntax. (In the table `MyStruct` is some subclass of `ctypes.Structure`.)

<table>
<thead>
<tr>
<th>ctypes</th>
<th>sharedctypes using type</th>
<th>sharedctypes using typecode</th>
</tr>
</thead>
<tbody>
<tr>
<td>c_double(2.4)</td>
<td>RawValue(c_double, 2.4)</td>
<td>RawValue('d', 2.4)</td>
</tr>
<tr>
<td>MyStruct(4, 6)</td>
<td>RawValue(MyStruct, 4, 6)</td>
<td></td>
</tr>
<tr>
<td>(c_short * 7)()</td>
<td>RawArray(c_short, 7)</td>
<td>RawArray('h', 7)</td>
</tr>
<tr>
<td>(c_int * 3)(9, 2, 8)</td>
<td>RawArray(c_int, (9, 2, 8))</td>
<td>RawArray('i', (9, 2, 8))</td>
</tr>
</tbody>
</table>

Below is an example where a number of ctypes objects are modified by a child process:

```
from multiprocessing import Process, Lock
from multiprocessing.sharedctypes import Value, Array
from ctypes import Structure, c_double

class Point(Structure):
    _fields_ = [('x', c_double), ('y', c_double)]

def modify(n, x, s, A):
    n.value **= 2
    x.value **= 2
    s.value = s.value.upper()
    for a in A:
        a.x **= 2
        a.y **= 2
```
if __name__ == '__main__':
    lock = Lock()

    n = Value('i', 7)
x = Value(c_double, 1.0/3.0, lock=False)
s = Array('c', b'hello world', lock=lock)
A = Array(Point, [(1.875,-6.25), (-5.75,2.0), (2.375,)], lock=lock)

    p = Process(target=modify, args=(n, x, s, A))
p.start()
p.join()

    print(n.value)
    print(x.value)
    print(s.value)
    print(((a.x, a.y) for a in A))

The results printed are

49
0.1111111111111111
HELLO WORLD
[(3.515625, 39.0625), (33.0625, 4.0), (5.640625, 90.

17.2.2.7. Managers

Managers provide a way to create data which can be shared between different processes, including sharing over a network between processes running on different machines. A manager object controls a server process which manages shared objects. Other processes can access the shared objects by using proxies.
multiprocessing.**Manager**()

Returns a started **SyncManager** object which can be used for sharing objects between processes. The returned manager object corresponds to a spawned child process and has methods which will create shared objects and return corresponding proxies.

Manager processes will be shutdown as soon as they are garbage collected or their parent process exits. The manager classes are defined in the *multiprocessing.managers* module:

```python
class multiprocessing.managers.BaseManager([address[, authkey]])

Create a BaseManager object.

Once created one should call **start()** or **get_server().serve_forever()** to ensure that the manager object refers to a started manager process.

**address** is the address on which the manager process listens for new connections. If **address** is **None** then an arbitrary one is chosen.

**authkey** is the authentication key which will be used to check the validity of incoming connections to the server process. If **authkey** is **None** then **current_process().authkey** is used. Otherwise **authkey** is used and it must be a byte string.

**start([initializer[, initargs]])**

Start a subprocess to start the manager. If **initializer** is not **None** then the subprocess will call **initializer(*initargs)** when it starts.
get_server()

Returns a Server object which represents the actual server under the control of the Manager. The Server object supports the serve_forever() method:

```python
>>> from multiprocessing.managers import BaseManager
>>> manager = BaseManager(address=('', 50000),
>>> server = manager.get_server()
>>> server.serve_forever()
```

Server additionally has an address attribute.

connect()

Connect a local manager object to a remote manager process:

```python
>>> from multiprocessing.managers import BaseManager
>>> m = BaseManager(address=('127.0.0.1', 5000))
>>> m.connect()
```

shutdown()

Stop the process used by the manager. This is only available if start() has been used to start the server process.

This can be called multiple times.

register(typeid[, callable[, proxytype[, exposed[, method_to_typeid[, create_method]]]]])

A classmethod which can be used for registering a type or callable with the manager class.

typeid is a “type identifier” which is used to identify a particular type of shared object. This must be a string.
callable is a callable used for creating objects for this type identifier. If a manager instance will be connected to the server using the connect() method, or if the create_method argument is False then this can be left as None.

proxytype is a subclass of BaseProxy which is used to create proxies for shared objects with this typeid. If None then a proxy class is created automatically.

exposed is used to specify a sequence of method names which proxies for this typeid should be allowed to access using BaseProxy._callmethod(). (If exposed is None then proxytype._exposed_ is used instead if it exists.) In the case where no exposed list is specified, all “public methods” of the shared object will be accessible. (Here a “public method” means any attribute which has a __call__() method and whose name does not begin with '_'.)

method_to_typeid is a mapping used to specify the return type of those exposed methods which should return a proxy. It maps method names to typeid strings. (If method_to_typeid is None then proxytype._method_to_typeid_ is used instead if it exists.) If a method's name is not a key of this mapping or if the mapping is None then the object returned by the method will be copied by value.

create_method determines whether a method should be created with name typeid which can be used to tell the server process to create a new shared object and return a proxy for it. By default it is True.

BaseManager instances also have one read-only property:
address

The address used by the manager.

*Changed in version 3.3:* Manager objects support the context manager protocol – see *Context Manager Types.* __enter__() starts the server process (if it has not already started) and then returns the manager object. __exit__() calls shutdown().

In previous versions __enter__() did not start the manager's server process if it was not already started.

class multiprocessing.managers.SyncManager

A subclass of BaseManager which can be used for the synchronization of processes. Objects of this type are returned by multiprocessing.Manager().

It also supports creation of shared lists and dictionaries.

**Barrier** *(parties[, action[, timeout]])*

Create a shared threading.Barrier object and return a proxy for it.

*New in version 3.3.*

**BoundedSemaphore** *(value)*

Create a shared threading.BoundedSemaphore object and return a proxy for it.

**Condition** *(lock)*

Create a shared threading.Condition object and return a proxy for it.

If lock is supplied then it should be a proxy for a
threading.Lock or threading.RLock object.

Changed in version 3.3: The wait_for() method was added.

**Event()**
Create a shared threading.Event object and return a proxy for it.

**Lock()**
Create a shared threading.Lock object and return a proxy for it.

**Namespace()**
Create a shared Namespace object and return a proxy for it.

**Queue([maxsize])**
Create a shared queue.Queue object and return a proxy for it.

**RLock()**
Create a shared threading.RLock object and return a proxy for it.

**Semaphore([value])**
Create a shared threading.Semaphore object and return a proxy for it.

**Array(typecode, sequence)**
Create an array and return a proxy for it.

**Value(typecode, value)**
Create an object with a writable value attribute and return a proxy for it.
dict()
dict(mapping)
dict(sequence)

Create a shared dict object and return a proxy for it.

list()
list(sequence)

Create a shared list object and return a proxy for it.

Note: Modifications to mutable values or items in dict and list proxies will not be propagated through the manager, because the proxy has no way of knowing when its values or items are modified. To modify such an item, you can re-assign the modified object to the container proxy:

```
# create a list proxy and append a mutable object
lproxy = manager.list()
lproxy.append({})
# now mutate the dictionary
d = lproxy[0]
d['a'] = 1
d['b'] = 2
# at this point, the changes to d are not yet sy
# reassigning the dictionary, the proxy is notif
lproxy[0] = d
```

17.2.2.7.1. Namespace objects

A namespace object has no public methods, but does have writable attributes. Its representation shows the values of its attributes.

However, when using a proxy for a namespace object, an attribute
beginning with `'_'` will be an attribute of the proxy and not an attribute of the referent:

```python
global. x = 10
global. y = 'hello'
global. _z = 12.3  # this is an attribute of the proxy
global. z = 12.3

def add(self, x, y):
    return x + y
def mul(self, x, y):
    return x * y

class MyManager(BaseManager):
    pass

MyManager.register('Maths', MathsClass)

if __name__ == '__main__':
    with MyManager() as manager:
        maths = manager.Maths()
        print(maths.add(4, 3))  # prints 7
        print(maths.mul(7, 8))  # prints 56
```
17.2.2.7.3. Using a remote manager

It is possible to run a manager server on one machine and have clients use it from other machines (assuming that the firewalls involved allow it).

Running the following commands creates a server for a single shared queue which remote clients can access:

```python
>>> from multiprocessing.managers import BaseManager
>>> import queue
>>> queue = queue.Queue()
>>> class QueueManager(BaseManager): pass
>>> QueueManager.register('get_queue', callable=lambda: queue)
>>> m = QueueManager(address=('localhost', 50000), authkey=b'abracadabra'
>>> s = m.get_server()
>>> s.serve_forever()
```

One client can access the server as follows:

```python
>>> from multiprocessing.managers import BaseManager
>>> class QueueManager(BaseManager): pass
>>> QueueManager.register('get_queue')
>>> m = QueueManager(address=('foo.bar.org', 50000),
>>> m.connect()
>>> queue = m.get_queue()
>>> queue.put('hello')
```

Another client can also use it:

```python
>>> from multiprocessing.managers import BaseManager
>>> class QueueManager(BaseManager): pass
>>> QueueManager.register('get_queue')
```
Local processes can also access that queue, using the code from above on the client to access it remotely:

```python
>>> from multiprocessing import Process, Queue
>>> from multiprocessing.managers import BaseManager

>>> class Worker(Process):
...     def __init__(self, q):
...         self.q = q
...         super(Worker, self).__init__()

>>> def run(self):
...     self.q.put('local hello')
...

>>> queue = Queue()
>>> w = Worker(queue)
>>> w.start()

class QueueManager(BaseManager): pass

>>> QueueManager.register('get_queue', callable=lambda: lambda)

>>> m = QueueManager(address=('', 50000), authkey=b'abracadabra')
>>> s = m.get_server()
>>> s.serve_forever()
```

### 17.2.2.8. Proxy Objects

A proxy is an object which refers to a shared object which lives (presumably) in a different process. The shared object is said to be the referent of the proxy. Multiple proxy objects may have the same referent.
A proxy object has methods which invoke corresponding methods of its referent (although not every method of the referent will necessarily be available through the proxy). A proxy can usually be used in most of the same ways that its referent can:

```python
>>> from multiprocessing import Manager
>>> manager = Manager()
>>> l = manager.list([i*i for i in range(10)])
>>> print(l)
[0, 1, 4, 9, 16, 25, 36, 49, 64, 81]
>>> print(repr(l))
<ListProxy object, typeid 'list' at 0x...>
>>> l[4]
16
>>> l[2:5]
[4, 9, 16]
```

Notice that applying `str()` to a proxy will return the representation of the referent, whereas applying `repr()` will return the representation of the proxy.

An important feature of proxy objects is that they are picklable so they can be passed between processes. Note, however, that if a proxy is sent to the corresponding manager’s process then unpickling it will produce the referent itself. This means, for example, that one shared object can contain a second:

```python
>>> a = manager.list()
>>> b = manager.list()
>>> a.append(b)  # referent of a now contains
>>> print(a, b)
[[], []]
>>> b.append('hello')
>>> print(a, b)
[[], ['hello']]
```
Note: The proxy types in multiprocessing do nothing to support comparisons by value. So, for instance, we have:

```python
>>> manager.list([1,2,3]) == [1,2,3]
False
```

One should just use a copy of the referent instead when making comparisons.

class multiprocessing.managers.BaseProxy
Proxy objects are instances of subclasses of BaseProxy.

_
callmethod(methodname[, args[, kwds]])
Call and return the result of a method of the proxy's referent.

If proxy is a proxy whose referent is obj then the expression

```python
proxy._callmethod(methodname, args, kwds)
```

will evaluate the expression

```python
getattr(obj, methodname)(*args, **kwds)
```

in the manager's process.

The returned value will be a copy of the result of the call or a proxy to a new shared object – see documentation for the method_to_typeid argument of BaseManager.register().

If an exception is raised by the call, then is re-raised by
_callmethod(). If some other exception is raised in the manager's process then this is converted into a RemoteError exception and is raised by _callmethod().

Note in particular that an exception will be raised if methodname has not been exposed.

An example of the usage of _callmethod():

```python
>>> l = manager.list(range(10))
>>> l._callmethod('__len__')
10
>>> l._callmethod('__getslice__', (2, 7)) # e [2, 3, 4, 5, 6]
>>> l._callmethod('__getitem__', (20,)) # e
Traceback (most recent call last):
  ... IndexError: list index out of range
```

_getvalue()

Return a copy of the referent.

If the referent is unpicklable then this will raise an exception.

__repr__()

Return a representation of the proxy object.

__str__()

Return the representation of the referent.

17.2.2.8.1. Cleanup

A proxy object uses a weakref callback so that when it gets garbage
collected it deregisters itself from the manager which owns its referent.

A shared object gets deleted from the manager process when there are no longer any proxies referring to it.

17.2.2.9. Process Pools

One can create a pool of processes which will carry out tasks submitted to it with the Pool class.

class multiprocessing.pool.Pool([processes[, initializer[, initargs[, maxtasksperchild[, context]]]]])

A process pool object which controls a pool of worker processes to which jobs can be submitted. It supports asynchronous results with timeouts and callbacks and has a parallel map implementation.

processes is the number of worker processes to use. If processes is None then the number returned by os.cpu_count() is used.

If initializer is not None then each worker process will call initializer(*initargs) when it starts.

maxtasksperchild is the number of tasks a worker process can complete before it will exit and be replaced with a fresh worker process, to enable unused resources to be freed. The default maxtasksperchild is None, which means worker processes will live as long as the pool.

context can be used to specify the context used for starting the worker processes. Usually a pool is created using the function multiprocessing.Pool() or the Pool() method of a context object. In both cases context is set appropriately.
Note that the methods of the pool object should only be called by the process which created the pool.

*New in version 3.2:* `maxtasksperchild`

*New in version 3.4:* `context`

**Note:** Worker processes within a `Pool` typically live for the complete duration of the Pool's work queue. A frequent pattern found in other systems (such as Apache, mod_wsgi, etc) to free resources held by workers is to allow a worker within a pool to complete only a set amount of work before exiting, being cleaned up and a new process spawned to replace the old one. The `maxtasksperchild` argument to the `Pool` exposes this ability to the end user.

### `apply(func[, args[, kwds]])`

Call `func` with arguments `args` and keyword arguments `kwds`. It blocks until the result is ready. Given this blocks, `apply_async()` is better suited for performing work in parallel. Additionally, `func` is only executed in one of the workers of the pool.

### `apply_async(func[, args[, kwds[, callback[, error_callback]]]])`

A variant of the `apply()` method which returns a result object.

If `callback` is specified then it should be a callable which accepts a single argument. When the result becomes ready `callback` is applied to it, that is unless the call failed, in which case the `error_callback` is applied instead.

If `error_callback` is specified then it should be a callable which accepts a single argument. If the target function fails, then the
error_callback is called with the exception instance.

Callbacks should complete immediately since otherwise the thread which handles the results will get blocked.

**map**(*func, iterable[, chunksize]*)

A parallel equivalent of the **map()** built-in function (it supports only one **iterable** argument though). It blocks until the result is ready.

This method chops the iterable into a number of chunks which it submits to the process pool as separate tasks. The (approximate) size of these chunks can be specified by setting **chunksize** to a positive integer.

**map_async**(*func, iterable[, chunksize[, callback[, error_callback]]]*)

A variant of the **map()** method which returns a result object.

If **callback** is specified then it should be a callable which accepts a single argument. When the result becomes ready **callback** is applied to it, that is unless the call failed, in which case the **error_callback** is applied instead.

If **error_callback** is specified then it should be a callable which accepts a single argument. If the target function fails, then the **error_callback** is called with the exception instance.

Callbacks should complete immediately since otherwise the thread which handles the results will get blocked.

**imap**(*func, iterable[, chunksize]*)

A lazier version of **map()**.
The `chunksize` argument is the same as the one used by the `map()` method. For very long iterables using a large value for `chunksize` can make the job complete much faster than using the default value of 1.

Also if `chunksize` is 1 then the `next()` method of the iterator returned by the `imap()` method has an optional `timeout` parameter: `next(timeout)` will raise `multiprocessing.TimeoutError` if the result cannot be returned within `timeout` seconds.

**`imap_unordered(func, iterable[, chunksize])`**

The same as `imap()` except that the ordering of the results from the returned iterator should be considered arbitrary. (Only when there is only one worker process is the order guaranteed to be “correct”.)

**`starmap(func, iterable[, chunksize])`**

Like `map()` except that the elements of the `iterable` are expected to be iterables that are unpacked as arguments.

Hence an `iterable` of `[(1,2), (3,4)]` results in `[func(1,2), func(3,4)].

*New in version 3.3.*

**`starmap_async(func, iterable[, chunksize[, callback[, error_back]]]]))`**

A combination of `starmap()` and `map_async()` that iterates over `iterable` of iterables and calls `func` with the iterables unpacked. Returns a result object.
New in version 3.3.

**close()**
Prevents any more tasks from being submitted to the pool. Once all the tasks have been completed the worker processes will exit.

**terminate()**
Stops the worker processes immediately without completing outstanding work. When the pool object is garbage collected `terminate()` will be called immediately.

**join()**
Wait for the worker processes to exit. One must call `close()` or `terminate()` before using `join()`.

New in version 3.3: Pool objects now support the context manager protocol – see *Context Manager Types*. `__enter__()` returns the pool object, and `__exit__()` calls `terminate()`.

**class multiprocessing.pool.AsyncResult**
The class of the result returned by `Pool.apply_async()` and `Pool.map_async()`.

**get([timeout])**
Return the result when it arrives. If `timeout` is not `None` and the result does not arrive within `timeout` seconds then `multiprocessing.TimeoutError` is raised. If the remote call raised an exception then that exception will be reraised by `get()`.

**wait([timeout])**
Wait until the result is available or until *timeout* seconds pass.

**ready()**

Return whether the call has completed.

**successful()**

Return whether the call completed without raising an exception. Will raise *AssertionError* if the result is not ready.

The following example demonstrates the use of a pool:

```python
from multiprocessing import Pool

def f(x):
    return x**x

if __name__ == '__main__':
    with Pool(processes=4) as pool:
        result = pool.apply_async(f, (10,))  # evaluate "f(10)" asynchronously
        print(result.get(timeout=1))  # prints "100" unless your computer is *very* slow

        print(pool.map(f, range(10)))  # prints 

        it = pool.imap(f, range(10))
        print(next(it))  # prints
        print(next(it))  # prints
        print(it.next(timeout=1))  # prints

import time
result = pool.apply_async(time.sleep, (10,))
print(result.get(timeout=1))  # raises
```

17.2.2.10. Listeners and Clients
Usually message passing between processes is done using queues or by using `Connection` objects returned by `Pipe()`.

However, the `multiprocessing.connection` module allows some extra flexibility. It basically gives a high level message oriented API for dealing with sockets or Windows named pipes. It also has support for *digest authentication* using the `hmac` module, and for polling multiple connections at the same time.

`multiprocessing.connection.deliver_challenge(connection, authkey)`

Send a randomly generated message to the other end of the connection and wait for a reply.

If the reply matches the digest of the message using `authkey` as the key then a welcome message is sent to the other end of the connection. Otherwise `AuthenticationError` is raised.

`multiprocessing.connection.answer_challenge(connection, authkey)`

Receive a message, calculate the digest of the message using `authkey` as the key, and then send the digest back.

If a welcome message is not received, then `AuthenticationError` is raised.

`multiprocessing.connection.Client(address[, family[, authenticate[, authkey]]]])`  

Attempt to set up a connection to the listener which is using address `address`, returning a `Connection`.

The type of the connection is determined by `family` argument, but this can generally be omitted since it can usually be inferred from
the format of `address`. (See *Address Formats*)

If `authenticate` is `True` or `authkey` is a byte string then digest authentication is used. The key used for authentication will be either `authkey` or `current_process().authkey` if `authkey` is `None`. If authentication fails then `AuthenticationError` is raised. See *Authentication keys*.

class multiprocessing.connection.Listener([`address`, `family`, `backlog`, `authenticate`, `authkey`])

A wrapper for a bound socket or Windows named pipe which is ‘listening’ for connections.

`address` is the address to be used by the bound socket or named pipe of the listener object.

Note: If an address of ‘0.0.0.0’ is used, the address will not be a connectable end point on Windows. If you require a connectable end-point, you should use ‘127.0.0.1’.

`family` is the type of socket (or named pipe) to use. This can be one of the strings `AF_INET` (for a TCP socket), `AF_UNIX` (for a Unix domain socket) or `AF_PIPE` (for a Windows named pipe). Of these only the first is guaranteed to be available. If `family` is `None` then the family is inferred from the format of `address`. If `address` is also `None` then a default is chosen. This default is the family which is assumed to be the fastest available. See *Address Formats*. Note that if `family` is `AF_UNIX` and `address` is `None` then the socket will be created in a private temporary directory created using `tempfile.mkstemp()`.

If the listener object uses a socket then `backlog` (1 by default) is
passed to the `listen()` method of the socket once it has been bound.

If `authenticate` is True (False by default) or `authkey` is not None then digest authentication is used.

If `authkey` is a byte string then it will be used as the authentication key; otherwise it must be `None`.

If `authkey` is `None` and `authenticate` is `True` then `current_process().authkey` is used as the authentication key. If `authkey` is `None` and `authenticate` is `False` then no authentication is done. If authentication fails then `AuthenticationError` is raised. See `Authentication keys`.

`accept()`

Accept a connection on the bound socket or named pipe of the listener object and return a `Connection` object. If authentication is attempted and fails, then `AuthenticationError` is raised.

`close()`

Close the bound socket or named pipe of the listener object. This is called automatically when the listener is garbage collected. However it is advisable to call it explicitly.

Listener objects have the following read-only properties:

`address`

The address which is being used by the Listener object.

`last_accepted`

The address from which the last accepted connection came. If
this is unavailable then it is None.

New in version 3.3: Listener objects now support the context manager protocol – see Context Manager Types. \texttt{\_\_enter\_\_()} returns the listener object, and \texttt{\_\_exit\_\_()} calls \texttt{\_\_close\_\_()}. multiprocessing.connection.\texttt{wait}(\texttt{object\_list}, \texttt{timeout=\_\_None\_\_})

Wait till an object in \texttt{object\_list} is ready. Returns the list of those objects in \texttt{object\_list} which are ready. If \texttt{timeout} is a float then the call blocks for at most that many seconds. If \texttt{timeout} is \texttt{\_\_None\_\_} then it will block for an unlimited period. A negative timeout is equivalent to a zero timeout.

For both Unix and Windows, an object can appear in \texttt{object\_list} if it is

- a readable \texttt{Connection} object;
- a connected and readable \texttt{socket\_socket} object; or
- the \texttt{sentinel} attribute of a \texttt{Process} object.

A connection or socket object is ready when there is data available to be read from it, or the other end has been closed.

\textbf{Unix}: \texttt{wait}(*\texttt{object\_list}, timeout)\ almost equivalent \texttt{select.select}(*\texttt{object\_list}, [], [], timeout). The difference is that, if \texttt{select.select()} is interrupted by a signal, it can raise \texttt{OSError} with an error number of EINTR, whereas \texttt{wait()} will not.

\textbf{Windows}: An item in \texttt{object\_list} must either be an integer handle which is waitable (according to the definition used by the documentation of the Win32 function \texttt{WaitForMultipleObjects()} or it can be an object with a
fileno() method which returns a socket handle or pipe handle. 
(Note that pipe handles and socket handles are not waitable handles.)

*New in version 3.3.*

**Examples**

The following server code creates a listener which uses 'secret password' as an authentication key. It then waits for a connection and sends some data to the client:

```python
from multiprocessing.connection import Listener
from array import array

address = ('localhost', 6000)  # family is deduced

with Listener(address, authkey=b'secret password') as listener:
    with listener.accept() as conn:
        print('connection accepted from', listener.last_accepted)

        conn.send([2.25, None, 'junk', float])
        conn.send_bytes(b'hello')
        conn.send_bytes(array('i', [42, 1729]))
```

The following code connects to the server and receives some data from the server:

```python
from multiprocessing.connection import Client
from array import array

address = ('localhost', 6000)
```
with Client(address, authkey=b'secret password') as:
    print(conn.recv())  # => [2.25,
    print(conn.recv_bytes())  # => 'hello'
    arr = array('i', [0, 0, 0, 0, 0])
    print(conn.recv_bytes_into(arr))  # => 8
    print(arr)  # => array('i', [42, 1729, 0, 0, 0])

The following code uses `wait()` to wait for messages from multiple processes at once:

```python
import time, random
from multiprocessing import Process, Pipe, current_process
from multiprocessing.connection import wait

def foo(w):
    for i in range(10):
        w.send((i, current_process().name))
    w.close()

if __name__ == '__main__':
    readers = []

    for i in range(4):
        r, w = Pipe(duplex=False)
        readers.append(r)
        p = Process(target=foo, args=(w,))
        p.start()
        # We close the writable end of the pipe now to ensure that when p closes its handle for
        # wait() will promptly report the readable end.
        w.close()

    while readers:
```
for r in wait(readers):
    try:
        msg = r.recv()
    except EOFError:
        readers.remove(r)
    else:
        print(msg)

17.2.2.10.1. Address Formats

- An 'AF_INET' address is a tuple of the form (hostname, port) where hostname is a string and port is an integer.

- An 'AF_UNIX' address is a string representing a filename on the filesystem.

- An 'AF_PIPE' address is a string of the form \"\pipe\PipeName\". To use Client() to connect to a named pipe on a remote computer called ServerName one should use an address of the form \"\ServerName\pipe\PipeName\" instead.

Note that any string beginning with two backslashes is assumed by default to be an 'AF_PIPE' address rather than an 'AF_UNIX' address.

17.2.2.11. Authentication keys

When one uses Connection.recv, the data received is automatically unpickled. Unfortunately unpickling data from an untrusted source is a security risk. Therefore Listener and Client() use the hmac module to provide digest authentication.
An authentication key is a byte string which can be thought of as a password: once a connection is established both ends will demand proof that the other knows the authentication key. (Demonstrating that both ends are using the same key does not involve sending the key over the connection.)

If authentication is requested but no authentication key is specified then the return value of `current_process().authkey` is used (see `Process`). This value will automatically inherited by any `Process` object that the current process creates. This means that (by default) all processes of a multi-process program will share a single authentication key which can be used when setting up connections between themselves.

Suitable authentication keys can also be generated by using `os.urandom()`.

### 17.2.2.12. Logging

Some support for logging is available. Note, however, that the `logging` package does not use process shared locks so it is possible (depending on the handler type) for messages from different processes to get mixed up.

`multiprocessing.get_logger()`

Returns the logger used by `multiprocessing`. If necessary, a new one will be created.

When first created the logger has level `logging.NOTSET` and no default handler. Messages sent to this logger will not by default propagate to the root logger.
Note that on Windows child processes will only inherit the level of the parent process's logger – any other customization of the logger will not be inherited.

**multiprocessing.log_to_stderr()**

This function performs a call to `get_logger()` but in addition to returning the logger created by get_logger, it adds a handler which sends output to `sys.stderr` using format `'[%(levelname)s/%(processName)s] %(message)s'`.

Below is an example session with logging turned on:

```python
>>> import multiprocessing, logging
>>> logger = multiprocessing.log_to_stderr()
>>> logger.setLevel(logging.INFO)
>>> logger.warning('doomed')
[WARNING/MainProcess] doomed
>>> m = multiprocessing.Manager()
[INFO/SyncManager-....] child process calling self.run()
[INFO/SyncManager-....] created temp directory /.../pymp...
[INFO/SyncManager-....] manager serving at '/.../listener-...'
>>> del m
[INFO/MainProcess] sending shutdown message to manager
[INFO/SyncManager-....] manager exiting with exitcode 0
```

For a full table of logging levels, see the `logging` module.

**17.2.2.13. The multiprocessing.dummy module**

`multiprocessing.dummy` replicates the API of `multiprocessing` but is no more than a wrapper around the `threading` module.
17.2.3. Programming guidelines

There are certain guidelines and idioms which should be adhered to when using multiprocessing.

17.2.3.1. All start methods

The following applies to all start methods.

Avoid shared state

As far as possible one should try to avoid shifting large amounts of data between processes.

It is probably best to stick to using queues or pipes for communication between processes rather than using the lower level synchronization primitives.

Picklability

Ensure that the arguments to the methods of proxies are picklable.

Thread safety of proxies

Do not use a proxy object from more than one thread unless you protect it with a lock.

(There is never a problem with different processes using the same proxy.)

Joining zombie processes

On Unix when a process finishes but has not been joined it
becomes a zombie. There should never be very many because each time a new process starts (or `active_children()` is called) all completed processes which have not yet been joined will be joined. Also calling a finished process's `Process.is_alive` will join the process. Even so it is probably good practice to explicitly join all the processes that you start.

Better to inherit than pickle/unpickle

When using the `spawn` or `forkserver` start methods many types from `multiprocessing` need to be picklable so that child processes can use them. However, one should generally avoid sending shared objects to other processes using pipes or queues. Instead you should arrange the program so that a process which needs access to a shared resource created elsewhere can inherit it from an ancestor process.

Avoid terminating processes

Using the `Process.terminate` method to stop a process is liable to cause any shared resources (such as locks, semaphores, pipes and queues) currently being used by the process to become broken or unavailable to other processes.

Therefore it is probably best to only consider using `Process.terminate` on processes which never use any shared resources.

Joining processes that use queues

Bear in mind that a process that has put items in a queue will wait before terminating until all the buffered items are fed by the “feeder” thread to the underlying pipe. (The child process can call the `Queue.cancel_join_thread` method of the queue to avoid this behaviour.)
This means that whenever you use a queue you need to make sure that all items which have been put on the queue will eventually be removed before the process is joined. Otherwise you cannot be sure that processes which have put items on the queue will terminate. Remember also that non-daemonic processes will be automatically be joined.

An example which will deadlock is the following:

```python
from multiprocessing import Process, Queue

def f(q):
    q.put('X' * 1000000)

if __name__ == '__main__':
    queue = Queue()
    p = Process(target=f, args=(queue,))
    p.start()
    p.join()  # this deadlocks
    obj = queue.get()
```

A fix here would be to swap the last two lines round (or simply remove the `p.join()` line).

Explicitly pass resources to child processes

On Unix using the `fork` start method, a child process can make use of a shared resource created in a parent process using a global resource. However, it is better to pass the object as an argument to the constructor for the child process.

Apart from making the code (potentially) compatible with Windows and the other start methods this also ensures that as long as the child process is still alive the object will not be garbage collected
in the parent process. This might be important if some resource is freed when the object is garbage collected in the parent process.

So for instance

```python
from multiprocessing import Process, Lock

def f():
    ... do something using "lock" ...

if __name__ == '__main__':
    lock = Lock()
    for i in range(10):
        Process(target=f).start()
```

should be rewritten as

```python
from multiprocessing import Process, Lock

def f(l):
    ... do something using "l" ...

if __name__ == '__main__':
    lock = Lock()
    for i in range(10):
        Process(target=f, args=(lock,)).start()
```

Beware of replacing `sys.stdin` with a “file like object”

`multiprocessing` originally unconditionally called:

```python
os.close(sys.stdin.fileno())
```

in the `multiprocessing.Process._bootstrap()` method — this resulted in issues with processes-in-processes. This has
been changed to:

```python
sys.stdin.close()
sys.stdin = open(os.devnull)
```

Which solves the fundamental issue of processes colliding with each other resulting in a bad file descriptor error, but introduces a potential danger to applications which replace `sys.stdin()` with a “file-like object” with output buffering. This danger is that if multiple processes call `close()` on this file-like object, it could result in the same data being flushed to the object multiple times, resulting in corruption.

If you write a file-like object and implement your own caching, you can make it fork-safe by storing the pid whenever you append to the cache, and discarding the cache when the pid changes. For example:

```python
@property
def cache(self):
    pid = os.getpid()
    if pid != self._pid:
        self._pid = pid
        self._cache = []
    return self._cache
```

For more information, see issue 5155, issue 5313 and issue 5331

17.2.3.2. The `spawn` and `forkserver` start methods

There are a few extra restriction which don’t apply to the `fork` start method.
More picklability

Ensure that all arguments to `Process.__init__() are picklable. This means, in particular, that bound or unbound methods cannot be used directly as the target (unless you use the `fork` start method) — just define a function and use that instead.

Also, if you subclass `Process` then make sure that instances will be picklable when the `Process.start` method is called.

Global variables

Bear in mind that if code run in a child process tries to access a global variable, then the value it sees (if any) may not be the same as the value in the parent process at the time that `Process.start` was called.

However, global variables which are just module level constants cause no problems.

Safe importing of main module

Make sure that the main module can be safely imported by a new Python interpreter without causing unintended side effects (such a starting a new process).

For example, using the `spawn` or `forkserver` start method running the following module would fail with a `RuntimeError`:

```python
from multiprocessing import Process
def foo():
    print('hello')
```
Instead one should protect the “entry point” of the program by using `if __name__ == '__main__':` as follows:

```python
from multiprocessing import Process, freeze_support

def foo():
    print('hello')

if __name__ == '__main__':
    freeze_support()
    set_start_method('spawn')
p = Process(target=foo)
p.start()
```

(The `freeze_support()` line can be omitted if the program will be run normally instead of frozen.)

This allows the newly spawned Python interpreter to safely import the module and then run the module’s `foo()` function.

Similar restrictions apply if a pool or manager is created in the main module.
17.2.4. Examples

Demonstration of how to create and use customized managers and proxies:

```python
from multiprocessing import freeze_support
from multiprocessing.managers import BaseManager, BaseProxy
import operator

class Foo:
    def f(self):
        print('you called Foo.f()')
    def g(self):
        print('you called Foo.g()')
    def _h(self):
        print('you called Foo._h()')

# A simple generator function
def baz():
    for i in range(10):
        yield i*i

# Proxy type for generator objects
class GeneratorProxy(BaseProxy):
    _exposed_ = ['__next__']
    def __iter__(self):
        return self
    def __next__(self):
        return self._callmethod('__next__')

# Function to return the operator module
def get_operator_module():
    return operator
```
class MyManager(BaseManager):
    pass

# register the Foo class; make `f()` and `g()` accessible via proxy
MyManager.register('Foo1', Foo)

# register the Foo class; make `g()` and `_h()` accessible via proxy
MyManager.register('Foo2', Foo, exposed=('g', '_h'))

# register the generator function baz; use `GeneratorProxy` to make proxies
MyManager.register('baz', baz, proxytype=GeneratorProxy)

# register get_operator_module(); make public functions accessible via proxy
MyManager.register('operator', get_operator_module)

##

def test():
    manager = MyManager()
    manager.start()

    print('-' * 20)

    f1 = manager.Foo1()
    f1.f()
    f1.g()
    assert not hasattr(f1, '_h')
    assert sorted(f1._exposed_) == sorted(['f', 'g'])

    print('-' * 20)

    f2 = manager.Foo2()
    f2.g()
    f2._h()
```python
assert not hasattr(f2, 'f')
assert sorted(f2._exposed_) == sorted(['g', '_h'])

print('-' * 20)

it = manager.baz()
for i in it:
    print('<%d>' % i, end=' ')
print()

print('-' * 20)

op = manager.operator()
print('op.add(23, 45) =', op.add(23, 45))
print('op.pow(2, 94) =', op.pow(2, 94))
print('op._exposed_ =', op._exposed_)

##

if __name__ == '__main__):
    freeze_support()
    test()
```

Using **Pool**:

```python
import multiprocessing
import time
import random
import sys

# # Functions used by test code #

def calculate(func, args):
    result = func(*args)
```
return '%s says that %s%s = %s' % (multiprocessing.current_process().name, func.__name__, args, result)

def calculatestar(args):
    return calculate(*args)

def mul(a, b):
    time.sleep(0.5 * random.random())
    return a * b

def plus(a, b):
    time.sleep(0.5 * random.random())
    return a + b

def f(x):
    return 1.0 / (x - 5.0)

def pow3(x):
    return x ** 3

def noop(x):
    pass

# # Test code # #

def test():
    PROCESSES = 4
    print('Creating pool with %d processes\n' % PROCESSES)

    with multiprocessing.Pool(PROCESSES) as pool:
        # # Tests # #
TASKS = [(mul, (i, 7)) for i in range(10)] +
[(plus, (i, 8)) for i in range(10)]

results = [pool.apply_async(calculate, t) for t in TASKS]
imap_it = pool.imap(calculatestar, TASKS)
imap_unordered_it = pool.imap_unordered(calculatestar)

print('Ordered results using pool.apply_async():')
for r in results:
    print('  ', r.get())
print()

print('Ordered results using pool.imap():')
for x in imap_it:
    print('  ', x)
print()

print('Unordered results using pool.imap_unordered():')
for x in imap_unordered_it:
    print('  ', x)
print()

print('Ordered results using pool.map() ---')
for x in pool.map(calculatestar, TASKS):

17.3. The concurrent package

Currently, there is only one module in this package:

- `concurrent.futures` – Launching parallel tasks
17.4. `concurrent.futures` —
Launching parallel tasks

New in version 3.2.

Source code: `Lib/concurrent/futures/thread.py` and `Lib/concurrent/futures/process.py`

The `concurrent.futures` module provides a high-level interface for asynchronously executing callables.

The asynchronous execution can be performed with threads, using `ThreadPoolExecutor`, or separate processes, using `ProcessPoolExecutor`. Both implement the same interface, which is defined by the abstract `Executor` class.
17.4.1. Executor Objects

class concurrent.futures.Executor
  
An abstract class that provides methods to execute calls asynchronously. It should not be used directly, but through its concrete subclasses.

  submit(fn, *args, **kwargs)
  
Schedules the callable, fn, to be executed as fn(*args, **kwargs) and returns a Future object representing the execution of the callable.

```python
with ThreadPoolExecutor(max_workers=1) as executor:
    future = executor.submit(pow, 323, 1235)
    print(future.result())
```

  map(func, *iterables, timeout=None)
  
Equivalent to map(func, *iterables) except func is executed asynchronously and several calls to func may be made concurrently. The returned iterator raises a TimeoutError if __next__() is called and the result isn't available after timeout seconds from the original call to Executor.map(). timeout can be an int or a float. If timeout is not specified or None, there is no limit to the wait time. If a call raises an exception, then that exception will be raised when its value is retrieved from the iterator.

  shutdown(wait=True)
  
Signal the executor that it should free any resources that it is using when the currently pending futures are done
executing. Calls to `Executor.submit()` and `Executor.map()` made after shutdown will raise `RuntimeError`.

If `wait` is `True` then this method will not return until all the pending futures are done executing and the resources associated with the executor have been freed. If `wait` is `False` then this method will return immediately and the resources associated with the executor will be freed when all pending futures are done executing. Regardless of the value of `wait`, the entire Python program will not exit until all pending futures are done executing.

You can avoid having to call this method explicitly if you use the `with` statement, which will shutdown the `Executor` (waiting as if `Executor.shutdown()` were called with `wait` set to `True`):

```python
import shutil
with ThreadPoolExecutor(max_workers=4) as e:
    e.submit(shutil.copy, 'src1.txt', 'dest1.txt')
    e.submit(shutil.copy, 'src2.txt', 'dest2.txt')
    e.submit(shutil.copy, 'src3.txt', 'dest3.txt')
    e.submit(shutil.copy, 'src3.txt', 'dest4.txt')
```
17.4.2. ThreadPoolExecutor

ThreadpoolExecutor is a Executor subclass that uses a pool of threads to execute calls asynchronously.

Deadlocks can occur when the callable associated with a Future waits on the results of another Future. For example:

```python
import time
def wait_on_b():
    time.sleep(5)
    print(b.result()) # b will never complete because
    return 5
def wait_on_a():
    time.sleep(5)
    print(a.result()) # a will never complete because
    return 6

executor = ThreadPoolExecutor(max_workers=2)
a = executor.submit(wait_on_b)
b = executor.submit(wait_on_a)
```

And:

```python
def wait_on_future():
    f = executor.submit(pow, 5, 2)
    # This will never complete because there is only
    # it is executing this function.
    print(f.result())

executor = ThreadPoolExecutor(max_workers=1)
executor.submit(wait_on_future)
```
class concurrent.futures.ThreadPoolExecutor(max_workers)
    
    An Executor subclass that uses a pool of at most max_workers threads to execute calls asynchronously.

17.4.2.1. ThreadPoolExecutor Example

```python
import concurrent.futures
import urllib.request

URLS = ['http://www.foxnews.com/',
        'http://www.cnn.com/',
        'http://europe.wsj.com/',
        'http://www.bbc.co.uk/',
        'http://some-made-up-domain.com/']

# Retrieve a single page and report the url and content
def load_url(url, timeout):
    conn = urllib.request.urlopen(url, timeout=timeout)
    return conn.readall()

# We can use a with statement to ensure threads are cleaned up promptly
with concurrent.futures.ThreadPoolExecutor(max_workers=)
    # Start the load operations and mark each future
    future_to_url = {executor.submit(load_url, url, timeout):
                     for future in concurrent.futures.as_completed(future_to_url)
                     url = future_to_url[future]
                     try:
                         data = future.result()  # in this case we have a .result()
                     except Exception as exc:
                         print('%r generated an exception: %s' % (url, exc))
                     else:
                         print('%r page is %d bytes' % (url, len(data)))
```

17.4.3. ProcessPoolExecutor

The `ProcessPoolExecutor` class is an `Executor` subclass that uses a pool of processes to execute calls asynchronously. `ProcessPoolExecutor` uses the `multiprocessing` module, which allows it to side-step the *Global Interpreter Lock* but also means that only picklable objects can be executed and returned.

The `__main__` module must be importable by worker subprocesses. This means that `ProcessPoolExecutor` will not work in the interactive interpreter.

Calling `Executor` or `Future` methods from a callable submitted to a `ProcessPoolExecutor` will result in deadlock.

```python
class concurrent.futures.ProcessPoolExecutor(max_workers=None):
    An Executor subclass that executes calls asynchronously using a pool of at most `max_workers` processes. If `max_workers` is `None` or not given, it will default to the number of processors on the machine.

Changed in version 3.3: When one of the worker processes terminates abruptly, a `BrokenProcessPool` error is now raised. Previously, behaviour was undefined but operations on the executor or its futures would often freeze or deadlock.
```

17.4.3.1. ProcessPoolExecutor Example

```python
import concurrent.futures
import math
```
PRIMES = [
    112272535095293,
    112582705942171,
    112272535095293,
    115280095190773,
    115797848077099,
    1099726899285419]

def is_prime(n):
    if n % 2 == 0:
        return False

    sqrt_n = int(math.floor(math.sqrt(n)))
    for i in range(3, sqrt_n + 1, 2):
        if n % i == 0:
            return False
    return True

def main():
    with concurrent.futures.ProcessPoolExecutor() as executor:
        for number, prime in zip(PRIMES, executor.map(is_prime, PRIMES)):
            print('%d is prime: %s' % (number, prime))

if __name__ == '__main__':
    main()
17.4.4. Future Objects

The **Future** class encapsulates the asynchronous execution of a callable. **Future** instances are created by **Executor.submit()**.

```python
class concurrent.futures.Future
    Encapsulates the asynchronous execution of a callable. **Future** instances are created by **Executor.submit()** and should not be created directly except for testing.

    cancel()
        Attempt to cancel the call. If the call is currently being executed and cannot be cancelled then the method will return **False**, otherwise the call will be cancelled and the method will return **True**.

    cancelled()
        Return **True** if the call was successfully cancelled.

    running()
        Return **True** if the call is currently being executed and cannot be cancelled.

    done()
        Return **True** if the call was successfully cancelled or finished running.

    result(timeout=None)
        Return the value returned by the call. If the call hasn’t yet completed then this method will wait up to **timeout** seconds. If the call hasn’t completed in **timeout** seconds,
then a `TimeoutError` will be raised. `timeout` can be an int or float. If `timeout` is not specified or `None`, there is no limit to the wait time.

If the future is cancelled before completing then `CancelledError` will be raised.

If the call raised, this method will raise the same exception.

**exception** *(timeout=``None``)*

Return the exception raised by the call. If the call hasn’t yet completed then this method will wait up to `timeout` seconds. If the call hasn't completed in `timeout` seconds, then a `TimeoutError` will be raised. `timeout` can be an int or float. If `timeout` is not specified or `None`, there is no limit to the wait time.

If the future is cancelled before completing then `CancelledError` will be raised.

If the call completed without raising, `None` is returned.

**add_done_callback** *(fn)*

Attaches the callable `fn` to the future. `fn` will be called, with the future as its only argument, when the future is cancelled or finishes running.

Added callables are called in the order that they were added and are always called in a thread belonging to the process that added them. If the callable raises a `Exception` subclass, it will be logged and ignored. If the callable raises a `BaseException` subclass, the behavior is undefined.
If the future has already completed or been cancelled, \textit{fn} will be called immediately.

The following \texttt{Future} methods are meant for use in unit tests and \texttt{Executor} implementations.

\textbf{set\_running\_or\_notify\_cancel()}

This method should only be called by \texttt{Executor} implementations before executing the work associated with the \texttt{Future} and by unit tests.

If the method returns \texttt{False} then the \texttt{Future} was cancelled, i.e. \texttt{Future.cancel()} was called and returned \texttt{True}. Any threads waiting on the \texttt{Future} completing (i.e. through \texttt{as\_completed()} or \texttt{wait()}) will be woken up.

If the method returns \texttt{True} then the \texttt{Future} was not cancelled and has been put in the running state, i.e. calls to \texttt{Future.running()} will return \texttt{True}.

This method can only be called once and cannot be called after \texttt{Future.set\_result()} or \texttt{Future.set\_exception()} have been called.

\textbf{set\_result}(\textit{result})

Sets the result of the work associated with the \texttt{Future} to \textit{result}.

This method should only be used by \texttt{Executor} implementations and unit tests.

\textbf{set\_exception}(\textit{exception})
Sets the result of the work associated with the `Future` to the `Exception` exception.

This method should only be used by `Executor` implementations and unit tests.
17.4.5. Module Functions

concurrent.futures.wait(fs, timeout=None, return_when=ALL_COMPLETED)

Wait for the Future instances (possibly created by different Executor instances) given by fs to complete. Returns a named 2-tuple of sets. The first set, named done, contains the futures that completed (finished or were cancelled) before the wait completed. The second set, named not_done, contains uncompleted futures.

timeout can be used to control the maximum number of seconds to wait before returning. timeout can be an int or float. If timeout is not specified or None, there is no limit to the wait time.

return_when indicates when this function should return. It must be one of the following constants:

<table>
<thead>
<tr>
<th>Constant</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>FIRST_COMPLETED</td>
<td>The function will return when any future finishes or is cancelled.</td>
</tr>
<tr>
<td>FIRST_EXCEPTION</td>
<td>The function will return when any future finishes by raising an exception. If no future raises an exception then it is equivalent to ALL_COMPLETED.</td>
</tr>
<tr>
<td>ALL_COMPLETED</td>
<td>The function will return when all futures finish or are cancelled.</td>
</tr>
</tbody>
</table>

concurrent.futures.as_completed(fs, timeout=None)

Returns an iterator over the Future instances (possibly created by different Executor instances) given by fs that yields futures as
they complete (finished or were cancelled). Any futures given by \textit{fs} that are duplicated will be returned once. Any futures that completed before \texttt{as\_completed()} is called will be yielded first. The returned iterator raises a \texttt{TimeoutError} if \texttt{__next__()} is called and the result isn't available after \textit{timeout} seconds from the original call to \texttt{as\_completed()} . \textit{timeout} can be an int or float. If \textit{timeout} is not specified or \texttt{None}, there is no limit to the wait time.

\begin{quote}
\textbf{See also:}

\textbf{PEP 3148 – futures - execute computations asynchronously}

The proposal which described this feature for inclusion in the Python standard library.
\end{quote}
17.4.6. Exception classes

exception concurrent.futures.BrokenProcessPool

Derived from RuntimeError, this exception class is raised when one of the workers of a ProcessPoolExecutor has terminated in a non-clean fashion (for example, if it was killed from the outside).

New in version 3.3.
17.5. `subprocess` — Subprocess management

The `subprocess` module allows you to spawn new processes, connect to their input/output/error pipes, and obtain their return codes. This module intends to replace several older modules and functions:

```python
os.system
os.spawn*
```

Information about how the `subprocess` module can be used to replace these modules and functions can be found in the following sections.

See also: PEP 324 – PEP proposing the subprocess module
17.5.1. Using the subprocess Module

The recommended approach to invoking subprocesses is to use the following convenience functions for all use cases they can handle. For more advanced use cases, the underlying Popen interface can be used directly.

subprocess.call(args, *, stdin=None, stdout=None, stderr=None, shell=False, timeout=None)

Run the command described by args. Wait for command to complete, then return the returncode attribute.

The arguments shown above are merely the most common ones, described below in Frequently Used Arguments (hence the use of keyword-only notation in the abbreviated signature). The full function signature is largely the same as that of the Popen constructor - this function passes all supplied arguments other than timeout directly through to that interface.

The timeout argument is passed to Popen.wait(). If the timeout expires, the child process will be killed and then waited for again. The TimeoutExpired exception will be re-raised after the child process has terminated.

Examples:

```python
>>> subprocess.call(['ls', '-l'])
0

>>> subprocess.call('exit 1', shell=True)
1
```
Warning: Invoking the system shell with `shell=True` can be a security hazard if combined with untrusted input. See the warning under *Frequently Used Arguments* for details.

Note: Do not use `stdout=PIPE` or `stderr=PIPE` with this function. As the pipes are not being read in the current process, the child process may block if it generates enough output to a pipe to fill up the OS pipe buffer.

*Changed in version 3.3:* `timeout` was added.

```python
calledprocess = subprocess.check_call(['ls', '-l'])
```

subprocess.**check_call**(args, *, stdin=None, stdout=None, stderr=None, shell=False, timeout=None)

Run command with arguments. Wait for command to complete. If the return code was zero then return, otherwise raise `CalledProcessError`. The `CalledProcessError` object will have the return code in the `returncode` attribute.

The arguments shown above are merely the most common ones, described below in *Frequently Used Arguments* (hence the use of keyword-only notation in the abbreviated signature). The full function signature is largely the same as that of the `Popen` constructor - this function passes all supplied arguments other than `timeout` directly through to that interface.

The `timeout` argument is passed to `Popen.wait()`. If the timeout expires, the child process will be killed and then waited for again. The `TimeoutExpired` exception will be re-raised after the child process has terminated.

Examples:

```python
g>>> subprocess.check_call(['ls', '-l'])
```
>>> subprocess.check_call("exit 1", shell=True)
Traceback (most recent call last):
... 
subprocess.CalledProcessError: Command 'exit 1' r

**Warning:** Invoking the system shell with `shell=True` can be a security hazard if combined with untrusted input. See the warning under *Frequently Used Arguments* for details.

**Note:** Do not use `stdout=PIPE` or `stderr=PIPE` with this function. As the pipes are not being read in the current process, the child process may block if it generates enough output to a pipe to fill up the OS pipe buffer.

*Changed in version 3.3: timeout was added.*

```
subprocess.check_output(args, *, input=None, stdin=None, stderr=None, shell=False, universal_newlines=False, timeout=None)
```

Run command with arguments and return its output.

If the return code was non-zero it raises a *CalledProcessError*. The *CalledProcessError* object will have the return code in the *returncode* attribute and any output in the *output* attribute.

The arguments shown above are merely the most common ones, described below in *Frequently Used Arguments* (hence the use of keyword-only notation in the abbreviated signature). The full function signature is largely the same as that of the *Popen* constructor - this functions passes all supplied arguments other
than input and timeout directly through to that interface. In addition, stdout is not permitted as an argument, as it is used internally to collect the output from the subprocess.

The timeout argument is passed to Popen.wait(). If the timeout expires, the child process will be killed and then waited for again. The TimeoutExpired exception will be re-raised after the child process has terminated.

The input argument is passed to Popen.communicate() and thus to the subprocess's stdin. If used it must be a byte sequence, or a string if universal_newlines=True. When used, the internal Popen object is automatically created with stdin=PIPE, and the stdin argument may not be used as well.

Examples:

```python
>>> subprocess.check_output(['echo', 'Hello World'], input=b'Hello World!\n')
>>> subprocess.check_output(['echo', 'Hello World'], input='Hello World!\n')
>>> subprocess.check_output(['sed', '-e', 's/foo/bar/'], input=b'when in the course of fooman events
')
>>> subprocess.check_output(['exit 1'], shell=True)
Traceback (most recent call last):
  subprocess.CalledProcessError: Command 'exit 1' r
```

By default, this function will return the data as encoded bytes. The actual encoding of the output data may depend on the command
being invoked, so the decoding to text will often need to be handled at the application level.

This behaviour may be overridden by setting `universal_newlines` to `True` as described below in *Frequently Used Arguments*.

To also capture standard error in the result, use `stderr=subprocess.STDOUT`:

```python
>>> subprocess.check_output(
    ... "ls non_existent_file; exit 0",
    ... stderr=subprocess.STDOUT,
    ... shell=True)
'ls: non_existent_file: No such file or directory
```

**Warning:** Invoking the system shell with `shell=True` can be a security hazard if combined with untrusted input. See the warning under *Frequently Used Arguments* for details.

**Note:** Do not use `stderr=PIPE` with this function. As the pipe is not being read in the current process, the child process may block if it generates enough output to the pipe to fill up the OS pipe buffer.

*New in version 3.1.*

*Changed in version 3.3:* `timeout` was added.

*Changed in version 3.4:* `input` was added.

`subprocess.DEVNULL`

Special value that can be used as the `stdin`, `stdout` or `stderr` argument to `Popen` and indicates that the special file `os.devnull`
will be used.

*New in version 3.3.*

**subprocess.PPIPE**
Special value that can be used as the `stdin`, `stdout` or `stderr` argument to `Popen` and indicates that a pipe to the standard stream should be opened.

**subprocess.STDOUT**
Special value that can be used as the `stderr` argument to `Popen` and indicates that standard error should go into the same handle as standard output.

**exception subprocess.SubprocessError**
Base class for all other exceptions from this module.

*New in version 3.3.*

**exception subprocess.TimeoutExpired**
Subclass of `SubprocessError`, raised when a timeout expires while waiting for a child process.

**cmd**
Command that was used to spawn the child process.

**timeout**
Timeout in seconds.

**output**
Output of the child process if this exception is raised by `check_output()`. Otherwise, `None`.

*New in version 3.3.*
exception subprocess. **CalledProcessError**

Subclass of **SubprocessError**, raised when a process run by `check_call()` or `check_output()` returns a non-zero exit status.

**returncode**

Exit status of the child process.

**cmd**

Command that was used to spawn the child process.

**output**

Output of the child process if this exception is raised by `check_output()`. Otherwise, `None`.

### 17.5.1.1. Frequently Used Arguments

To support a wide variety of use cases, the **Popen** constructor (and the convenience functions) accept a large number of optional arguments. For most typical use cases, many of these arguments can be safely left at their default values. The arguments that are most commonly needed are:

- **`args`** is required for all calls and should be a string, or a sequence of program arguments. Providing a sequence of arguments is generally preferred, as it allows the module to take care of any required escaping and quoting of arguments (e.g. to permit spaces in file names). If passing a single string, either `shell` must be `True` (see below) or else the string must simply name the program to be executed without specifying any arguments.

- **`stdin`, `stdout` and `stderr`** specify the executed program’s standard
input, standard output and standard error file handles, respectively. Valid values are PIPE, DEVNULL, an existing file descriptor (a positive integer), an existing file object, and None. PIPE indicates that a new pipe to the child should be created. DEVNULL indicates that the special file os.devnull will be used. With the default settings of None, no redirection will occur; the child's file handles will be inherited from the parent. Additionally, stderr can be STDOUT, which indicates that the stderr data from the child process should be captured into the same file handle as for stdout.

If universal_newlines is False the file objects stdin, stdout and stderr will be opened as binary streams, and no line ending conversion is done.

If universal_newlines is True, these file objects will be opened as text streams in universal newlines mode using the encoding returned by locale.getpreferredencoding(False). For stdin, line ending characters '\n' in the input will be converted to the default line separator os.linesep. For stdout and stderr, all line endings in the output will be converted to '\n'. For more information see the documentation of the io.TextIOWrapper class when the newline argument to its constructor is None.

Note: The newlines attribute of the file objects Popen.stdin, Popen.stdout and Popen.stderr are not updated by the Popen.communicate() method.

If shell is True, the specified command will be executed through the shell. This can be useful if you are using Python primarily for the enhanced control flow it offers over most system shells and
still want convenient access to other shell features such as shell pipes, filename wildcards, environment variable expansion, and expansion of \~ to a user’s home directory. However, note that Python itself offers implementations of many shell-like features (in particular, \texttt{glob}, \texttt{fnmatch}, \texttt{os.walk()}, \texttt{os.path.expandvars()}, \texttt{os.path.expanduser()}, and \texttt{shutil}).

\textit{Changed in version 3.3:} When \texttt{universal_newlines} is \texttt{True}, the class uses the encoding \texttt{locale.getpreferredencoding(False)} instead of \texttt{locale.getpreferredencoding()}. See the \texttt{io.TextIOWrapper} class for more information on this change.

\textbf{Warning:} Executing shell commands that incorporate unsanitized input from an untrusted source makes a program vulnerable to \textit{shell injection}, a serious security flaw which can result in arbitrary command execution. For this reason, the use of \texttt{shell=True} is \textbf{strongly discouraged} in cases where the command string is constructed from external input:

\begin{verbatim}
>>> from subprocess import call
>>> filename = input("What file would you like to display?"
non_existent; rm -rf / #
>>> call("cat " + filename, shell=True) # Uh-oh
\end{verbatim}

\texttt{shell=False} disables all shell based features, but does not suffer from this vulnerability; see the Note in the \texttt{Popen} constructor documentation for helpful hints in getting \texttt{shell=False} to work.
When using `shell=True`, `shlex.quote()` can be used to properly escape whitespace and shell metacharacters in strings that are going to be used to construct shell commands.

These options, along with all of the other options, are described in more detail in the `Popen` constructor documentation.

17.5.1.2. Popen Constructor

The underlying process creation and management in this module is handled by the `Popen` class. It offers a lot of flexibility so that developers are able to handle the less common cases not covered by the convenience functions.

```
class subprocess.Popen(args, bufsize=-1, executable=None, stdin=None, stdout=None, stderr=None, preexec_fn=None, close_fds=True, shell=False, cwd=None, env=None, universal_newlines=False, startupinfo=None, creationflags=0, restore_signals=True, start_new_session=False, pass_fds=())
```

Execute a child program in a new process. On Unix, the class uses `os.execvp()`-like behavior to execute the child program. On Windows, the class uses the Windows `CreateProcess()` function. The arguments to `Popen` are as follows.

`args` should be a sequence of program arguments or else a single string. By default, the program to execute is the first item in `args` if `args` is a sequence. If `args` is a string, the interpretation is platform-dependent and described below. See the `shell` and `executable` arguments for additional differences from the default behavior. Unless otherwise stated, it is recommended to pass `args` as a sequence.
On Unix, if `args` is a string, the string is interpreted as the name or path of the program to execute. However, this can only be done if not passing arguments to the program.

**Note:** `shlex.split()` can be useful when determining the correct tokenization for `args`, especially in complex cases:

```python
>>> import shlex, subprocess
>>> command_line = input()
/bin/vikings -input eggs.txt -output "spam spam."
>>> args = shlex.split(command_line)
>>> print(args)
['/bin/vikings', '-input', 'eggs.txt', '-output'
>>> p = subprocess.Popen(args) # Success!
```

Note in particular that options (such as `-input`) and arguments (such as `eggs.txt`) that are separated by whitespace in the shell go in separate list elements, while arguments that need quoting or backslash escaping when used in the shell (such as filenames containing spaces or the `echo` command shown above) are single list elements.

On Windows, if `args` is a sequence, it will be converted to a string in a manner described in *Converting an argument sequence to a string on Windows*. This is because the underlying `CreateProcess()` operates on strings.

The `shell` argument (which defaults to `False`) specifies whether to use the shell as the program to execute. If `shell` is `True`, it is recommended to pass `args` as a string rather than as a sequence.

On Unix with `shell=True`, the shell defaults to `/bin/sh`. If `args` is a string, the string specifies the command to execute through the
This means that the string must be formatted exactly as it would be when typed at the shell prompt. This includes, for example, quoting or backslash escaping filenames with spaces in them. If \texttt{args} is a sequence, the first item specifies the command string, and any additional items will be treated as additional arguments to the shell itself. That is to say, \texttt{Popen} does the equivalent of:

\begin{verbatim}
Popen(['/bin/sh', '-c', args[0], args[1], ...])
\end{verbatim}

On Windows with \texttt{shell=True}, the \texttt{COMSPEC} environment variable specifies the default shell. The only time you need to specify \texttt{shell=True} on Windows is when the command you wish to execute is built into the shell (e.g. \texttt{dir} or \texttt{copy}). You do not need \texttt{shell=True} to run a batch file or console-based executable.

\textbf{Warning:} Passing \texttt{shell=True} can be a security hazard if combined with untrusted input. See the warning under \textit{Frequently Used Arguments} for details.

\texttt{bufsize} will be supplied as the corresponding argument to the \texttt{open()} function when creating the stdin/stdout/stderr pipe file objects: 0 means unbuffered (read and write are one system call and can return short), 1 means line buffered, any other positive value means use a buffer of approximately that size. A negative \texttt{bufsize} (the default) means the system default of \texttt{io.DEFAULT_BUFFER_SIZE} will be used.

\textit{Changed in version 3.3.1:} \texttt{bufsize} now defaults to -1 to enable buffering by default to match the behavior that most code expects. In versions prior to Python 3.2.4 and 3.3.1 it incorrectly defaulted to 0 which was unbuffered and allowed short reads. This was
unintentional and did not match the behavior of Python 2 as most code expected.

The *executable* argument specifies a replacement program to execute. It is very seldom needed. When `shell=False`, *executable* replaces the program to execute specified by `args`. However, the original `args` is still passed to the program. Most programs treat the program specified by `args` as the command name, which can then be different from the program actually executed. On Unix, the `args` name becomes the display name for the executable in utilities such as `ps`. If `shell=True`, on Unix the *executable* argument specifies a replacement shell for the default `/bin/sh`.

`stdin`, `stdout` and `stderr` specify the executed program’s standard input, standard output and standard error file handles, respectively. Valid values are PIPE, DEVNULL, an existing file descriptor (a positive integer), an existing *file object*, and None. PIPE indicates that a new pipe to the child should be created. DEVNULL indicates that the special file `os.devnull` will be used. With the default settings of None, no redirection will occur; the child’s file handles will be inherited from the parent. Additionally, `stderr` can be STDOUT, which indicates that the stderr data from the applications should be captured into the same file handle as for stdout.

If `preexec_fn` is set to a callable object, this object will be called in the child process just before the child is executed. (Unix only)

**Warning:** The `preexec_fn` parameter is not safe to use in the presence of threads in your application. The child process could deadlock before `exec` is called. If you must use it, keep it trivial! Minimize the number of libraries you call into.
Note: If you need to modify the environment for the child use the `env` parameter rather than doing it in a `preexec_fn`. The `start_new_session` parameter can take the place of a previously common use of `preexec_fn` to call `os.setsid()` in the child.

If `close_fds` is true, all file descriptors except 0, 1 and 2 will be closed before the child process is executed. (Unix only). The default varies by platform: Always true on Unix. On Windows it is true when `stdin/stdout/stderr` are `None`, false otherwise. On Windows, if `close_fds` is true then no handles will be inherited by the child process. Note that on Windows, you cannot set `close_fds` to true and also redirect the standard handles by setting `stdin`, `stdout` or `stderr`.

*Changed in version 3.2:* The default for `close_fds` was changed from `False` to what is described above.

`pass_fds` is an optional sequence of file descriptors to keep open between the parent and child. Providing any `pass_fds` forces `close_fds` to be `True`. (Unix only)

*New in version 3.2:* The `pass_fds` parameter was added.

If `cwd` is not `None`, the function changes the working directory to `cwd` before executing the child. In particular, the function looks for `executable` (or for the first item in `args`) relative to `cwd` if the executable path is a relative path.

If `restore_signals` is true (the default) all signals that Python has set to `SIG_IGN` are restored to `SIG_DFL` in the child process before the exec. Currently this includes the SIGPIPE, SIGXFZ and SIGXFSZ signals. (Unix only)
Changed in version 3.2: restore_signals was added.

If start_new_session is true the setsid() system call will be made in the child process prior to the execution of the subprocess. (Unix only)

Changed in version 3.2: start_new_session was added.

If env is not None, it must be a mapping that defines the environment variables for the new process; these are used instead of the default behavior of inheriting the current process’ environment.

**Note:** If specified, env must provide any variables required for the program to execute. On Windows, in order to run a side-by-side assembly the specified env must include a valid SystemRoot.

If universal_newlines is True, the file objects stdin, stdout and stderr are opened as text streams in universal newlines mode, as described above in *Frequently Used Arguments*, otherwise they are opened as binary streams.

If given, startupinfo will be a STARTUPINFO object, which is passed to the underlying CreateProcess function. creationflags, if given, can be CREATE_NEW_CONSOLE or CREATE_NEW_PROCESS_GROUP. (Windows only)

Popen objects are supported as context managers via the with statement: on exit, standard file descriptors are closed, and the process is waited for.

```python
with Popen(['ifconfig'], stdout=PIPE) as proc:
```
log.write(proc.stdout.read())

*Changed in version 3.2:* Added context manager support.

### 17.5.1.3. Exceptions

Exceptions raised in the child process, before the new program has started to execute, will be re-raised in the parent. Additionally, the exception object will have one extra attribute called child_traceback, which is a string containing traceback information from the child's point of view.

The most common exception raised is **OSError**. This occurs, for example, when trying to execute a non-existent file. Applications should prepare for **OSError** exceptions.

A **ValueError** will be raised if **Popen** is called with invalid arguments.

**check_call()** and **check_output()** will raise **CalledProcessError** if the called process returns a non-zero return code.

All of the functions and methods that accept a **timeout** parameter, such as **call()** and **Popen.communicate()** will raise **TimeoutExpired** if the timeout expires before the process exits.

Exceptions defined in this module all inherit from **SubprocessError**.

*New in version 3.3:* The **SubprocessError** base class was added.
17.5.1.4. Security

Unlike some other popen functions, this implementation will never call a system shell implicitly. This means that all characters, including shell metacharacters, can safely be passed to child processes. Obviously, if the shell is invoked explicitly, then it is the application’s responsibility to ensure that all whitespace and metacharacters are quoted appropriately.
17.5.2. Popen Objects

Instances of the `Popen` class have the following methods:

Popen. **poll()**

Check if child process has terminated. Set and return `returncode` attribute.

Popen. **wait**(timeout=None)

Wait for child process to terminate. Set and return `returncode` attribute.

If the process does not terminate after `timeout` seconds, raise a `TimeoutExpired` exception. It is safe to catch this exception and retry the wait.

**Note:** The function is implemented using a busy loop (non-blocking call and short sleeps). Use the `asyncio` module for an asynchronous wait: see `asyncio.create_subprocess_exec`.

**Warning:** This will deadlock when using `stdout=PIPE` and/or `stderr=PIPE` and the child process generates enough output to a pipe such that it blocks waiting for the OS pipe buffer to accept more data. Use `communicate()` to avoid that.

*Changed in version 3.3: timeout was added.*

*Deprecated since version 3.4: Do not use the undocumented `endtime` parameter. It is was unintentionally exposed in 3.3 but was intended to be private for internal use. Use `timeout` instead.*
Popen. **communicate**(*input=None, timeout=None*)

Interact with process: Send data to stdin. Read data from stdout and stderr, until end-of-file is reached. Wait for process to terminate. The optional *input* argument should be data to be sent to the child process, or None, if no data should be sent to the child. The type of *input* must be bytes or, if *universal_newlines* was True, a string.

**communicate()** returns a tuple (stdoutdata, stderrdata).

Note that if you want to send data to the process’s stdin, you need to create the Popen object with stdin=PIPE. Similarly, to get anything other than None in the result tuple, you need to give stdout=PIPE and/or stderr=PIPE too.

If the process does not terminate after *timeout* seconds, a **TimeoutExpired** exception will be raised. Catching this exception and retrying communication will not lose any output.

The child process is not killed if the timeout expires, so in order to cleanup properly a well-behaved application should kill the child process and finish communication:

```
proc = subprocess.Popen(...) 
try: 
    outs, errs = proc.communicate(timeout=15) 
except TimeoutExpired: 
    proc.kill() 
    outs, errs = proc.communicate()
```

**Note:** The data read is buffered in memory, so do not use this method if the data size is large or unlimited.
Changed in version 3.3: `timeout` was added.

Popen. **send_signal**(*signal*)

Sends the signal `signal` to the child.

**Note:** On Windows, SIGTERM is an alias for `terminate()`. CTRL_C_EVENT and CTRL_BREAK_EVENT can be sent to processes started with a `creationflags` parameter which includes `CREATE_NEW_PROCESS_GROUP`.

Popen. **terminate**()

Stop the child. On Posix OSs the method sends SIGTERM to the child. On Windows the Win32 API function TerminateProcess() is called to stop the child.

Popen. **kill**()

Kills the child. On Posix OSs the function sends SIGKILL to the child. On Windows `kill()` is an alias for `terminate()`.

The following attributes are also available:

**Warning:** Use `communicate()` rather than `.stdin.write`, `.stdout.read` or `.stderr.read` to avoid deadlocks due to any of the other OS pipe buffers filling up and blocking the child process.

Popen. **stdin**

If the `stdin` argument was PIPE, this attribute is a writeable stream object as returned by `open()`. If the `universal_newlines` argument was True, the stream is a text stream, otherwise it is a byte stream. If the `stdin` argument was not PIPE, this attribute is None.

Popen. **stdout**
If the `stdout` argument was `PIPE`, this attribute is a readable stream object as returned by `open()`. Reading from the stream provides output from the child process. If the `universal_newlines` argument was `True`, the stream is a text stream, otherwise it is a byte stream. If the `stdout` argument was not `PIPE`, this attribute is `None`.

**Popen. **`stdout`

If the `stderr` argument was `PIPE`, this attribute is a readable stream object as returned by `open()`. Reading from the stream provides error output from the child process. If the `universal_newlines` argument was `True`, the stream is a text stream, otherwise it is a byte stream. If the `stderr` argument was not `PIPE`, this attribute is `None`.

**Popen. **`pid`

The process ID of the child process.

Note that if you set the `shell` argument to `True`, this is the process ID of the spawned shell.

**Popen. **`returncode`

The child return code, set by `poll()` and `wait()` (and indirectly by `communicate()`). A None value indicates that the process hasn't terminated yet.

A negative value `-N` indicates that the child was terminated by signal `N` (Unix only).
17.5.3. Windows Popen Helpers

The `STARTUPINFO` class and following constants are only available on Windows.

class subprocess.STARTUPINFO

Partial support of the Windows `STARTUPINFO` structure is used for `Popen` creation.

dwFlags

A bit field that determines whether certain `STARTUPINFO` attributes are used when the process creates a window.

```
si = subprocess.STARTUPINFO()
si.dwFlags = subprocess.STARTF_USESTDHANDLES | subprocess.STARTF_USESTDHANDLES
```

hStdInput

If `dwFlags` specifies `STARTF_USESTDHANDLES`, this attribute is the standard input handle for the process. If `STARTF_USESTDHANDLES` is not specified, the default for standard input is the keyboard buffer.

hStdOutput

If `dwFlags` specifies `STARTF_USESTDHANDLES`, this attribute is the standard output handle for the process. Otherwise, this attribute is ignored and the default for standard output is the console window's buffer.

hStdError

If `dwFlags` specifies `STARTF_USESTDHANDLES`, this attribute is the standard error handle for the process. Otherwise, this
attribute is ignored and the default for standard error is the console window's buffer.

**wShowWindow**
If `dwFlags` specifies `STARTF_USESHOWWINDOW`, this attribute can be any of the values that can be specified in the `nCmdShow` parameter for the `ShowWindow` function, except for `SW_SHOWDEFAULT`. Otherwise, this attribute is ignored.

`SW_HIDE` is provided for this attribute. It is used when `Popen` is called with `shell=True`.

### 17.5.3.1. Constants

The `subprocess` module exposes the following constants.

**subprocess.**`STD_INPUT_HANDLE`

The standard input device. Initially, this is the console input buffer, `CONIN$`.

**subprocess.**`STD_OUTPUT_HANDLE`

The standard output device. Initially, this is the active console screen buffer, `CONOUT$`.

**subprocess.**`STD_ERROR_HANDLE`

The standard error device. Initially, this is the active console screen buffer, `CONOUT$`.

**subprocess.**`SW_HIDE`

Hides the window. Another window will be activated.

**subprocess.**`STARTF_USESTDHANDLES`
Specifies that the `STARTUPINFO.hStdInput`, `STARTUPINFO.hStdOutput`, and `STARTUPINFO.hStdError` attributes contain additional information.

```
subprocess.STARTF_USESHOWWINDOW
```
Specifies that the `STARTUPINFO.wShowWindow` attribute contains additional information.

```
subprocess.CREATE_NEW_CONSOLE
```
The new process has a new console, instead of inheriting its parent's console (the default).

```
subprocess.CREATE_NEW_PROCESS_GROUP
```
A `Popen` `creationflags` parameter to specify that a new process group will be created. This flag is necessary for using `os.kill()` on the subprocess.

This flag is ignored if `CREATE_NEW_CONSOLE` is specified.
17.5.4. Replacing Older Functions with the `subprocess` Module

In this section, “a becomes b” means that b can be used as a replacement for a.

**Note:** All “a” functions in this section fail (more or less) silently if the executed program cannot be found; the “b” replacements raise `OSError` instead.

In addition, the replacements using `check_output()` will fail with a `CalledProcessError` if the requested operation produces a non-zero return code. The output is still available as the `output` attribute of the raised exception.

In the following examples, we assume that the relevant functions have already been imported from the `subprocess` module.

### 17.5.4.1. Replacing `/bin/sh` shell backquote

```python
output=`mycmd myarg`
# becomes
output = check_output(['mycmd', 'myarg'])
```

### 17.5.4.2. Replacing shell pipeline

```python
output=`dmesg | grep hda`
# becomes
p1 = Popen(['dmesg'], stdout=PIPE)
p2 = Popen(['grep', 'hda'], stdin=p1.stdout, stdout=...```
The `p1.stdout.close()` call after starting the `p2` is important in order for `p1` to receive a SIGPIPE if `p2` exits before `p1`.

Alternatively, for trusted input, the shell's own pipeline support may still be used directly:

```bash
output=`dmesg | grep hda`
# becomes
output=check_output("dmesg | grep hda", shell=True)
```

### 17.5.4.3. Replacing `os.system()`

```python
sts = os.system("mycmd" + " myarg")
# becomes
sts = call("mycmd" + " myarg", shell=True)
```

**Notes:**

- Calling the program through the shell is usually not required.

A more realistic example would look like this:

```python
try:
    retcode = call("mycmd" + " myarg", shell=True)
    if retcode < 0:
        print("Child was terminated by signal", -retcode)
    else:
        print("Child returned", retcode, file=sys.stderr)
except OSError as e:
    print("Execution failed:", e, file=sys.stderr)
```
17.5.4.4. Replacing the \texttt{os\_spawn} family

\textbf{P\_NOWAIT example:}

\begin{verbatim}
pid = os.spawnlp(os.P_NOWAIT, "/bin/mymcd", "mymcd",
==>
pid = Popen(["/bin/mymcd", "myarg"]).pid
\end{verbatim}

\textbf{P\_WAIT example:}

\begin{verbatim}
retcode = os.spawnlp(os.P_WAIT, "/bin/mymcd", "mymcd",
==>
retcode = call(["/bin/mymcd", "myarg"])
\end{verbatim}

\textbf{Vector example:}

\begin{verbatim}
os.spawnvp(os.P_NOWAIT, path, args)
==>
Popen([path] + args[1:])
\end{verbatim}

\textbf{Environment example:}

\begin{verbatim}
os.spawnlpe(os.P_NOWAIT, "/bin/mymcd", "mymcd", "myargs",
==>
Popen(["/bin/mymcd", "myarg"], env={"PATH": "/usr/bin"})
\end{verbatim}

17.5.4.5. Replacing \texttt{os\_popen()}, \texttt{os\_popen2()}, \texttt{os\_popen3()}

\begin{verbatim}
(child_stdin, child_stdout) = os.popen2(cmd, mode, buffer)
==>
\end{verbatim}
Return code handling translates as follows:

```
pipe = os.popen(cmd, 'w')
...
rc = pipe.close()
if rc is not None and rc >> 8:
    print("There were some errors")
=>
process = Popen(cmd, 'w', stdin=PIPE)
...
process.stdin.close()
if process.wait() != 0:
    print("There were some errors")
```
17.5.4.6. Replacing functions from the popen2 module

**Note:** If the cmd argument to popen2 functions is a string, the command is executed through `/bin/sh`. If it is a list, the command is directly executed.

```python
(child_stdout, child_stdin) = popen2.popen2("somestring")
p = Popen(['somestring'], shell=True, bufsize=bufsize,
           stdin=PIPE, stdout=PIPE, close_fds=True)
(child_stdout, child_stdin) = (p.stdout, p.stdin)
```

```python
(child_stdout, child_stdin) = popen2.popen2(['mycmd'])
p = Popen(['mycmd', 'myarg'], bufsize=bufsize,
           stdin=PIPE, stdout=PIPE, close_fds=True)
(child_stdout, child_stdin) = (p.stdout, p.stdin)
```

`popen2.Popen3` and `popen2.Popen4` basically work as `subprocess.Popen`, except that:

- **Popen** raises an exception if the execution fails.
- the `capturestderr` argument is replaced with the `stderr` argument.
- `stdin=PIPE` and `stdout=PIPE` must be specified.
- `popen2` closes all file descriptors by default, but you have to specify `close_fds=True` with **Popen** to guarantee this behavior on all platforms or past Python versions.
17.5.5. Legacy Shell Invocation Functions

This module also provides the following legacy functions from the 2.x commands module. These operations implicitly invoke the system shell and none of the guarantees described above regarding security and exception handling consistency are valid for these functions.

subprocess.getstatusoutput(cmd)
Return (status, output) of executing cmd in a shell.

Execute the string cmd in a shell with Popen.check_output() and return a 2-tuple (status, output). Universal newlines mode is used; see the notes on Frequently Used Arguments for more details.

A trailing newline is stripped from the output. The exit status for the command can be interpreted according to the rules for the C function wait(). Example:

```python
>>> subprocess.getstatusoutput('ls /bin/ls')
(0, '/bin/ls')
>>> subprocess.getstatusoutput('cat /bin/junk')
(256, 'cat: /bin/junk: No such file or directory')
>>> subprocess.getstatusoutput('/bin/junk')
(256, 'sh: /bin/junk: not found')
```

Availability: Unix & Windows

Changed in version 3.3.4: Windows support added

subprocess.getoutput(cmd)
Return output (stdout and stderr) of executing cmd in a shell.
Like `getstatusoutput()`, except the exit status is ignored and the return value is a string containing the command's output. Example:

```python
>>> subprocess.getoutput('ls /bin/ls')
'/bin/ls'
```

Availability: Unix & Windows

*Changed in version 3.3.4:* Windows support added
17.5.6. Notes

17.5.6.1. Converting an argument sequence to a string on Windows

On Windows, an \texttt{args} sequence is converted to a string that can be parsed using the following rules (which correspond to the rules used by the MS C runtime):

1. Arguments are delimited by white space, which is either a space or a tab.
2. A string surrounded by double quotation marks is interpreted as a single argument, regardless of white space contained within. A quoted string can be embedded in an argument.
3. A double quotation mark preceded by a backslash is interpreted as a literal double quotation mark.
4. Backslashes are interpreted literally, unless they immediately precede a double quotation mark.
5. If backslashes immediately precede a double quotation mark, every pair of backslashes is interpreted as a literal backslash. If the number of backslashes is odd, the last backslash escapes the next double quotation mark as described in rule 3.

\textbf{See also:}

\texttt{shlex}

Module which provides function to parse and escape command lines.
The `sched` module defines a class which implements a general purpose event scheduler:

```python
class sched.scheduler(timefunc=time.monotonic,
                      delayfunc=time.sleep)
```

The `scheduler` class defines a generic interface to scheduling events. It needs two functions to actually deal with the “outside world” — `timefunc` should be callable without arguments, and return a number (the “time”, in any units whatsoever). If `time.monotonic` is not available, the `timefunc` default is `time.time` instead. The `delayfunc` function should be callable with one argument, compatible with the output of `timefunc`, and should delay that many time units. `delayfunc` will also be called with the argument 0 after each event is run to allow other threads an opportunity to run in multi-threaded applications.

*Changed in version 3.3:* `timefunc` and `delayfunc` parameters are optional.

*Changed in version 3.3:* `scheduler` class can be safely used in multi-threaded environments.

Example:

```python
>>> import sched, time
>>> s = sched.scheduler(time.time, time.sleep)
>>> def print_time(a='default'):
```
... print("From print_time", time.time(), a)
...

>>> def print_some_times():
...     print(time.time())
...     s.enter(10, 1, print_time)
...     s.enter(5, 2, print_time, argument=('positional'))
...     s.enter(5, 1, print_time, kwargs={'a': 'keyword'})
...     s.run()
...     print(time.time())
...

>>> print_some_times()
930343690.257
From print_time 930343695.274 positional
From print_time 930343695.275 keyword
From print_time 930343700.273 default
930343700.276
17.6.1. Scheduler Objects

scheduler instances have the following methods and attributes:

scheduler.**enterabs**(time, priority, action, argument=(), kwargs={})

Schedule a new event. The *time* argument should be a numeric type compatible with the return value of the *timefunc* function passed to the constructor. Events scheduled for the same *time* will be executed in the order of their *priority*.

Executing the event means executing `action(*argument,**kwargs)`.

Return value is an event which may be used for later cancellation of the event (see `cancel()`).

*Changed in version 3.3:* *argument* parameter is optional.

*New in version 3.3:* *kwargs* parameter was added.

scheduler.**enter**(delay, priority, action, argument=(), kwargs={})

Schedule an event for *delay* more time units. Other than the relative time, the other arguments, the effect and the return value are the same as those for `enterabs()`.

*Changed in version 3.3:* *argument* parameter is optional.

*New in version 3.3:* *kwargs* parameter was added.

scheduler.**cancel**(event)
Remove the event from the queue. If *event* is not an event currently in the queue, this method will raise a *ValueError*.

 scheduler.**empty**()
  Return true if the event queue is empty.

 scheduler.**run**(blocking=True)
  Run all scheduled events. This method will wait (using the delayfunc() function passed to the constructor) for the next event, then execute it and so on until there are no more scheduled events.

  If *blocking* is false executes the scheduled events due to expire soonest (if any) and then return the deadline of the next scheduled call in the scheduler (if any).

  Either *action* or delayfunc can raise an exception. In either case, the scheduler will maintain a consistent state and propagate the exception. If an exception is raised by *action*, the event will not be attempted in future calls to run().

  If a sequence of events takes longer to run than the time available before the next event, the scheduler will simply fall behind. No events will be dropped; the calling code is responsible for canceling events which are no longer pertinent.

  *New in version 3.3: blocking parameter was added.*

 scheduler.**queue**
  Read-only attribute returning a list of upcoming events in the order they will be run. Each event is shown as a *named tuple* with the following fields: time, priority, action, argument, kwargs.
17.7. queue — A synchronized queue class

Source code: Lib/queue.py

The queue module implements multi-producer, multi-consumer queues. It is especially useful in threaded programming when information must be exchanged safely between multiple threads. The Queue class in this module implements all the required locking semantics. It depends on the availability of thread support in Python; see the threading module.

The module implements three types of queue, which differ only in the order in which the entries are retrieved. In a FIFO queue, the first tasks added are the first retrieved. In a LIFO queue, the most recently added entry is the first retrieved (operating like a stack). With a priority queue, the entries are kept sorted (using the heapq module) and the lowest valued entry is retrieved first.

The queue module defines the following classes and exceptions:

class queue.Queue(maxsize=0)

Constructor for a FIFO queue. maxsize is an integer that sets the upperbound limit on the number of items that can be placed in the queue. Insertion will block once this size has been reached, until queue items are consumed. If maxsize is less than or equal to zero, the queue size is infinite.

class queue.LifoQueue(maxsize=0)

Constructor for a LIFO queue. maxsize is an integer that sets the
upperbound limit on the number of items that can be placed in the queue. Insertion will block once this size has been reached, until queue items are consumed. If \textit{maxsize} is less than or equal to zero, the queue size is infinite.

\texttt{class queue.\texttt{PriorityQueue}(maxsize=0)}

Constructor for a priority queue. \textit{maxsize} is an integer that sets the upperbound limit on the number of items that can be placed in the queue. Insertion will block once this size has been reached, until queue items are consumed. If \textit{maxsize} is less than or equal to zero, the queue size is infinite.

The lowest valued entries are retrieved first (the lowest valued entry is the one returned by \texttt{sorted(list(entries))[0]}). A typical pattern for entries is a tuple in the form: \texttt{(priority\_number, data)}.

\texttt{exception queue.\texttt{Empty}}

Exception raised when non-blocking \texttt{get()} (or \texttt{get\_nowait()}) is called on a \texttt{Queue} object which is empty.

\texttt{exception queue.\texttt{Full}}

Exception raised when non-blocking \texttt{put()} (or \texttt{put\_nowait()}) is called on a \texttt{Queue} object which is full.
17.7.1. Queue Objects

Queue objects (Queue, LifoQueue, or PriorityQueue) provide the public methods described below.

Queue.qsize()
Return the approximate size of the queue. Note, qsize() > 0 doesn’t guarantee that a subsequent get() will not block, nor will qsize() < maxsize guarantee that put() will not block.

Queue.empty()
Return True if the queue is empty, False otherwise. If empty() returns True it doesn’t guarantee that a subsequent call to put() will not block. Similarly, if empty() returns False it doesn’t guarantee that a subsequent call to get() will not block.

Queue.full()
Return True if the queue is full, False otherwise. If full() returns True it doesn’t guarantee that a subsequent call to get() will not block. Similarly, if full() returns False it doesn’t guarantee that a subsequent call to put() will not block.

Queue.put(item, block=True, timeout=None)
Put item into the queue. If optional args block is true and timeout is None (the default), block if necessary until a free slot is available. If timeout is a positive number, it blocks at most timeout seconds and raises the Full exception if no free slot was available within that time. Otherwise (block is false), put an item on the queue if a free slot is immediately available, else raise the Full exception (timeout is ignored in that case).
Queue. **put_nowait**(item)

Equivalent to `put(item, False)`.

Queue. **get**(block=True, timeout=None)

Remove and return an item from the queue. If optional args `block` is true and `timeout` is None (the default), block if necessary until an item is available. If `timeout` is a positive number, it blocks at most `timeout` seconds and raises the **Empty** exception if no item was available within that time. Otherwise (`block` is false), return an item if one is immediately available, else raise the **Empty** exception (`timeout` is ignored in that case).

Queue. **get_nowait**()

Equivalent to `get(False)`.

Two methods are offered to support tracking whether enqueued tasks have been fully processed by daemon consumer threads.

Queue. **task_done**()

Indicate that a formerly enqueued task is complete. Used by queue consumer threads. For each `get()` used to fetch a task, a subsequent call to `task_done()` tells the queue that the processing on the task is complete.

If a `join()` is currently blocking, it will resume when all items have been processed (meaning that a `task_done()` call was received for every item that had been `put()` into the queue).

Raises a **ValueError** if called more times than there were items placed in the queue.

Queue. **join**()
Blocks until all items in the queue have been gotten and processed.

The count of unfinished tasks goes up whenever an item is added to the queue. The count goes down whenever a consumer thread calls `task_done()` to indicate that the item was retrieved and all work on it is complete. When the count of unfinished tasks drops to zero, `join()` unblocks.

Example of how to wait for enqueued tasks to be completed:

```python
def worker():
    while True:
        item = q.get()
        do_work(item)
        q.task_done()

q = Queue()
for i in range(num_worker_threads):
    t = Thread(target=worker)
    t.daemon = True
    t.start()

for item in source():
    q.put(item)

q.join()  # block until all tasks are done
```

See also:

**Class `multiprocessing.Queue`**

A queue class for use in a multi-processing (rather than multi-threading) context.

`collections.deque` is an alternative implementation of
unbounded queues with fast atomic `append()` and `popleft()` operations that do not require locking.
17.8. **dummy_threading** — Drop-in replacement for the `threading` module

**Source code:** Lib/dummy_threading.py

This module provides a duplicate interface to the `threading` module. It is meant to be imported when the `_thread` module is not provided on a platform.

Suggested usage is:

```python
try:
    import threading
except ImportError:
    import dummy_threading as threading
```

Be careful to not use this module where deadlock might occur from a thread being created that blocks waiting for another thread to be created. This often occurs with blocking I/O.
17.9. _thread — Low-level threading API

This module provides low-level primitives for working with multiple threads (also called light-weight processes or tasks) — multiple threads of control sharing their global data space. For synchronization, simple locks (also called mutexes or binary semaphores) are provided. The threading module provides an easier to use and higher-level threading API built on top of this module.

The module is optional. It is supported on Windows, Linux, SGI IRIX, Solaris 2.x, as well as on systems that have a POSIX thread (a.k.a. “pthread”) implementation. For systems lacking the _thread module, the _dummy_thread module is available. It duplicates this module's interface and can be used as a drop-in replacement.

It defines the following constants and functions:

(exception) _thread.error
Raised on thread-specific errors.

  Changed in version 3.3: This is now a synonym of the built-in RuntimeError.

_thread.LockType
This is the type of lock objects.

_thread.start_new_thread(function, args[, kwargs])
Start a new thread and return its identifier. The thread executes the function function with the argument list args (which must be a
tuple). The optional *kwargs argument specifies a dictionary of keyword arguments. When the function returns, the thread silently exits. When the function terminates with an unhandled exception, a stack trace is printed and then the thread exits (but other threads continue to run).

_thread.interrupt_main()

Raise a KeyboardInterrupt exception in the main thread. A subthread can use this function to interrupt the main thread.

_thread.exit()

Raise the SystemExit exception. When not caught, this will cause the thread to exit silently.

_thread.allocate_lock()

Return a new lock object. Methods of locks are described below. The lock is initially unlocked.

_thread.get_ident()

Return the ‘thread identifier’ of the current thread. This is a nonzero integer. Its value has no direct meaning; it is intended as a magic cookie to be used e.g. to index a dictionary of thread-specific data. Thread identifiers may be recycled when a thread exits and another thread is created.

_thread.stack_size([size])

Return the thread stack size used when creating new threads. The optional size argument specifies the stack size to be used for subsequently created threads, and must be 0 (use platform or configured default) or a positive integer value of at least 32,768 (32 KiB). If changing the thread stack size is unsupported, a RuntimeError is raised. If the specified stack size is invalid,
**ValueError** is raised and the stack size is unmodified. 32 KiB is currently the minimum supported stack size value to guarantee sufficient stack space for the interpreter itself. Note that some platforms may have particular restrictions on values for the stack size, such as requiring a minimum stack size > 32 KiB or requiring allocation in multiples of the system memory page size - platform documentation should be referred to for more information (4 KiB pages are common; using multiples of 4096 for the stack size is the suggested approach in the absence of more specific information). Availability: Windows, systems with POSIX threads.

**_thread.TIMEOUT_MAX**

The maximum value allowed for the `timeout` parameter of `Lock.acquire()`. Specifying a timeout greater than this value will raise an *OverflowError*.

*New in version 3.2.*

Lock objects have the following methods:

**lock.acquire(waitflag=1, timeout=-1)**

Without any optional argument, this method acquires the lock unconditionally, if necessary waiting until it is released by another thread (only one thread at a time can acquire a lock — that’s their reason for existence).

If the integer `waitflag` argument is present, the action depends on its value: if it is zero, the lock is only acquired if it can be acquired immediately without waiting, while if it is nonzero, the lock is acquired unconditionally as above.

If the floating-point `timeout` argument is present and positive, it specifies the maximum wait time in seconds before returning. A
negative \textit{timeout} argument specifies an unbounded wait. You cannot specify a \textit{timeout} if \textit{waitflag} is zero.

The return value is \texttt{True} if the lock is acquired successfully, \texttt{False} if not.

\textit{Changed in version 3.2:} The \textit{timeout} parameter is new.

\textit{Changed in version 3.2:} Lock acquires can now be interrupted by signals on POSIX.

\texttt{lock.release()}

Releases the lock. The lock must have been acquired earlier, but not necessarily by the same thread.

\texttt{lock.locked()}

Return the status of the lock: \texttt{True} if it has been acquired by some thread, \texttt{False} if not.

In addition to these methods, lock objects can also be used via the \texttt{with} statement, e.g.:

\begin{verbatim}
import _thread

a_lock = _thread.allocate_lock()

with a_lock:
    print("a_lock is locked while this executes")
\end{verbatim}

\textbf{Caveats:}

- Threads interact strangely with interrupts: the \texttt{KeyboardInterrupt} exception will be received by an arbitrary thread. (When the \texttt{signal} module is available, interrupts always
go to the main thread.)

- Calling `sys.exit()` or raising the `SystemExit` exception is equivalent to calling `_thread.exit()`.
- Not all built-in functions that may block waiting for I/O allow other threads to run. (The most popular ones (`time.sleep()`, `io.FileIO.read()`, `select.select()`) work as expected.)
- It is not possible to interrupt the `acquire()` method on a lock — the `KeyboardInterrupt` exception will happen after the lock has been acquired.
- When the main thread exits, it is system defined whether the other threads survive. On most systems, they are killed without executing `try ... finally` clauses or executing object destructors.
- When the main thread exits, it does not do any of its usual cleanup (except that `try ... finally` clauses are honored), and the standard I/O files are not flushed.
17.10. **_dummy_thread** — Drop-in replacement for the **_thread** module

**Source code:** Lib/_dummy_thread.py

This module provides a duplicate interface to the **_thread** module. It is meant to be imported when the **_thread** module is not provided on a platform.

Suggested usage is:

```python
try:
    import _thread
except ImportError:
    import _dummy_thread as _thread
```

Be careful to not use this module where deadlock might occur from a thread being created that blocks waiting for another thread to be created. This often occurs with blocking I/O.
18. Interprocess Communication and Networking

The modules described in this chapter provide mechanisms for different processes to communicate.

Some modules only work for two processes that are on the same machine, e.g. signal and mmap. Other modules support networking protocols that two or more processes can use to communicate across machines.

The list of modules described in this chapter is:

- **18.1. socket** — Low-level networking interface
  - 18.1.1. Socket families
  - 18.1.2. Module contents
    - 18.1.2.1. Exceptions
    - 18.1.2.2. Constants
    - 18.1.2.3. Functions
      - 18.1.2.3.1. Creating sockets
      - 18.1.2.3.2. Other functions
  - 18.1.3. Socket Objects
  - 18.1.4. Notes on socket timeouts
    - 18.1.4.1. Timeouts and the connect method
    - 18.1.4.2. Timeouts and the accept method
  - 18.1.5. Example
- **18.2. ssl** — TLS/SSL wrapper for socket objects
  - 18.2.1. Functions, Constants, and Exceptions
    - 18.2.1.1. Socket creation
    - 18.2.1.2. Context creation
    - 18.2.1.3. Random generation
    - 18.2.1.4. Certificate handling
18.2.1.5. Constants
  - 18.2.2. SSL Sockets
  - 18.2.3. SSL Contexts
  - 18.2.4. Certificates
    - 18.2.4.1. Certificate chains
    - 18.2.4.2. CA certificates
    - 18.2.4.3. Combined key and certificate
    - 18.2.4.4. Self-signed certificates
  - 18.2.5. Examples
    - 18.2.5.1. Testing for SSL support
    - 18.2.5.2. Client-side operation
    - 18.2.5.3. Server-side operation
  - 18.2.6. Notes on non-blocking sockets
  - 18.2.7. Security considerations
    - 18.2.7.1. Verifying certificates
    - 18.2.7.2. Protocol versions
    - 18.2.7.3. Cipher selection
    - 18.2.7.4. Multi-processing

18.3. select — Waiting for I/O completion
  - 18.3.1. /dev/poll Polling Objects
  - 18.3.2. Edge and Level Trigger Polling (epoll) Objects
  - 18.3.3. Polling Objects
  - 18.3.4. Kqueue Objects
  - 18.3.5. Kevent Objects

18.4. selectors – High-level I/O multiplexing
  - 18.4.1. Introduction
  - 18.4.2. Classes
  - 18.4.3. Examples

18.5. asyncio – Asynchronous I/O, event loop, coroutines and tasks
  - 18.5.1. Event loops
    - 18.5.1.1. Event loop policies and the default policy
    - 18.5.1.2. Event loop functions
    - 18.5.1.3. Event loop policy interface
- 18.5.1.4. Access to the global loop policy
- 18.5.1.5. Run an event loop
- 18.5.1.6. Calls
- 18.5.1.7. Delayed calls
- 18.5.1.8. Creating connections
- 18.5.1.9. Creating listening connections
- 18.5.1.10. Watch file descriptors
- 18.5.1.11. Low-level socket operations
- 18.5.1.12. Resolve host name
- 18.5.1.13. Running subprocesses
- 18.5.1.14. UNIX signals
- 18.5.1.15. Executor
- 18.5.1.16. Error Handling API
- 18.5.1.17. Debug mode
- 18.5.1.18. Server
- 18.5.1.19. Handle
- 18.5.1.20. Example: Hello World (callback)
- 18.5.1.21. Example: Set signal handlers for SIGINT and SIGTERM

○ 18.5.2. Tasks and coroutines
  - 18.5.2.1. Coroutines
    - 18.5.2.1.1. Example: “Hello World” coroutine
    - 18.5.2.1.2. Example: Chain coroutines
  - 18.5.2.2. InvalidStateError
  - 18.5.2.3. Future
    - 18.5.2.3.1. Example: Future with run_until_complete()
    - 18.5.2.3.2. Example: Future with run_forever()
  - 18.5.2.4. Task
    - 18.5.2.4.1. Example: Parallel execution of tasks
  - 18.5.2.5. Task functions

○ 18.5.3. Transports and protocols (low-level API)
  - 18.5.3.1. Transports
    - 18.5.3.1.1. BaseTransport
18.5.3.1.2. ReadTransport
18.5.3.1.3. WriteTransport
18.5.3.1.4. DatagramTransport
18.5.3.1.5. BaseSubprocessTransport

18.5.3.2. Protocols
  18.5.3.2.1. Protocol classes
  18.5.3.2.2. Connection callbacks
  18.5.3.2.3. Streaming protocols
  18.5.3.2.4. Datagram protocols
  18.5.3.2.5. Flow control callbacks
  18.5.3.2.6. Coroutines and protocols

18.5.3.3. Protocol example: TCP echo server and client
  18.5.3.3.1. Echo client
  18.5.3.3.2. Echo server

18.5.4. Streams (high-level API)
  18.5.4.1. Stream functions
  18.5.4.2. StreamReader
  18.5.4.3. StreamWriter
  18.5.4.4. StreamReaderProtocol
  18.5.4.5. IncompleteReadError
  18.5.4.6. Example

18.5.5. Subprocess
  18.5.5.1. Create a subprocess
  18.5.5.2. Constants
  18.5.5.3. Process
  18.5.5.4. Example

18.5.6. Synchronization primitives
  18.5.6.1. Locks
    18.5.6.1.1. Lock
    18.5.6.1.2. Event
    18.5.6.1.3. Condition
  18.5.6.2. Semaphores
    18.5.6.2.1. Semaphore
    18.5.6.2.2. BoundedSemaphore
- 18.5.6.3. Queues
  - 18.5.6.3.1. Queue
  - 18.5.6.3.2. PriorityQueue
  - 18.5.6.3.3. LifoQueue
  - 18.5.6.3.4. JoinableQueue
  - 18.5.6.3.5. Exceptions
- 18.5.7. Develop with asyncio
  - 18.5.7.1. Concurrency and multithreading
  - 18.5.7.2. Handle blocking functions correctly
  - 18.5.7.3. Logging
  - 18.5.7.4. Detect coroutine objects never scheduled
  - 18.5.7.5. Detect exceptions not consumed
  - 18.5.7.6. Chain coroutines correctly
- 18.6. asyncore — Asynchronous socket handler
  - 18.6.1. asyncore Example basic HTTP client
  - 18.6.2. asyncore Example basic echo server
- 18.7. asynchat — Asynchronous socket command/response handler
  - 18.7.1. asynchat - Auxiliary Classes
  - 18.7.2. asynchat Example
- 18.8. signal — Set handlers for asynchronous events
  - 18.8.1. General rules
    - 18.8.1.1. Execution of Python signal handlers
    - 18.8.1.2. Signals and threads
  - 18.8.2. Module contents
  - 18.8.3. Example
- 18.9. mmap — Memory-mapped file support
18.1. **socket** — Low-level networking interface

This module provides access to the BSD `socket` interface. It is available on all modern Unix systems, Windows, MacOS, and probably additional platforms.

**Note:** Some behavior may be platform dependent, since calls are made to the operating system socket APIs.

The Python interface is a straightforward transliteration of the Unix system call and library interface for sockets to Python's object-oriented style: the `socket()` function returns a `socket object` whose methods implement the various socket system calls. Parameter types are somewhat higher-level than in the C interface: as with `read()` and `write()` operations on Python files, buffer allocation on receive operations is automatic, and buffer length is implicit on send operations.

**See also:**

**Module** `socketserver`
- Classes that simplify writing network servers.

**Module** `ssl`
- A TLS/SSL wrapper for socket objects.
18.1.1. Socket families

Depending on the system and the build options, various socket families are supported by this module.

The address format required by a particular socket object is automatically selected based on the address family specified when the socket object was created. Socket addresses are represented as follows:

- The address of an AF_UNIX socket bound to a file system node is represented as a string, using the file system encoding and the 'surrogateescape' error handler (see PEP 383). An address in Linux's abstract namespace is returned as a bytes object with an initial null byte; note that sockets in this namespace can communicate with normal file system sockets, so programs intended to run on Linux may need to deal with both types of address. A string or bytes object can be used for either type of address when passing it as an argument.

  Changed in version 3.3: Previously, AF_UNIX socket paths were assumed to use UTF-8 encoding.

- A pair (host, port) is used for the AF_INET address family, where host is a string representing either a hostname in Internet domain notation like 'daring.cwi.nl' or an IPv4 address like '100.50.200.5', and port is an integer.

- For AF_INET6 address family, a four-tuple (host, port, flowinfo, scopeid) is used, where flowinfo and scopeid represent the sin6_flowinfo and sin6_scope_id members.
in *struct sockaddr_in6* in C. For *socket* module methods, *flowinfo* and *scopeid* can be omitted just for backward compatibility. Note, however, omission of *scopeid* can cause problems in manipulating scoped IPv6 addresses.

- **AF_NETLINK** sockets are represented as pairs (*pid*, *groups*).

- Linux-only support for TIPC is available using the **AF_TIPC** address family. TIPC is an open, non-IP based networked protocol designed for use in clustered computer environments. Addresses are represented by a tuple, and the fields depend on the address type. The general tuple form is `(addr_type, v1, v2, v3 [, scope])`, where:
  
  - *addr_type* is one of  **TIPC_ADDR_NAMESEQ**,  **TIPC_ADDR_NAME**, or **TIPC_ADDR_ID**.
  
  - *scope* is one of  **TIPC_ZONE_SCOPE**,  **TIPC_CLUSTER_SCOPE**, and **TIPC_NODE_SCOPE**.

  - If *addr_type* is **TIPC_ADDR_NAME**, then *v1* is the server type, *v2* is the port identifier, and *v3* should be 0.

  If *addr_type* is **TIPC_ADDR_NAMESEQ**, then *v1* is the server type, *v2* is the lower port number, and *v3* is the upper port number.

  If *addr_type* is **TIPC_ADDR_ID**, then *v1* is the node, *v2* is the reference, and *v3* should be set to 0.

  If *addr_type* is **TIPC_ADDR_ID**, then *v1* is the node, *v2* is the reference, and *v3* should be set to 0.
A tuple `(interface,)` is used for the `AF_CAN` address family, where `interface` is a string representing a network interface name like 'can0'. The network interface name '' can be used to receive packets from all network interfaces of this family.

A string or a tuple `(id, unit)` is used for the `SYSPROTO_CONTROL` protocol of the `PF_SYSTEM` family. The string is the name of a kernel control using a dynamically-assigned ID. The tuple can be used if ID and unit number of the kernel control are known or if a registered ID is used.

*New in version 3.3.*

- Certain other address families (`AF_BLUETOOTH`, `AF_PACKET`, `AF_CAN`) support specific representations.

For IPv4 addresses, two special forms are accepted instead of a host address: the empty string represents `INADDR_ANY`, and the string '<broadcast>' represents `INADDR_BROADCAST`. This behavior is not compatible with IPv6, therefore, you may want to avoid these if you intend to support IPv6 with your Python programs.

If you use a hostname in the `host` portion of IPv4/v6 socket address, the program may show a nondeterministic behavior, as Python uses the first address returned from the DNS resolution. The socket address will be resolved differently into an actual IPv4/v6 address, depending on the results from DNS resolution and/or the host configuration. For deterministic behavior use a numeric address in `host` portion.

All errors raise exceptions. The normal exceptions for invalid argument types and out-of-memory conditions can be raised; starting from Python 3.3, errors related to socket or address semantics raise
OSError or one of its subclasses (they used to raise socket.error).

Non-blocking mode is supported through setblocking(). A generalization of this based on timeouts is supported through settimeout().
18.1.2. Module contents

The module `socket` exports the following elements.

18.1.2.1. Exceptions

`exception` `socket.error`
A deprecated alias of `OSError`.

*Changed in version 3.3:* Following PEP 3151, this class was made an alias of `OSError`.

`exception` `socket.herror`
A subclass of `OSError`, this exception is raised for address-related errors, i.e. for functions that use `h_errno` in the POSIX C API, including `gethostbyname_ex()` and `gethostbyaddr()`. The accompanying value is a pair `(h_errno, string)` representing an error returned by a library call. `h_errno` is a numeric value, while `string` represents the description of `h_errno`, as returned by the `hstrerror()` C function.

*Changed in version 3.3:* This class was made a subclass of `OSError`.

`exception` `socket.gaierror`
A subclass of `OSError`, this exception is raised for address-related errors by `getaddrinfo()` and `getnameinfo()`. The accompanying value is a pair `(error, string)` representing an error returned by a library call. `string` represents the description of `error`, as returned by the `gai_strerror()` C function. The numeric `error` value will match one of the EAI_* constants defined...
in this module.

*Changed in version 3.3:* This class was made a subclass of OSError.

**exception socket.timeout**

A subclass of OSError, this exception is raised when a timeout occurs on a socket which has had timeouts enabled via a prior call to `settimeout()` (or implicitly through `setdefaulttimeout()`). The accompanying value is a string whose value is currently always “timed out”.

*Changed in version 3.3:* This class was made a subclass of OSError.

### 18.1.2.2. Constants

**socket.AF_UNIX**
**socket.AF_INET**
**socket.AF_INET6**

These constants represent the address (and protocol) families, used for the first argument to `socket()`. If the AF_UNIX constant is not defined then this protocol is unsupported. More constants may be available depending on the system.

**socket.SOCK_STREAM**
**socket.SOCK_DGRAM**
**socket.SOCK_RAW**
**socket.SOCK_RDM**
**socket.SOCK_SEQPACKET**

These constants represent the socket types, used for the second argument to `socket()`. More constants may be available
depending on the system. (Only \texttt{SOCK\_STREAM} and \texttt{SOCK\_DGRAM} appear to be generally useful.)

\begin{verbatim}
socket.SOCK_CLOEXEC
socket.SOCK_NONBLOCK
\end{verbatim}

These two constants, if defined, can be combined with the socket types and allow you to set some flags atomically (thus avoiding possible race conditions and the need for separate calls).

\begin{verbatim}
See also: Secure File Descriptor Handling for a more thorough explanation.
\end{verbatim}

Availability: Linux \textgreater= 2.6.27.

\textit{New in version 3.2.}

\begin{verbatim}
SO_*
socket.SOMAXCONN
MSG_*
SOL_*
SCM_*
IPPROTO_*
IPPORT_*
INADDR_*
IP_*
IPV6_*
EAI_*
AI_*
NI_*
TCP_*
\end{verbatim}

Many constants of these forms, documented in the Unix documentation on sockets and/or the IP protocol, are also defined in the socket module. They are generally used in arguments to the
setsockopt() and getsockopt() methods of socket objects. In most cases, only those symbols that are defined in the Unix header files are defined; for a few symbols, default values are provided.

socket.AF_CAN
socket.PF_CAN
SOL_CAN_*
CAN_*

Many constants of these forms, documented in the Linux documentation, are also defined in the socket module.

Availability: Linux >= 2.6.25.

New in version 3.3.

socket.CAN_BCM
CAN_BCM_*

CAN_BCM, in the CAN protocol family, is the broadcast manager (BCM) protocol. Broadcast manager constants, documented in the Linux documentation, are also defined in the socket module.

Availability: Linux >= 2.6.25.

New in version 3.4.

socket.AF_RDS
socket.PF_RDS
socket.SOL_RDS
RDS_*

Many constants of these forms, documented in the Linux documentation, are also defined in the socket module.

Availability: Linux >= 2.6.30.
New in version 3.3.

**SIO_***
**RCVALL_***

Constants for Windows' WSAIoctl(). The constants are used as arguments to the `ioctl()` method of socket objects.

**TIPC_***

TIPC related constants, matching the ones exported by the C socket API. See the TIPC documentation for more information.

socket. **AF_LINK**

Availability: BSD, OSX.

New in version 3.4.

socket. **has_ipv6**

This constant contains a boolean value which indicates if IPv6 is supported on this platform.

### 18.1.2.3. Functions

#### 18.1.2.3.1. Creating sockets

The following functions all create *socket objects*.

socket. **socket**(family=AF_INET, type=SOCK_STREAM, proto=0, fileno=None)

Create a new socket using the given address family, socket type and protocol number. The address family should be *AF_INET* (the default), *AF_INET6*, *AF_UNIX*, *AF_CAN* or *AF_RDS*. The socket type should be *SOCK_STREAM* (the default), *SOCK_DGRAM*, *SOCK_RAW* or perhaps one of the other *SOCK_* constants. The
protocol number is usually zero and may be omitted or in the case where the address family is **AF_CAN** the protocol should be one of **CAN_RAW** or **CAN_BCM**.

The newly created socket is **non-inheritable**.

*Changed in version 3.3*: The **AF_CAN** family was added. The **AF_RDS** family was added.

*Changed in version 3.4*: The **CAN_BCM** protocol was added.

*Changed in version 3.4*: The returned socket is now non-inheritable.

```python
socket.socketpair([family[, type[, proto]]])
```

Build a pair of connected socket objects using the given address family, socket type, and protocol number. Address family, socket type, and protocol number are as for the `socket()` function above. The default family is **AF_UNIX** if defined on the platform; otherwise, the default is **AF_INET**. Availability: Unix.

The newly created sockets are **non-inheritable**.

*Changed in version 3.2*: The returned socket objects now support the whole socket API, rather than a subset.

*Changed in version 3.4*: The returned sockets are now non-inheritable.

```python
socket.create_connection(address[, timeout[, source_address]])
```

Connect to a TCP service listening on the Internet **address** (a 2-tuple `(host, port)`), and return the socket object. This is a
higher-level function than `socket.connect()`: if `host` is a non-numeric hostname, it will try to resolve it for both `AF_INET` and `AF_INET6`, and then try to connect to all possible addresses in turn until a connection succeeds. This makes it easy to write clients that are compatible to both IPv4 and IPv6.

Passing the optional `timeout` parameter will set the timeout on the socket instance before attempting to connect. If no `timeout` is supplied, the global default timeout setting returned by `getdefaulttimeout()` is used.

If supplied, `source_address` must be a 2-tuple `(host, port)` for the socket to bind to as its source address before connecting. If `host` or `port` are "" or 0 respectively the OS default behavior will be used.

*Changed in version 3.2*: `source_address` was added.

*Changed in version 3.2*: support for the `with` statement was added.

`sокет .fromfd(fd, family, type, proto=0)`

Duplicate the file descriptor `fd` (an integer as returned by a file object's `fileno()` method) and build a socket object from the result. Address family, socket type and protocol number are as for the `socket()` function above. The file descriptor should refer to a socket, but this is not checked — subsequent operations on the object may fail if the file descriptor is invalid. This function is rarely needed, but can be used to get or set socket options on a socket passed to a program as standard input or output (such as a server started by the Unix inet daemon). The socket is assumed to be in blocking mode.
The newly created socket is *non-inheritable*.

*Changed in version 3.4:* The returned socket is now non-inheritable.

socket.`fromshare`(data)

Instantiate a socket from data obtained from the `socket.share()` method. The socket is assumed to be in blocking mode.

Availability: Windows.

*New in version 3.3.*

socket.`SocketType`

This is a Python type object that represents the socket object type. It is the same as `type(socket(...))`.

18.1.2.3.2. Other functions

The `socket` module also offers various network-related services:

socket.`getaddrinfo`(host, port, family=0, type=0, proto=0, flags=0)

Translate the *host/port* argument into a sequence of 5-tuples that contain all the necessary arguments for creating a socket connected to that service. *host* is a domain name, a string representation of an IPv4/v6 address or None. *port* is a string service name such as 'http', a numeric port number or None. By passing None as the value of *host* and *port*, you can pass NULL to the underlying C API.

The *family, type* and *proto* arguments can be optionally specified in
order to narrow the list of addresses returned. Passing zero as a value for each of these arguments selects the full range of results. The flags argument can be one or several of the AI_* constants, and will influence how results are computed and returned. For example, AI_NUMERICHOST will disable domain name resolution and will raise an error if host is a domain name.

The function returns a list of 5-tuples with the following structure:

(family, type, proto, canonname, sockaddr)

In these tuples, family, type, proto are all integers and are meant to be passed to the socket() function. canonname will be a string representing the canonical name of the host if AI_CANONNAME is part of the flags argument; else canonname will be empty. sockaddr is a tuple describing a socket address, whose format depends on the returned family (a (address, port) 2-tuple for AF_INET, a (address, port, flow info, scope id) 4-tuple for AF_INET6), and is meant to be passed to the socket.connect() method.

The following example fetches address information for a hypothetical TCP connection to www.python.org on port 80 (results may differ on your system if IPv6 isn’t enabled):

```python
>>> socket.getaddrinfo("www.python.org", 80, proto[(2, 1, 6, '', ('82.94.164.162', 80)),
         (10, 1, 6, '', ('2001:888:2000:d::a2', 80, 0, 0))]
```

*Changed in version 3.2:* parameters can now be passed using keyword arguments.
socket.**getfqdn**(\*name\*)

Return a fully qualified domain name for \*name\*. If \*name\* is omitted or empty, it is interpreted as the local host. To find the fully qualified name, the hostname returned by **gethostbyaddr()** is checked, followed by aliases for the host, if available. The first name which includes a period is selected. In case no fully qualified domain name is available, the hostname as returned by **gettextname()** is returned.

socket.**gethostbyname**(hostname)

Translate a host name to IPv4 address format. The IPv4 address is returned as a string, such as '100.50.200.5'. If the host name is an IPv4 address itself it is returned unchanged. See **gethostbyname_ex()** for a more complete interface. **gethostbyname()** does not support IPv6 name resolution, and **getaddrinfo()** should be used instead for IPv4/v6 dual stack support.

socket.**gethostbyname_ex**(hostname)

Translate a host name to IPv4 address format, extended interface. Return a triple (hostname, aliaslist, ipaddrlist) where hostname is the primary host name responding to the given ip_address, aliaslist is a (possibly empty) list of alternative host names for the same address, and ipaddrlist is a list of IPv4 addresses for the same interface on the same host (often but not always a single address). **gethostbyname_ex()** does not support IPv6 name resolution, and **getaddrinfo()** should be used instead for IPv4/v6 dual stack support.

socket.**gethostname()**

Return a string containing the hostname of the machine where the
Python interpreter is currently executing.

If you want to know the current machine’s IP address, you may want to use `gethostbyname(gethostname())`. This operation assumes that there is a valid address-to-host mapping for the host, and the assumption does not always hold.

Note: `gethostname()` doesn’t always return the fully qualified domain name; use `getfqdn()` (see above).

**socket.** `gethostbyaddr(ip_address)`

Return a triple `(hostname, aliaslist, ipaddrlist)` where `hostname` is the primary host name responding to the given `ip_address`, `aliaslist` is a (possibly empty) list of alternative host names for the same address, and `ipaddrlist` is a list of IPv4/IPv6 addresses for the same interface on the same host (most likely containing only a single address). To find the fully qualified domain name, use the function `getfqdn()`. `gethostbyaddr()` supports both IPv4 and IPv6.

**socket.** `getnameinfo(sockaddr, flags)`

Translate a socket address `sockaddr` into a 2-tuple `(host, port)`. Depending on the settings of `flags`, the result can contain a fully-qualified domain name or numeric address representation in `host`. Similarly, `port` can contain a string port name or a numeric port number.

**socket.** `getprotobynname(protocolname)`

Translate an Internet protocol name (for example, `'icmp'`) to a constant suitable for passing as the (optional) third argument to the `socket()` function. This is usually only needed for sockets opened in “raw” mode (`SOCK_RAW`); for the normal socket modes,
the correct protocol is chosen automatically if the protocol is omitted or zero.

socket.getservbyname(servicename[, protocolname])
Translate an Internet service name and protocol name to a port number for that service. The optional protocol name, if given, should be 'tcp' or 'udp', otherwise any protocol will match.

socket.getservbyport(port[, protocolname])
Translate an Internet port number and protocol name to a service name for that service. The optional protocol name, if given, should be 'tcp' or 'udp', otherwise any protocol will match.

socket.ntohl(x)
Convert 32-bit positive integers from network to host byte order. On machines where the host byte order is the same as network byte order, this is a no-op; otherwise, it performs a 4-byte swap operation.

socket.ntohs(x)
Convert 16-bit positive integers from network to host byte order. On machines where the host byte order is the same as network byte order, this is a no-op; otherwise, it performs a 2-byte swap operation.

socket.htonl(x)
Convert 32-bit positive integers from host to network byte order. On machines where the host byte order is the same as network byte order, this is a no-op; otherwise, it performs a 4-byte swap operation.

socket.htons(x)
Convert 16-bit positive integers from host to network byte order. On machines where the host byte order is the same as network byte order, this is a no-op; otherwise, it performs a 2-byte swap operation.

**socket.inet_aton(ip_string)**

Convert an IPv4 address from dotted-quad string format (for example, ‘123.45.67.89’) to 32-bit packed binary format, as a bytes object four characters in length. This is useful when conversing with a program that uses the standard C library and needs objects of type `struct in_addr`, which is the C type for the 32-bit packed binary this function returns.

`inet_aton()` also accepts strings with less than three dots; see the Unix manual page `inet(3)` for details.

If the IPv4 address string passed to this function is invalid, **OSError** will be raised. Note that exactly what is valid depends on the underlying C implementation of `inet_aton()`.

`inet_aton()` does not support IPv6, and `inet_ntop()` should be used instead for IPv4/v6 dual stack support.

**socket.inet_ntoa(packed_ip)**

Convert a 32-bit packed IPv4 address (a bytes object four characters in length) to its standard dotted-quad string representation (for example, ‘123.45.67.89’). This is useful when conversing with a program that uses the standard C library and needs objects of type `struct in_addr`, which is the C type for the 32-bit packed binary data this function takes as an argument.

If the byte sequence passed to this function is not exactly 4 bytes in length, **OSError** will be raised. `inet_ntoa()` does not support
IPv6, and `inet_ntop()` should be used instead for IPv4/v6 dual stack support.

```python
socket.inet_pton(address_family, ip_string)
```

Convert an IP address from its family-specific string format to a packed, binary format. `inet_pton()` is useful when a library or network protocol calls for an object of type `struct in_addr` (similar to `inet_aton()`) or `struct in6_addr`.

Supported values for `address_family` are currently `AF_INET` and `AF_INET6`. If the IP address string `ip_string` is invalid, `OSError` will be raised. Note that exactly what is valid depends on both the value of `address_family` and the underlying implementation of `inet_pton()`.

Availability: Unix (maybe not all platforms), Windows.

*Changed in version 3.4:* Windows support added

```python
socket.inet_ntop(address_family, packed_ip)
```

Convert a packed IP address (a bytes object of some number of characters) to its standard, family-specific string representation (for example, '7.10.0.5' or '5aef:2b::8'). `inet_ntop()` is useful when a library or network protocol returns an object of type `struct in_addr` (similar to `inet_ntoa()`) or `struct in6_addr`.

Supported values for `address_family` are currently `AF_INET` and `AF_INET6`. If the string `packed_ip` is not the correct length for the specified address family, `ValueError` will be raised. A `OSError` is raised for errors from the call to `inet_ntop()`.
Availability: Unix (maybe not all platforms), Windows.

*Changed in version 3.4:* Windows support added

**socket.** `CMSG_LEN(length)`

Return the total length, without trailing padding, of an ancillary data item with associated data of the given `length`. This value can often be used as the buffer size for `recvmsg()` to receive a single item of ancillary data, but **RFC 3542** requires portable applications to use `CMSG_SPACE()` and thus include space for padding, even when the item will be the last in the buffer. Raises `OverflowError` if `length` is outside the permissible range of values.

Availability: most Unix platforms, possibly others.

*New in version 3.3.*

**socket.** `CMSG_SPACE(length)`

Return the buffer size needed for `recvmsg()` to receive an ancillary data item with associated data of the given `length`, along with any trailing padding. The buffer space needed to receive multiple items is the sum of the `CMSG_SPACE()` values for their associated data lengths. Raises `OverflowError` if `length` is outside the permissible range of values.

Note that some systems might support ancillary data without providing this function. Also note that setting the buffer size using the results of this function may not precisely limit the amount of ancillary data that can be received, since additional data may be able to fit into the padding area.

Availability: most Unix platforms, possibly others.
New in version 3.3.

socket.getdefaulttimeout()
Return the default timeout in seconds (float) for new socket objects. A value of None indicates that new socket objects have no timeout. When the socket module is first imported, the default is None.

socket.setdefaulttimeout(timeout)
Set the default timeout in seconds (float) for new socket objects. When the socket module is first imported, the default is None. See settimeout() for possible values and their respective meanings.

socket.sethostname(name)
Set the machine's hostname to name. This will raise a OSError if you don't have enough rights.

Availability: Unix.

New in version 3.3.

socket.if_nameindex()
Return a list of network interface information (index int, name string) tuples. OSError if the system call fails.

Availability: Unix.

New in version 3.3.

socket.if_nametoindex(if_name)
Return a network interface index number corresponding to an interface name. OSError if no interface with the given name exists.
Availability: Unix.

*New in version 3.3.*

socket.\texttt{if\_indextoname}(\texttt{if\_index})

Return a network interface name corresponding to an interface index number. \texttt{OSError} if no interface with the given index exists.

Availability: Unix.

*New in version 3.3.*
18.1.3. Socket Objects

Socket objects have the following methods. Except for `makefile()`, these correspond to Unix system calls applicable to sockets.

socket. **accept**()

Accept a connection. The socket must be bound to an address and listening for connections. The return value is a pair `(conn, address)` where `conn` is a new socket object usable to send and receive data on the connection, and `address` is the address bound to the socket on the other end of the connection.

The newly created socket is **non-inheritable**.

*Changed in version 3.4:* The socket is now non-inheritable.

socket. **bind**(address)

Bind the socket to `address`. The socket must not already be bound. (The format of `address` depends on the address family — see above.)

socket. **close**()

Mark the socket closed. The underlying system resource (e.g. a file descriptor) is also closed when all file objects from `makefile()` are closed. Once that happens, all future operations on the socket object will fail. The remote end will receive no more data (after queued data is flushed).

Sockets are automatically closed when they are garbage-collected, but it is recommended to `close()` them explicitly, or to use a `with` statement around them.
Note: close() releases the resource associated with a connection but does not necessarily close the connection immediately. If you want to close the connection in a timely fashion, call shutdown() before close().

socket.connect(address)

Connect to a remote socket at address. (The format of address depends on the address family — see above.)

socket.connect_ex(address)

Like connect(address), but return an error indicator instead of raising an exception for errors returned by the C-level connect() call (other problems, such as “host not found,” can still raise exceptions). The error indicator is 0 if the operation succeeded, otherwise the value of the errno variable. This is useful to support, for example, asynchronous connects.

socket.detach()

Put the socket object into closed state without actually closing the underlying file descriptor. The file descriptor is returned, and can be reused for other purposes.

New in version 3.2.

socket.dup()

Duplicate the socket.

The newly created socket is non-inheritable.

Changed in version 3.4: The socket is now non-inheritable.

socket.fileno()
Return the socket's file descriptor (a small integer). This is useful with `select.select()`.

Under Windows the small integer returned by this method cannot be used where a file descriptor can be used (such as `os.fdopen()`). Unix does not have this limitation.

`socket.get_inheritable()`

Get the *inheritable flag* of the socket's file descriptor or socket's handle: True if the socket can be inherited in child processes, False if it cannot.

*New in version 3.4.*

`socket.getpeername()`

Return the remote address to which the socket is connected. This is useful to find out the port number of a remote IPv4/v6 socket, for instance. (The format of the address returned depends on the address family — see above.) On some systems this function is not supported.

`socket.getsockname()`

Return the socket's own address. This is useful to find out the port number of an IPv4/v6 socket, for instance. (The format of the address returned depends on the address family — see above.)

`socket.getsockopt(level, optname[, buflen])`  
Return the value of the given socket option (see the Unix man page `getsockopt(2)`). The needed symbolic constants (SO_* etc.) are defined in this module. If `buflen` is absent, an integer option is assumed and its integer value is returned by the function. If `buflen` is present, it specifies the maximum length of the buffer used to
receive the option in, and this buffer is returned as a bytes object. It is up to the caller to decode the contents of the buffer (see the optional built-in module `struct` for a way to decode C structures encoded as byte strings).

**socket.gettimeout()**

Return the timeout in seconds (float) associated with socket operations, or `None` if no timeout is set. This reflects the last call to `setblocking()` or `settimeout()`.

**socket.ioctl(control, option)**

| Platform: | Windows |

The `ioctl()` method is a limited interface to the WSAIoctl system interface. Please refer to the [Win32 documentation](#) for more information.

On other platforms, the generic `fcntl.fcntl()` and `fcntl.ioctl()` functions may be used; they accept a socket object as their first argument.

**socket.listen(backlog)**

Listen for connections made to the socket. The `backlog` argument specifies the maximum number of queued connections and should be at least 0; the maximum value is system-dependent (usually 5), the minimum value is forced to 0.

**socket.makefile(mode='r', buffering=None, *, encoding=None, errors=None, newline=None)**

Return a `file object` associated with the socket. The exact returned type depends on the arguments given to `makefile()`. These arguments are interpreted the same way as by the built-in `open()`
function.

The socket must be in blocking mode; it can have a timeout, but the file object’s internal buffer may end up in an inconsistent state if a timeout occurs.

Closing the file object returned by `makefile()` won’t close the original socket unless all other file objects have been closed and `socket.close()` has been called on the socket object.

**Note:** On Windows, the file-like object created by `makefile()` cannot be used where a file object with a file descriptor is expected, such as the stream arguments of `subprocess.Popen()`.

```
socket.recv(bufsize[, flags])
```

Receive data from the socket. The return value is a bytes object representing the data received. The maximum amount of data to be received at once is specified by `bufsize`. See the Unix manual page `recv(2)` for the meaning of the optional argument `flags`; it defaults to zero.

**Note:** For best match with hardware and network realities, the value of `bufsize` should be a relatively small power of 2, for example, 4096.

```
socket.recvfrom(bufsize[, flags])
```

Receive data from the socket. The return value is a pair `(bytes, address)` where `bytes` is a bytes object representing the data received and `address` is the address of the socket sending the data. See the Unix manual page `recv(2)` for the meaning of the
optional argument flags; it defaults to zero. (The format of address depends on the address family — see above.)

socket.recvmsg(bufsize[, ancbufsize[, flags]])

Receive normal data (up to bufsize bytes) and ancillary data from the socket. The ancbufsize argument sets the size in bytes of the internal buffer used to receive the ancillary data; it defaults to 0, meaning that no ancillary data will be received. Appropriate buffer sizes for ancillary data can be calculated using CMSG_SPACE() or CMSG_LEN(), and items which do not fit into the buffer might be truncated or discarded. The flags argument defaults to 0 and has the same meaning as for recv().

The return value is a 4-tuple: (data, ancdata, msg_flags, address). The data item is a bytes object holding the non-ancillary data received. The ancdata item is a list of zero or more tuples (cmsg_level, cmsg_type, cmsg_data) representing the ancillary data (control messages) received: cmsg_level and cmsg_type are integers specifying the protocol level and protocol-specific type respectively, and cmsg_data is a bytes object holding the associated data. The msg_flags item is the bitwise OR of various flags indicating conditions on the received message; see your system documentation for details. If the receiving socket is unconnected, address is the address of the sending socket, if available; otherwise, its value is unspecified.

On some systems, sendmsg() and recvmsg() can be used to pass file descriptors between processes over an AF_UNIX socket. When this facility is used (it is often restricted to SOCK_STREAM sockets), recvmsg() will return, in its ancillary data, items of the form (socket.SOL_SOCKET, socket.SCM_RIGHTS, fds),
where `fds` is a `bytes` object representing the new file descriptors as a binary array of the native C `int` type. If `recvmsg()` raises an exception after the system call returns, it will first attempt to close any file descriptors received via this mechanism.

Some systems do not indicate the truncated length of ancillary data items which have been only partially received. If an item appears to extend beyond the end of the buffer, `recvmsg()` will issue a `RuntimeWarning`, and will return the part of it which is inside the buffer provided it has not been truncated before the start of its associated data.

On systems which support the SCM_RIGHTS mechanism, the following function will receive up to `maxfds` file descriptors, returning the message data and a list containing the descriptors (while ignoring unexpected conditions such as unrelated control messages being received). See also `sendmsg()`.

```python
import socket, array

def recv_fds(sock, msglen, maxfds):
    fds = array.array("i")  # Array of ints
    msg, ancdata, flags, addr = sock.recvmsg(msglen)
    for cmsg_level, cmsg_type, cmsg_data in ancdata:
        if (cmsg_level == socket.SOL_SOCKET and cmsg_type == socket.SCM_RIGHTS):
            # Append data, ignoring any truncated
            fds.fromstring(cmsg_data[:len(cmsg_data)])
    return msg, list(fds)
```

Availability: most Unix platforms, possibly others.

*New in version 3.3.*
socket.**recvmsg_into**(buffers[, ancbufsize[, flags]])

Receive normal data and ancillary data from the socket, behaving as `recvmsg()` would, but scatter the non-ancillary data into a series of buffers instead of returning a new bytes object. The `buffers` argument must be an iterable of objects that export writable buffers (e.g. `bytearray` objects); these will be filled with successive chunks of the non-ancillary data until it has all been written or there are no more buffers. The operating system may set a limit (`sysconf()` value `SC_IOV_MAX`) on the number of buffers that can be used. The `ancbufsize` and `flags` arguments have the same meaning as for `recvmsg()`.

The return value is a 4-tuple: `(nbytes, ancdata, msg_flags, address)`, where `nbytes` is the total number of bytes of non-ancillary data written into the buffers, and `ancdata`, `msg_flags` and `address` are the same as for `recvmsg()`.

Example:

```python
>>> import socket
>>> s1, s2 = socket.socketpair()
>>> b1 = bytearray(b'-----')
>>> b2 = bytearray(b'0123456789')
>>> b3 = bytearray(b'--------------')
>>> s1.send(b'Mary had a little lamb')
22
>>> s2.recvmsg_into([[b1, memoryview(b2)[2:9]], b3])
(22, [], 0, None)
>>> [b1, b2, b3]
[bytearray(b'Mary'), bytearray(b'01 had a 9'), bytearray(b'little lamb--')]
```

Availability: most Unix platforms, possibly others.
New in version 3.3.

socket.**recvfrom_into**(buffer[, nbytes[, flags]])

Receive data from the socket, writing it into buffer instead of creating a new bytestring. The return value is a pair (nbytes, address) where nbytes is the number of bytes received and address is the address of the socket sending the data. See the Unix manual page **recv**(2) for the meaning of the optional argument flags; it defaults to zero. (The format of address depends on the address family — see above.)

socket.**recv_into**(buffer[, nbytes[, flags]])

Receive up to nbytes bytes from the socket, storing the data into a buffer rather than creating a new bytestring. If nbytes is not specified (or 0), receive up to the size available in the given buffer. Returns the number of bytes received. See the Unix manual page **recv**(2) for the meaning of the optional argument flags; it defaults to zero.

socket.**send**(bytes[, flags])

Send data to the socket. The socket must be connected to a remote socket. The optional flags argument has the same meaning as for recv() above. Returns the number of bytes sent. Applications are responsible for checking that all data has been sent; if only some of the data was transmitted, the application needs to attempt delivery of the remaining data. For further information on this topic, consult the **Socket Programming HOWTO**.

socket.**sendall**(bytes[, flags])

Send data to the socket. The socket must be connected to a
remote socket. The optional flags argument has the same meaning as for `recv()` above. Unlike `send()`, this method continues to send data from bytes until either all data has been sent or an error occurs. `None` is returned on success. On error, an exception is raised, and there is no way to determine how much data, if any, was successfully sent.

```python
socket.sendto(bytes, address)
```

Send data to the socket. The socket should not be connected to a remote socket, since the destination socket is specified by `address`. The optional flags argument has the same meaning as for `recv()` above. Return the number of bytes sent. (The format of `address` depends on the address family — see above.)

```python
socket.sendmsg(buffers[, ancdata[, flags[, address]]]])
```

Send normal and ancillary data to the socket, gathering the non-ancillary data from a series of buffers and concatenating it into a single message. The `buffers` argument specifies the non-ancillary data as an iterable of buffer-compatible objects (e.g. bytes objects); the operating system may set a limit (`sysconf()` value `SC_IOV_MAX`) on the number of buffers that can be used. The `ancdata` argument specifies the ancillary data (control messages) as an iterable of zero or more tuples `(cmsg_level, cmsg_type, cmsg_data)`, where `cmsg_level` and `cmsg_type` are integers specifying the protocol level and protocol-specific type respectively, and `cmsg_data` is a buffer-compatible object holding the associated data. Note that some systems (in particular, systems without `CMMSG_SPACE()`) might support sending only one control message per call. The `flags` argument defaults to 0 and has the same meaning as for `send()`. If `address` is supplied and not
None, it sets a destination address for the message. The return value is the number of bytes of non-ancillary data sent.

The following function sends the list of file descriptors *fds* over an AF_UNIX socket, on systems which support the SCM_RIGHTS mechanism. See also `recvmsg()`.

```python
import socket, array

def send_fds(sock, msg, fds):
    return sock.sendmsg([msg], [(socket.SOL_SOCKET, )])
```

Availability: most Unix platforms, possibly others.

*New in version 3.3.*

**socket.set_inheritable(inheritable)**

Set the *inheritable flag* of the socket's file descriptor or socket's handle.

*New in version 3.4.*

**socket.setblocking(flag)**

Set blocking or non-blocking mode of the socket: if *flag* is false, the socket is set to non-blocking, else to blocking mode.

This method is a shorthand for certain `settimeout()` calls:

- ```python
    sock.setblocking(True)
    is equivalent to
    sock.settimeout(None)
    ```
- ```python
    sock.setblocking(False)
    is equivalent to
    sock.settimeout(0.0)
    ```
socket. **settimeout**(value)
Set a timeout on blocking socket operations. The value argument can be a nonnegative floating point number expressing seconds, or None. If a non-zero value is given, subsequent socket operations will raise a timeout exception if the timeout period value has elapsed before the operation has completed. If zero is given, the socket is put in non-blocking mode. If None is given, the socket is put in blocking mode.

For further information, please consult the *notes on socket timeouts*.

socket. **setsockopt**(level, optname, value)
Set the value of the given socket option (see the Unix manual page `setsockopt(2)`). The needed symbolic constants are defined in the socket module (SO_* etc.). The value can be an integer or a bytes object representing a buffer. In the latter case it is up to the caller to ensure that the bytestring contains the proper bits (see the optional built-in module `struct` for a way to encode C structures as bytestrings).

socket. **shutdown**(how)
Shut down one or both halves of the connection. If how is SHUT_RD, further receives are disallowed. If how is SHUT_WR, further sends are disallowed. If how is SHUT_RDWR, further sends and receives are disallowed.

socket. **share**(process_id)
Duplicate a socket and prepare it for sharing with a target process. The target process must be provided with process_id. The resulting bytes object can then be passed to the target process using some form of interprocess communication and the socket can be
recreated there using `fromshare()`.

Once this method has been called, it is safe to close the socket since the operating system has already duplicated it for the target process.

Availability: Windows.

*New in version 3.3.*

Note that there are no methods `read()` or `write()`; use `recv()` and `send()` without `flags` argument instead.

Socket objects also have these (read-only) attributes that correspond to the values given to the `socket` constructor.

- `socket.family`
  - The socket family.

- `socket.type`
  - The socket type.

- `socket.proto`
  - The socket protocol.
18.1.4. Notes on socket timeouts

A socket object can be in one of three modes: blocking, non-blocking, or timeout. Sockets are by default always created in blocking mode, but this can be changed by calling `setdefaulttimeout()`.

- In **blocking mode**, operations block until complete or the system returns an error (such as connection timed out).
- In **non-blocking mode**, operations fail (with an error that is unfortunately system-dependent) if they cannot be completed immediately: functions from the `select` can be used to know when and whether a socket is available for reading or writing.
- In **timeout mode**, operations fail if they cannot be completed within the timeout specified for the socket (they raise a `timeout` exception) or if the system returns an error.

**Note:** At the operating system level, sockets in timeout mode are internally set in non-blocking mode. Also, the blocking and timeout modes are shared between file descriptors and socket objects that refer to the same network endpoint. This implementation detail can have visible consequences if e.g. you decide to use the `fileno()` of a socket.

18.1.4.1. Timeouts and the connect method

The `connect()` operation is also subject to the timeout setting, and in general it is recommended to call `settimeout()` before calling `connect()` or pass a timeout parameter to `create_connection()`. However, the system network stack may also return a connection timeout error of its own regardless of any Python socket timeout setting.
18.1.4.2. Timeouts and the accept method

If `getdefaulttimeout()` is not `None`, sockets returned by the `accept()` method inherit that timeout. Otherwise, the behaviour depends on settings of the listening socket:

- if the listening socket is in *blocking mode* or in *timeout mode*, the socket returned by `accept()` is in *blocking mode*;
- if the listening socket is in *non-blocking mode*, whether the socket returned by `accept()` is in blocking or non-blocking mode is operating system-dependent. If you want to ensure cross-platform behaviour, it is recommended you manually override this setting.
18.1.5. Example

Here are four minimal example programs using the TCP/IP protocol: a server that echoes all data that it receives back (servicing only one client), and a client using it. Note that a server must perform the sequence `socket()`, `bind()`, `listen()`, `accept()` (possibly repeating the `accept()` to service more than one client), while a client only needs the sequence `socket()`, `connect()`. Also note that the server does not `sendall()/recv()` on the socket it is listening on but on the new socket returned by `accept()`.

The first two examples support IPv4 only.

```python
# Echo server program
import socket

HOST = '' # Symbolic name meaning all available interfaces
PORT = 50007 # Arbitrary non-privileged port

s = socket.socket(socket.AF_INET, socket.SOCK_STREAM)
s.bind((HOST, PORT))
s.listen(1)
conn, addr = s.accept()
print('Connected by', addr)
while True:
    data = conn.recv(1024)
    if not data: break
    conn.sendall(data)
conn.close()
```

```python
# Echo client program
import socket

HOST = 'daring.cwi.nl' # The remote host
```
PORT = 50007          # The same port as used by
s = socket.socket(socket.AF_INET, socket.SOCK_STREAM)
s.connect((HOST, PORT))
s.sendall(b'Hello, world')
data = s.recv(1024)
s.close()
print('Received', repr(data))

The next two examples are identical to the above two, but support both IPv4 and IPv6. The server side will listen to the first address family available (it should listen to both instead). On most of IPv6-ready systems, IPv6 will take precedence and the server may not accept IPv4 traffic. The client side will try to connect to the all addresses returned as a result of the name resolution, and sends traffic to the first one connected successfully.

# Echo server program
import socket
import sys

HOST = None          # Symbolic name meaning all available interfaces
PORT = 50007         # Arbitrary non-privileged port
s = None
for res in socket.getaddrinfo(HOST, PORT, socket.AF_UNSPEC,
                               socket.SOCK_STREAM, 0,
                               af, socktype, proto, canonname, sa = res
try:
    s = socket.socket(AF_INET, socktype, proto)
extexcept OSError as msg:
    s = None
    continue
try:
    s.bind(sa)
    s.listen(1)
extexcept OSError as msg:
s.close()

if s is None:
    print('could not open socket')
    sys.exit(1)

conn, addr = s.accept()
print('Connected by', addr)
while True:
    data = conn.recv(1024)
    if not data: break
    conn.send(data)
conn.close()
if s is None:
    print('could not open socket')
    sys.exit(1)
s.sendall(b'Hello, world')
data = s.recv(1024)
s.close()
print('Received', repr(data))

The next example shows how to write a very simple network sniffer with raw sockets on Windows. The example requires administrator privileges to modify the interface:

```python
import socket

# the public network interface
HOST = socket.gethostbyname(socket.gethostname())

# create a raw socket and bind it to the public interface
s = socket.socket(socket.AF_INET, socket.SOCK_RAW, socket.IPPROTO_IP)
s.bind((HOST, 0))

# Include IP headers
s.setsockopt(socket.IPPROTO_IP, socket.IP_HDRINCL, 1)

# receive all packages
s.ioctl(socket.SIO_RCVALL, socket.RCVALL_ON)

# receive a package
print(s.recvfrom(65565))

# disabled promiscuous mode
s.ioctl(socket.SIO_RCVALL, socket.RCVALL_OFF)
```

The last example shows how to use the socket interface to communicate to a CAN network using the raw socket protocol. To use
CAN with the broadcast manager protocol instead, open a socket with:

```python
socket.socket(socket.AF_CAN, socket.SOCK_DGRAM, socket.SOL_CAN_RAW)
```

After binding (CAN_RAW) or connecting (CAN_BCM) the socket, you can use the `socket.send()` and the `socket.recv()` operations (and their counterparts) on the socket object as usual.

This example might require special privilege:

```python
import socket
import struct

# CAN frame packing/unpacking (see 'struct can_frame' in <linux/can.h>)
can_frame_fmt = '=IB3x8s'
can_frame_size = struct.calcsize(can_frame_fmt)

def build_can_frame(can_id, data):
    can_dlc = len(data)
    data = data.ljust(8, b'\x00')
    return struct.pack(can_frame_fmt, can_id, can_dlc, data)

def dissect_can_frame(frame):
    can_id, can_dlc, data = struct.unpack(can_frame_fmt, frame)
    return (can_id, can_dlc, data[:can_dlc])

# create a raw socket and bind it to the 'vcan0' interface
s = socket.socket(socket.AF_CAN, socket.SOCK_RAW, socket.SOL_CAN_RAW)
s.bind(('vcan0',))

while True:
    cf, addr = s.recvfrom(can_frame_size)
```
Running an example several times with too small delay between executions, could lead to this error:

```
OSErrror: [Errno 98] Address already in use
```

This is because the previous execution has left the socket in a `TIME_WAIT` state, and can't be immediately reused.

There is a `socket` flag to set, in order to prevent this, `socket.SO_REUSEADDR`:

```
s = socket.socket(socket.AF_INET, socket.SOCK_STREAM)
s.setsockopt(socket.SOL_SOCKET, socket.SO_REUSEADDR)
s.bind((HOST, PORT))
```

the `SO_REUSEADDR` flag tells the kernel to reuse a local socket in `TIME_WAIT` state, without waiting for its natural timeout to expire.

**See also:** For an introduction to socket programming (in C), see the following papers:
Both in the UNIX Programmer’s Manual, Supplementary Documents 1 (sections PS1:7 and PS1:8). The platform-specific reference material for the various socket-related system calls are also a valuable source of information on the details of socket semantics. For Unix, refer to the manual pages; for Windows, see the WinSock (or Winsock 2) specification. For IPv6-ready APIs, readers may want to refer to RFC 3493 titled Basic Socket Interface Extensions for IPv6.
This module provides access to Transport Layer Security (often known as “Secure Sockets Layer”) encryption and peer authentication facilities for network sockets, both client-side and server-side. This module uses the OpenSSL library. It is available on all modern Unix systems, Windows, Mac OS X, and probably additional platforms, as long as OpenSSL is installed on that platform.

**Note:** Some behavior may be platform dependent, since calls are made to the operating system socket APIs. The installed version of OpenSSL may also cause variations in behavior. For example, TLSv1.1 and TLSv1.2 come with openssl version 1.0.1.

**Warning:** Don’t use this module without reading the *Security considerations*. Doing so may lead to a false sense of security, as the default settings of the ssl module are not necessarily appropriate for your application.

This section documents the objects and functions in the `ssl` module; for more general information about TLS, SSL, and certificates, the reader is referred to the documents in the “See Also” section at the bottom.

This module provides a class, `ssl.SSLSocket`, which is derived from the `socket.socket` type, and provides a socket-like wrapper that
also encrypts and decrypts the data going over the socket with SSL. It supports additional methods such as getpeercert(), which retrieves the certificate of the other side of the connection, and cipher(), which retrieves the cipher being used for the secure connection.

For more sophisticated applications, the ssl.SSLContext class helps manage settings and certificates, which can then be inherited by SSL sockets created through the SSLContext.wrap_socket() method.
18.2.1. Functions, Constants, and Exceptions

exception ssl.SSLError

Raised to signal an error from the underlying SSL implementation (currently provided by the OpenSSL library). This signifies some problem in the higher-level encryption and authentication layer that’s superimposed on the underlying network connection. This error is a subtype of OSError. The error code and message of SSLError instances are provided by the OpenSSL library.

Changed in version 3.3: SSLError used to be a subtype of socket.error.

library

A string mnemonic designating the OpenSSL submodule in which the error occurred, such as SSL, PEM or X509. The range of possible values depends on the OpenSSL version.

New in version 3.3.

reason

A string mnemonic designating the reason this error occurred, for example CERTIFICATE_VERIFY_FAILED. The range of possible values depends on the OpenSSL version.

New in version 3.3.

exception ssl.SSLZeroReturnError

A subclass of SSLError raised when trying to read or write and the SSL connection has been closed cleanly. Note that this doesn’t
mean that the underlying transport (read TCP) has been closed.

New in version 3.3.

exception ssl. **SSLWantReadError**
A subclass of SSLError raised by a *non-blocking SSL socket* when trying to read or write data, but more data needs to be received on the underlying TCP transport before the request can be fulfilled.

New in version 3.3.

exception ssl. **SSLWantWriteError**
A subclass of SSLError raised by a *non-blocking SSL socket* when trying to read or write data, but more data needs to be sent on the underlying TCP transport before the request can be fulfilled.

New in version 3.3.

exception ssl. **SSLSyscallError**
A subclass of SSLError raised when a system error was encountered while trying to fulfill an operation on a SSL socket. Unfortunately, there is no easy way to inspect the original errno number.

New in version 3.3.

exception ssl. **SSLEOFError**
A subclass of SSLError raised when the SSL connection has been terminated abruptly. Generally, you shouldn’t try to reuse the underlying transport when this error is encountered.

New in version 3.3.
exception ssl.CertificateError

Raised to signal an error with a certificate (such as mismatching hostname). Certificate errors detected by OpenSSL, though, raise an SSLError.

18.2.1.1. Socket creation

The following function allows for standalone socket creation. Starting from Python 3.2, it can be more flexible to use SSLContext.wrap_socket() instead.

ssl.wrap_socket(sock, keyfile=None, certfile=None, server_side=False, cert_reqs=CERT_NONE, ssl_version={see docs}, ca_certs=None, do_handshake_on_connect=True, suppress_ragged_eofs=True, ciphers=None)

Takes an instance sock of socket.socket, and returns an instance of ssl.SSLSocket, a subtype of socket.socket, which wraps the underlying socket in an SSL context. sock must be a SOCK_STREAM socket; other socket types are unsupported.

For client-side sockets, the context construction is lazy; if the underlying socket isn’t connected yet, the context construction will be performed after connect() is called on the socket. For server-side sockets, if the socket has no remote peer, it is assumed to be a listening socket, and the server-side SSL wrapping is automatically performed on client connections accepted via the accept() method. wrap_socket() may raise SSLError.

The keyfile and certfile parameters specify optional files which contain a certificate to be used to identify the local side of the connection. See the discussion of Certificates for more information on how the certificate is stored in the certfile.
The parameter `server_side` is a boolean which identifies whether server-side or client-side behavior is desired from this socket.

The parameter `cert_reqs` specifies whether a certificate is required from the other side of the connection, and whether it will be validated if provided. It must be one of the three values `CERT_NONE` (certificates ignored), `CERT_OPTIONAL` (not required, but validated if provided), or `CERT_REQUIRED` (required and validated). If the value of this parameter is not `CERT_NONE`, then the `ca_certs` parameter must point to a file of CA certificates.

The `ca_certs` file contains a set of concatenated “certification authority” certificates, which are used to validate certificates passed from the other end of the connection. See the discussion of `Certificates` for more information about how to arrange the certificates in this file.

The parameter `ssl_version` specifies which version of the SSL protocol to use. Typically, the server chooses a particular protocol version, and the client must adapt to the server’s choice. Most of the versions are not interoperable with the other versions. If not specified, the default is `PROTOCOL_SSLv23`; it provides the most compatibility with other versions.

Here’s a table showing which versions in a client (down the side) can connect to which versions in a server (along the top):

<table>
<thead>
<tr>
<th>client / server</th>
<th>SSLv2</th>
<th>SSLv3</th>
<th>SSLv23</th>
<th>TLSv1</th>
<th>TLSv1.1</th>
<th>TLSv2</th>
</tr>
</thead>
<tbody>
<tr>
<td>SSLv2</td>
<td>yes</td>
<td>no</td>
<td>yes</td>
<td>no</td>
<td>no</td>
<td>no</td>
</tr>
<tr>
<td>SSLv3</td>
<td>no</td>
<td>yes</td>
<td>yes</td>
<td>no</td>
<td>no</td>
<td>no</td>
</tr>
<tr>
<td>Protocol</td>
<td>SSLv23</td>
<td>yes</td>
<td>no</td>
<td>yes</td>
<td>no</td>
<td>no</td>
</tr>
<tr>
<td>------------</td>
<td>--------</td>
<td>-----</td>
<td>-----</td>
<td>------</td>
<td>-----</td>
<td>-----</td>
</tr>
<tr>
<td>SSLv1</td>
<td>no</td>
<td>no</td>
<td>no</td>
<td>yes</td>
<td>yes</td>
<td>no</td>
</tr>
<tr>
<td>TLSv1.1</td>
<td>no</td>
<td>no</td>
<td>no</td>
<td>yes</td>
<td>no</td>
<td>yes</td>
</tr>
<tr>
<td>TLSv1.2</td>
<td>no</td>
<td>no</td>
<td>no</td>
<td>yes</td>
<td>no</td>
<td>no</td>
</tr>
</tbody>
</table>

**Note:** Which connections succeed will vary depending on the version of OpenSSL. For instance, in some older versions of OpenSSL (such as 0.9.7l on OS X 10.4), an SSLv2 client could not connect to an SSLv23 server. Another example: beginning with OpenSSL 1.0.0, an SSLv23 client will not actually attempt SSLv2 connections unless you explicitly enable SSLv2 ciphers; for example, you might specify "ALL" or "SSLv2" as the `ciphers` parameter to enable them.

The `ciphers` parameter sets the available ciphers for this SSL object. It should be a string in the OpenSSL cipher list format.

The parameter `do_handshake_on_connect` specifies whether to do the SSL handshake automatically after doing a `socket.connect()`, or whether the application program will call it explicitly, by invoking the `SSLSocket.do_handshake()` method. Calling `SSLSocket.do_handshake()` explicitly gives the program control over the blocking behavior of the socket I/O involved in the handshake.

The parameter `suppress_ragged_eofs` specifies how the `SSLSocket.recv()` method should signal unexpected EOF from the other end of the connection. If specified as `True` (the default), it returns a normal EOF (an empty bytes object) in response to unexpected EOF errors raised from the underlying socket; if `False`, it will raise the exceptions back to the caller.
18.2.1.2. Context creation

A convenience function helps create `SSLContext` objects for common purposes.

```python
ssl.create_default_context(purpose=Purpose.SERVER_AUTH, cafile=None, capath=None, cadata=None)
```

Return a new `SSLContext` object with default settings for the given `purpose`. The settings are chosen by the `ssl` module, and usually represent a higher security level than when calling the `SSLContext` constructor directly.

`cafile`, `capath`, `cadata` represent optional CA certificates to trust for certificate verification, as in `SSLContext.load_verify_locations()`. If all three are `None`, this function can choose to trust the system’s default CA certificates instead.

The settings in Python 3.4 are: `PROTOCOL_TLSv1` with high encryption cipher suites without RC4 and without unauthenticated cipher suites. Passing `SERVER_AUTH` as `purpose` sets `verify_mode` to `CERT_REQUIRED` and either loads CA certificates (when at least one of `cafile`, `capath` or `cadata` is given) or uses `SSLContext.load_default_certs()` to load default CA certificates.

**Note:** The protocol, options, cipher and other settings may change to more restrictive values anytime without prior deprecation. The values represent a fair balance between...
compatibility and security.
If your application needs specific settings, you should create a `SSLContext` and apply the settings yourself.

*New in version 3.4.*

### 18.2.1.3. Random generation

**ssl. `RAND_bytes(num)`**

Returns `num` cryptographically strong pseudo-random bytes. Raises an `SSLError` if the PRNG has not been seeded with enough data or if the operation is not supported by the current RAND method. `RAND_status()` can be used to check the status of the PRNG and `RAND_add()` can be used to seed the PRNG.

Read the Wikipedia article, [Cryptographically secure pseudorandom number generator (CSPRNG)](https://en.wikipedia.org/wiki/Cryptographically_secure_pseudorandom_number_generator), to get the requirements of a cryptographically generator.

*New in version 3.3.*

**ssl. `RAND_pseudo_bytes(num)`**

Returns `(bytes, is_cryptographic)`: bytes are `num` pseudo-random bytes, `is_cryptographic` is `True` if the bytes generated are cryptographically strong. Raises an `SSLError` if the operation is not supported by the current RAND method.

Generated pseudo-random byte sequences will be unique if they are of sufficient length, but are not necessarily unpredictable. They can be used for non-cryptographic purposes and for certain purposes in cryptographic protocols, but usually not for key generation etc.
New in version 3.3.

**ssl.RAND_status()**

Returns `True` if the SSL pseudo-random number generator has been seeded with 'enough' randomness, and `False` otherwise. You can use `ssl.RAND_egg()` and `ssl.RAND_add()` to increase the randomness of the pseudo-random number generator.

**ssl.RAND_egg(path)**

If you are running an entropy-gathering daemon (EGD) somewhere, and `path` is the pathname of a socket connection open to it, this will read 256 bytes of randomness from the socket, and add it to the SSL pseudo-random number generator to increase the security of generated secret keys. This is typically only necessary on systems without better sources of randomness.

**ssl.RAND_add(bytes, entropy)**

Mixes the given `bytes` into the SSL pseudo-random number generator. The parameter `entropy` (a float) is a lower bound on the entropy contained in string (so you can always use `0.0`). See RFC 1750 for more information on sources of entropy.

### 18.2.1.4. Certificate handling

**ssl.match_hostname(cert, hostname)**

Verify that `cert` (in decoded format as returned by `SSLSocket.getpeercert()`) matches the given `hostname`. The rules applied are those for checking the identity of HTTPS servers as outlined in RFC 2818 and RFC 6125, except that IP addresses
are not currently supported. In addition to HTTPS, this function should be suitable for checking the identity of servers in various SSL-based protocols such as FTPS, IMAPS, POPS and others.

**CertificateError** is raised on failure. On success, the function returns nothing:

```python
cert = {'subject': ('commonName', 'example.com')
ssl.match_hostname(cert, 'example.com')
ssl.match_hostname(cert, 'example.org')
```

```
Traceback (most recent call last):
  File "<stdin>", line 1, in <module>
  File "/home/py3k/Lib/ssl.py", line 130, in match_hostname
ssl.CertificateError: hostname 'example.org' doesn't match 'example.com'
```

*New in version 3.2.*

*Changed in version 3.3.3:* The function now follows [RFC 6125](https://tools.ietf.org/html/rfc6125), section 6.4.3 and does neither match multiple wildcards (e.g. `*.com` or `*a*.example.org`) nor a wildcard inside an internationalized domain names (IDN) fragment. IDN A-labels such as `www*.xn--pthon-kva.org` are still supported, but `x*.python.org` no longer matches `xn--tda.python.org`.

**ssl.cert_time_to_seconds(timestring)**

Returns a floating-point value containing a normal seconds-after-the-epoch time value, given the time-string representing the “notBefore” or “notAfter” date from a certificate.

Here’s an example:

```python
>>> import ssl
>>> ssl.cert_time_to_seconds("May 9 00:00:00 200")
```
ssl.get_server_certificate(addr,  
ssl_version=PROTOCOL_SSLv3, ca_certs=None)

Given the address addr of an SSL-protected server, as a (hostname, port-number) pair, fetches the server’s certificate, and returns it as a PEM-encoded string. If ssl_version is specified, uses that version of the SSL protocol to attempt to connect to the server. If ca_certs is specified, it should be a file containing a list of root certificates, the same format as used for the same parameter in wrap_socket(). The call will attempt to validate the server certificate against that set of root certificates, and will fail if the validation attempt fails.

Changed in version 3.3: This function is now IPv6-compatible.

ssl.DER_cert_to_PEM_cert(DER_cert_bytes)

Given a certificate as a DER-encoded blob of bytes, returns a PEM-encoded string version of the same certificate.

ssl.PEM_cert_to_DER_cert(PEM_cert_string)

Given a certificate as an ASCII PEM string, returns a DER-encoded sequence of bytes for that same certificate.

ssl.get_default_verify_paths()

Returns a named tuple with paths to OpenSSL’s default cafile and capath. The paths are the same as used by SSLContext.set_default_verify_paths(). The return value is a named tuple DefaultVerifyPaths:
- `cafile` - resolved path to cafile or None if the file doesn't exist,
- `capath` - resolved path to capath or None if the directory doesn't exist,
- `openssl_cafile_env` - OpenSSL's environment key that points to a cafile,
- `openssl_cafile` - hard coded path to a cafile,
- `openssl_capath_env` - OpenSSL's environment key that points to a capath,
- `openssl_capath` - hard coded path to a capath directory

*New in version 3.4.*

**ssl.enum_certificates(store_name)**

Retrieve certificates from Windows' system cert store. `store_name` may be one of CA, ROOT or MY. Windows may provide additional cert stores, too.

The function returns a list of (cert_bytes, encoding_type, trust) tuples. The encoding_type specifies the encoding of cert_bytes. It is either `x509_asn` for X.509 ASN.1 data or `pkcs_7_asn` for PKCS#7 ASN.1 data. Trust specifies the purpose of the certificate as a set of OIDS or exactly `True` if the certificate is trustworthy for all purposes.

Example:

```python
>>> ssl.enum_certificates("CA")
[(b'data...', 'x509_asn', {'1.3.6.1.5.5.7.3.1', '1.3.6.1.5.5.7.3.2'}),
 (b'data...', 'x509_asn', True)]
```

Availability: Windows.
New in version 3.4.

**ssl.enum_crls(store_name)**

Retrieve CRLs from Windows’ system cert store. `store_name` may be one of `CA`, `ROOT` or `MY`. Windows may provide additional cert stores, too.

The function returns a list of `(cert_bytes, encoding_type, trust)` tuples. The `encoding_type` specifies the encoding of `cert_bytes`. It is either `x509_asn` for X.509 ASN.1 data or `pkcs_7_asn` for PKCS#7 ASN.1 data.

Availability: Windows.

New in version 3.4.

18.2.1.5. Constants

**ssl.CERT_NONE**

Possible value for `SSLContext.verify_mode`, or the `cert_reqs` parameter to `wrap_socket()`. In this mode (the default), no certificates will be required from the other side of the socket connection. If a certificate is received from the other end, no attempt to validate it is made.

See the discussion of *Security considerations* below.

**ssl.CERT_OPTIONAL**

Possible value for `SSLContext.verify_mode`, or the `cert_reqs` parameter to `wrap_socket()`. In this mode no certificates will be required from the other side of the socket connection; but if they are provided, validation will be attempted
and an `SSLError` will be raised on failure.

Use of this setting requires a valid set of CA certificates to be passed, either to `SSLContext.load_verify_locations()` or as a value of the `ca_certs` parameter to `wrap_socket()`.

**ssl. CERT_REQUIRED**
Possible value for `SSLContext.verify_mode`, or the `cert_reqs` parameter to `wrap_socket()`. In this mode, certificates are required from the other side of the socket connection; an `SSLError` will be raised if no certificate is provided, or if its validation fails.

Use of this setting requires a valid set of CA certificates to be passed, either to `SSLContext.load_verify_locations()` or as a value of the `ca_certs` parameter to `wrap_socket()`.

**ssl. VERIFY_DEFAULT**
Possible value for `SSLContext.verify_flags`. In this mode, certificate revocation lists (CRLs) are not checked. By default OpenSSL does neither require nor verify CRLs.

*New in version 3.4.*

**ssl. VERIFY_CRL_CHECK_LEAF**
Possible value for `SSLContext.verify_flags`. In this mode, only the peer cert is check but non of the intermediate CA certificates. The mode requires a valid CRL that is signed by the peer cert’s issuer (its direct ancestor CA). If no proper has been loaded `SSLContext.load_verify_locations`, validation will fail.

*New in version 3.4.*
ssl. `VERIFY_CRL_CHECK_CHAIN`
Possible value for `SSLContext.verify_flags`. In this mode, CRLs of all certificates in the peer cert chain are checked.

*New in version 3.4.*

ssl. `VERIFY_X509_STRICT`
Possible value for `SSLContext.verify_flags` to disable workarounds for broken X.509 certificates.

*New in version 3.4.*

ssl. `PROTOCOL_SSLv2`
Selects SSL version 2 as the channel encryption protocol.

This protocol is not available if OpenSSL is compiled with `OPENSSL_NO_SSL2` flag.

**Warning:** SSL version 2 is insecure. Its use is highly discouraged.

ssl. `PROTOCOL_SSLv23`
Selects SSL version 2 or 3 as the channel encryption protocol. This is a setting to use with servers for maximum compatibility with the other end of an SSL connection, but it may cause the specific ciphers chosen for the encryption to be of fairly low quality.

ssl. `PROTOCOL_SSLv3`
Selects SSL version 3 as the channel encryption protocol. For clients, this is the maximally compatible SSL variant.

ssl. `PROTOCOL_TLSv1`
Selects TLS version 1.0 as the channel encryption protocol.
ssl. **PROTOCOL_TLSv1_1**
Selects TLS version 1.1 as the channel encryption protocol. Available only with openssl version 1.0.1+.

*New in version 3.4.*

ssl. **PROTOCOL_TLSv1_2**
Selects TLS version 1.2 as the channel encryption protocol. This is the most modern version, and probably the best choice for maximum protection, if both sides can speak it. Available only with openssl version 1.0.1+.

*New in version 3.4.*

**ssl. OP_ALL**
Enables workarounds for various bugs present in other SSL implementations. This option is set by default. It does not necessarily set the same flags as OpenSSL's SSL_0P_ALL constant.

*New in version 3.2.*

**ssl. OP_NO_SSLv2**
Prevents an SSLv2 connection. This option is only applicable in conjunction with `PROTOCOL_SSLv23`. It prevents the peers from choosing SSLv2 as the protocol version.

*New in version 3.2.*

**ssl. OP_NO_SSLv3**
Prevents an SSLv3 connection. This option is only applicable in conjunction with `PROTOCOL_SSLv23`. It prevents the peers from choosing SSLv3 as the protocol version.
New in version 3.2.

ssl. **OP_NO_TLSv1**
Prevents a TLSv1 connection. This option is only applicable in conjunction with `PROTOCOL_SSLv23`. It prevents the peers from choosing TLSv1 as the protocol version.

New in version 3.2.

ssl. **OP_NO_TLSv1_1**
Prevents a TLSv1.1 connection. This option is only applicable in conjunction with `PROTOCOL_SSLv23`. It prevents the peers from choosing TLSv1.1 as the protocol version. Available only with openssl version 1.0.1+.

New in version 3.4.

ssl. **OP_NO_TLSv1_2**
Prevents a TLSv1.2 connection. This option is only applicable in conjunction with `PROTOCOL_SSLv23`. It prevents the peers from choosing TLSv1.2 as the protocol version. Available only with openssl version 1.0.1+.

New in version 3.4.

ssl. **OP_CIPHER_SERVER_PREFERENCE**
Use the server's cipher ordering preference, rather than the client's. This option has no effect on client sockets and SSLv2 server sockets.

New in version 3.3.

ssl. **OP_SINGLE_DH_USE**
Prevents re-use of the same DH key for distinct SSL sessions. This
improves forward secrecy but requires more computational resources. This option only applies to server sockets.

New in version 3.3.

**ssl. OP_SINGLE_ECDH_USE**
Prevents re-use of the same ECDH key for distinct SSL sessions. This improves forward secrecy but requires more computational resources. This option only applies to server sockets.

New in version 3.3.

**ssl. OP_NO_COMPRESSION**
Disable compression on the SSL channel. This is useful if the application protocol supports its own compression scheme.

This option is only available with OpenSSL 1.0.0 and later.

New in version 3.3.

**ssl. HAS_ECDH**
Whether the OpenSSL library has built-in support for Elliptic Curve-based Diffie-Hellman key exchange. This should be true unless the feature was explicitly disabled by the distributor.

New in version 3.3.

**ssl. HAS_SNI**
Whether the OpenSSL library has built-in support for the Server Name Indication extension to the SSLv3 and TLSv1 protocols (as defined in RFC 4366). When true, you can use the server_hostname argument to SSLContext.wrap_socket().

New in version 3.2.
ssl. **HAS_NPN**

Whether the OpenSSL library has built-in support for *Next Protocol Negotiation* as described in the *NPN draft specification*. When true, you can use the `SSLContext.set_npn_protocols()` method to advertise which protocols you want to support.

*New in version 3.3.*

ssl. **CHANNEL_BINDING_TYPES**

List of supported TLS channel binding types. Strings in this list can be used as arguments to `SSLContext.set_npn_protocols()`.

*New in version 3.3.*

ssl. **OPENSSL_VERSION**

The version string of the OpenSSL library loaded by the interpreter:

```
>>> ssl.OPENSSL_VERSION
'OpenSSL 0.9.8k 25 Mar 2009'
```

*New in version 3.2.*

ssl. **OPENSSL_VERSION_INFO**

A tuple of five integers representing version information about the OpenSSL library:

```
>>> ssl.OPENSSL_VERSION_INFO
(0, 9, 8, 11, 15)
```

*New in version 3.2.*

ssl. **OPENSSL_VERSION_NUMBER**

The raw version number of the OpenSSL library, as a single
integer:

```python
>>> ssl.OPENSSL_VERSION_NUMBER
9470143
>>> hex(ssl.OPENSSL_VERSION_NUMBER)
'0x9080bf'
```

New in version 3.2.

**ssl. ALERT_DESCRIPTION_HANDSHAKE_FAILURE**
**ssl. ALERT_DESCRIPTION_INTERNAL_ERROR**
**ALERT_DESCRIPTION_***

Alert Descriptions from **RFC 5246** and others. The IANA TLS Alert Registry contains this list and references to the RFCs where their meaning is defined.

Used as the return value of the callback function in `SSLContext.set_servername_callback()`.

New in version 3.4.

**Purpose. SERVER_AUTH**

Option for `create_default_context()` and `SSLContext.load_default_certs()`. This value indicates that the context may be used to authenticate Web servers (therefore, it will be used to create client-side sockets).

New in version 3.4.

**Purpose. CLIENT_AUTH**

Option for `create_default_context()` and `SSLContext.load_default_certs()`. This value indicates that the context may be used to authenticate Web clients (therefore, it will be used to create server-side sockets).
New in version 3.4.
18.2.2. SSL Sockets

SSL sockets provide the following methods of *Socket Objects*:

- accept()
- bind()
- close()
- connect()
- detach()
- fileno()
- getpeername(), getsockname()
- getsockopt(), setsockopt()
- gettimeout(), settimeout(), setblocking()
- listen()
- makefile()
- recv(), recv_into() (but passing a non-zero flags argument is not allowed)
- send(), sendall() (with the same limitation)
- shutdown()

However, since the SSL (and TLS) protocol has its own framing atop of TCP, the SSL sockets abstraction can, in certain respects, diverge from the specification of normal, OS-level sockets. See especially the *notes on non-blocking sockets*.

SSL sockets also have the following additional methods and attributes:

**SSLSocket**. **do_handshake()**

Perform the SSL setup handshake.

*Changed in version 3.4*: The handshake method also performce **match_hostname()** when the **check_hostname** attribute of the
socket's context is true.

**SSLSocket.getpeercert(binary_form=False)**

If there is no certificate for the peer on the other end of the connection, return None. If the SSL handshake hasn't been done yet, raise ValueError.

If the binary_form parameter is False, and a certificate was received from the peer, this method returns a dict instance. If the certificate was not validated, the dict is empty. If the certificate was validated, it returns a dict with several keys, amongst them subject (the principal for which the certificate was issued) and issuer (the principal issuing the certificate). If a certificate contains an instance of the Subject Alternative Name extension (see RFC 3280), there will also be a subjectAltName key in the dictionary.

The subject and issuer fields are tuples containing the sequence of relative distinguished names (RDNs) given in the certificate's data structure for the respective fields, and each RDN is a sequence of name-value pairs. Here is a real-world example:

```json
{'issuer': (((('countryName', 'IL'),),
    (('organizationName', 'StartCom Ltd.'
    (('organizationalUnitName',
        'Secure Digital Certificate Signing
    (('commonName',
        'StartCom Class 2 Primary Intermediate Server CA'
    ,
    'notAfter': 'Nov 22 08:15:19 2013 GMT',
    'notBefore': 'Nov 21 03:09:52 2011 GMT',
    'serialNumber': '95F0',
    'subject': (((('description', '571208-SLe257oHY9f'
    (((('countryName', 'US'),),),
        ('stateOrProvinceName', 'California'))
```
Note: To validate a certificate for a particular service, you can use the `match_hostname()` function.

If the `binary_form` parameter is `True`, and a certificate was provided, this method returns the DER-encoded form of the entire certificate as a sequence of bytes, or `None` if the peer did not provide a certificate. Whether the peer provides a certificate depends on the SSL socket's role:

- for a client SSL socket, the server will always provide a certificate, regardless of whether validation was required;
- for a server SSL socket, the client will only provide a certificate when requested by the server; therefore `getpeercert()` will return `None` if you used `CERT_NONE` (rather than `CERT_OPTIONAL` or `CERT_REQUIRED`).

*Changed in version 3.2:* The returned dictionary includes additional items such as `issuer` and `notBefore`.

*Changed in version 3.4:* `ValueError` is raised when the handshake isn't done. The returned dictionary includes additional X509v3 extension items such as `crlDistributionPoints`, `caIssuers` and OCSP URIs.

`SSLSocket.cipher()`

Returns a three-value tuple containing the name of the cipher
being used, the version of the SSL protocol that defines its use, and the number of secret bits being used. If no connection has been established, returns None.

SSLSocket compression()

Return the compression algorithm being used as a string, or None if the connection isn’t compressed.

If the higher-level protocol supports its own compression mechanism, you can use OP_NO_COMPRESSION to disable SSL-level compression.

*New in version 3.3.*

SSLSocket get_channel_binding(cb_type="tls-unique")

Get channel binding data for current connection, as a bytes object. Returns None if not connected or the handshake has not been completed.

The cb_type parameter allow selection of the desired channel binding type. Valid channel binding types are listed in the CHANNEL_BINDING_TYPES list. Currently only the ‘tls-unique’ channel binding, defined by RFC 5929, is supported. ValueError will be raised if an unsupported channel binding type is requested.

*New in version 3.3.*

SSLSocket selected_npn_protocol()

Returns the protocol that was selected during the TLS/SSL handshake. If SSLContext.set_npn_protocols() was not called, or if the other party does not support NPN, or if the handshake has not yet happened, this will return None.
New in version 3.3.

**SSLSocket**. **unwrap()**
Perform the SSL shutdown handshake, which removes the TLS layer from the underlying socket, and returns the underlying socket object. This can be used to go from encrypted operation over a connection to unencrypted. The returned socket should always be used for further communication with the other side of the connection, rather than the original socket.

**SSLSocket**. **context**
The **SSLContext** object this SSL socket is tied to. If the SSL socket was created using the top-level **wrap_socket()** function (rather than **SSLContext.wrap_socket()**), this is a custom context object created for this SSL socket.

New in version 3.2.
18.2.3. SSL Contexts

New in version 3.2.

An SSL context holds various data longer-lived than single SSL connections, such as SSL configuration options, certificate(s) and private key(s). It also manages a cache of SSL sessions for server-side sockets, in order to speed up repeated connections from the same clients.

```python
class ssl.SSLContext(protocol)
```

Create a new SSL context. You must pass `protocol` which must be one of the `PROTOCOL_*` constants defined in this module. `PROTOCOL_SSLv23` is currently recommended for maximum interoperability.

**See also:** `create_default_context()` lets the `ssl` module choose security settings for a given purpose.

`SSLContext` objects have the following methods and attributes:

```python
SSLContext.cert_store_stats()
```

Get statistics about quantities of loaded X.509 certificates, count of X.509 certificates flagged as CA certificates and certificate revocation lists as dictionary.

Example for a context with one CA cert and one other cert:

```python
>>> context.cert_store_stats()
{'crl': 0, 'x509_ca': 1, 'x509': 2}
```

New in version 3.4.
SSLContext.load_cert_chain(certfile, keyfile=None, password=None)

Load a private key and the corresponding certificate. The certfile string must be the path to a single file in PEM format containing the certificate as well as any number of CA certificates needed to establish the certificate’s authenticity. The keyfile string, if present, must point to a file containing the private key in. Otherwise the private key will be taken from certfile as well. See the discussion of Certificates for more information on how the certificate is stored in the certfile.

The password argument may be a function to call to get the password for decrypting the private key. It will only be called if the private key is encrypted and a password is necessary. It will be called with no arguments, and it should return a string, bytes, or bytearray. If the return value is a string it will be encoded as UTF-8 before using it to decrypt the key. Alternatively a string, bytes, or bytearray value may be supplied directly as the password argument. It will be ignored if the private key is not encrypted and no password is needed.

If the password argument is not specified and a password is required, OpenSSL’s built-in password prompting mechanism will be used to interactively prompt the user for a password.

An SSLError is raised if the private key doesn’t match with the certificate.

Changed in version 3.3: New optional argument password.

SSLContext.load_default_certs(purpose=Purpose.SERVEI)

Load a set of default “certification authority” (CA) certificates from default locations. On Windows it loads CA certs from the CA and
ROOT system stores. On other systems it calls `SSLContext.set_default_verify_paths()`. In the future the method may load CA certificates from other locations, too.

The `purpose` flag specifies what kind of CA certificates are loaded. The default settings `Purpose.SERVER_AUTH` loads certificates, that are flagged and trusted for TLS web server authentication (client side sockets). `Purpose.CLIENT_AUTH` loads CA certificates for client certificate verification on the server side.

*New in version 3.4.*

`SSLContext.load_verify_locations(cafile=None, capath=None, cadata=None)`

Load a set of “certification authority” (CA) certificates used to validate other peers' certificates when `verify_mode` is other than `CERT_NONE`. At least one of `cafile` or `capath` must be specified.

This method can also load certification revocation lists (CRLs) in PEM or DER format. In order to make use of CRLs, `SSLContext.verify_flags` must be configured properly.

The `cafile` string, if present, is the path to a file of concatenated CA certificates in PEM format. See the discussion of `Certificates` for more information about how to arrange the certificates in this file.

The `capath` string, if present, is the path to a directory containing several CA certificates in PEM format, following an OpenSSL specific layout.

The `cadata` object, if present, is either an ASCII string of one or more PEM-encoded certificates or a bytes-like object of DER-encoded certificates. Like with `capath` extra lines around PEM-
encoded certificates are ignored but at least one certificate must be present.

*Changed in version 3.4:* New optional argument `cadata`

```python
SSLContext.get_ca_certs(binary_form=False)
```
Get a list of loaded “certification authority” (CA) certificates. If the `binary_form` parameter is `False` each list entry is a dict like the output of `SSLSocket.getpeercert()`. Otherwise, the method returns a list of DER-encoded certificates. The returned list does not contain certificates from `capath` unless a certificate was requested and loaded by a SSL connection.

*New in version 3.4.*

```python
SSLContext.set_default_verify_paths()
```
Load a set of default “certification authority” (CA) certificates from a filesystem path defined when building the OpenSSL library. Unfortunately, there’s no easy way to know whether this method succeeds: no error is returned if no certificates are to be found. When the OpenSSL library is provided as part of the operating system, though, it is likely to be configured properly.

```python
SSLContext.set_ciphers(ciphers)
```
Set the available ciphers for sockets created with this context. It should be a string in the OpenSSL cipher list format. If no cipher can be selected (because compile-time options or other configuration forbids use of all the specified ciphers), an `SSLError` will be raised.

**Note:** when connected, the `SSLSocket.cipher()` method of SSL sockets will give the currently selected cipher.
SSLContext.set_npn_protocols(protocols)

Specify which protocols the socket should advertise during the SSL/TLS handshake. It should be a list of strings, like ['http/1.1', 'spdy/2'], ordered by preference. The selection of a protocol will happen during the handshake, and will play out according to the NPN draft specification. After a successful handshake, the SSLSocket.selected_npn_protocol() method will return the agreed-upon protocol.

This method will raise NotImplementedError if HAS_NPN is False.

New in version 3.3.

SSLContext.set_servername_callback(server_name_callback)

Register a callback function that will be called after the TLS Client Hello handshake message has been received by the SSL/TLS server when the TLS client specifies a server name indication. The server name indication mechanism is specified in RFC 6066 section 3 - Server Name Indication.

Only one callback can be set per SSLContext. If server_name_callback is None then the callback is disabled. Calling this function a subsequent time will disable the previously registered callback.

The callback function, server_name_callback, will be called with three arguments; the first being the ssl.SSLSocket, the second is a string that represents the server name that the client is intending to communicate (or None if the TLS Client Hello does not contain a server name) and the third argument is the original SSLContext. The server name argument is the IDNA decoded
server name.

A typical use of this callback is to change the ssl.SSLSocket's `SSLContext` attribute to a new object of type `SSLContext` representing a certificate chain that matches the server name.

Due to the early negotiation phase of the TLS connection, only limited methods and attributes are usable like `SSLContext.selected_npn_protocol()` and `SSLContext.getpeercert()`. Other methods require that the TLS connection has progressed beyond the TLS Client Hello and therefore will not contain return meaningful values nor can they be called safely.

The `server_name_callback` function must return `None` to allow the TLS negotiation to continue. If a TLS failure is required, a constant `ALERT_DESCRIPTION_*` can be returned. Other return values will result in a TLS fatal error with `ALERT_DESCRIPTION_INTERNAL_ERROR`.

If there is a IDNA decoding error on the server name, the TLS connection will terminate with an `ALERT_DESCRIPTION_INTERNAL_ERROR` fatal TLS alert message to the client.

If an exception is raised from the `server_name_callback` function the TLS connection will terminate with a fatal TLS alert message `ALERT_DESCRIPTION_HANDSHAKE_FAILURE`. 
This method will raise `NotImplementedError` if the OpenSSL library had `OPENSSL_NO_TLSEXT` defined when it was built.

*New in version 3.4.*

`SSLContext.load_dh_params(dhfile)`

Load the key generation parameters for Diffie-Helman (DH) key exchange. Using DH key exchange improves forward secrecy at the expense of computational resources (both on the server and on the client). The `dhfile` parameter should be the path to a file containing DH parameters in PEM format.

This setting doesn’t apply to client sockets. You can also use the `OP_SINGLE_DH_USE` option to further improve security.

*New in version 3.3.*

`SSLContext.set_ecdh_curve(curve_name)`

Set the curve name for Elliptic Curve-based Diffie-Hellman (ECDH) key exchange. ECDH is significantly faster than regular DH while arguably as secure. The `curve_name` parameter should be a string describing a well-known elliptic curve, for example `prime256v1` for a widely supported curve.

This setting doesn’t apply to client sockets. You can also use the `OP_SINGLE_ECDH_USE` option to further improve security.

This method is not available if `HAS_ECDH` is False.

*New in version 3.3.*

**See also:**

SSL/TLS & Perfect Forward Secrecy
SSLContext.wrap_socket(sock, server_side=False,
do_handshake_on_connect=True, suppress_ragged_eofs=True,
server_hostname=None)

Wrap an existing Python socket sock and return an SSLSocket object. sock must be a SOCK_STREAM socket; other socket types are unsupported.

The returned SSL socket is tied to the context, its settings and certificates. The parameters server_side, do_handshake_on_connect and suppress_ragged_eofs have the same meaning as in the top-level wrap_socket() function.

On client connections, the optional parameter server_hostname specifies the hostname of the service which we are connecting to. This allows a single server to host multiple SSL-based services with distinct certificates, quite similarly to HTTP virtual hosts. Specifying server_hostname will raise a ValueError if the OpenSSL library doesn’t have support for it (that is, if HAS_SNI is False). Specifying server_hostname will also raise a ValueError if server_side is true.

SSLContext.session_stats()

Get statistics about the SSL sessions created or managed by this context. A dictionary is returned which maps the names of each piece of information to their numeric values. For example, here is the total number of hits and misses in the session cache since the context was created:

```python
>>> stats = context.session_stats()
>>> stats['hits'], stats['misses']
```
SSLContext.get_ca_certs(binary_form=False)

Returns a list of dicts with information of loaded CA certs. If the optional argument is true, returns a DER-encoded copy of the CA certificate.

**Note:** Certificates in a capath directory aren't loaded unless they have been used at least once.

*New in version 3.4.*

SSLContext.check_hostname

Wether to match the peer cert's hostname with match_hostname() in SSLSocket.do_handshake(). The context's verify_mode must be set to CERT_OPTIONAL or CERT_REQUIRED, and you must pass server_hostname to wrap_socket() in order to match the hostname.

Example:

```python
import socket, ssl

context = ssl.SSLContext(ssl.PROTOCOL_TLSv1)
context.verify_mode = ssl.CERT_REQUIRED
context.check_hostname = True
context.load_default_certs()

s = socket.socket(socket.AF_INET, socket.SOCK_STREAM)
ssl_sock = context.wrap_socket(s, server_hostname='www.verisign.com', 443)

s.connect(('www.verisign.com', 443))
```

*New in version 3.4.*
Note: This features requires OpenSSL 0.9.8f or newer.

SSLContext.options
An integer representing the set of SSL options enabled on this context. The default value is OP_ALL, but you can specify other options such as OP_NO_SSLv2 by ORing them together.

Note: With versions of OpenSSL older than 0.9.8m, it is only possible to set options, not to clear them. Attempting to clear an option (by resetting the corresponding bits) will raise a ValueError.

SSLContext.protocol
The protocol version chosen when constructing the context. This attribute is read-only.

SSLContext.verify_flags
The flags for certificate verification operations. You can set flags like VERIFY_CRL_CHECK_LEAF by ORing them together. By default OpenSSL does neither require nor verify certificate revocation lists (CRLs). Available only with openssl version 0.9.8+.

New in version 3.4.

SSLContext.verify_mode
Whether to try to verify other peers’ certificates and how to behave if verification fails. This attribute must be one of CERT_NONE, CERT_OPTIONAL or CERT_REQUIRED.
18.2.4. Certificates

Certificates in general are part of a public-key / private-key system. In this system, each principal, (which may be a machine, or a person, or an organization) is assigned a unique two-part encryption key. One part of the key is public, and is called the public key; the other part is kept secret, and is called the private key. The two parts are related, in that if you encrypt a message with one of the parts, you can decrypt it with the other part, and only with the other part.

A certificate contains information about two principals. It contains the name of a subject, and the subject’s public key. It also contains a statement by a second principal, the issuer, that the subject is who he claims to be, and that this is indeed the subject’s public key. The issuer’s statement is signed with the issuer’s private key, which only the issuer knows. However, anyone can verify the issuer’s statement by finding the issuer’s public key, decrypting the statement with it, and comparing it to the other information in the certificate. The certificate also contains information about the time period over which it is valid. This is expressed as two fields, called “notBefore” and “notAfter”.

In the Python use of certificates, a client or server can use a certificate to prove who they are. The other side of a network connection can also be required to produce a certificate, and that certificate can be validated to the satisfaction of the client or server that requires such validation. The connection attempt can be set to raise an exception if the validation fails. Validation is done automatically, by the underlying OpenSSL framework; the application need not concern itself with its mechanics. But the application does usually need to provide sets of certificates to allow this process to take place.

Python uses files to contain certificates. They should be formatted as
“PEM” (see RFC 1422), which is a base-64 encoded form wrapped with a header line and a footer line:

```
-----BEGIN CERTIFICATE-----
...(certificate in base64 PEM encoding)...
-----END CERTIFICATE-----
```

18.2.4.1. Certificate chains

The Python files which contain certificates can contain a sequence of certificates, sometimes called a certificate chain. This chain should start with the specific certificate for the principal who “is” the client or server, and then the certificate for the issuer of that certificate, and then the certificate for the issuer of that certificate, and so on up the chain till you get to a certificate which is self-signed, that is, a certificate which has the same subject and issuer, sometimes called a root certificate. The certificates should just be concatenated together in the certificate file. For example, suppose we had a three certificate chain, from our server certificate to the certificate of the certification authority that signed our server certificate, to the root certificate of the agency which issued the certification authority’s certificate:

```
-----BEGIN CERTIFICATE-----
...(certificate for your server)...
-----END CERTIFICATE-----
-----BEGIN CERTIFICATE-----
...(the certificate for the CA)...
-----END CERTIFICATE-----
-----BEGIN CERTIFICATE-----
...(the root certificate for the CA's issuer)...
-----END CERTIFICATE-----
```

18.2.4.2. CA certificates
If you are going to require validation of the other side of the connection's certificate, you need to provide a “CA certs” file, filled with the certificate chains for each issuer you are willing to trust. Again, this file just contains these chains concatenated together. For validation, Python will use the first chain it finds in the file which matches. Some “standard” root certificates are available from various certification authorities: CACert.org, Thawte, Verisign, Positive SSL (used by python.org), Equifax and GeoTrust.

In general, if you are using SSL3 or TLS1, you don’t need to put the full chain in your “CA certs” file; you only need the root certificates, and the remote peer is supposed to furnish the other certificates necessary to chain from its certificate to a root certificate. See RFC 4158 for more discussion of the way in which certification chains can be built.

18.2.4.3. Combined key and certificate

Often the private key is stored in the same file as the certificate; in this case, only the `certfile` parameter to `SSLContext.load_cert_chain()` and `wrap_socket()` needs to be passed. If the private key is stored with the certificate, it should come before the first certificate in the certificate chain:

```
-----BEGIN RSA PRIVATE KEY-----
... (private key in base64 encoding) ...
-----END RSA PRIVATE KEY-----
-----BEGIN CERTIFICATE-----
... (certificate in base64 PEM encoding) ...
-----END CERTIFICATE-----
```

18.2.4.4. Self-signed certificates
If you are going to create a server that provides SSL-encrypted connection services, you will need to acquire a certificate for that service. There are many ways of acquiring appropriate certificates, such as buying one from a certification authority. Another common practice is to generate a self-signed certificate. The simplest way to do this is with the OpenSSL package, using something like the following:

```bash
% openssl req -new -x509 -days 365 -nodes -out cert.pem
Generating a 1024 bit RSA private key
........+++++
.................................+++++
writing new private key to 'cert.pem'
-----
You are about to be asked to enter information that into your certificate request. What you are about to enter **is** what **is** called a Dist
There are quite a few fields but you can leave some For some fields there will be a default value, If you enter '.', the field will be left blank.
-----
Country Name (2 letter code) [AU]:US
State or Province Name (full name) [Some-State]:MySt
Locality Name (eg, city) []:Some City
Organization Name (eg, company) [Internet Wdigits Pt
Organizational Unit Name (eg, section) []:My Group
Common Name (eg, YOUR name) []:myserver.mygroup.myorganization
Email Address []:ops@myserver.mygroup.myorganization
%
```

The disadvantage of a self-signed certificate is that it is its own root certificate, and no one else will have it in their cache of known (and trusted) root certificates.
18.2.5. Examples

18.2.5.1. Testing for SSL support

To test for the presence of SSL support in a Python installation, user code should use the following idiom:

```python
try:
    import ssl
except ImportError:
    pass
else:
    ... # do something that requires SSL support
```

18.2.5.2. Client-side operation

This example connects to an SSL server and prints the server's certificate:

```python
import socket, ssl, pprint
s = socket.socket(socket.AF_INET, socket.SOCK_STREAM)
# require a certificate from the server
ssl_sock = ssl.wrap_socket(s,
    ca_certs="/etc/ca_certs_file",
    cert_reqs=ssl.CERT_REQUIRED)
ssl_sock.connect(('www.verisign.com', 443))
pprint.pprint(ssl_sock.getpeercert())
# note that closing the SSLSocket will also close the socket
ssl_sock.close()
```

As of January 6, 2012, the certificate printed by this program looks like
This other example first creates an SSL context, instructs it to verify certificates sent by peers, and feeds it a set of recognized certificate
When you use the context to connect to a server, `CERT_REQUIRED` validates the server certificate: it ensures that the server certificate was signed with one of the CA certificates, and checks the signature for correctness:

```python
>>> conn = context.wrap_socket(socket.socket(socket.
>>> conn.connect(("linuxfr.org", 443))
```

You should then fetch the certificate and check its fields for conformity:

```python
>>> cert = conn.getpeercert()
>>> ssl.match_hostname(cert, "linuxfr.org")
```

Visual inspection shows that the certificate does identify the desired service (that is, the HTTPS host `linuxfr.org`):

```python
>>> pprint.pprint(cert)
{'issuer': ((("organizationName", 'CAcert Inc.')),
(("organizationalUnitName", 'http://www.CAcert.org'),
(("commonName", 'CAcert Class 3 Root'),)

'notAfter': 'Jun  7 21:02:24 2013 GMT',
'notBefore': 'Jun  8 21:02:24 2011 GMT',
'serialNumber': 'D3E9',
```
Now that you are assured of its authenticity, you can proceed to talk with the server:

```python
>>> conn.sendall(b"HEAD / HTTP/1.0\r\nHost: linuxfr.org\n\r\n")
>>> pprint.pprint(conn.recv(1024).split(b"\r\n"))
[b'HTTP/1.1 302 Found', b'Date: Sun, 16 May 2010 13:43:28 GMT', b'Server: Apache/2.2', b'Location: https://linuxfr.org/pub/', b'Vary: Accept-Encoding', b'Connection: close', b'Content-Type: text/html; charset=iso-8859-1', b'']
```

See the discussion of **Security considerations** below.

### 18.2.5.3. Server-side operation
For server operation, typically you’ll need to have a server certificate, and private key, each in a file. You’ll first create a context holding the key and the certificate, so that clients can check your authenticity. Then you’ll open a socket, bind it to a port, call `listen()` on it, and start waiting for clients to connect:

```python
import socket, ssl

context = ssl.SSLContext(ssl.PROTOCOL_TLSv1)
context.load_cert_chain(certfile="mycertfile", keyfile="mykeyfile")

bindsocket = socket.socket()
bindsocket.bind(('myaddr.mydomain.com', 10023))
bindsocket.listen(5)
```

When a client connects, you’ll call `accept()` on the socket to get the new socket from the other end, and use the context’s `SSLContext.wrap_socket()` method to create a server-side SSL socket for the connection:

```python
while True:
    newsocket, fromaddr = bindsocket.accept()
    connstream = context.wrap_socket(newsocket, server_side=True)
    try:
        deal_with_client(connstream)
    finally:
        connstream.shutdown(socket.SHUT_RDWR)
        connstream.close()
```

Then you’ll read data from the `connstream` and do something with it till you are finished with the client (or the client is finished with you):

```python
def deal_with_client(connstream):
```
data = connstream.recv(1024)
# empty data means the client is finished with us
while data:
    if not do_something(connstream, data):
        # we'll assume do_something returns False
        # when we're finished with client
        break
    data = connstream.recv(1024)
    # finished with client

And go back to listening for new client connections (of course, a real server would probably handle each client connection in a separate thread, or put the sockets in non-blocking mode and use an event loop).
18.2.6. Notes on non-blocking sockets

When working with non-blocking sockets, there are several things you need to be aware of:

- Calling `select()` tells you that the OS-level socket can be read from (or written to), but it does not imply that there is sufficient data at the upper SSL layer. For example, only part of an SSL frame might have arrived. Therefore, you must be ready to handle `SSLSocket.recv()` and `SSLSocket.send()` failures, and retry after another call to `select()`.

  (of course, similar provisions apply when using other primitives such as `poll()`)

- The SSL handshake itself will be non-blocking: the `SSLSocket.do_handshake()` method has to be retried until it returns successfully. Here is a synopsis using `select()` to wait for the socket's readiness:

```python
while True:
    try:
        sock.do_handshake()
        break
    except ssl.SSLWantReadError:
        select.select([sock], [], [])
    except ssl.SSLWantWriteError:
        select.select([], [sock], [])
```
18.2.7. Security considerations

18.2.7.1. Verifying certificates

**CERT_NONE** is the default. Since it does not authenticate the other peer, it can be insecure, especially in client mode where most of time you would like to ensure the authenticity of the server you're talking to. Therefore, when in client mode, it is highly recommended to use **CERT_REQUIRED**. However, it is in itself not sufficient; you also have to check that the server certificate, which can be obtained by calling `SSLSocket.getpeercert()` matches the desired service. For many protocols and applications, the service can be identified by the hostname; in this case, the `match_hostname()` function can be used. This common check is automatically performed when `SSLContext.check_hostname` is enabled.

In server mode, if you want to authenticate your clients using the SSL layer (rather than using a higher-level authentication mechanism), you'll also have to specify **CERT_REQUIRED** and similarly check the client certificate.

**Note:** In client mode, **CERT_OPTIONAL** and **CERT_REQUIRED** are equivalent unless anonymous ciphers are enabled (they are disabled by default).

18.2.7.2. Protocol versions

SSL version 2 is considered insecure and is therefore dangerous to use. If you want maximum compatibility between clients and servers, it is recommended to use **PROTOCOL_SSLv23** as the protocol version
and then disable SSLv2 explicitly using the `SSLContext.options` attribute:

```python
class = ssl.SSLContext(ssl.PROTOCOL_SSLv23)
class.options |= ssl.OP_NO_SSLv2
```

The SSL context created above will allow SSLv3 and TLSv1 connections, but not SSLv2.

### 18.2.7.3. Cipher selection

If you have advanced security requirements, fine-tuning of the ciphers enabled when negotiating a SSL session is possible through the `SSLContext.set_ciphers()` method. Starting from Python 3.2.3, the ssl module disables certain weak ciphers by default, but you may want to further restrict the cipher choice. For example:

```python
class = ssl.SSLContext(ssl.PROTOCOL_TLSv1)
class.set_ciphers('HIGH:!aNULL:!eNULL')
```

The !aNULL:!eNULL part of the cipher spec is necessary to disable ciphers which don't provide both encryption and authentication. Be sure to read OpenSSL's documentation about the cipher list format. If you want to check which ciphers are enabled by a given cipher list, use the `openssl ciphers` command on your system.

### 18.2.7.4. Multi-processing

If using this module as part of a multi-processed application (using, for example the `multiprocessing` or `concurrent.futures` modules), be aware that OpenSSL's internal random number generator does not properly handle forked processes. Applications
must change the PRNG state of the parent process if they use any SSL feature with `os.fork()`. Any successful call of `RAND_add()`, `RAND_bytes()` or `RAND_pseudo_bytes()` is sufficient.

18.3. **select** — Waiting for I/O completion

This module provides access to the `select()` and `poll()` functions available in most operating systems, `devpoll()` available on Solaris and derivatives, `epoll()` available on Linux 2.5+ and `kqueue()` available on most BSD. Note that on Windows, it only works for sockets; on other operating systems, it also works for other file types (in particular, on Unix, it works on pipes). It cannot be used on regular files to determine whether a file has grown since it was last read.

**Note:** The `selectors` module allows high-level and efficient I/O multiplexing, built upon the `select` module primitives. Users are encouraged to use the `selectors` module instead, unless they want precise control over the OS-level primitives used.

The module defines the following:

**exception select.error**

A deprecated alias of `OSError`.

*Changed in version 3.3:* Following PEP 3151, this class was made an alias of `OSError`.

`select.devpoll()`

(Only supported on Solaris and derivatives.) Returns a `/dev/poll` polling object; see section `/dev/poll Polling Objects` below for the methods supported by `devpoll` objects.

`devpoll()` objects are linked to the number of file descriptors
allowed at the time of instantiation. If your program reduces this value, devpoll() will fail. If your program increases this value, devpoll() may return an incomplete list of active file descriptors.

The new file descriptor is \textit{non-inheritable}.

\textit{New in version 3.3.}

\textit{Changed in version 3.4:} The new file descriptor is now non-inheritable.

\texttt{select.epoll(sizehint=-1, flags=0)}

(Only supported on Linux 2.5.44 and newer.) Return an edge polling object, which can be used as Edge or Level Triggered interface for I/O events. \texttt{sizehint} is deprecated and completely ignored. \texttt{flags} can be set to \texttt{EPOLL_CLOEXEC}, which causes the epoll descriptor to be closed automatically when \texttt{os.execve()} is called.

See the \textit{Edge and Level Trigger Polling (epoll) Objects} section below for the methods supported by epolling objects.

\texttt{epoll} objects support the context management protocol: when used in a \texttt{with} statement, the new file descriptor is automatically closed at the end of the block.

The new file descriptor is \textit{non-inheritable}.

\textit{Changed in version 3.3:} Added the \texttt{flags} parameter.

\textit{Changed in version 3.4:} Support for the \texttt{with} statement was added. The new file descriptor is now non-inheritable.

\texttt{select.poll()}
(Not supported by all operating systems.) Returns a polling object, which supports registering and unregistering file descriptors, and then polling them for I/O events; see section *Polling Objects* below for the methods supported by polling objects.

**select.kqueue()**

(Only supported on BSD.) Returns a kernel queue object; see section *Kqueue Objects* below for the methods supported by kqueue objects.

The new file descriptor is *non-inheritable*.

*Changed in version 3.4:* The new file descriptor is now non-inheritable.

**select.kevent(ident, filter=KQ_FILTER_READ, flags=KQ_EV_ADD, fflags=0, data=0, udata=0)**

(Only supported on BSD.) Returns a kernel event object; see section *Kevent Objects* below for the methods supported by kevent objects.

**select.select(rlist, wlist, xlist[, timeout])**

This is a straightforward interface to the Unix `select()` system call. The first three arguments are sequences of ‘waitable objects’: either integers representing file descriptors or objects with a parameterless method named `fileno()` returning such an integer:

- `rlist`: wait until ready for reading
- `wlist`: wait until ready for writing
- `xlist`: wait for an “exceptional condition” (see the manual page for what your system considers such a condition)

Empty sequences are allowed, but acceptance of three empty
sequences is platform-dependent. (It is known to work on Unix but not on Windows.) The optional *timeout* argument specifies a time-out as a floating point number in seconds. When the *timeout* argument is omitted the function blocks until at least one file descriptor is ready. A time-out value of zero specifies a poll and never blocks.

The return value is a triple of lists of objects that are ready: subsets of the first three arguments. When the time-out is reached without a file descriptor becoming ready, three empty lists are returned.

Among the acceptable object types in the sequences are Python *file objects* (e.g. `sys.stdin`, or objects returned by `open()` or `os.popen()`), socket objects returned by `socket.socket()`. You may also define a wrapper class yourself, as long as it has an appropriate `fileno()` method (that really returns a file descriptor, not just a random integer).

**Note:** File objects on Windows are not acceptable, but sockets are. On Windows, the underlying `select()` function is provided by the WinSock library, and does not handle file descriptors that don't originate from WinSock.

**select**. **PIPE_BUF**

The minimum number of bytes which can be written without blocking to a pipe when the pipe has been reported as ready for writing by `select()`, `poll()` or another interface in this module. This doesn't apply to other kind of file-like objects such as sockets.

This value is guaranteed by POSIX to be at least 512. Availability: Unix.
New in version 3.2.
18.3.1. /dev/poll Polling Objects

Solaris and derivatives have /dev/poll. While select() is O(highest file descriptor) and poll() is O(number of file descriptors), /dev/poll is O(active file descriptors).

/dev/poll behaviour is very close to the standard poll() object.

devpoll.close()

Close the file descriptor of the polling object.

    New in version 3.4.

devpoll.closed

True if the polling object is closed.

    New in version 3.4.

devpoll.fileno()

Return the file descriptor number of the polling object.

    New in version 3.4.

devpoll.register(fd[, eventmask])

Register a file descriptor with the polling object. Future calls to the poll() method will then check whether the file descriptor has any pending I/O events. fd can be either an integer, or an object with a fileno() method that returns an integer. File objects implement fileno(), so they can also be used as the argument.
eventmask is an optional bitmask describing the type of events you want to check for. The constants are the same that with poll() object. The default value is a combination of the constants POLLIN, POLLPRI, and POLLOUT.

**Warning:** Registering a file descriptor that’s already registered is not an error, but the result is undefined. The appropriate action is to unregister or modify it first. This is an important difference compared with poll().

**devpoll.modify**(fd[, eventmask])

This method does an unregister() followed by a register(). It is (a bit) more efficient that doing the same explicitly.

**devpoll.unregister**(fd)

Remove a file descriptor being tracked by a polling object. Just like the register() method, fd can be an integer or an object with a fileno() method that returns an integer.

Attempting to remove a file descriptor that was never registered is safely ignored.

**devpoll.poll**([timeout])

Polls the set of registered file descriptors, and returns a possibly-empty list containing (fd, event) 2-tuples for the descriptors that have events or errors to report. fd is the file descriptor, and event is a bitmask with bits set for the reported events for that descriptor — POLLIN for waiting input, POLLOUT to indicate that the descriptor can be written to, and so forth. An empty list indicates that the call timed out and no file descriptors had any events to report. If timeout is given, it specifies the length of time in
milliseconds which the system will wait for events before returning. If *timeout* is omitted, -1, or *None*, the call will block until there is an event for this poll object.
18.3.2. Edge and Level Trigger Polling (epoll) Objects

http://linux.die.net/man/4/epoll

eventmask

<table>
<thead>
<tr>
<th>Constant</th>

</tr>
</tbody>
</table>

epoll.close()  
Close the control file descriptor of the epoll object.

epoll.closed
True if the epoll object is closed.

epoll. **fileno()**
  Return the file descriptor number of the control fd.

epoll. **fromfd(fd)**
  Create an epoll object from a given file descriptor.

epoll. **register(fd[, eventmask])**
  Register a fd descriptor with the epoll object.

epoll. **modify(fd, eventmask)**
  Modify a registered file descriptor.

epoll. **unregister(fd)**
  Remove a registered file descriptor from the epoll object.

epoll. **poll(timeout=-1, maxevents=-1)**
  Wait for events. timeout in seconds (float)
18.3.3. Polling Objects

The `poll()` system call, supported on most Unix systems, provides better scalability for network servers that service many, many clients at the same time. `poll()` scales better because the system call only requires listing the file descriptors of interest, while `select()` builds a bitmap, turns on bits for the fds of interest, and then afterward the whole bitmap has to be linearly scanned again. `select()` is $O(\text{highest file descriptor})$, while `poll()` is $O(\text{number of file descriptors})$.

`poll.register(fd[, eventmask])`

Register a file descriptor with the polling object. Future calls to the `poll()` method will then check whether the file descriptor has any pending I/O events. `fd` can be either an integer, or an object with a `fileno()` method that returns an integer. File objects implement `fileno()`, so they can also be used as the argument.

`eventmask` is an optional bitmask describing the type of events you want to check for, and can be a combination of the constants `POLLIN`, `POLLPRI`, and `POLLOUT`, described in the table below. If not specified, the default value used will check for all 3 types of events.

<table>
<thead>
<tr>
<th>Constant</th>
<th>Meaning</th>
</tr>
</thead>
<tbody>
<tr>
<td>POLLIN</td>
<td>There is data to read</td>
</tr>
<tr>
<td>POLLPRI</td>
<td>There is urgent data to read</td>
</tr>
<tr>
<td>POLLOUT</td>
<td>Ready for output: writing will not block</td>
</tr>
<tr>
<td>POLLERR</td>
<td>Error condition of some sort</td>
</tr>
</tbody>
</table>
POLLHUP | Hung up
--- | ---
POLLNVAL | Invalid request: descriptor not open

Registering a file descriptor that’s already registered is not an error, and has the same effect as registering the descriptor exactly once.

**poll. modify**(*fd, eventmask*)

Modifies an already registered *fd*. This has the same effect as **register**(/*fd, eventmask*). Attempting to modify a file descriptor that was never registered causes an **IOError** exception with errno ENOENT to be raised.

**poll. unregister**(*fd*)

Remove a file descriptor being tracked by a polling object. Just like the register() method, *fd* can be an integer or an object with a **fileno()** method that returns an integer.

Attempting to remove a file descriptor that was never registered causes a **KeyError** exception to be raised.

**poll. poll**(/*timeout*)

Polls the set of registered file descriptors, and returns a possibly-empty list containing (*fd, event*) 2-tuples for the descriptors that have events or errors to report. *fd* is the file descriptor, and *event* is a bitmask with bits set for the reported events for that descriptor — POLLIN for waiting input, POLLOUT to indicate that the descriptor can be written to, and so forth. An empty list indicates that the call timed out and no file descriptors had any events to report. If *timeout* is given, it specifies the length of time in milliseconds which the system will wait for events before returning. If *timeout* is omitted, negative, or **None**, the call will block until there is an event for this poll object.
18.3.4. Kqueue Objects

kqueue.close()
   Close the control file descriptor of the kqueue object.

kqueue.closed
   True if the kqueue object is closed.

kqueue.fileno()
   Return the file descriptor number of the control fd.

kqueue.fromfd(fd)
   Create a kqueue object from a given file descriptor.

kqueue.control(changelist, max_events[, timeout=None]) → eventlist
   Low level interface to kevent
   - changelist must be an iterable of kevent object or None
   - max_events must be 0 or a positive integer
   - timeout in seconds (floats possible)
18.3.5. Kevent Objects

http://www.freebsd.org/cgi/man.cgi?query=kqueue&sektion=2

**kevent. ident**

Value used to identify the event. The interpretation depends on the filter but it's usually the file descriptor. In the constructor ident can either be an int or an object with a `fileno()` method. `kevent` stores the integer internally.

**kevent. filter**

Name of the kernel filter.

<table>

\texttt{kevent.data}
Filter specific data.

kevent.udata
User defined value.
18.4. selectors – High-level I/O multiplexing

New in version 3.4.
18.4.1. Introduction

This module allows high-level and efficient I/O multiplexing, built upon the select module primitives. Users are encouraged to use this module instead, unless they want precise control over the OS-level primitives used.

It defines a BaseSelector abstract base class, along with several concrete implementations (KqueueSelector, EpollSelector...), that can be used to wait for I/O readiness notification on multiple file objects. In the following, “file object” refers to any object with a fileno() method, or a raw file descriptor. See file object.

DefaultSelector is an alias to the most efficient implementation available on the current platform: this should be the default choice for most users.

**Note:** The type of file objects supported depends on the platform: on Windows, sockets are supported, but not pipes, whereas on Unix, both are supported (some other types may be supported as well, such as fifos or special file devices).

**See also:**

select
Low-level I/O multiplexing module.
18.4.2. Classes

Classes hierarchy:

```
BaseSelector
  +- SelectSelector
  +- PollSelector
  +- EpollSelector
  +- KqueueSelector
```

In the following, _events_ is a bitwise mask indicating which I/O events should be waited for on a given file object. It can be a combination of the constants below:

<table>
<thead>
<tr>
<th>Constant</th>
<th>Meaning</th>
</tr>
</thead>
<tbody>
<tr>
<td>EVENT_READ</td>
<td>Available for read</td>
</tr>
<tr>
<td>EVENT_WRITE</td>
<td>Available for write</td>
</tr>
</tbody>
</table>

### class selectors. **SelectorKey**

A **SelectorKey** is a namedtuple used to associate a file object to its underlying file descriptor, selected event mask and attached data. It is returned by several **BaseSelector** methods.

**fileobj**

File object registered.

**fd**

Underlying file descriptor.

**events**

Events that must be waited for on this file object.
Optional opaque data associated to this file object: for example, this could be used to store a per-client session ID.

### class selectors. BaseSelector

A BaseSelector is used to wait for I/O event readiness on multiple file objects. It supports file stream registration, unregistration, and a method to wait for I/O events on those streams, with an optional timeout. It’s an abstract base class, so cannot be instantiated. Use DefaultSelector instead, or one of SelectSelector, KqueueSelector etc. if you want to specifically use an implementation, and your platform supports it. BaseSelector and its concrete implementations support the context manager protocol.

#### register(fileobj, events, data=None)

Register a file object for selection, monitoring it for I/O events.

*fileobj* is the file object to monitor. It may either be an integer file descriptor or an object with a `fileno()` method. *events* is a bitwise mask of events to monitor. *data* is an opaque object.

This returns a new SelectorKey instance, or raises a ValueError in case of invalid event mask or file descriptor, or KeyError if the file object is already registered.

#### unregister(fileobj)

Unregister a file object from selection, removing it from monitoring. A file object shall be unregistered prior to being closed.

*fileobj* must be a file object previously registered.
This returns the associated `SelectorKey` instance, or raises a `KeyError` if `fileobj` is not registered. It will raise `ValueError` if `fileobj` is invalid (e.g. it has no `fileno()` method or its `fileno()` method has an invalid return value).

**modify**(*fileobj, events, data=None*)  
Change a registered file object's monitored events or attached data.

This is equivalent to `BaseSelector.unregister(fileobj)()` followed by `BaseSelector.register(fileobj, events, data)()`, except that it can be implemented more efficiently.

This returns a new `SelectorKey` instance, or raises a `ValueError` in case of invalid event mask or file descriptor, or `KeyError` if the file object is not registered.

**select**(timeout=None)  
Wait until some registered file objects become ready, or the timeout expires.

If `timeout > 0`, this specifies the maximum wait time, in seconds. If `timeout <= 0`, the call won't block, and will report the currently ready file objects. If `timeout` is `None`, the call will block until a monitored file object becomes ready.

This returns a list of `(key, events)` tuples, one for each ready file object.

`key` is the `SelectorKey` instance corresponding to a ready file object. `events` is a bitmask of events ready on this file object.
Note: This method can return before any file object becomes ready or the timeout has elapsed if the current process receives a signal: in this case, an empty list will be returned.

**close()**

Close the selector.

This must be called to make sure that any underlying resource is freed. The selector shall not be used once it has been closed.

**get_key(fileobj)**

Return the key associated with a registered file object.

This returns the `SelectorKey` instance associated to this file object, or raises `KeyError` if the file object is not registered.

**get_map()**

Return a mapping of file objects to selector keys.

This returns a `Mapping` instance mapping registered file objects to their associated `SelectorKey` instance.

**class selectors.DefaultSelector**

The default selector class, using the most efficient implementation available on the current platform. This should be the default choice for most users.

**class selectors.SelectSelector**

`select.select()`-based selector.

**class selectors.PollSelector**

`select.poll()`-based selector.
class selectors. **EpollSelector**

`select.epoll()`-based selector.

**fileno()**
This returns the file descriptor used by the underlying `select.epoll()` object.

class selectors. **KqueueSelector**

`select.kqueue()`-based selector.

**fileno()**
This returns the file descriptor used by the underlying `select.kqueue()` object.
18.4.3. Examples

Here is a simple echo server implementation:

```python
import selectors
import socket

sel = selectors.DefaultSelector()

def accept(sock, mask):
    conn, addr = sock.accept()  # Should be ready
    print('accepted', conn, 'from', addr)
    conn.setblocking(False)
    sel.register(conn, selectors.EVENT_READ, read)

def read(conn, mask):
    data = conn.recv(1000)  # Should be ready
    if data:
        print('echoing', repr(data), 'to', conn)
        conn.send(data)  # Hope it won't block
    else:
        print('closing', conn)
        sel.unregister(conn)
        conn.close()

sock = socket.socket()
sock.bind(('localhost', 1234))
sock.listen(100)
sock.setblocking(False)
sel.register(sock, selectors.EVENT_READ, accept)

while True:
    events = sel.select()
    for key, mask in events:
        callback = key.data
```

callback(key.fileobj, mask)
18.5. asyncio – Asynchronous I/O, event loop, coroutines and tasks

New in version 3.4.

Source code: Lib/asyncio/

This module provides infrastructure for writing single-threaded concurrent code using coroutines, multiplexing I/O access over sockets and other resources, running network clients and servers, and other related primitives. Here is a more detailed list of the package contents:

- a pluggable event loop with various system-specific implementations;
- transport and protocol abstractions (similar to those in Twisted);
- concrete support for TCP, UDP, SSL, subprocess pipes, delayed calls, and others (some may be system-dependent);
- a Future class that mimics the one in the concurrent.futures module, but adapted for use with the event loop;
- coroutines and tasks based on yield from (PEP 380), to help write concurrent code in a sequential fashion;
- cancellation support for Futures and coroutines;
- synchronization primitives for use between coroutines in a single thread, mimicking those in the threading module;
- an interface for passing work off to a threadpool, for times when you absolutely, positively have to use a library that makes blocking I/O calls.
Table of content:

- 18.5.7.4. Detect coroutine objects never scheduled
- 18.5.7.5. Detect exceptions not consumed
- 18.5.7.6. Chain coroutines correctly

See also: The asyncio module was designed in the PEP 3156. For a motivational primer on transports and protocols, see PEP 3153.
18.5.1. Event loops

The event loop is the central execution device provided by asyncio. It provides multiple facilities, amongst which:

- Registering, executing and cancelling delayed calls (timeouts).
- Creating client and server transports for various kinds of communication.
- Launching subprocesses and the associated transports for communication with an external program.
- Delegating costly function calls to a pool of threads.
18.5.1.1. Event loop policies and the default policy

Event loop management is abstracted with a policy pattern, to provide maximal flexibility for custom platforms and frameworks. Throughout the execution of a process, a single global policy object manages the event loops available to the process based on the calling context. A policy is an object implementing the `AbstractEventLoopPolicy` interface.

For most users of `asyncio`, policies never have to be dealt with explicitly, since the default global policy is sufficient.

The default policy defines context as the current thread, and manages an event loop per thread that interacts with `asyncio`. The module-level functions `get_event_loop()` and `set_event_loop()` provide convenient access to event loops managed by the default policy.
18.5.1.2. Event loop functions

The following functions are convenient shortcuts to accessing the methods of the global policy. Note that this provides access to the default policy, unless an alternative policy was set by calling `set_event_loop_policy()` earlier in the execution of the process.

```python
asyncio.get_event_loop()
Equivalent to calling
get_event_loop_policy().get_event_loop().
```

```python
asyncio.set_event_loop(loop)
Equivalent to calling
get_event_loop_policy().set_event_loop(loop).
```

```python
asyncio.new_event_loop()
Equivalent to calling
get_event_loop_policy().new_event_loop().
```
18.5.1.3. Event loop policy interface

An event loop policy must implement the following interface:

class asyncio.AbstractEventLoopPolicy
    get_event_loop()

Get the event loop for current context. Returns an event loop object implementing BaseEventLoop interface, or raises an exception in case no event loop has been set for the current context and the current policy does not specify to create one. It should never return None.

set_event_loop(loop)

Set the event loop of the current context to loop.

new_event_loop()

Create and return a new event loop object according to this policy's rules. If there's need to set this loop as the event loop of the current context, set_event_loop() must be called explicitly.
18.5.1.4. Access to the global loop policy

asyncio.get_event_loop_policy()
    Get the current event loop policy.

asyncio.set_event_loop_policy(policy)
    Set the current event loop policy. If policy is None, the default policy is restored.
18.5.1.5. Run an event loop

BaseEventLoop.run_forever()
Run until stop() is called.

BaseEventLoop.run_until_complete(future)
Run until the Future is done.

If the argument is a coroutine, it is wrapped in a Task.

Return the Future's result, or raise its exception.

BaseEventLoop.is_running()
Returns running status of event loop.

BaseEventLoop.stop()
Stop running the event loop.

Every callback scheduled before stop() is called will run. Callback scheduled after stop() is called won’t. However, those callbacks will run if run_forever() is called again later.

BaseEventLoop.close()
Close the event loop. The loop should not be running.

This clears the queues and shuts down the executor, but does not wait for the executor to finish.

This is idempotent and irreversible. No other methods should be called after this one.
18.5.1.6. Calls

BaseEventLoop. **call_soon**(callback, *args)

Arrange for a callback to be called as soon as possible.

This operates as a FIFO queue, callbacks are called in the order in which they are registered. Each callback will be called exactly once.

Any positional arguments after the callback will be passed to the callback when it is called.

An instance of `asyncio.Handle` is returned.

BaseEventLoop. **call_soon_threadsafe**(callback, *args)

Like `call_soon()`, but thread safe.
18.5.1.7. Delayed calls

The event loop has its own internal clock for computing timeouts. Which clock is used depends on the (platform-specific) event loop implementation; ideally it is a monotonic clock. This will generally be a different clock than `time.time()`.

**Note:** Timeouts (relative *delay* or absolute *when*) should not exceed one day.

BaseEventLoop. `call_later`(*delay*, *callback*, *args*)

Arrange for the *callback* to be called after the given *delay* seconds (either an int or float).

An instance of `asyncio.Handle` is returned.

*callback* will be called exactly once per call to `call_later()`. If two callbacks are scheduled for exactly the same time, it is undefined which will be called first.

The optional positional *args* will be passed to the callback when it is called. If you want the callback to be called with some named arguments, use a closure or `functools.partial()`.

BaseEventLoop. `call_at`(*when*, *callback*, *args*)

Arrange for the *callback* to be called at the given absolute timestamp *when* (an int or float), using the same time reference as `time()`.

This method’s behavior is the same as `call_later()`.

BaseEventLoop. `time()`
Return the current time, as a float value, according to the event loop’s internal clock.

See also: The asyncio.sleep() function.
18.5.1.8. Creating connections

BaseEventLoop. `create_connection`(*protocol_factory*, *host=None, port=None, *, ssl=None, family=0, proto=0, flags=0, sock=None, local_addr=None, server_hostname=None)*

Create a streaming transport connection to a given Internet *host* and *port*: socket family `AF_INET` or `AF_INET6` depending on *host* (or *family* if specified), socket type `SOCK_STREAM`. `protocol_factory` must be a callable returning a `protocol` instance.

This method is a coroutine which will try to establish the connection in the background. When successful, the coroutine returns a `(transport, protocol)` pair.

The chronological synopsis of the underlying operation is as follows:

1. The connection is established, and a `transport` is created to represent it.
2. `protocol_factory` is called without arguments and must return a `protocol` instance.
3. The protocol instance is tied to the transport, and its `connection_made()` method is called.
4. The coroutine returns successfully with the `(transport, protocol)` pair.

The created transport is an implementation-dependent bidirectional stream.

**Note:** `protocol_factory` can be any kind of callable, not necessarily a class. For example, if you want to use a pre-created protocol instance, you can pass lambda: `my_protocol`.
Options allowing to change how the connection is created:

- **ssl**: if given and not false, a SSL/TLS transport is created (by default a plain TCP transport is created). If `ssl` is a `ssl.SSLContext` object, this context is used to create the transport; if `ssl` is `True`, a context with some unspecified default settings is used.

- **server_hostname**, is only for use together with `ssl`, and sets or overrides the hostname that the target server’s certificate will be matched against. By default the value of the `host` argument is used. If `host` is empty, there is no default and you must pass a value for `server_hostname`. If `server_hostname` is an empty string, hostname matching is disabled (which is a serious security risk, allowing for man-in-the-middle-attacks).

- **family**, **proto**, **flags** are the optional address family, protocol and flags to be passed through to `getaddrinfo()` for `host` resolution. If given, these should all be integers from the corresponding `socket` module constants.

- **sock**, if given, should be an existing, already connected `socket.socket` object to be used by the transport. If `sock` is given, none of `host`, `port`, `family`, `proto`, `flags` and `local_addr` should be specified.

- **local_addr**, if given, is a `(local_host, local_port)` tuple used to bind the socket to locally. The `local_host` and `local_port` are looked up using `getaddrinfo()`, similarly to `host` and `port`.

**See also:** The `open_connection()` function can be used to get a pair of `(StreamReader, StreamWriter)` instead of a protocol.

```python
BaseEventLoop.create_datagram_endpoint(protocol_factory, local_addr=None, remote_addr=None, *, family=0, proto=0, flags=0)
```
Create datagram connection: socket family `AF_INET` or `AF_INET6` depending on `host` (or `family` if specified), socket type `SOCK_DGRAM`.

This method is a coroutine which will try to establish the connection in the background. When successful, the coroutine returns a `(transport, protocol)` pair.

See the `BaseEventLoop.create_connection()` method for parameters.

```python
BaseEventLoop.create_unix_connection(protocol_factory, path, *, ssl=None, sock=None, server_hostname=None)
```

Create UNIX connection: socket family `AF_UNIX`, socket type `SOCK_STREAM`. The `AF_UNIX` socket family is used to communicate between processes on the same machine efficiently.

This method is a coroutine which will try to establish the connection in the background. When successful, the coroutine returns a `(transport, protocol)` pair.

See the `BaseEventLoop.create_connection()` method for parameters.

Availability: UNIX.
18.5.1.9. Creating listening connections

BaseEventLoop\.create_server(\textit{protocol\_factory, host=\textit{None, port=\textit{None, *, family=socket.AF\_UNSPEC, flags=socket.AI\_PASSIVE, sock=\textit{None, backlog=100, ssl=\textit{None, reuse\_address=\textit{None})}}}

A \textit{coroutine} method which creates a TCP server bound to host and port.

The return value is a \textit{AbstractServer} object which can be used to stop the service.

If \textit{host} is an empty string or \textit{None} all interfaces are assumed and a list of multiple sockets will be returned (most likely one for IPv4 and another one for IPv6).

\textit{family} can be set to either \texttt{AF\_INET} or \texttt{AF\_INET6} to force the socket to use IPv4 or IPv6. If not set it will be determined from host (defaults to \texttt{AF\_UNSPEC}).

\textit{flags} is a bitmask for \textit{getaddrinfo()}.

\textit{sock} can optionally be specified in order to use a preexisting socket object.

\textit{backlog} is the maximum number of queued connections passed to \textit{listen()} (defaults to 100).

\textit{ssl} can be set to an \texttt{SSLContext} to enable SSL over the accepted connections.

\textit{reuse\_address} tells the kernel to reuse a local socket in \texttt{TIME\_WAIT} state, without waiting for its natural timeout to expire. If not specified will automatically be set to True on UNIX.
See also: The function `start_server()` creates a `(StreamReader, StreamWriter)` pair and calls back a function with this pair.

BaseEventLoop.\texttt{create_unix_server}(\textit{protocol\_factory},
\textit{path=\texttt{None}}, *, \textit{sock=\texttt{None}}, \textit{backlog=100}, \textit{ssl=\texttt{None}})

Similar to \texttt{BaseEventLoop.create_server()}, but specific to the socket family \texttt{AF\_UNIX}.

Availability: UNIX.
18.5.1.10. Watch file descriptors

BaseEventLoop. `add_reader(fd, callback, *args)`
Start watching the file descriptor for read availability and then call the `callback` with specified arguments.

BaseEventLoop. `remove_reader(fd)`
Stop watching the file descriptor for read availability.

BaseEventLoop. `add_writer(fd, callback, *args)`
Start watching the file descriptor for write availability and then call the `callback` with specified arguments.

BaseEventLoop. `remove_writer(fd)`
Stop watching the file descriptor for write availability.
18.5.1.11. Low-level socket operations

BaseEventLoop. **sock_recv**(sock, nbytes)

Receive data from the socket. The return value is a bytes object representing the data received. The maximum amount of data to be received at once is specified by nbytes.

This method is a *coroutine*.

**See also:** The `socket.socket.recv()` method.

BaseEventLoop. **sock_sendall**(sock, data)

Send data to the socket. The socket must be connected to a remote socket. This method continues to send data from *data* until either all data has been sent or an error occurs. None is returned on success. On error, an exception is raised, and there is no way to determine how much data, if any, was successfully processed by the receiving end of the connection.

This method is a *coroutine*.

**See also:** The `socket.socket.sendall()` method.

BaseEventLoop. **sock_connect**(sock, address)

Connect to a remote socket at *address*.

The *address* must be already resolved to avoid the trap of hanging the entire event loop when the address requires doing a DNS lookup. For example, it must be an IP address, not an hostname, for AF_INET and AF_INET6 address families. Use `getaddrinfo()` to resolve the hostname asynchronously.
This method is a `coroutine`.

See also: The `BaseEventLoop.create_connection()` method, the `open_connection()` function and the `socket.socket.connect()` method.

**BaseEventLoop. `sock_accept(sock)`**

Accept a connection. The socket must be bound to an address and listening for connections. The return value is a pair `((conn, address))` where `conn` is a *new* socket object usable to send and receive data on the connection, and `address` is the address bound to the socket on the other end of the connection.

This method is a `coroutine`.

See also: The `BaseEventLoop.create_server()` method, the `start_server()` function and the `socket.socket.accept()` method.
18.5.1.12. Resolve host name

BaseEventLoop. **getaddrinfo**(host, port, *, family=0, type=0, proto=0, flags=0)

This method is a **coroutine**, similar to `socket.getaddrinfo()` function but non-blocking.

BaseEventLoop. **getnameinfo**(sockaddr, flags=0)

This method is a **coroutine**, similar to `socket.getnameinfo()` function but non-blocking.
18.5.1.13. Running subprocesses

Run subprocesses asynchronously using the `subprocess` module.

**Note:** On Windows, the default event loop uses `selectors.SelectSelector` which only supports sockets. The `ProactorEventLoop` should be used to support subprocesses.

**Note:** On Mac OS X older than 10.9 (Mavericks), `selectors.KqueueSelector` does not support character devices like PTY, whereas it is used by the default event loop. The `SelectorEventLoop` can be used with `SelectSelector` or `PollSelector` to handle character devices on Mac OS X 10.6 (Snow Leopard) and later.

BaseEventLoop. `subprocess_exec`(`protocol_factory`, *args, stdin=subprocess.PIPE, stdout=subprocess.PIPE, stderr=subprocess.PIPE, **kwargs)

Create a subprocess from one or more string arguments, where the first string specifies the program to execute, and the remaining strings specify the program's arguments. (Thus, together the string arguments form the `sys.argv` value of the program, assuming it is a Python script.) This is similar to the standard library `subprocess.Popen` class called with `shell=False` and the list of strings passed as the first argument; however, where `Popen` takes a single argument which is list of strings, `subprocess_exec()` takes multiple string arguments.

Other parameters:

- `stdin`: Either a file-like object representing the pipe to be
connected to the subprocess’s standard input stream using `connect_write_pipe()`, or the constant `subprocess.PIPE` (the default). By default a new pipe will be created and connected.

- **stdout**: Either a file-like object representing the pipe to be connected to the subprocess’s standard output stream using `connect_read_pipe()`, or the constant `subprocess.PIPE` (the default). By default a new pipe will be created and connected.

- **stderr**: Either a file-like object representing the pipe to be connected to the subprocess’s standard error stream using `connect_read_pipe()`, or one of the constants `subprocess.PIPE` (the default) or `subprocess.STDOUT`. By default a new pipe will be created and connected. When `subprocess.STDOUT` is specified, the subprocess’s standard error stream will be connected to the same pipe as the standard output stream.

- All other keyword arguments are passed to `subprocess.Popen` without interpretation, except for `bufsize`, `universal_newlines` and `shell`, which should not be specified at all.

Returns a pair of `(transport, protocol)`, where `transport` is an instance of `BaseSubprocessTransport`.

This method is a coroutine.

See the constructor of the `subprocess.Popen` class for parameters.

```python
BaseEventLoop.subprocess_shell(protocol_factory, cmd, *, stdin=subprocess.PIPE, stdout=subprocess.PIPE, stderr=subprocess.PIPE, **kwargs)
```

Create a subprocess from `cmd`, which is a string using the
platform's “shell” syntax. This is similar to the standard library subprocess.Popen class called with `shell=True`.

See `subprocess_exec()` for more details about the remaining arguments.

Returns a pair of `(transport, protocol)`, where `transport` is an instance of `BaseSubprocessTransport`.

This method is a coroutine.

See the constructor of the `subprocess.Popen` class for parameters.

BaseEventLoop.**connect_read_pipe**(protocol_factory, pipe)

Register read pipe in eventloop.

`protocol_factory` should instantiate object with `Protocol` interface. Pipe is file-like object already switched to nonblocking. Return pair `(transport, protocol)`, where transport support `ReadTransport` interface.

This method is a coroutine.

BaseEventLoop.**connect_write_pipe**(protocol_factory, pipe)

Register write pipe in eventloop.

`protocol_factory` should instantiate object with `BaseProtocol` interface. Pipe is file-like object already switched to nonblocking. Return pair `(transport, protocol)`, where transport support `WriteTransport` interface.

This method is a coroutine.
See also: The `create_subprocess_exec()` and `create_subprocess_shell()` functions.
18.5.1.14. UNIX signals

Availability: UNIX only.

BaseEventLoop. **add_signal_handler**(signum, callback, *args)

Add a handler for a signal.

Raise **ValueError** if the signal number is invalid or uncatchable. Raise **RuntimeError** if there is a problem setting up the handler.

BaseEventLoop. **remove_signal_handler**(sig)

Remove a handler for a signal.

Return **True** if a signal handler was removed, **False** if not.

**See also:** The **signal** module.
18.5.1.15. Executor

Call a function in an Executor (pool of threads or pool of processes). By default, an event loop uses a thread pool executor (ThreadPoolExecutor).

BaseEventLoop.run_in_executor(executor, callback, *args)
   Arrange for a callback to be called in the specified executor.

   The executor argument should be an Executor instance. The default executor is used if executor is None.

   This method is a coroutine.

BaseEventLoop.set_default_executor(executor)
   Set the default executor used by run_in_executor().
18.5.1.16. Error Handling API

Allows to customize how exceptions are handled in the event loop.

BaseEventLoop. `set_exception_handler(handler)`

Set `handler` as the new event loop exception handler.

If `handler` is `None`, the default exception handler will be set.

If `handler` is a callable object, it should have a matching signature to `(loop, context)`, where `loop` will be a reference to the active event loop, `context` will be a `dict` object (see `call_exception_handler()` documentation for details about `context`).

BaseEventLoop. `default_exception_handler(context)`

Default exception handler.

This is called when an exception occurs and no exception handler is set, and can be called by a custom exception handler that wants to defer to the default behavior.

`context` parameter has the same meaning as in `call_exception_handler()`.

BaseEventLoop. `call_exception_handler(context)`

Call the current event loop exception handler.

`context` is a `dict` object containing the following keys (new keys may be introduced later):

- ‘message’: Error message;
- ‘exception’ (optional): Exception object;
- ‘future’ (optional): `asyncio.Future` instance;
- ‘handle’ (optional): `asyncio.Handle` instance;
- ‘protocol’ (optional): `Protocol` instance;
- ‘transport’ (optional): `Transport` instance;
- ‘socket’ (optional): `socket.socket` instance.

**Note:** Note: this method should not be overloaded in subclassed event loops. For any custom exception handling, use `set_exception_handler()` method.
18.5.1.17. Debug mode

BaseEventLoop.get_debug()
    Get the debug mode (bool) of the event loop, False by default.

BaseEventLoop.set_debug(enabled: bool)
    Set the debug mode of the event loop.

See also: The Develop with asyncio section.
18.5.1.18. Server

class asyncio.AbstractServer
    Abstract server returned by BaseEventLoop.create_server().

    close()
    Stop serving. This leaves existing connections open.

    wait_closed()
    A coroutine to wait until service is closed.
18.5.1.19. Handle

class asyncio.Handle

A callback wrapper object returned by
BaseEventLoop.call_soon(),
BaseEventLoop.call_soon_threadsafe(),
BaseEventLoop.call_later(),
and
BaseEventLoop.call_at().

cancel()

Cancel the call.
18.5.1.20. Example: Hello World (callback)

Print Hello World every two seconds, using a callback:

```python
import asyncio
def print_and_repeat(loop):
    print('Hello World')
    loop.callLater(2, print_and_repeat, loop)

loop = asyncio.get_event_loop()
loop.call_soon(print_and_repeat, loop)
loop.run_forever()
```

See also: Hello World example using a coroutine.
18.5.1.21. Example: Set signal handlers for SIGINT and SIGTERM

Register handlers for signals SIGINT and SIGTERM:

```python
import asyncio
import functools
import os
import signal

def ask_exit(signame):
    print("got signal %s: exit" % signame)
    loop.stop()

loop = asyncio.get_event_loop()
for signame in ('SIGINT', 'SIGTERM'):
    loop.add_signal_handler(getattr(signal, signame),
                            functools.partial(ask_exit))

print("Event loop running forever, press CTRL+c to interrupt.
     pid %s: send SIGINT or SIGTERM to exit." % os.getpid())
loop.run_forever()
```

Created using Sphinx 1.2.
18.5.2. Tasks and coroutines
18.5.2.1. Coroutines

A coroutine is a generator that follows certain conventions. For documentation purposes, all coroutines should be decorated with `@asyncio.coroutine`, but this cannot be strictly enforced.

Coroutines use the `yield from` syntax introduced in PEP 380, instead of the original `yield` syntax.

The word “coroutine”, like the word “generator”, is used for two different (though related) concepts:

- The function that defines a coroutine (a function definition decorated with `@asyncio.coroutine`). If disambiguation is needed we will call this a coroutine function (`iscoroutinefunction()` returns True).
- The object obtained by calling a coroutine function. This object represents a computation or an I/O operation (usually a combination) that will complete eventually. If disambiguation is needed we will call it a coroutine object (`iscoroutine()` returns True).

Things a coroutine can do:

- `result = yield from future` – suspends the coroutine until the future is done, then returns the future's result, or raises an exception, which will be propagated. (If the future is cancelled, it will raise a `CancelledError` exception.) Note that tasks are futures, and everything said about futures also applies to tasks.
- `result = yield from coroutine` – wait for another coroutine to produce a result (or raise an exception, which will be propagated). The coroutine expression must be a `call` to another coroutine.
• **return expression** – produce a result to the coroutine that is waiting for this one using `yield from`.
• **raise exception** – raise an exception in the coroutine that is waiting for this one using `yield from`.

Calling a coroutine does not start its code running – it is just a generator, and the coroutine object returned by the call is really a generator object, which doesn’t do anything until you iterate over it. In the case of a coroutine object, there are two basic ways to start it running: call `yield from` coroutine from another coroutine (assuming the other coroutine is already running!), or convert it to a `Task`.

Coroutines (and tasks) can only run when the event loop is running.

```python
@asyncio.coroutine
```

Decorator to mark coroutines.

If the coroutine is not yielded from before it is destroyed, an error message is logged. See *Detect coroutines never scheduled*.

**Note:** In this documentation, some methods are documented as coroutines, even if they are plain Python functions returning a `Future`. This is intentional to have a freedom of tweaking the implementation of these functions in the future. If such a function is needed to be used in a callback-style code, wrap its result with `async()`.

### 18.5.2.1.1. Example: “Hello World” coroutine

Print "Hello World" every two seconds using a coroutine:
import asyncio

@asyncio.coroutine
def greet_every_two_seconds():
    while True:
        print('Hello World')
        yield from asyncio.sleep(2)

loop = asyncio.get_event_loop()
loop.run_until_complete(greet_every_two_seconds())

See also: Hello World example using a callback.

18.5.2.1.2. Example: Chain coroutines

Example chaining coroutines:

import asyncio

@asyncio.coroutine
def compute(x, y):
    print("Compute %s + %s ..." % (x, y))
    yield from asyncio.sleep(1.0)
    return x + y

@asyncio.coroutine
def print_sum(x, y):
    result = yield from compute(x, y)
    print("%s + %s = %s" % (x, y, result))

loop = asyncio.get_event_loop()
loop.run_until_complete(print_sum(1, 2))
loop.close()

compute() is chained to print_sum(): print_sum() coroutine
waits until `compute()` is completed before returning its result.

Sequence diagram of the example:

The "Task" is created by the `BaseEventLoop.run_until_complete()` method when it gets a coroutine object instead of a task.

The diagram shows the control flow, it does not describe exactly how things work internally. For example, the sleep coroutine creates an internal future which uses `BaseEventLoop.call_later()` to wake up the task in 1 second.
18.5.2.2. InvalidStateError

*exception* asyncio.**InvalidStateError**

The operation is not allowed in this state.
18.5.2.3. Future

`class asyncio.Future(*, loop=None)`

This class is almost compatible with `concurrent.futures.Future`.

Differences:

- `result()` and `exception()` do not take a timeout argument and raise an exception when the future isn’t done yet.
- Callbacks registered with `add_done_callback()` are always called via the event loop’s `call_soon_threadsafe()`.
- This class is not compatible with the `wait()` and `as_completed()` functions in the `concurrent.futures` package.

`cancel()`

Cancel the future and schedule callbacks.

If the future is already done or cancelled, return `False`. Otherwise, change the future’s state to cancelled, schedule the callbacks and return `True`.

`cancelled()`

Return `True` if the future was cancelled.

`done()`

Return `True` if the future is done.

Done means either that a result / exception are available, or that the future was cancelled.
result()
Return the result this future represents.

If the future has been cancelled, raises CancelledError. If the future's result isn't yet available, raises InvalidStateError. If the future is done and has an exception set, this exception is raised.

exception()
Return the exception that was set on this future.

The exception (or None if no exception was set) is returned only if the future is done. If the future has been cancelled, raises CancelledError. If the future isn't done yet, raises InvalidStateError.

add_done_callback(fn)
Add a callback to be run when the future becomes done.

The callback is called with a single argument - the future object. If the future is already done when this is called, the callback is scheduled with call_soon().

remove_done_callback(fn)
Remove all instances of a callback from the “call when done” list.

Returns the number of callbacks removed.

set_result(result)
Mark the future done and set its result.

If the future is already done when this method is called, raises
**InvalidStateError.**

**set_exception**(exception)
Mark the future done and set an exception.

If the future is already done when this method is called, raises **InvalidStateError.**

18.5.2.3.1. Example: Future with run_until_complete()

Example combining a **Future** and a **coroutine function**:

```python
import asyncio

@asyncio.coroutine
def slow_operation(future):
    yield from asyncio.sleep(1)
    future.set_result('Future is done!')

loop = asyncio.get_event_loop()
future = asyncio.Future()
asyncio.Task(slow_operation(future))
loop.run_until_complete(future)
print(future.result())
loop.close()
```

The coroutine function is responsible of the computation (which takes 1 second) and it stores the result into the future. The `run_until_complete()` method waits for the completion of the future.

**Note:** The `run_until_complete()` method uses internally the
add_done_callback() method to be notified when the future is done.

18.5.2.3.2. Example: Future with run_forever()

The previous example can be written differently using the Future.add_done_callback() method to describe explicitly the control flow:

```python
import asyncio

@asyncio.coroutine
def slow_operation(future):
    yield from asyncio.sleep(1)
    future.set_result('Future is done!')

def got_result(future):
    print(future.result())
    loop.stop()

loop = asyncio.get_event_loop()
future = asyncio.Future()
asyncio.Task(slow_operation(future))
future.add_done_callback(got_result)
try:
    loop.run_forever()
finally:
    loop.close()
```

In this example, the future is responsible to display the result and to stop the loop.

Note: The “slow_operation” coroutine object is only executed when the event loop starts running, so it is possible to add a “done
callback” to the future after creating the task scheduling the coroutine object.
18.5.2.4. Task

class asyncio.Task(coro, *, loop=None)

A coroutine object wrapped in a Future. Subclass of Future.

classmethod all_tasks(loop=None)

Return a set of all tasks for an event loop.

By default all tasks for the current event loop are returned.

classmethod current_task(loop=None)

Return the currently running task in an event loop or None.

By default the current task for the current event loop is returned.

None is returned when called not in the context of a Task.

get_stack(self, *, limit=None)

Return the list of stack frames for this task’s coroutine.

If the coroutine is active, this returns the stack where it is suspended. If the coroutine has completed successfully or was cancelled, this returns an empty list. If the coroutine was terminated by an exception, this returns the list of traceback frames.

The frames are always ordered from oldest to newest.

The optional limit gives the maximum number of frames to return; by default all available frames are returned. Its meaning differs depending on whether a stack or a traceback is returned: the newest frames of a stack are returned, but the oldest frames of a traceback are returned. (This matches the behavior
of the traceback module.)

For reasons beyond our control, only one stack frame is returned for a suspended coroutine.

**print_stack**(*, limit=None, file=None)
Print the stack or traceback for this task’s coroutine.

This produces output similar to that of the traceback module, for the frames retrieved by get_stack(). The limit argument is passed to get_stack(). The file argument is an I/O stream to which the output goes; by default it goes to sys.stderr.

18.5.2.4.1. Example: Parallel execution of tasks

Example executing 3 tasks (A, B, C) in parallel:

```python
import asyncio

@asyncio.coroutine
def factorial(name, number):
    f = 1
    for i in range(2, number+1):
        yield from asyncio.sleep(1)
        f *= i
    print("Task %s: factorial(%s) = %s" % (name, number, f))

tasks = [
    asyncio.Task(factorial("A", 2)),
    asyncio.Task(factorial("B", 3)),
    asyncio.Task(factorial("C", 4))]

loop = asyncio.get_event_loop()
loop.run_until_complete(asyncio.wait(tasks))
```
loop.close()

Output:

<table>
<thead>
<tr>
<th>Task</th>
<th>Function Call</th>
<th>Result</th>
</tr>
</thead>
<tbody>
<tr>
<td>Task A</td>
<td>Compute factorial(2)</td>
<td>2</td>
</tr>
<tr>
<td>Task B</td>
<td>Compute factorial(2)</td>
<td></td>
</tr>
<tr>
<td>Task C</td>
<td>Compute factorial(2)</td>
<td></td>
</tr>
<tr>
<td>Task A</td>
<td>factorial(2) = 2</td>
<td></td>
</tr>
<tr>
<td>Task B</td>
<td>Compute factorial(3)</td>
<td>6</td>
</tr>
<tr>
<td>Task C</td>
<td>Compute factorial(3)</td>
<td></td>
</tr>
<tr>
<td>Task B</td>
<td>factorial(3) = 6</td>
<td></td>
</tr>
<tr>
<td>Task C</td>
<td>Compute factorial(4)</td>
<td>24</td>
</tr>
<tr>
<td>Task C</td>
<td>factorial(4) = 24</td>
<td></td>
</tr>
</tbody>
</table>

A task is automatically scheduled for execution when it is created. The event loop stops when all tasks are done.
18.5.2.5. Task functions

**Note:** In the functions below, the optional *loop* argument allows to explicitly set the event loop object used by the underlying task or coroutine. If it’s not provided, the default event loop is used.

```python
asyncio.as_completed(fs, *, loop=None, timeout=None)
```

Return an iterator whose values, when waited for, are *Future* instances.

Raises *TimeoutError* if the timeout occurs before all Futures are done.

Example:

```python
for f in as_completed(fs):
    result = yield from f  # The 'yield from' may raise
    # Use result
```

**Note:** The futures `f` are not necessarily members of `fs`.

```python
asyncio.async(coro_or_future, *, loop=None)
```

Wrap a *coroutine object* in a future.

If the argument is a *Future*, it is returned directly.

```python
asyncio.gather(*coros_or_futures, loop=None, return_exceptions=False)
```

Return a future aggregating results from the given coroutine objects or futures.
All futures must share the same event loop. If all the tasks are done successfully, the returned future's result is the list of results (in the order of the original sequence, not necessarily the order of results arrival). If return_exceptions is True, exceptions in the tasks are treated the same as successful results, and gathered in the result list; otherwise, the first raised exception will be immediately propagated to the returned future.

Cancellation: if the outer Future is cancelled, all children (that have not completed yet) are also cancelled. If any child is cancelled, this is treated as if it raised CancelledError – the outer Future is not cancelled in this case. (This is to prevent the cancellation of one child to cause other children to be cancelled.)

asyncio.**iscoroutine**(obj)

Return True if obj is a coroutine object.

asyncio.**iscoroutinefunction**(obj)

Return True if func is a decorated coroutine function.

asyncio.**sleep**(delay, result=None, *, loop=None)

Create a coroutine that completes after a given time (in seconds). If result is provided, it is produced to the caller when the coroutine completes.

The resolution of the sleep depends on the granularity of the event loop.

asyncio.**shield**(arg, *, loop=None)

Wait for a future, shielding it from cancellation.

The statement:
res = `yield from shield(something())`

is exactly equivalent to the statement:

res = `yield from something()`

except that if the coroutine containing it is cancelled, the task running in `something()` is not cancelled. From the point of view of `something()`, the cancellation did not happen. But its caller is still cancelled, so the yield-from expression still raises CancelledError. Note: If `something()` is cancelled by other means this will still cancel `shield()`.

If you want to completely ignore cancellation (not recommended) you can combine `shield()` with a try/except clause, as follows:

```python
try:
    res = `yield from shield(something())`
except CancelledError:
    res = `None`
```

`asyncio.wait(futures, *, loop=None, timeout=None, return_when=ALL_COMPLETED)`

Wait for the Futures and coroutine objects given by the sequence `futures` to complete. Coroutines will be wrapped in Tasks. Returns two sets of `Future`: (done, pending).

`timeout` can be used to control the maximum number of seconds to wait before returning. `timeout` can be an int or float. If `timeout` is not specified or `None`, there is no limit to the wait time.

`return_when` indicates when this function should return. It must be one of the following constants of the `concurrent.futures`.
### Constant Description

<table>
<thead>
<tr>
<th>Constant</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>FIRST_COMPLETED</td>
<td>The function will return when any future finishes or is cancelled.</td>
</tr>
<tr>
<td>FIRST_EXCEPTION</td>
<td>The function will return when any future finishes by raising an exception. If no future raises an exception then it is equivalent to ALL_COMPLETED.</td>
</tr>
<tr>
<td>ALL_COMPLETED</td>
<td>The function will return when all futures finish or are cancelled.</td>
</tr>
</tbody>
</table>

This function is a **coroutine**.

**Usage:**

```python
done, pending = yield from asyncio.wait(fs)
```

**Note:** This does not raise **TimeoutError**! Futures that aren’t done when the timeout occurs are returned in the second set.

**asyncio.wait_for(fut, timeout, *, loop=None)**

Wait for the single **Future** or **coroutine object** to complete, with timeout. If **timeout** is **None**, block until the future completes.

Coroutine will be wrapped in **Task**.

Returns result of the Future or coroutine. When a timeout occurs, it cancels the task and raises **TimeoutError**. To avoid the task cancellation, wrap it in **shield()**.

This function is a **coroutine**.
Usage:

```
result = yield from asyncio.wait_for(fut, 60.0)
```
18.5.3. Transports and protocols (low-level API)
18.5.3.1. Transports

Transports are classed provided by asyncio in order to abstract various kinds of communication channels. You generally won’t instantiate a transport yourself; instead, you will call a BaseEventLoop method which will create the transport and try to initiate the underlying communication channel, calling you back when it succeeds.

Once the communication channel is established, a transport is always paired with a protocol instance. The protocol can then call the transport’s methods for various purposes.

asyncio currently implements transports for TCP, UDP, SSL, and subprocess pipes. The methods available on a transport depend on the transport’s kind.

18.5.3.1.1. BaseTransport

class asyncio.BaseTransport
    Base class for transports.

    close(self)
        Close the transport. If the transport has a buffer for outgoing data, buffered data will be flushed asynchronously. No more data will be received. After all buffered data is flushed, the protocol's connection_lost() method will be called with None as its argument.

    get_extra_info(name, default=None)
        Return optional transport information. name is a string
representing the piece of transport-specific information to get, 
*
*default* is the value to return if the information doesn’t exist.

This method allows transport implementations to easily expose channel-specific information.

- **socket:**
  - `'peername'`: the remote address to which the socket is connected, result of `socket.socket.getpeername()` (None on error)
  - `'socket'`: `socket.socket` instance
  - `'sockname'`: the socket's own address, result of `socket.socket.getsockname()`

- **SSL socket:**
  - `'compression'`: the compression algorithm being used as a string, or `None` if the connection isn’t compressed; result of `ssl.SSLSocket.compression()`
  - `'cipher'`: a three-value tuple containing the name of the cipher being used, the version of the SSL protocol that defines its use, and the number of secret bits being used; result of `ssl.SSLSocket.cipher()`
  - `'peercert'`: peer certificate; result of `ssl.SSLSocket.getpeercert()`
  - `'sslcontext'`: `ssl.SSLContext` instance

- **pipe:**
  - `'pipe'`: pipe object

- **subprocess:**
  - `'subprocess'`: `subprocess.Popen` instance

### 18.5.3.1.2. ReadTransport
class asyncio.ReadTransport

Interface for read-only transports.

pause_reading()

Pause the receiving end of the transport. No data will be passed to the protocol's data_received() method until meth:resume_reading is called.

resume_reading()

Resume the receiving end. The protocol's data_received() method will be called once again if some data is available for reading.

18.5.3.1.3. WriteTransport

class asyncio.WriteTransport

Interface for write-only transports.

abort()

Close the transport immediately, without waiting for pending operations to complete. Buffered data will be lost. No more data will be received. The protocol's connection_lost() method will eventually be called with None as its argument.

can_write_eof()

Return True if the transport supports write_eof(), False if not.

get_write_buffer_size()

Return the current size of the output buffer used by the transport.
set_write_buffer_limits\( (high=\text{None}, \ low=\text{None}) \)
Set the \textit{high-} and \textit{low-water} limits for write flow control.

These two values control when call the protocol's pause\_writing() and resume\_writing() methods are called. If specified, the low-water limit must be less than or equal to the high-water limit. Neither \textit{high} nor \textit{low} can be negative.

The defaults are implementation-specific. If only the high-water limit is given, the low-water limit defaults to a implementation-specific value less than or equal to the high-water limit. Setting \textit{high} to zero forces \textit{low} to zero as well, and causes pause\_writing() to be called whenever the buffer becomes non-empty. Setting \textit{low} to zero causes resume\_writing() to be called only once the buffer is empty. Use of zero for either limit is generally sub-optimal as it reduces opportunities for doing I/O and computation concurrently.

\textbf{write}(\textit{data})
Write some \textit{data} bytes to the transport.

This method does not block; it buffers the data and arranges for it to be sent out asynchronously.

\textbf{writelines}(\textit{list\_of\_data})
Write a list (or any iterable) of data bytes to the transport. This is functionally equivalent to calling \textbf{write()} on each element yielded by the iterable, but may be implemented more efficiently.

\textbf{write\_eof()}
Close the write end of the transport after flushing buffered data.
Data may still be received.

This method can raise `NotImplementedError` if the transport (e.g. SSL) doesn't support half-closes.

### 18.5.3.1.4. DatagramTransport

`DatagramTransport.sendto(data, addr=None)`

Send the `data` bytes to the remote peer given by `addr` (a transport-dependent target address). If `addr` is `None`, the data is sent to the target address given on transport creation.

This method does not block; it buffers the data and arranges for it to be sent out asynchronously.

`DatagramTransport.abort()`

Close the transport immediately, without waiting for pending operations to complete. Buffered data will be lost. No more data will be received. The protocol's `connection_lost()` method will eventually be called with `None` as its argument.

### 18.5.3.1.5. BaseSubprocessTransport

`class asyncio.BaseSubprocessTransport
get_pid()`

Return the subprocess process id as an integer.

`get_pipe_transport(fd)`

Return the transport for the communication pipe corresponding to the integer file descriptor `fd`. The return value can be a readable or writable streaming transport, depending on the `fd`. If
fd doesn't correspond to a pipe belonging to this transport, None is returned.

**get_returncode**
Return the subprocess returncode as an integer or None if it hasn't returned, similarly to the subprocess.Popen.returncode attribute.

**kill**(self)
Kill the subprocess, as in subprocess.Popen.kill()

On POSIX systems, the function sends SIGKILL to the subprocess. On Windows, this method is an alias for terminate().

**send_signal**(signal)
Send the signal number to the subprocess, as in subprocess.Popen.send_signal().

**terminate**
Ask the subprocess to stop, as in subprocess.Popen.terminate(). This method is an alias for the close() method.

On POSIX systems, this method sends SIGTERM to the subprocess. On Windows, the Windows API function TerminateProcess() is called to stop the subprocess.
18.5.3.2. Protocols

asyncio provides base classes that you can subclass to implement your network protocols. Those classes are used in conjunction with transports (see below): the protocol parses incoming data and asks for the writing of outgoing data, while the transport is responsible for the actual I/O and buffering.

When subclassing a protocol class, it is recommended you override certain methods. Those methods are callbacks: they will be called by the transport on certain events (for example when some data is received); you shouldn’t call them yourself, unless you are implementing a transport.

Note: All callbacks have default implementations, which are empty. Therefore, you only need to implement the callbacks for the events in which you are interested.

18.5.3.2.1. Protocol classes

class asyncio.\texttt{Protocol}

The base class for implementing streaming protocols (for use with e.g. TCP and SSL transports).

class asyncio.\texttt{DatagramProtocol}

The base class for implementing datagram protocols (for use with e.g. UDP transports).

class asyncio.\texttt{SubprocessProtocol}

The base class for implementing protocols communicating with child processes (through a set of unidirectional pipes).
18.5.3.2.2. Connection callbacks

These callbacks may be called on Protocol and SubprocessProtocol instances:

BaseProtocol.\texttt{connection\_made}(\texttt{transport})
Called when a connection is made.

The transport argument is the transport representing the connection. You are responsible for storing it somewhere (e.g. as an attribute) if you need to.

BaseProtocol.\texttt{connection\_lost}(\texttt{exc})
Called when the connection is lost or closed.

The argument is either an exception object or \texttt{None}. The latter means a regular EOF is received, or the connection was aborted or closed by this side of the connection.

connection\_made() and connection\_lost() are called exactly once per successful connection. All other callbacks will be called between those two methods, which allows for easier resource management in your protocol implementation.

The following callbacks may be called only on SubprocessProtocol instances:

SubprocessProtocol.\texttt{pipe\_data\_received}(\texttt{fd}, \texttt{data})
Called when the child process writes data into its stdout or stderr pipe. \texttt{fd} is the integer file descriptor of the pipe. \texttt{data} is a non-empty bytes object containing the data.

SubprocessProtocol.\texttt{pipe\_connection\_lost}(\texttt{fd}, \texttt{exc})
Called when one of the pipes communicating with the child process is closed. *fd* is the integer file descriptor that was closed.

SubprocessProtocol. **process_exited()**

Called when the child process has exited.

### 18.5.3.2.3. Streaming protocols

The following callbacks are called on Protocol instances:

**Protocol.** **data_received**(*data*)

Called when some data is received. *data* is a non-empty bytes object containing the incoming data.

**Note:** Whether the data is buffered, chunked or reassembled depends on the transport. In general, you shouldn’t rely on specific semantics and instead make your parsing generic and flexible enough. However, data is always received in the correct order.

**Protocol.** **eof_received()**

Calls when the other end signals it won’t send any more data (for example by calling write_eof(), if the other end also uses asyncio).

This method may return a false value (including None), in which case the transport will close itself. Conversely, if this method returns a true value, closing the transport is up to the protocol. Since the default implementation returns None, it implicitly closes the connection.

**Note:** Some transports such as SSL don’t support half-closed
connections, in which case returning true from this method will not prevent closing the connection.

data_received() can be called an arbitrary number of times during a connection. However, eof_received() is called at most once and, if called, data_received() won’t be called after it.

18.5.3.2.4. Datagram protocols

The following callbacks are called on DatagramProtocol instances.

DatagramProtocol.data_received(data, addr)
Called when a datagram is received. data is a bytes object containing the incoming data. addr is the address of the peer sending the data; the exact format depends on the transport.

DatagramProtocol.error_received(exc)
Called when a previous send or receive operation raises an OSError. exc is the OSError instance.

This method is called in rare conditions, when the transport (e.g. UDP) detects that a datagram couldn’t be delivered to its recipient. In many conditions though, undeliverable datagrams will be silently dropped.

18.5.3.2.5. Flow control callbacks

These callbacks may be called on Protocol, DatagramProtocol and SubprocessProtocol instances:

BaseProtocol.pause_writing()
Called when the transport’s buffer goes over the high-water mark.

BaseProtocol.\texttt{resume\_writing()}

Called when the transport’s buffer drains below the low-water mark.

\texttt{pause\_writing()} and \texttt{resume\_writing()} calls are paired – \texttt{pause\_writing()} is called once when the buffer goes strictly over the high-water mark (even if subsequent writes increases the buffer size even more), and eventually \texttt{resume\_writing()} is called once when the buffer size reaches the low-water mark.

\begin{itemize}
  \item \textbf{Note:} If the buffer size equals the high-water mark, \texttt{pause\_writing()} is not called – it must go strictly over.
  \item Conversely, \texttt{resume\_writing()} is called when the buffer size is equal or lower than the low-water mark. These end conditions are important to ensure that things go as expected when either mark is zero.
\end{itemize}

\begin{itemize}
  \item \textbf{Note:} On BSD systems (OS X, FreeBSD, etc.) flow control is not supported for \texttt{DatagramProtocol}, because send failures caused by writing too many packets cannot be detected easily. The socket always appears ‘ready’ and excess packets are dropped; an \texttt{OSError} with \texttt{errno} set to \texttt{errno.\text{ENOBUFS}} may or may not be raised; if it is raised, it will be reported to \texttt{DatagramProtocol.error\_received()} but otherwise ignored.
\end{itemize}

\textbf{18.5.3.2.6. Coroutines and protocols}

Coroutines can be scheduled in a protocol method using \texttt{async()}, but there is not guarantee on the execution order. Protocols are not aware of coroutines created in protocol methods and so will not wait
for them.

To have a reliable execution order, use *stream objects* in a coroutine with `yield from`. For example, the `StreamWriter.drain()` coroutine can be used to wait until the write buffer is flushed.
18.5.3.3. Protocol example: TCP echo server and client

18.5.3.3.1. Echo client

TCP echo client example, send data and wait until the connection is closed:

```python
import asyncio

class EchoClient(asyncio.Protocol):
    message = 'This is the message. It will be echoed.'

    def connection_made(self, transport):
        transport.write(self.message.encode())
        print('data sent: {}' .format(self.message))

    def data_received(self, data):
        print('data received: {}' .format(data.decode()))

    def connection_lost(self, exc):
        print('server closed the connection')
        asyncio.get_event_loop().stop()

loop = asyncio.get_event_loop()
coro = loop.create_connection(EchoClient, '127.0.0.1')
loop.run_until_complete(coro)
loop.run_forever()
loop.close()
```

The event loop is running twice. The `run_until_complete()` method is preferred in this short example to raise an exception if the server is not listening, instead of having to write a short coroutine to
handle the exception and stop the running loop. At `run_until_complete()` exit, the loop is no more running, so there is no need to stop the loop in case of an error.

18.5.3.3.2. Echo server

TCP echo server example, send back received data and close the connection:

```python
import asyncio

class EchoServer(asyncio.Protocol):
    def connection_made(self, transport):
        peername = transport.get_extra_info('peername')
        print('connection from {}'.format(peername))
        self.transport = transport

    def data_received(self, data):
        print('data received: {}'.format(data.decode()])
        self.transport.write(data)

        # close the socket
        self.transport.close()

loop = asyncio.get_event_loop()
co = asyncio.create_server(EchoServer, '127.0.0.1', 8888)
server = loop.run_until_complete(co)
print('serving on {}'.format(server.sockets[0].getsockname()))

try:
    loop.run_forever()
except KeyboardInterrupt:
    print("exit")
finally:
    server.close()
```
Transport.close() can be called immediately after WriteTransport.write() even if data are not sent yet on the socket: both methods are asynchronous. yield from is not needed because these transport methods are not coroutines.
18.5.4. Streams (high-level API)
18.5.4.1. Stream functions

```python
asyncio.open_connection(host=None, port=None, *, loop=None, limit=None, **kwds)
```

A wrapper for `create_connection()` returning a (reader, writer) pair.

The reader returned is a `StreamReader` instance; the writer is a `StreamWriter` instance.

The arguments are all the usual arguments to `BaseEventLoop.create_connection()` except `protocol_factory`; most common are positional host and port, with various optional keyword arguments following.

Additional optional keyword arguments are `loop` (to set the event loop instance to use) and `limit` (to set the buffer limit passed to the `StreamReader`).

(If you want to customize the `StreamReader` and/or `StreamReaderProtocol` classes, just copy the code – there's really nothing special here except some convenience.)

This function is a `coroutine`.

```python
asyncio.start_server(client_connected_cb, host=None, port=None, *, loop=None, limit=None, **kwds)
```

Start a socket server, with a callback for each client connected.

The first parameter, `client_connected_cb`, takes two parameters: `client_reader`, `client_writer`. `client_reader` is a `StreamReader` object, while `client_writer` is a `StreamWriter` object. This
parameter can either be a plain callback function or a coroutine function; if it is a coroutine function, it will be automatically converted into a Task.

The rest of the arguments are all the usual arguments to create_server() except protocol_factory; most common are positional host and port, with various optional keyword arguments following. The return value is the same as create_server().

Additional optional keyword arguments are loop (to set the event loop instance to use) and limit (to set the buffer limit passed to the StreamReader).

The return value is the same as create_server(), i.e. a AbstractServer object which can be used to stop the service.

This function is a coroutine.

asyncio.open_unix_connection(path=None, *, loop=None, limit=None, **kwds)

A wrapper for create_unix_connection() returning a (reader, writer) pair.

See open_connection() for information about return value and other details.

This function is a coroutine.

Availability: UNIX.

asyncio.start_unix_server(client_connected_cb, path=None, *, loop=None, limit=None, **kwds)

Start a UNIX Domain Socket server, with a callback for each client
connected.

See `start_server()` for information about return value and other details.

This function is a **coroutine**.

Availability: UNIX.
18.5.4.2. StreamReader

class asyncio StreamReader(limit=None, loop=None)

    exception()
    Get the exception.

    feed_eof()
    Acknowledge the EOF.

    feed_data(data)
    Feed data bytes in the internal buffer. Any operations waiting for the data will be resumed.

    set_exception(exc)
    Set the exception.

    set_transport(transport)
    Set the transport.

    read(n=-1)
    Read up to n bytes. If n is not provided, or set to -1, read until EOF and return all read bytes.

    If the EOF was received and the internal buffer is empty, return an empty bytes object.

    This method is a coroutine.

    readline()
    Read one line, where “line” is a sequence of bytes ending with \n.
If EOF is received, and `\n` was not found, the method will return the partial read bytes.

If the EOF was received and the internal buffer is empty, return an empty `bytes` object.

This method is a coroutine.

**readexactly**(\(n\))

Read exactly \(n\) bytes. Raise an `IncompleteReadError` if the end of the stream is reached before \(n\) can be read, the `IncompleteReadError.partial` attribute of the exception contains the partial read bytes.

This method is a coroutine.

**at_eof()**

Return `True` if the buffer is empty and `feed_eof()` was called.
18.5.4.3. StreamWriter

```python
class asyncio.StreamWriter(transport, protocol, reader, loop)
    Wraps a Transport.

    This exposes write(), writelines(), can_write_eof(), write_eof(), get_extra_info() and close(). It adds drain() which returns an optional Future on which you can wait for flow control. It also adds a transport attribute which references the Transport directly.

transport
    Transport.

can_write_eof()
    Return True if the transport supports write_eof(), False if not. See WriteTransport.can_write_eof().

close()
    Close the transport: see BaseTransport.close().

drain()
    Wait until the write buffer of the underlying transport is flushed.

    This method has an unusual return value. The intended use is to write:

    >>> w.write(data)
    >>> yield from w.drain()

    When there's nothing to wait for, drain() returns (), and the yield-from continues immediately. When the transport buffer is
full (the protocol is paused), `drain()` creates and returns a `Future` and the `yield-from` will block until that Future is completed, which will happen when the buffer is (partially) drained and the protocol is resumed.

**get_extra_info**(name, default=None)
Return optional transport information: see `BaseTransport.get_extra_info()`.

**write**(data)
Write some data bytes to the transport: see `WriteTransport.write()`.

**writelines**(data)
Write a list (or any iterable) of data bytes to the transport: see `WriteTransport.writelines()`.

**write_eof()**
Close the write end of the transport after flushing buffered data: see `WriteTransport.write_eof()`.
18.5.4.4. StreamReaderProtocol

class asyncio.StreamReaderProtocol(stream_reader, client_connected_cb=None, loop=None)

    Trivial helper class to adapt between Protocol and StreamReader. Subclass of Protocol.

    stream_reader is a StreamReader instance, client_connected_cb is an optional function called with (stream_reader, stream_writer) when a connection is made, loop is the event loop instance to use.

    (This is a helper class instead of making StreamReader itself a Protocol subclass, because the StreamReader has other potential uses, and to prevent the user of the StreamReader to accidentally call inappropriate methods of the protocol.)
18.5.4.5. IncompleteReadError

exception asyncio.IncompleteReadError

Incomplete read error, subclass of EOFError.

expected
Total number of expected bytes (int).

partial
Read bytes string before the end of stream was reached (bytes).
18.5.4.6. Example

Simple example querying HTTP headers of the URL passed on the command line:

```python
import asyncio
import urllib.parse
import sys

@asyncio.coroutine
def print_http_headers(url):
    url = urllib.parse.urlsplit(url)
    reader, writer = yield from asyncio.open_connection(url)
    query = ('HEAD {url.path} HTTP/1.0\r\n    'Host: {url.hostname}\r\n    \r\n'.format(url=url))
    writer.write(query.encode('latin-1'))
    while True:
        line = yield from reader.readline()
        if not line:
            break
        line = line.decode('latin1').rstrip()
        if line:
            print('HTTP header> %s' % line)

url = sys.argv[1]
loop = asyncio.get_event_loop()
task = asyncio.async(print_http_headers(url))
loop.run_until_complete(task)
loop.close()
```

Usage:

```
python example.py http://example.com/path/page.html
```
18.5. asyncio – Asynchronous I/O, event loop, coroutines and tasks
18.5.5. Subprocess
18.5.5.1. Create a subprocess

asyncio.create_subprocess_shell(cmd, stdin=None, stdout=None, stderr=None, loop=None, limit=None, **kwds)

Run the shell command `cmd` given as a string. Return a `Process` instance.

This function is a coroutine.

asyncio.create_subprocess_exec(*args, stdin=None, stdout=None, stderr=None, loop=None, limit=None, **kwds)

Create a subprocess. Return a `Process` instance.

This function is a coroutine.

Use the `BaseEventLoop.connect_read_pipe()` and `BaseEventLoop.connect_write_pipe()` methods to connect pipes.

See also: The `BaseEventLoop.subprocess_exec()` and `BaseEventLoop.subprocess_shell()` methods.
18.5.5.2. Constants

asyncio.subprocess.PIPE
Special value that can be used as the stdin, stdout or stderr argument to create_subprocess_shell() and create_subprocess_exec() and indicates that a pipe to the standard stream should be opened.

asyncio.subprocess.STDOUT
Special value that can be used as the stderr argument to create_subprocess_shell() and create_subprocess_exec() and indicates that standard error should go into the same handle as standard output.

asyncio.subprocess.DEVNULL
Special value that can be used as the stderr argument to create_subprocess_shell() and create_subprocess_exec() and indicates that standard error should go into the same handle as standard output.
18.5.5.3. Process

```python
class asyncio.subprocess.Process
```

**pid**

The identifier of the process. Note that if you set the `shell` argument to `True`, this is the process identifier of the spawned shell.

**returncode**

Return code of the process when it exited. A `None` value indicates that the process has not terminated yet.

A negative value `-N` indicates that the child was terminated by signal `N` (Unix only).

**stdin**

Standard input stream (write), `None` if the process was created with `stdin=None`.

**stdout**

Standard output stream (read), `None` if the process was created with `stdout=None`.

**stderr**

Standard error stream (read), `None` if the process was created with `stderr=None`.

**communicate**(input=`None`)

Interact with process: Send data to stdin. Read data from stdout and stderr, until end-of-file is reached. Wait for process to terminate. The optional `input` argument should be data to be
sent to the child process, or None, if no data should be sent to the child. The type of input must be bytes.

communicate() returns a tuple (stdoutdata, stderrdata).

Note that if you want to send data to the process’s stdin, you need to create the Process object with stdin=PIPE. Similarly, to get anything other than None in the result tuple, you need to give stdout=PIPE and/or stderr=PIPE too.

**Note:** The data read is buffered in memory, so do not use this method if the data size is large or unlimited.

**kill()**

Kills the child. On Posix OSs the function sends SIGKILL to the child. On Windows kill() is an alias for terminate().

**send_signal(signal)**

Sends the signal signal to the child process.

**Note:** On Windows, SIGTERM is an alias for terminate(). CTRL_C_EVENT and CTRL_BREAK_EVENT can be sent to processes started with a creationflags parameter which includes CREATE_NEW_PROCESS_GROUP.

**terminate()**

Stop the child. On Posix OSs the method sends signal.SIGTERM to the child. On Windows the Win32 API function TerminateProcess() is called to stop the child.

**wait(self):**
Wait for child process to terminate. Set and return \texttt{returncode} attribute.
Implement a function similar to `subprocess.getstatusoutput()`, except that it does not use a shell. Get the output of the “python -m platform” command and display the output:

```python
import asyncio
import sys
from asyncio import subprocess

@asyncio.coroutine
def getstatusoutput(*args):
    proc = yield from asyncio.create_subprocess_exec(*args,
                                                      stdout=subprocess.PIPE,
                                                      stderr=subprocess.PIPE)

    try:
        stdout, _ = yield from proc.communicate()
    except:
        proc.kill()
        yield from proc.wait()
        raise

    exitcode = yield from proc.wait()
    return (exitcode, stdout)

loop = asyncio.get_event_loop()
coro = getstatusoutput(sys.executable, '-m', 'platform')
exitcode, stdout = loop.run_until_complete(coro)
if not exitcode:
    stdout = stdout.decode('ascii').rstrip()
    print("Platform: %s" % stdout)
else:
    print("Python failed with exit code %s:") % exitcode
    sys.stdout.flush()
    sys.stdout.buffer.flush()
```
sys.stdout.buffer.write(stdout)
sys.stdout.buffer.flush()
loop.close()
18. Interprocess Communication and Networking | 18.5. asyncio – Asynchronous I/O, event loop, coroutines and tasks
18.5.6. Synchronization primitives
18.5.6.1. Locks

18.5.6.1.1. Lock

class asyncio.Lock(*, loop=None)

Primitive lock objects.

A primitive lock is a synchronization primitive that is not owned by a particular coroutine when locked. A primitive lock is in one of two states, ‘locked’ or ‘unlocked’.

It is created in the unlocked state. It has two basic methods, acquire() and release(). When the state is unlocked, acquire() changes the state to locked and returns immediately. When the state is locked, acquire() blocks until a call to release() in another coroutine changes it to unlocked, then the acquire() call resets it to locked and returns. The release() method should only be called in the locked state; it changes the state to unlocked and returns immediately. If an attempt is made to release an unlocked lock, a RuntimeError will be raised.

When more than one coroutine is blocked in acquire() waiting for the state to turn to unlocked, only one coroutine proceeds when a release() call resets the state to unlocked; first coroutine which is blocked in acquire() is being processed.

acquire() is a coroutine and should be called with yield from.

Locks also support the context manager protocol. (yield from lock) should be used as context manager expression.
Usage:

```python
lock = Lock()
...
yield from lock
try:
    ...
finally:
    lock.release()
```

Context manager usage:

```python
lock = Lock()
...
with (yield from lock):
    ...
```

Lock objects can be tested for locking state:

```python
if not lock.locked():
    yield from lock
else:
    # lock is acquired
    ...
```

```python
locked()
```

Return True if the lock is acquired.

```python
acquire()
```

Acquire a lock.

This method blocks until the lock is unlocked, then sets it to locked and returns True.

This method is a coroutine.
release()
Release a lock.

When the lock is locked, reset it to unlocked, and return. If any other coroutines are blocked waiting for the lock to become unlocked, allow exactly one of them to proceed.

When invoked on an unlocked lock, a RuntimeError is raised.

There is no return value.

18.5.6.1.2. Event

class asyncio.Event(*, loop=None)
An Event implementation, asynchronous equivalent to threading.Event.

Class implementing event objects. An event manages a flag that can be set to true with the set() method and reset to false with the clear() method. The wait() method blocks until the flag is true. The flag is initially false.

clear()
Reset the internal flag to false. Subsequently, coroutines calling wait() will block until set() is called to set the internal flag to true again.

is_set()
Return True if and only if the internal flag is true.

set()
Set the internal flag to true. All coroutines waiting for it to become true are awakened. Coroutine that call `wait()` once the flag is true will not block at all.

**wait()**
Block until the internal flag is true.

If the internal flag is true on entry, return `True` immediately. Otherwise, block until another coroutine calls `set()` to set the flag to true, then return `True`.

This method is a **coroutine**.

18.5.6.1.3. Condition

```python
class asyncio.Condition(*, loop=None)
    A Condition implementation, asynchronous equivalent to threading.Condition.
```

This class implements condition variable objects. A condition variable allows one or more coroutines to wait until they are notified by another coroutine.

A new **Lock** object is created and used as the underlying lock.

**acquire()**
Acquire the underlying lock.

This method blocks until the lock is unlocked, then sets it to locked and returns `True`.

This method is a **coroutine**.
**notify**\((n=1)\)
By default, wake up one coroutine waiting on this condition, if any. If the calling coroutine has not acquired the lock when this method is called, a `RuntimeError` is raised.

This method wakes up at most \(n\) of the coroutines waiting for the condition variable; it is a no-op if no coroutines are waiting.

**Note:** An awakened coroutine does not actually return from its `wait()` call until it can reacquire the lock. Since `notify()` does not release the lock, its caller should.

**locked()**
Return `True` if the underlying lock is acquired.

**notify_all()**
Wake up all threads waiting on this condition. This method acts like `notify()`, but wakes up all waiting threads instead of one. If the calling thread has not acquired the lock when this method is called, a `RuntimeError` is raised.

**release()**
Release the underlying lock.

When the lock is locked, reset it to unlocked, and return. If any other coroutines are blocked waiting for the lock to become unlocked, allow exactly one of them to proceed.

When invoked on an unlocked lock, a `RuntimeError` is raised.

There is no return value.
wait()
Wait until notified.

If the calling coroutine has not acquired the lock when this method is called, a RuntimeError is raised.

This method releases the underlying lock, and then blocks until it is awakened by a notify() or notify_all() call for the same condition variable in another coroutine. Once awakened, it re-acquires the lock and returns True.

This method is a coroutine.

wait_for(predicate)
Wait until a predicate becomes true.

The predicate should be a callable which result will be interpreted as a boolean value. The final predicate value is the return value.

This method is a coroutine.
18.5.6.2. Semaphores

18.5.6.2.1. Semaphore

class asyncio.Semaphore(value=1, *, loop=None)

A Semaphore implementation.

A semaphore manages an internal counter which is decremented by each acquire() call and incremented by each release() call. The counter can never go below zero; when acquire() finds that it is zero, it blocks, waiting until some other thread calls release().

Semaphores also support the context manager protocol.

The optional argument gives the initial value for the internal counter; it defaults to 1. If the value given is less than 0, ValueError is raised.

acquire()

Acquire a semaphore.

If the internal counter is larger than zero on entry, decrement it by one and return True immediately. If it is zero on entry, block, waiting until some other coroutine has called release() to make it larger than 0, and then return True.

This method is a coroutine.

locked()

Returns True if semaphore can not be acquired immediately.
release()

Release a semaphore, incrementing the internal counter by one. When it was zero on entry and another coroutine is waiting for it to become larger than zero again, wake up that coroutine.

18.5.6.2.2. BoundedSemaphore

class asyncio.BoundedSemaphore(value=1, *, loop=None)

A bounded semaphore implementation. Inherit from Semaphore.

This raises ValueError in release() if it would increase the value above the initial value.
18.5.6.3. Queues

18.5.6.3.1. Queue

```python
class asyncio.Queue(maxsize=0, *, loop=None)
```

A queue, useful for coordinating producer and consumer coroutines.

If `maxsize` is less than or equal to zero, the queue size is infinite. If it is an integer greater than 0, then `yield from put()` will block when the queue reaches `maxsize`, until an item is removed by `get()`.

Unlike the standard library `queue`, you can reliably know this Queue's size with `qsize()`, since your single-threaded asyncio application won't be interrupted between calling `qsize()` and doing an operation on the Queue.

**empty()**

Return `True` if the queue is empty, `False` otherwise.

**full()**

Return `True` if there are `maxsize` items in the queue.

**Note:** If the Queue was initialized with `maxsize=0` (the default), then `full()` is never `True`.

**get()**

Remove and return an item from the queue.

If you yield from `get()`, wait until a item is available.
This method is a coroutine.

**get_nowait()**
Remove and return an item from the queue.

Return an item if one is immediately available, else raise QueueEmpty.

**put(item)**
Put an item into the queue.

If you yield from `put()`, wait until a free slot is available before adding item.

This method is a coroutine.

**put_nowait(item)**
Put an item into the queue without blocking.

If no free slot is immediately available, raise QueueFull.

**qsize()**
Number of items in the queue.

**maxsize**
Number of items allowed in the queue.

18.5.6.3.2. PriorityQueue

*class asyncio.PriorityQueue*
A subclass of Queue; retrieves entries in priority order (lowest first).
Entries are typically tuples of the form: (priority number, data).

### 18.5.6.3.3. LifoQueue

```python
class asyncio.LifoQueue
```

A subclass of `Queue` that retrieves most recently added entries first.

### 18.5.6.3.4. JoinableQueue

```python
class asyncio.JoinableQueue
```

A subclass of `Queue` with `task_done()` and `join()` methods.

#### `join()`

Block until all items in the queue have been gotten and processed.

The count of unfinished tasks goes up whenever an item is added to the queue. The count goes down whenever a consumer thread calls `task_done()` to indicate that the item was retrieved and all work on it is complete. When the count of unfinished tasks drops to zero, `join()` unblocks.

This method is a **coroutine**.

#### `task_done()`

Indicate that a formerly enqueued task is complete.

Used by queue consumers. For each `get()` used to fetch a task, a subsequent call to `task_done()` tells the queue that the processing on the task is complete.
If a `join()` is currently blocking, it will resume when all items have been processed (meaning that a `task_done()` call was received for every item that had been `put()` into the queue).

Raises `ValueError` if called more times than there were items placed in the queue.

### 18.5.6.3.5. Exceptions

**exception `asyncio.QueueEmpty`**

Exception raised when non-blocking `get()` (or `get_nowait()`) is called on a `Queue` object which is empty.

**exception `asyncio.QueueFull`**

Exception raised when non-blocking `put()` (or `put_nowait()`) is called on a `Queue` object which is full.
asyncio – Asynchronous I/O, event loop, coroutines and tasks
Asynchronous programming is different than classical “sequential” programming. This page lists common traps and explains how to avoid them.
18.5.7.1. Concurrency and multithreading

An event loop runs in a thread and executes all callbacks and tasks in the same thread. While a task is running in the event loop, no other task is running in the same thread. But when the task uses `yield from`, the task is suspended and the event loop executes the next task.

To schedule a callback from a different thread, the `BaseEventLoop.call_soon-threadsafe()` method should be used. Example to schedule a coroutine from a different thread:

```python
loop.call_soon_threadsafe(asyncio.async, coro_func())
```

Most asyncio objects are not thread safe. You should only worry if you access objects outside the event loop. For example, to cancel a future, don't call directly its `Future.cancel()` method, but:

```python
loop.call_soon_threadsafe(fut.cancel)
```

To handle signals and to execute subprocesses, the event loop must be run in the main thread.

The `BaseEventLoop.run_in_executor()` method can be used with a thread pool executor to execute a callback in different thread to not block the thread of the event loop.

**See also:** See the `Synchronization primitives` section to synchronize tasks.
18.5.7.2. Handle blocking functions correctly

Blocking functions should not be called directly. For example, if a function blocks for 1 second, other tasks are delayed by 1 second which can have an important impact on reactivity.

For networking and subprocesses, the asyncio module provides high-level APIs like protocols.

An executor can be used to run a task in a different thread or even in a different process, to not block the thread of the event loop. See the BaseEventLoop.run_in_executor() method.

See also: The Delayed calls section details how the event loop handles time.
18.5.7.3. Logging

The asyncio module logs information with the logging module in the logger 'asyncio'.
18.5.7.4. Detect coroutine objects never scheduled

When a coroutine function is called but not passed to `async()` or to the `Task` constructor, it is not scheduled and it is probably a bug.

To detect such bug, set the environment variable `PYTHONASYNCIODEBUG` to 1. When the coroutine object is destroyed by the garbage collector, a log will be emitted with the traceback where the coroutine function was called. See the `asyncio logger`.

The debug flag changes the behaviour of the `coroutine()` decorator. The debug flag value is only used when then coroutine function is defined, not when it is called. Coroutine functions defined before the debug flag is set to `True` will not be tracked. For example, it is not possible to debug coroutines defined in the `asyncio` module, because the module must be imported before the flag value can be changed.

Example with the bug:

```python
import asyncio

@asyncio.coroutine
def test():
    print("never scheduled")

test()
```

Output in debug mode:

```
Coroutine 'test' defined at test.py:4 was never yield
```
The fix is to call the `async()` function or create a `Task` object with this coroutine object.
18.5.7.5. Detect exceptions not consumed

Python usually calls `sys.displayhook()` on unhandled exceptions. If `Future.set_exception()` is called, but the exception is not consumed, `sys.displayhook()` is not called. Instead, a log is emitted when the future is deleted by the garbage collector, with the traceback where the exception was raised. See the `asyncio logger`.

Example of unhandled exception:

```python
import asyncio

@asyncio.coroutine
def bug():
    raise Exception("not consumed")

loop = asyncio.get_event_loop()
asyncio.async(bug())
loop.run_forever()
```

Output:

```
Future/Task exception was never retrieved:
Traceback (most recent call last):
  File "/usr/lib/python3.4/asyncio/tasks.py", line 279
    result = next(coro)
  File "/usr/lib/python3.4/asyncio/tasks.py", line 80
    res = func(*args, **kw)
  File "test.py", line 5, in bug
    raise Exception("not consumed")
Exception: not consumed
```

There are different options to fix this issue. The first option is to chain
to coroutine in another coroutine and use classic try/except:

```python
@asyncio.coroutine
def handle_exception():
    try:
        yield from bug()
    except Exception:
        print("exception consumed")

loop = asyncio.get_event_loop()
asyncio.async(handle_exception())
loop.run_forever()
```

Another option is to use the `BaseEventLoop.run_until_complete()` function:

```python

try:
    loop.run_until_complete(task)
except Exception:
    print("exception consumed")

```

See also the `Future.exception()` method.
18.5.7.6. Chain coroutines correctly

When a coroutine function calls other coroutine functions and tasks, they should be chained explicitly with `yield from`. Otherwise, the execution is not guaranteed to be sequential.

Example with different bugs using `asyncio.sleep()` to simulate slow operations:

```python
import asyncio

@asyncio.coroutine
def create():
    yield from asyncio.sleep(3.0)
    print("(1) create file")

@asyncio.coroutine
def write():
    yield from asyncio.sleep(1.0)
    print("(2) write into file")

@asyncio.coroutine
def close():
    print("(3) close file")

@asyncio.coroutine
def test():
    asyncio.async(create())
    asyncio.async(write())
    asyncio.async(close())
    yield from asyncio.sleep(2.0)
    loop.stop()

loop = asyncio.get_event_loop()
asyncio.async(test())
```
```python
loop.run_forever()
print("Pending tasks at exit: %s" % asyncio.Task.all_tasks())
loop.close()
```

Expected output:

```
(1) create file
(2) write into file
(3) close file
Pending tasks at exit: set()
```

Actual output:

```
(3) close file
(2) write into file
Pending tasks at exit: {Task(<create>)<PENDING>}
```

The loop stopped before the `create()` finished, `close()` has been called before `write()`, whereas coroutine functions were called in this order: `create()`, `write()`, `close()`.

To fix the example, tasks must be marked with `yield from`:

```python
@asyncio.coroutine
def test():
    yield from asyncio.async(create())
    yield from asyncio.async(write())
    yield from asyncio.async(close())
    yield from asyncio.sleep(2.0)
loop.stop()
```

Or without `asyncio.async()`:

```python
@asyncio.coroutine
def test():
    yield from create()
    yield from write()
    yield from close()
    yield from asyncio.sleep(2.0)
loop.stop()
```
```python
def test():
    yield from create()
    yield from write()
    yield from close()
    yield from asyncio.sleep(2.0)
    loop.stop()
```
18.6. `asyncore` — Asynchronous socket handler

**Source code:** Lib/asyncore.py

**Note:** This module exists for backwards compatibility only. For new code we recommend using `asyncio`.

This module provides the basic infrastructure for writing asynchronous socket service clients and servers.

There are only two ways to have a program on a single processor do “more than one thing at a time.” Multi-threaded programming is the simplest and most popular way to do it, but there is another very different technique, that lets you have nearly all the advantages of multi-threading, without actually using multiple threads. It's really only practical if your program is largely I/O bound. If your program is processor bound, then pre-emptive scheduled threads are probably what you really need. Network servers are rarely processor bound, however.

If your operating system supports the `select()` system call in its I/O library (and nearly all do), then you can use it to juggle multiple communication channels at once; doing other work while your I/O is taking place in the “background.” Although this strategy can seem strange and complex, especially at first, it is in many ways easier to understand and control than multi-threaded programming. The `asyncore` module solves many of the difficult problems for you, making the task of building sophisticated high-performance network
servers and clients a snap. For “conversational” applications and protocols the companion `asynchat` module is invaluable.

The basic idea behind both modules is to create one or more network `channels`, instances of class `asyncore.dispatcher` and `asynchat.async_chat`. Creating the channels adds them to a global map, used by the `loop()` function if you do not provide it with your own `map`.

Once the initial channel(s) is(are) created, calling the `loop()` function activates channel service, which continues until the last channel (including any that have been added to the map during asynchronous service) is closed.

```python
asyncore.loop([timeout[, use_poll[, map[, count]]]])
```

Enter a polling loop that terminates after `count` passes or all open channels have been closed. All arguments are optional. The `count` parameter defaults to None, resulting in the loop terminating only when all channels have been closed. The `timeout` argument sets the timeout parameter for the appropriate `select()` or `poll()` call, measured in seconds; the default is 30 seconds. The `use_poll` parameter, if true, indicates that `poll()` should be used in preference to `select()` (the default is False).

The `map` parameter is a dictionary whose items are the channels to watch. As channels are closed they are deleted from their map. If `map` is omitted, a global map is used. Channels (instances of `asyncore.dispatcher`, `asynchat.async_chat` and subclasses thereof) can freely be mixed in the map.

```python
class asyncore.dispatcher
```

The `dispatcher` class is a thin wrapper around a low-level
socket object. To make it more useful, it has a few methods for event-handling which are called from the asynchronous loop. Otherwise, it can be treated as a normal non-blocking socket object.

The firing of low-level events at certain times or in certain connection states tells the asynchronous loop that certain higher-level events have taken place. For example, if we have asked for a socket to connect to another host, we know that the connection has been made when the socket becomes writable for the first time (at this point you know that you may write to it with the expectation of success). The implied higher-level events are:

<table>
<thead>
<tr>
<th>Event</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>handle_connect()</td>
<td>Implied by the first read or write event</td>
</tr>
<tr>
<td>handle_close()</td>
<td>Implied by a read event with no data available</td>
</tr>
<tr>
<td>handle_accepted()</td>
<td>Implied by a read event on a listening socket</td>
</tr>
</tbody>
</table>

During asynchronous processing, each mapped channel's readable() and writable() methods are used to determine whether the channel's socket should be added to the list of channels select()ed or poll()ed for read and write events.

Thus, the set of channel events is larger than the basic socket events. The full set of methods that can be overridden in your subclass follows:

**handle_read()**

Called when the asynchronous loop detects that a read() call on the channel's socket will succeed.
**handle_write()**
Called when the asynchronous loop detects that a writable socket can be written. Often this method will implement the necessary buffering for performance. For example:

```python
def handle_write(self):
    sent = self.send(self.buffer)
    self.buffer = self.buffer[sent:]
```

**handle_expt()**
Called when there is out of band (OOB) data for a socket connection. This will almost never happen, as OOB is tenuously supported and rarely used.

**handle_connect()**
Called when the active opener’s socket actually makes a connection. Might send a “welcome” banner, or initiate a protocol negotiation with the remote endpoint, for example.

**handle_close()**
Called when the socket is closed.

**handle_error()**
Called when an exception is raised and not otherwise handled. The default version prints a condensed traceback.

**handle_accept()**
Called on listening channels (passive openers) when a connection can be established with a new remote endpoint that has issued a `connect()` call for the local endpoint. Deprecated in version 3.2; use `handle_accepted()` instead.
 Deprecated since version 3.2.

**handle_accepted** *(sock, addr)*
Called on listening channels (passive openers) when a connection has been established with a new remote endpoint that has issued a `connect()` call for the local endpoint. `sock` is a *new* socket object usable to send and receive data on the connection, and `addr` is the address bound to the socket on the other end of the connection.

*New in version 3.2.*

**readable()**
Called each time around the asynchronous loop to determine whether a channel's socket should be added to the list on which read events can occur. The default method simply returns `True`, indicating that by default, all channels will be interested in read events.

**writable()**
Called each time around the asynchronous loop to determine whether a channel's socket should be added to the list on which write events can occur. The default method simply returns `True`, indicating that by default, all channels will be interested in write events.

In addition, each channel delegates or extends many of the socket methods. Most of these are nearly identical to their socket partners.

**create_socket**(family=socket.AF_INET,
*type=socket.SOCK_STREAM*)
This is identical to the creation of a normal socket, and will use
the same options for creation. Refer to the socket documentation for information on creating sockets.

*Changed in version 3.3:* `family` and `type` arguments can be omitted.

**connect**(address)

As with the normal socket object, `address` is a tuple with the first element the host to connect to, and the second the port number.

**send**(data)

Send `data` to the remote end-point of the socket.

**recv**(buffer_size)

Read at most `buffer_size` bytes from the socket’s remote end-point. An empty bytes object implies that the channel has been closed from the other end.

**listen**(backlog)

Listen for connections made to the socket. The `backlog` argument specifies the maximum number of queued connections and should be at least 1; the maximum value is system-dependent (usually 5).

**bind**(address)

Bind the socket to `address`. The socket must not already be bound. (The format of `address` depends on the address family — refer to the socket documentation for more information.) To mark the socket as re-usable (setting the SO_REUSEADDR option), call the `dispatcher` object's `set_reuse_addr()` method.
**accept()**

Accept a connection. The socket must be bound to an address and listening for connections. The return value can be either None or a pair (conn, address) where conn is a new socket object usable to send and receive data on the connection, and address is the address bound to the socket on the other end of the connection. When None is returned it means the connection didn't take place, in which case the server should just ignore this event and keep listening for further incoming connections.

**close()**

Close the socket. All future operations on the socket object will fail. The remote end-point will receive no more data (after queued data is flushed). Sockets are automatically closed when they are garbage-collected.

**class asyncore.dispatcher_with_send**

A dispatcher subclass which adds simple buffered output capability, useful for simple clients. For more sophisticated usage use asynchat.async_chat.

**class asyncore.file_dispatcher**

A file_dispatcher takes a file descriptor or file object along with an optional map argument and wraps it for use with the poll() or loop() functions. If provided a file object or anything with a fileno() method, that method will be called and passed to the file_wrapper constructor. Availability: UNIX.

**class asyncore.file_wrapper**

A file_wrapper takes an integer file descriptor and calls os.dup() to duplicate the handle so that the original handle may be closed
independently of the file_wrapper. This class implements sufficient methods to emulate a socket for use by the file_dispatcher class. Availability: UNIX.
18.6.1. asyncore Example basic HTTP client

Here is a very basic HTTP client that uses the `dispatcher` class to implement its socket handling:

```python
import asyncore

class HTTPClient(asyncore.dispatcher):
    def __init__(self, host, path):
        asyncore.dispatcher.__init__(self)
        self.create_socket()
        self.connect((host, 80))
        self.buffer = bytes('GET %s HTTP/1.0\r\nHost: %s (path, host), 'ascii')

    def handle_connect(self):
        pass

    def handle_close(self):
        self.close()

    def handle_read(self):
        print(self.recv(8192))

    def writable(self):
        return (len(self.buffer) > 0)

    def handle_write(self):
        sent = self.send(self.buffer)
        self.buffer = self.buffer[sent:]

client = HTTPClient('www.python.org', '/')
```
asyncore.loop()
18.6.2. asyncore Example basic echo server

Here is a basic echo server that uses the `dispatcher` class to accept connections and dispatches the incoming connections to a handler:

```python
import asyncore

class EchoHandler(asyncore.dispatcher_with_send):
    def handle_read(self):
        data = self.recv(8192)
        if data:
            self.send(data)

class EchoServer(asyncore.dispatcher):
    def __init__(self, host, port):
        asyncore.dispatcher.__init__(self)
        self.create_socket()
        self.set_reuse_addr()
        self.bind((host, port))
        self.listen(5)

    def handle_accepted(self, sock, addr):
        print('Incoming connection from %s' % repr(addr))
        handler = EchoHandler(sock)

server = EchoServer('localhost', 8080)
asyncore.loop()
```
18.7. **asynchat** — Asynchronous socket command/response handler

**Source code:** Lib/asynchat.py

**Note:** This module exists for backwards compatibility only. For new code we recommend using **asyncio**.

This module builds on the **asyncore** infrastructure, simplifying asynchronous clients and servers and making it easier to handle protocols whose elements are terminated by arbitrary strings, or are of variable length. **asynchat** defines the abstract class **async_chat** that you subclass, providing implementations of the `collect_incoming_data()` and `found_terminator()` methods. It uses the same asynchronous loop as **asyncore**, and the two types of channel, **asyncore.dispatcher** and **asynchat.async_chat**, can freely be mixed in the channel map. Typically an **asyncore.dispatcher** server channel generates new **asynchat.async_chat** channel objects as it receives incoming connection requests.

**class** asynchat.**async_chat**

This class is an abstract subclass of **asyncore.dispatcher**. To make practical use of the code you must subclass **async_chat**, providing meaningful `collect_incoming_data()` and `found_terminator()` methods. The **asyncore.dispatcher** methods can be used, although not all make sense in a message/response context.
Like `asyncore.dispatcher`, `async_chat` defines a set of events that are generated by an analysis of socket conditions after a `select()` call. Once the polling loop has been started the `async_chat` object's methods are called by the event-processing framework with no action on the part of the programmer.

Two class attributes can be modified, to improve performance, or possibly even to conserve memory.

**ac_in_buffer_size**
- The asynchronous input buffer size (default 4096).

**ac_out_buffer_size**
- The asynchronous output buffer size (default 4096).

Unlike `asyncore.dispatcher`, `async_chat` allows you to define a first-in-first-out queue (fifo) of *producers*. A producer need have only one method, `more()`, which should return data to be transmitted on the channel. The producer indicates exhaustion (*i.e.* that it contains no more data) by having its `more()` method return the empty bytes object. At this point the `async_chat` object removes the producer from the fifo and starts using the next producer, if any. When the producer fifo is empty the `handle_write()` method does nothing. You use the channel object’s `set_terminator()` method to describe how to recognize the end of, or an important breakpoint in, an incoming transmission from the remote endpoint.

To build a functioning `async_chat` subclass your input methods `collect_incoming_data()` and `found_terminator()` must handle the data that the channel receives asynchronously. The methods are described below.
async_chat.close_when_done()
    Pushes a `None` on to the producer fifo. When this producer is popped off the fifo it causes the channel to be closed.

async_chat.collect_incoming_data(data)
    Called with `data` holding an arbitrary amount of received data. The default method, which must be overridden, raises a `NotImplementedError` exception.

async_chat.discard_buffers()
    In emergencies this method will discard any data held in the input and/or output buffers and the producer fifo.

async_chat.found_terminator()
    Called when the incoming data stream matches the termination condition set by `set_terminator()`. The default method, which must be overridden, raises a `NotImplementedError` exception. The buffered input data should be available via an instance attribute.

async_chat.get_terminator()
    Returns the current terminator for the channel.

async_chat.push(data)
    Pushes data on to the channel's fifo to ensure its transmission. This is all you need to do to have the channel write the data out to the network, although it is possible to use your own producers in more complex schemes to implement encryption and chunking, for example.

async_chat.push_with_producer(producer)
    Takes a producer object and adds it to the producer fifo associated
with the channel. When all currently-pushed producers have been exhausted the channel will consume this producer's data by calling its `more()` method and send the data to the remote endpoint.

`async_chat.set_terminator(term)`

Sets the terminating condition to be recognized on the channel. `term` may be any of three types of value, corresponding to three different ways to handle incoming protocol data.

<table>
<thead>
<tr>
<th>term</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td><code>string</code></td>
<td>Will call <code>found_terminator()</code> when the string is found in the input stream</td>
</tr>
<tr>
<td><code>integer</code></td>
<td>Will call <code>found_terminator()</code> when the indicated number of characters have been received</td>
</tr>
<tr>
<td><code>None</code></td>
<td>The channel continues to collect data forever</td>
</tr>
</tbody>
</table>

Note that any data following the terminator will be available for reading by the channel after `found_terminator()` is called.
class asynchat.fifo(list=None)

A fifo holding data which has been pushed by the application but not yet popped for writing to the channel. A fifo is a list used to hold data and/or producers until they are required. If the list argument is provided then it should contain producers or data items to be written to the channel.

is_empty()

Returns True if and only if the fifo is empty.

first()

Returns the least-recently push() ed item from the fifo.

push(data)

Adds the given data (which may be a string or a producer object) to the producer fifo.

pop()

If the fifo is not empty, returns True, first(), deleting the popped item. Returns False, None for an empty fifo.
18.7.2. asynchat Example

The following partial example shows how HTTP requests can be read with `async_chat`. A web server might create an `http_request_handler` object for each incoming client connection. Notice that initially the channel terminator is set to match the blank line at the end of the HTTP headers, and a flag indicates that the headers are being read.

Once the headers have been read, if the request is of type POST (indicating that further data are present in the input stream) then the `Content-Length:` header is used to set a numeric terminator to read the right amount of data from the channel.

The `handle_request()` method is called once all relevant input has been marshalled, after setting the channel terminator to `None` to ensure that any extraneous data sent by the web client are ignored.

```python
import asynchat

class http_request_handler(asynchat.async_chat):
    def __init__(self, sock, addr, sessions, log):
        asynchat.async_chat.__init__(self, sock=sock)
        self.addr = addr
        self.sessions = sessions
        self.ibuffer = []
        self.obuffer = b""
        self.set_terminator(b"\r\n\r\n")
        self.reading_headers = True
        self.handling = False
        self.cgi_data = None
        self.log = log
```
```python
def collect_incoming_data(self, data):
    """Buffer the data""
    self.ibuffer.append(data)

def found_terminator(self):
    if self.reading_headers:
        self.reading_headers = False
        self.parse_headers(b"".join(self.ibuffer)
        self.ibuffer = []
    if self.op.upper() == b"POST":
        clen = self.headers.getheader("content-length")
        self.set_terminator(int(clen))
    else:
        selfhandling = True
        self.set_terminator(None)
        self.handle_request()
    elif not selfhandling:
        self.set_terminator(None) # browsers sometimes
        self.cgi_data = parse(self.headers, b"
        self.handle_request()```
18.8. **signal** — Set handlers for asynchronous events

This module provides mechanisms to use signal handlers in Python.
18.8.1. General rules

The `signal.signal()` function allows to define custom handlers to be executed when a signal is received. A small number of default handlers are installed: SIGPIPE is ignored (so write errors on pipes and sockets can be reported as ordinary Python exceptions) and SIGINT is translated into a `KeyboardInterrupt` exception.

A handler for a particular signal, once set, remains installed until it is explicitly reset (Python emulates the BSD style interface regardless of the underlying implementation), with the exception of the handler for SIGCHLD, which follows the underlying implementation.

There is no way to “block” signals temporarily from critical sections (since this is not supported by all Unix flavors).

18.8.1.1. Execution of Python signal handlers

A Python signal handler does not get executed inside the low-level (C) signal handler. Instead, the low-level signal handler sets a flag which tells the virtual machine to execute the corresponding Python signal handler at a later point(for example at the next bytecode instruction). This has consequences:

- It makes little sense to catch synchronous errors like SIGFPE or SIGSEGV that are caused by an invalid operation in C code. Python will return from the signal handler to the C code, which is likely to raise the same signal again, causing Python to apparently hang. From Python 3.3 onwards, you can use the `faulthandler` module to report on synchronous errors.
- A long-running calculation implemented purely in C (such as regular expression matching on a large body of text) may run
uninterrupted for an arbitrary amount of time, regardless of any signals received. The Python signal handlers will be called when the calculation finishes.

18.8.1.2. Signals and threads

Python signal handlers are always executed in the main Python thread, even if the signal was received in another thread. This means that signals can’t be used as a means of inter-thread communication. You can use the synchronization primitives from the `threading` module instead.

Besides, only the main thread is allowed to set a new signal handler.
18.8.2. Module contents

The variables defined in the `signal` module are:

**signal.SIG_DFL**

This is one of two standard signal handling options; it will simply perform the default function for the signal. For example, on most systems the default action for SIGQUIT is to dump core and exit, while the default action for SIGCHLD is to simply ignore it.

**signal.SIG_IGN**

This is another standard signal handler, which will simply ignore the given signal.

**SIG**

All the signal numbers are defined symbolically. For example, the hangup signal is defined as `signal.SIGHUP`; the variable names are identical to the names used in C programs, as found in `<signal.h>`. The Unix man page for ‘`signal()`’ lists the existing signals (on some systems this is `signal(2)`, on others the list is in `signal(7)`). Note that not all systems define the same set of signal names; only those names defined by the system are defined by this module.

**signal.CTRL_C_EVENT**

The signal corresponding to the CTRL+C keystroke event. This signal can only be used with `os.kill()`.

Availability: Windows.

*New in version 3.2.*
signal. **CTRL_BREAK_EVENT**

The signal corresponding to the CTRL+BREAK keystroke event. This signal can only be used with `os.kill()`.

Availability: Windows.

*New in version 3.2.*

signal. **NSIG**

One more than the number of the highest signal number.

signal. **ITIMER_REAL**

Decrements interval timer in real time, and delivers SIGALRM upon expiration.

signal. **ITIMER_VIRTUAL**

Decrements interval timer only when the process is executing, and delivers SIGVTALRM upon expiration.

signal. **ITIMER_PROF**

Decrements interval timer both when the process executes and when the system is executing on behalf of the process. Coupled with ITIMER_VIRTUAL, this timer is usually used to profile the time spent by the application in user and kernel space. SIGPROF is delivered upon expiration.

signal. **SIG_BLOCK**

A possible value for the *how* parameter to `pthread_sigmask()` indicating that signals are to be blocked.

*New in version 3.3.*

signal. **SIG_UNBLOCK**
A possible value for the *how* parameter to `pthread_sigmask()` indicating that signals are to be unblocked.

*New in version 3.3.*

**signal:** *SIG_SETMASK*

A possible value for the *how* parameter to `pthread_sigmask()` indicating that the signal mask is to be replaced.

*New in version 3.3.*

The *signal* module defines one exception:

**exception signal:** *ItimerError*

Raised to signal an error from the underlying `setitimer()` or `getitimer()` implementation. Expect this error if an invalid interval timer or a negative time is passed to `setitimer()`. This error is a subtype of *OSError*.

*New in version 3.3:* This error used to be a subtype of *IOError*, which is now an alias of *OSError*.

The *signal* module defines the following functions:

**signal:** *alarm(time)*

If *time* is non-zero, this function requests that a SIGALRM signal be sent to the process in *time* seconds. Any previously scheduled alarm is canceled (only one alarm can be scheduled at any time). The returned value is then the number of seconds before any previously set alarm was to have been delivered. If *time* is zero, no alarm is scheduled, and any scheduled alarm is canceled. If the return value is zero, no alarm is currently scheduled. (See the Unix man page *alarm(2).* ) Availability: Unix.
signal.\texttt{getsignal}(\texttt{signalnum})

Return the current signal handler for the signal \texttt{signalnum}. The returned value may be a callable Python object, or one of the special values \texttt{signal.SIG_IGN}, \texttt{signal.SIG_DFL} or \texttt{None}. Here, \texttt{signal.SIG_IGN} means that the signal was previously ignored, \texttt{signal.SIG_DFL} means that the default way of handling the signal was previously in use, and \texttt{None} means that the previous signal handler was not installed from Python.

signal.\texttt{pause}()

Cause the process to sleep until a signal is received; the appropriate handler will then be called. Returns nothing. Not on Windows. (See the Unix man page \texttt{signal(2)}.)

See also \texttt{sigwait()}, \texttt{sigwaitinfo()}, \texttt{sigtimedwait()} and \texttt{sigpending()}.

signal.\texttt{pthread_kill}(\texttt{thread_id}, \texttt{signum})

Send the signal \texttt{signum} to the thread \texttt{thread_id}, another thread in the same process as the caller. The target thread can be executing any code (Python or not). However, if the target thread is executing the Python interpreter, the Python signal handlers will be \texttt{executed by the main thread}. Therefore, the only point of sending a signal to a particular Python thread would be to force a running system call to fail with \texttt{InterruptedError}.

Use \texttt{threading.get_ident()} or the \texttt{ident} attribute of \texttt{threading.Thread} objects to get a suitable value for \texttt{thread_id}.

If \texttt{signum} is 0, then no signal is sent, but error checking is still performed; this can be used to check if the target thread is still running.
Availability: Unix (see the man page `pthread_kill(3)` for further information).

See also `os.kill()`.

*New in version 3.3.*

**signal.pthread_sigmask**(how, mask)

Fetch and/or change the signal mask of the calling thread. The signal mask is the set of signals whose delivery is currently blocked for the caller. Return the old signal mask as a set of signals.

The behavior of the call is dependent on the value of `how`, as follows.

- **SIG_BLOCK**: The set of blocked signals is the union of the current set and the `mask` argument.
- **SIG_UNBLOCK**: The signals in `mask` are removed from the current set of blocked signals. It is permissible to attempt to unblock a signal which is not blocked.
- **SIG_SETMASK**: The set of blocked signals is set to the `mask` argument.

`mask` is a set of signal numbers (e.g. `{signal.SIGINT, signal.SIGTERM}`). Use `range(1, signal.NSIG)` for a full mask including all signals.

For example, `signal.pthread_sigmask(signal.SIG_BLOCK, [])` reads the signal mask of the calling thread.

Availability: Unix. See the man page `sigprocmask(3)` and `pthread_sigmask(3)` for further information.
See also `pause()`, `sigpending()` and `sigwait()`.

*New in version 3.3.*

**signal.setitimer**(``which``, ``seconds[, interval]``)

Sets given interval timer (one of `signal.ITIMER_REAL`, `signal.ITIMER_VIRTUAL` or `signal.ITIMER_PROF`) specified by `which` to fire after `seconds` (float is accepted, different from `alarm()`) and after that every `interval` seconds. The interval timer specified by `which` can be cleared by setting `seconds` to zero.

When an interval timer fires, a signal is sent to the process. The signal sent is dependent on the timer being used; `signal.ITIMER_REAL` will deliver `SIGALRM`, `signal.ITIMER_VIRTUAL` sends `SIGVTALRM`, and `signal.ITIMER_PROF` will deliver `SIGPROF`.

The old values are returned as a tuple: (delay, interval).

Attempting to pass an invalid interval timer will cause an `ItimerError`. Availability: Unix.

**signal.getitimer**(``which``)

Returns current value of a given interval timer specified by `which`. Availability: Unix.

**signal.set_wakeup_fd**(``fd``)

Set the wakeup file descriptor to `fd`. When a signal is received, the signal number is written as a single byte into the `fd`. This can be used by a library to wakeup a poll or select call, allowing the signal to be fully processed.

The old wakeup `fd` is returned. `fd` must be non-blocking. It is up to
the library to remove any bytes before calling poll or select again.

Use for example `struct.unpack('%uB' % len(data), data)` to decode the signal numbers list.

When threads are enabled, this function can only be called from the main thread; attempting to call it from other threads will cause a `ValueError` exception to be raised.

**signal.siginterrupt(signalnum, flag)**

Change system call restart behaviour: if `flag` is `False`, system calls will be restarted when interrupted by signal `signalnum`, otherwise system calls will be interrupted. Returns nothing. Availability: Unix (see the man page `siginterrupt(3)` for further information).

Note that installing a signal handler with `signal()` will reset the restart behaviour to interruptible by implicitly calling `siginterrupt()` with a true `flag` value for the given signal.

**signal.signal(signalnum, handler)**

Set the handler for signal `signalnum` to the function `handler`. `handler` can be a callable Python object taking two arguments (see below), or one of the special values `signal.SIG_IGN` or `signal.SIG_DFL`. The previous signal handler will be returned (see the description of `getsignal()` above). (See the Unix man page `signal(2)`.)

When threads are enabled, this function can only be called from the main thread; attempting to call it from other threads will cause a `ValueError` exception to be raised.

The `handler` is called with two arguments: the signal number and
the current stack frame (None or a frame object; for a description of frame objects, see the description in the type hierarchy or see the attribute descriptions in the inspect module).

On Windows, signal() can only be called with SIGABRT, SIGFPE, SIGILL, SIGINT, SIGSEGV, or SIGTERM. A ValueError will be raised in any other case.

signal. sigpending()
Examine the set of signals that are pending for delivery to the calling thread (i.e., the signals which have been raised while blocked). Return the set of the pending signals.

Availability: Unix (see the man page sigpending(2) for further information).

See also pause(), pthread_sigmask() and sigwait().

New in version 3.3.

signal. sigwait(sigset)
Suspend execution of the calling thread until the delivery of one of the signals specified in the signal set sigset. The function accepts the signal (removes it from the pending list of signals), and returns the signal number.

Availability: Unix (see the man page sigwait(3) for further information).

See also pause(), pthread_sigmask(), sigpending(), sigwaitinfo() and sigtimedwait().

New in version 3.3.
signal. **sigwaitinfo**(*sigset*)

Suspend execution of the calling thread until the delivery of one of the signals specified in the signal set *sigset*. The function accepts the signal and removes it from the pending list of signals. If one of the signals in *sigset* is already pending for the calling thread, the function will return immediately with information about that signal. The signal handler is not called for the delivered signal. The function raises an **InterruptedError** if it is interrupted by a signal that is not in *sigset*.

The return value is an object representing the data contained in the *siginfo_t* structure, namely: *si_signo*, *si_code*, *si_errno*, *si_pid*, *si_uid*, *si_status*, *si_band*.

Availability: Unix (see the man page **sigwaitinfo**(2) for further information).

See also **pause()**, **sigwait()** and **sigtimedwait()**.

*New in version 3.3.*

signal. **sigtimedwait**(*sigset*, *timeout*)

Like **sigwaitinfo()**, but takes an additional *timeout* argument specifying a timeout. If *timeout* is specified as 0, a poll is performed. Returns **None** if a timeout occurs.

Availability: Unix (see the man page **sigtimedwait**(2) for further information).

See also **pause()**, **sigwait()** and **sigwaitinfo()**.

*New in version 3.3.*
18.8.3. Example

Here is a minimal example program. It uses the `alarm()` function to limit the time spent waiting to open a file; this is useful if the file is for a serial device that may not be turned on, which would normally cause the `os.open()` to hang indefinitely. The solution is to set a 5-second alarm before opening the file; if the operation takes too long, the alarm signal will be sent, and the handler raises an exception.

```python
import signal, os

def handler(signum, frame):
    print('Signal handler called with signal', signum)
    raise OSError("Couldn't open device!")

# Set the signal handler and a 5-second alarm
signal.signal(signal.SIGALRM, handler)
signal.alarm(5)

# This open() may hang indefinitely
fd = os.open('/dev/ttyS0', os.O_RDWR)

signal.alarm(0)  # Disable the alarm
```

18.9. `mmap` — Memory-mapped file support

Memory-mapped file objects behave like both `bytearray` and like `file objects`. You can use mmap objects in most places where `bytearray` are expected; for example, you can use the `re` module to search through a memory-mapped file. You can also change a single byte by doing `obj[index] = 97`, or change a subsequence by assigning to a slice: `obj[i1:i2] = b'...'`. You can also read and write data starting at the current file position, and `seek()` through the file to different positions.

A memory-mapped file is created by the `mmap` constructor, which is different on Unix and on Windows. In either case you must provide a file descriptor for a file opened for update. If you wish to map an existing Python file object, use its `fileno()` method to obtain the correct value for the `fileno` parameter. Otherwise, you can open the file using the `os.open()` function, which returns a file descriptor directly (the file still needs to be closed when done).

**Note:** If you want to create a memory-mapping for a writable, buffered file, you should `flush()` the file first. This is necessary to ensure that local modifications to the buffers are actually available to the mapping.

For both the Unix and Windows versions of the constructor, `access` may be specified as an optional keyword parameter. `access` accepts one of three values: `ACCESS_READ`, `ACCESS_WRITE`, or `ACCESS_COPY` to specify read-only, write-through or copy-on-write
memory respectively. *access* can be used on both Unix and Windows. If *access* is not specified, Windows mmap returns a write-through mapping. The initial memory values for all three access types are taken from the specified file. Assignment to an ACCESS_READ memory map raises a *TypeError* exception. Assignment to an ACCESS_WRITE memory map affects both memory and the underlying file. Assignment to an ACCESS_COPY memory map affects memory but does not update the underlying file.

To map anonymous memory, -1 should be passed as the fileno along with the length.

```python
class mmap:
    __init__(fileno, length, tagname=None,
             access=ACCESS_DEFAULT, [, offset])
```

*(Windows version)* Maps *length* bytes from the file specified by the file handle *fileno*, and creates a mmap object. If *length* is larger than the current size of the file, the file is extended to contain *length* bytes. If *length* is 0, the maximum length of the map is the current size of the file, except that if the file is empty Windows raises an exception (you cannot create an empty mapping on Windows).

*tagname*, if specified and not *None*, is a string giving a tag name for the mapping. Windows allows you to have many different mappings against the same file. If you specify the name of an existing tag, that tag is opened, otherwise a new tag of this name is created. If this parameter is omitted or *None*, the mapping is created without a name. Avoiding the use of the tag parameter will assist in keeping your code portable between Unix and Windows.

*offset* may be specified as a non-negative integer offset. mmap references will be relative to the offset from the beginning of the
file. offset defaults to 0. offset must be a multiple of the ALLOCATIONGRANULARITY.

```
class mmap.mmap(fileno, length, flags=MAP_SHARED,
prot=PROT_WRITE|PROT_READ, access=ACCESS_DEFAULT[, offset])
```

(Unix version) Maps length bytes from the file specified by the file descriptor fileno, and returns a mmap object. If length is 0, the maximum length of the map will be the current size of the file when mmap is called.

flags specifies the nature of the mapping. MAP_PRIVATE creates a private copy-on-write mapping, so changes to the contents of the mmap object will be private to this process, and MAP_SHARED creates a mapping that's shared with all other processes mapping the same areas of the file. The default value is MAP_SHARED.

prot, if specified, gives the desired memory protection; the two most useful values are PROT_READ and PROT_WRITE, to specify that the pages may be read or written. prot defaults to PROT_READ | PROT_WRITE.

access may be specified in lieu of flags and prot as an optional keyword parameter. It is an error to specify both flags, prot and access. See the description of access above for information on how to use this parameter.

offset may be specified as a non-negative integer offset. mmap references will be relative to the offset from the beginning of the file. offset defaults to 0. offset must be a multiple of the PAGESIZE or ALLOCATIONGRANULARITY.
To ensure validity of the created memory mapping the file specified by the descriptor `fileno` is internally automatically synchronized with physical backing store on Mac OS X and OpenVMS.

This example shows a simple way of using `mmap`:

```python
import mmap

# write a simple example file
with open("hello.txt", "wb") as f:
    f.write(b"Hello Python!\n")

with open("hello.txt", "r+b") as f:
    # memory-map the file, size 0 means whole file
    mm = mmap.mmap(f.fileno(), 0)
    # read content via standard file methods
    print(mm.readline())  # prints b"Hello Python
    # read content via slice notation
    print(mm[:5])  # prints b"Hello"
    # update content using slice notation;
    # note that new content must have same size
    mm[6:] = b" world!\n"
    # ... and read again using standard file methods
    mm.seek(0)
    print(mm.readline())  # prints b"Hello world
    # close the map
    mm.close()
```

`mmap` can also be used as a context manager in a `with` statement:

```python
import mmap

with mmap.mmap(-1, 13) as mm:
    mm.write("Hello world!")
```
New in version 3.2: Context manager support.

The next example demonstrates how to create an anonymous map and exchange data between the parent and child processes:

```python
import mmap
import os

mm = mmap.mmap(-1, 13)
mm.write(b"Hello world!")

pid = os.fork()

if pid == 0:  # In a child process
    mm.seek(0)
    print(mm.readline())
    mm.close()
```

Memory-mapped file objects support the following methods:

**mmap.close()**

Closes the mmap. Subsequent calls to other methods of the object will result in a ValueError exception being raised. This will not close the open file.

**mmap.closed**

`True` if the file is closed.

New in version 3.2.

**mmap.find(sub[, start[, end]])**

Returns the lowest index in the object where the subsequence `sub` is found, such that `sub` is contained in the range `[start,
Optional arguments start and end are interpreted as in slice notation. Returns -1 on failure.

```python
mmap.flush([offset[, size]])
```
Flushes changes made to the in-memory copy of a file back to disk. Without use of this call there is no guarantee that changes are written back before the object is destroyed. If offset and size are specified, only changes to the given range of bytes will be flushed to disk; otherwise, the whole extent of the mapping is flushed.

**(Windows version)** A nonzero value returned indicates success; zero indicates failure.

**(Unix version)** A zero value is returned to indicate success. An exception is raised when the call failed.

```python
mmap.move(dest, src, count)
```
Copy the count bytes starting at offset src to the destination index dest. If the mmap was created with ACCESS_READ, then calls to move will raise a TypeError exception.

```python
mmap.read([n])
```
Return a bytes containing up to n bytes starting from the current file position. If the argument is omitted, None or negative, return all bytes from the current file position to the end of the mapping. The file position is updated to point after the bytes that were returned.

*Changed in version 3.3:* Argument can be omitted or None.

```python
mmap.read_byte()
```
Returns a byte at the current file position as an integer, and advances the file position by 1.

\texttt{mmap.readline()}

Returns a single line, starting at the current file position and up to the next newline.

\texttt{mmap.resize(newsize)}

Resizes the map and the underlying file, if any. If the mmap was created with \texttt{ACCESS\_READ} or \texttt{ACCESS\_COPY}, resizing the map will raise a \texttt{TypeError} exception.

\texttt{mmap.rfind(sub[, start[, end]])}

Returns the highest index in the object where the subsequence \texttt{sub} is found, such that \texttt{sub} is contained in the range \texttt{[start, end]}. Optional arguments \texttt{start} and \texttt{end} are interpreted as in slice notation. Returns -1 on failure.

\texttt{mmap.seek(pos[, whence])}

Set the file's current position. \texttt{whence} argument is optional and defaults to \texttt{os.SEEK\_SET} or 0 (absolute file positioning); other values are \texttt{os.SEEK\_CUR} or 1 (seek relative to the current position) and \texttt{os.SEEK\_END} or 2 (seek relative to the file's end).

\texttt{mmap.size()}

Return the length of the file, which can be larger than the size of the memory-mapped area.

\texttt{mmap.tell()}

Returns the current position of the file pointer.
mmap.\texttt{write}(\texttt{bytes})

Write the bytes in \texttt{bytes} into memory at the current position of the file pointer; the file position is updated to point after the bytes that were written. If the mmap was created with \texttt{ACCESS\_READ}, then writing to it will raise a \texttt{TypeError} exception.

mmap.\texttt{write\_byte}(\texttt{byte})

Write the integer \texttt{byte} into memory at the current position of the file pointer; the file position is advanced by \texttt{1}. If the mmap was created with \texttt{ACCESS\_READ}, then writing to it will raise a \texttt{TypeError} exception.
19. Internet Data Handling

This chapter describes modules which support handling data formats commonly used on the Internet.

- 19.1. email — An email and MIME handling package
  - 19.1.1. email.message: Representing an email message
  - 19.1.2. email.parser: Parsing email messages
    - 19.1.2.1. FeedParser API
    - 19.1.2.2. Parser class API
    - 19.1.2.3. Additional notes
  - 19.1.3. email.generator: Generating MIME documents
  - 19.1.4. email.policy: Policy Objects
  - 19.1.5. email.headerregistry: Custom Header Objects
  - 19.1.6. email.contentmanager: Managing MIME Content
    - 19.1.6.1. Content Manager Instances
  - 19.1.7. email.mime: Creating email and MIME objects from scratch
  - 19.1.8. email.header: Internationalized headers
  - 19.1.9. email.charset: Representing character sets
  - 19.1.10. email.encoders: Encoders
  - 19.1.11. email.errors: Exception and Defect classes
  - 19.1.12. email.utils: Miscellaneous utilities
  - 19.1.13. email.iterators: Iterators
  - 19.1.14. email: Examples
    - 19.1.14.1. Examples using the Provisional API
  - 19.1.15. Package History
  - 19.1.16. Differences from mimelib

- 19.2. json — JSON encoder and decoder
  - 19.2.1. Basic Usage
  - 19.2.2. Encoders and Decoders
19.2.3. Standard Compliance
- 19.2.3.1. Character Encodings
- 19.2.3.2. Top-level Non-Object, Non-Array Values
- 19.2.3.3. Infinite and NaN Number Values
- 19.2.3.4. Repeated Names Within an Object

• 19.3. mailcap — Mailcap file handling
• 19.4. mailbox — Manipulate mailboxes in various formats
  - 19.4.1. Mailbox objects
    - 19.4.1.1. Maildir
    - 19.4.1.2. mbox
    - 19.4.1.3. MH
    - 19.4.1.4. Baby1
    - 19.4.1.5. MMDF
  - 19.4.2. Message objects
    - 19.4.2.1. MaildirMessage
    - 19.4.2.2. mboxMessage
    - 19.4.2.3. MHMessage
    - 19.4.2.4. Baby1Message
    - 19.4.2.5. MMDFMessage
  - 19.4.3. Exceptions
  - 19.4.4. Examples

• 19.5. mimetypes — Map filenames to MIME types
  - 19.5.1. MimeTypes Objects
• 19.6. base64 — Base16, Base32, Base64, Base85 Data Encodings
• 19.7. binhex — Encode and decode binhex4 files
  - 19.7.1. Notes
• 19.8. binascii — Convert between binary and ASCII
• 19.9. quopri — Encode and decode MIME quoted-printable data
• 19.10. uu — Encode and decode uuencode files
19.1. email — An email and MIME handling package

The email package is a library for managing email messages, including MIME and other RFC 2822-based message documents. It is specifically not designed to do any sending of email messages to SMTP (RFC 2821), NNTP, or other servers; those are functions of modules such as smtplib and nntplib. The email package attempts to be as RFC-compliant as possible, supporting in addition to RFC 2822, such MIME-related RFCs as RFC 2045, RFC 2046, RFC 2047, and RFC 2231.

The primary distinguishing feature of the email package is that it splits the parsing and generating of email messages from the internal object model representation of email. Applications using the email package deal primarily with objects; you can add sub-objects to messages, remove sub-objects from messages, completely re-arrange the contents, etc. There is a separate parser and a separate generator which handles the transformation from flat text to the object model, and then back to flat text again. There are also handy subclasses for some common MIME object types, and a few miscellaneous utilities that help with such common tasks as extracting and parsing message field values, creating RFC-compliant dates, etc.

The following sections describe the functionality of the email package. The ordering follows a progression that should be common in applications: an email message is read as flat text from a file or other source, the text is parsed to produce the object structure of the email message, this structure is manipulated, and finally, the object tree is rendered back into flat text.
It is perfectly feasible to create the object structure out of whole cloth — i.e. completely from scratch. From there, a similar progression can be taken as above.

Also included are detailed specifications of all the classes and modules that the email package provides, the exception classes you might encounter while using the email package, some auxiliary utilities, and a few examples. For users of the older mimelib package, or previous versions of the email package, a section on differences and porting is provided.

Contents of the email package documentation:

- 19.1.1. email.message: Representing an email message
- 19.1.2. email.parser: Parsing email messages
  - 19.1.2.1. FeedParser API
  - 19.1.2.2. Parser class API
  - 19.1.2.3. Additional notes
- 19.1.3. email.generator: Generating MIME documents
- 19.1.4. email.policy: Policy Objects
- 19.1.5. email.headerregistry: Custom Header Objects
- 19.1.6. email.contentmanager: Managing MIME Content
  - 19.1.6.1. Content Manager Instances
- 19.1.7. email.mime: Creating email and MIME objects from scratch
- 19.1.8. email.header: Internationalized headers
- 19.1.9. email.charset: Representing character sets
- 19.1.10. email.encoders: Encoders
- 19.1.11. email.errors: Exception and Defect classes
- 19.1.12. email.utils: Miscellaneous utilities
- 19.1.13. email.iterators: Iterators
- 19.1.14. email: Examples
  - 19.1.14.1. Examples using the Provisional API

19.1.15. Package History

This table describes the release history of the email package, corresponding to the version of Python that the package was released with. For purposes of this document, when you see a note about change or added versions, these refer to the Python version the change was made in, not the email package version. This table also describes the Python compatibility of each version of the package.

<table>
<thead>
<tr>

</tbody>
</table>

Here are the major differences between email version 5.1 and version 5.0:

- It is once again possible to parse messages containing non-ASCII bytes, and to reproduce such messages if the data containing the non-ASCII bytes is not modified.
- New functions `message_from_bytes()` and `message_from_binary_file()`, and new classes `BytesFeedParser` and `BytesParser` allow binary message data to be parsed into model objects.
- Given bytes input to the model, `get_payload()` will by default
decode a message body that has a `Content-Transfer-Encoding` of 8bit using the charset specified in the MIME headers and return the resulting string.

- Given bytes input to the model, `Generator` will convert message bodies that have a `Content-Transfer-Encoding` of 8bit to instead have a 7bit Content-Transfer-Encoding.
- New class `BytesGenerator` produces bytes as output, preserving any unchanged non-ASCII data that was present in the input used to build the model, including message bodies with a `Content-Transfer-Encoding` of 8bit.

Here are the major differences between `email` version 5.0 and version 4:

- All operations are on unicode strings. Text inputs must be strings, text outputs are strings. Outputs are limited to the ASCII character set and so can be encoded to ASCII for transmission. Inputs are also limited to ASCII; this is an acknowledged limitation of email 5.0 and means it can only be used to parse email that is 7bit clean.

Here are the major differences between `email` version 4 and version 3:

- All modules have been renamed according to PEP 8 standards. For example, the version 3 module `email.Message` was renamed to `email.message` in version 4.

- A new subpackage `email.mime` was added and all the version 3 `email.MIME*` modules were renamed and situated into the `email.mime` subpackage. For example, the version 3 module `email.MIMEText` was renamed to `email.mime.text`.

  `Note that the version 3 names will continue to work until Python`
2.6.

- The `email.mime.application` module was added, which contains the `MIMEApplication` class.

- Methods that were deprecated in version 3 have been removed. These include `Generator.__call__()`, `Message.get_type()`, `Message.get_main_type()`, and `Message.get_subtype()`.

- Fixes have been added for RFC 2231 support which can change some of the return types for `Message.get_param` and friends. Under some circumstances, values which used to return a 3-tuple now return simple strings (specifically, if all extended parameter segments were unencoded, there is no language and charset designation expected, so the return type is now a simple string). Also, %-decoding used to be done for both encoded and unencoded segments; this decoding is now done only for encoded segments.

Here are the major differences between `email` version 3 and version 2:

- The `FeedParser` class was introduced, and the `Parser` class was implemented in terms of the `FeedParser`. All parsing therefore is non-strict, and parsing will make a best effort never to raise an exception. Problems found while parsing messages are stored in the message's `defect` attribute.

- All aspects of the API which raised `DeprecationWarnings` in version 2 have been removed. These include the `_encoder` argument to the `MIMEText` constructor, the `Message.add_payload()` method, the `Utils.dump_address_pair()` function, and the functions
Utils.decode() and Utils.encode()

- New DeprecationWarnings have been added to: Generator.__call__(), Message.get_type(), Message.get_main_type(), Message.get_subtype(), and the strict argument to the Parser class. These are expected to be removed in future versions.
- Support for Pythons earlier than 2.3 has been removed.

Here are the differences between email version 2 and version 1:

- The email.Header and email.Charset modules have been added.
- The pickle format for Message instances has changed. Since this was never (and still isn't) formally defined, this isn't considered a backward incompatibility. However if your application pickles and unpickles Message instances, be aware that in email version 2, Message instances now have private variables _charset and _default_type.
- Several methods in the Message class have been deprecated, or their signatures changed. Also, many new methods have been added. See the documentation for the Message class for details. The changes should be completely backward compatible.
- The object structure has changed in the face of message/rfc822 content types. In email version 1, such a type would be represented by a scalar payload, i.e. the container message's is_multipart() returned false, get_payload() was not a list object, but a single Message instance.

This structure was inconsistent with the rest of the package, so the object representation for message/rfc822 content types was
changed. In email version 2, the container does return True from is_multipart(), and get_payload() returns a list containing a single Message item.

Note that this is one place that backward compatibility could not be completely maintained. However, if you’re already testing the return type of get_payload(), you should be fine. You just need to make sure your code doesn’t do a set_payload() with a Message instance on a container with a content type of message/rfc822.

- The Parser constructor’s strict argument was added, and its parse() and parsestr() methods grew a headersonly argument. The strict flag was also added to functions email.message_from_file() and email.message_from_string().

- Generator.__call__() is deprecated; use Generator.flatten instead. The Generator class has also grown the clone() method.

- The DecodedGenerator class in the email.generator module was added.

- The intermediate base classes MIMENonMultipart and MIMEMultipart have been added, and interposed in the class hierarchy for most of the other MIME-related derived classes.

- The _encoder argument to the MIMEText constructor has been deprecated. Encoding now happens implicitly based on the _charset argument.
• The following functions in the `email.Utils` module have been deprecated: `dump_address_pairs()`, `decode()`, and `encode()`. The following functions have been added to the module: `make_msgid()`, `decode_rfc2231()`, `encode_rfc2231()`, and `decode_params()`.

• The non-public function `email.Iterators._structure()` was added.
19.1.16. Differences from mimelib

The email package was originally prototyped as a separate library called mimelib. Changes have been made so that method names are more consistent, and some methods or modules have either been added or removed. The semantics of some of the methods have also changed. For the most part, any functionality available in mimelib is still available in the email package, albeit often in a different way. Backward compatibility between the mimelib package and the email package was not a priority.

Here is a brief description of the differences between the mimelib and the email packages, along with hints on how to port your applications.

Of course, the most visible difference between the two packages is that the package name has been changed to email. In addition, the top-level package has the following differences:

- messageFromString() has been renamed to message_from_string().
- messageFromFile() has been renamed to message_from_file().

The Message class has the following differences:

- The method asString() was renamed to as_string().
- The method ismultipart() was renamed to is_multipart().
- The get_payload() method has grown a decode optional argument.
- The method getall() was renamed to get_all().
The `addheader()` method was renamed to `add_header()`.
The method `gettype()` was renamed to `get_type()`.
The method `getmaintype()` was renamed to `get_main_type()`.
The method `getsubtype()` was renamed to `get_subtype()`.
The method `getparams()` was renamed to `get_params()`. Also, whereas `getparams()` returned a list of strings, `get_params()` returns a list of 2-tuples, effectively the key/value pairs of the parameters, split on the '=' sign.
The method `getparam()` was renamed to `get_param()`.
The method `getcharset()` was renamed to `get_charsets()`.
The method `getfilename()` was renamed to `get_filename()`.
The method `getboundary()` was renamed to `get_boundary()`.
The method `setboundary()` was renamed to `set_boundary()`.
The method `getdecodedpayload()` was removed. To get similar functionality, pass the value 1 to the `decode` flag of the `get_payload()` method.
The method `getpayloadastext()` was removed. Similar functionality is supported by the `DecodedGenerator` class in the `email.generator` module.
The method `getbodyastext()` was removed. You can get similar functionality by creating an iterator with `typed_subpart_iterator()` in the `email.iterators` module.

The `Parser` class has no differences in its public interface. It does have some additional smarts to recognize `message/delivery-status` type messages, which it represents as a `Message` instance containing
separate Message subparts for each header block in the delivery status notification [1].

The Generator class has no differences in its public interface. There is a new class in the email.generator module though, called DecodedGenerator which provides most of the functionality previously available in the Message.getpayloadastext() method.

The following modules and classes have been changed:

- The MIMEBase class constructor arguments _major and _minor have changed to _maintype and _subtype respectively.
- The Image class/module has been renamed to MIMEImage. The _minor argument has been renamed to _subtype.
- The Text class/module has been renamed to MIMEText. The _minor argument has been renamed to _subtype.
- The MessageRFC822 class/module has been renamed to MIMEMessage. Note that an earlier version of mimelib called this class/module RFC822, but that clashed with the Python standard library module rfc822 on some case-insensitive file systems.

Also, the MIMEMessage class now represents any kind of MIME message with main type message. It takes an optional argument _subtype which is used to set the MIME subtype. _subtype defaults to rfc822.

mimelib provided some utility functions in its address and date modules. All of these functions have been moved to the
The `MsgReader` class/module has been removed. Its functionality is most closely supported in the `body_line_iterator()` function in the `email.iterators` module.

**Footnotes**

[1] Delivery Status Notifications (DSN) are defined in RFC 1894.
19. Internet Data Handling

19.1. `email` — An email and MIME handling package
19.1.1. `email.message`: Representing an email message

The central class in the `email` package is the `Message` class, imported from the `email.message` module. It is the base class for the `email` object model. `Message` provides the core functionality for setting and querying header fields, and for accessing message bodies.

Conceptually, a `Message` object consists of `headers` and `payloads`. Headers are **RFC 2822** style field names and values where the field name and value are separated by a colon. The colon is not part of either the field name or the field value.

Headers are stored and returned in case-preserving form but are matched case-insensitively. There may also be a single envelope header, also known as the `Unix-From` header or the `From_` header. The payload is either a string in the case of simple message objects or a list of `Message` objects for MIME container documents (e.g. `multipart/*` and `message/rfc822`).

`Message` objects provide a mapping style interface for accessing the message headers, and an explicit interface for accessing both the headers and the payload. It provides convenience methods for generating a flat text representation of the message object tree, for accessing commonly used header parameters, and for recursively walking over the object tree.

Here are the methods of the `Message` class:

```python
class email.message.Message(policy=compat32)
```
If `policy` is specified (it must be an instance of a `policy` class) use the rules it specifies to update and serialize the representation of the message. If `policy` is not set, use the `compat32` policy, which maintains backward compatibility with the Python 3.2 version of the email package. For more information see the `policy` documentation.

*Changed in version 3.3:* The `policy` keyword argument was added.

**as_string**(`unixfrom=False, maxheaderlen=0, policy=None`)

Return the entire message flattened as a string. When optional `unixfrom` is true, the envelope header is included in the returned string. `unixfrom` defaults to `False`. For backward compatibility reasons, `maxheaderlen` defaults to 0, so if you want a different value you must override it explicitly (the value specified for `max_line_length` in the policy will be ignored by this method). The `policy` argument may be used to override the default policy obtained from the message instance. This can be used to control some of the formatting produced by the method, since the specified `policy` will be passed to the `Generator`.

Flattening the message may trigger changes to the `Message` if defaults need to be filled in to complete the transformation to a string (for example, MIME boundaries may be generated or modified).

Note that this method is provided as a convenience and may not always format the message the way you want. For example, by default it does not do the mangling of lines that begin with `From` that is required by the unix mbox format. For more flexibility, instantiate a `Generator` instance and use its `flatten()` method directly. For example:
from io import StringIO
from email.generator import Generator
fp = StringIO()
g = Generator(fp, mangle_from_=True, maxheaderlen=)
g.flatten(msg)
text = fp.getvalue()

If the message object contains binary data that is not encoded according to RFC standards, the non-compliant data will be replaced by unicode “unknown character” code points. (See also as_bytes() and BytesGenerator.)

Changed in version 3.4: the policy keyword argument was added.

__str__()
Equivalent to as_string(). Allows str(msg) to produce a string containing the formatted message.

as_bytes(unixfrom=False, policy=None)
Return the entire message flattened as a bytes object. When optional unixfrom is true, the envelope header is included in the returned string. unixfrom defaults to False. The policy argument may be used to override the default policy obtained from the message instance. This can be used to control some of the formatting produced by the method, since the specified policy will be passed to the BytesGenerator.

Flattening the message may trigger changes to the Message if defaults need to be filled in to complete the transformation to a string (for example, MIME boundaries may be generated or modified).
Note that this method is provided as a convenience and may not always format the message the way you want. For example, by default it does not do the mangling of lines that begin with `From` that is required by the unix mbox format. For more flexibility, instantiate a `BytesGenerator` instance and use its `flatten()` method directly. For example:

```python
from io import BytesIO
from email.generator import BytesGenerator
fp = BytesIO()
g = BytesGenerator(fp, mangle_from_=True, maxheaderlen)
g.flatten(msg)
text = fp.getvalue()
```

*New in version 3.4.*

`__bytes__()`

Equivalent to `as_bytes()`. Allows `bytes(msg)` to produce a bytes object containing the formatted message.

*New in version 3.4.*

`is_multipart()`

Return `True` if the message's payload is a list of sub-`Message` objects, otherwise return `False`. When `is_multipart()` returns `False`, the payload should be a string object.

`set_unixfrom(unixfrom)`

Set the message's envelope header to `unixfrom`, which should be a string.

`get_unixfrom()`
Return the message’s envelope header. Defaults to None if the envelope header was never set.

**attach(payload)**

Add the given *payload* to the current payload, which must be None or a list of *Message* objects before the call. After the call, the payload will always be a list of *Message* objects. If you want to set the payload to a scalar object (e.g. a string), use *set_payload()* instead.

**get_payload**(i=None, decode=False)

Return the current payload, which will be a list of *Message* objects when *is_multipart()* is True, or a string when *is_multipart()* is False. If the payload is a list and you mutate the list object, you modify the message's payload in place.

With optional argument *i*, *get_payload()* will return the *i*-th element of the payload, counting from zero, if *is_multipart()* is True. An IndexError will be raised if *i* is less than 0 or greater than or equal to the number of items in the payload. If the payload is a string (i.e. *is_multipart()* is False) and *i* is given, a TypeError is raised.

Optional *decode* is a flag indicating whether the payload should be decoded or not, according to the *Content-Transfer-Encoding* header. When True and the message is not a multipart, the payload will be decoded if this header's value is quoted-printable or base64. If some other encoding is used, or *Content-Transfer-Encoding* header is missing, the payload is returned as-is (undecoded). In all cases the returned value is binary data. If the message is a multipart and the *decode* flag is
True, then None is returned. If the payload is base64 and it was not perfectly formed (missing padding, characters outside the base64 alphabet), then an appropriate defect will be added to the message's defect property (InvalidBase64PaddingDefect or InvalidBase64CharactersDefect, respectively).

When decode is False (the default) the body is returned as a string without decoding the Content-Transfer-Encoding. However, for a Content-Transfer-Encoding of 8bit, an attempt is made to decode the original bytes using the charset specified by the Content-Type header, using the replace error handler. If no charset is specified, or if the charset given is not recognized by the email package, the body is decoded using the default ASCII charset.

**set_payload**(payload, charset=None)
Set the entire message object's payload to payload. It is the client's responsibility to ensure the payload invariants. Optional charset sets the message's default character set; see set_charset() for details.

**set_charset**(charset)
Set the character set of the payload to charset, which can either be a Charset instance (see email.charset), a string naming a character set, or None. If it is a string, it will be converted to a Charset instance. If charset is None, the charset parameter will be removed from the Content-Type header (the message will not be otherwise modified). Anything else will generate a TypeError.

If there is no existing MIME-Version header one will be added. If
there is no existing Content-Type header, one will be added with a value of text/plain. Whether the Content-Type header already exists or not, its charset parameter will be set to charset.output_charset. If charset.input_charset and charset.output_charset differ, the payload will be re-encoded to the output charset. If there is no existing Content-Transfer-Encoding header, then the payload will be transfer-encoded, if needed, using the specified Charset, and a header with the appropriate value will be added. If a Content-Transfer-Encoding header already exists, the payload is assumed to already be correctly encoded using that Content-Transfer-Encoding and is not modified.

get_charset()

Return the Charset instance associated with the message’s payload.

The following methods implement a mapping-like interface for accessing the message’s RFC 2822 headers. Note that there are some semantic differences between these methods and a normal mapping (i.e. dictionary) interface. For example, in a dictionary there are no duplicate keys, but here there may be duplicate message headers. Also, in dictionaries there is no guaranteed order to the keys returned by keys(), but in a Message object, headers are always returned in the order they appeared in the original message, or were added to the message later. Any header deleted and then re-added are always appended to the end of the header list.

These semantic differences are intentional and are biased toward maximal convenience.
Note that in all cases, any envelope header present in the message is not included in the mapping interface.

In a model generated from bytes, any header values that (in contravention of the RFCs) contain non-ASCII bytes will, when retrieved through this interface, be represented as Header objects with a charset of unknown-8bit.

__len__()  
Return the total number of headers, including duplicates.

__contains__(name)  
Return true if the message object has a field named name. Matching is done case-insensitively and name should not include the trailing colon. Used for the in operator, e.g.:

```python
if 'message-id' in myMessage:
    print('Message-ID:', myMessage['message-id'])
```

__getitem__(name)  
Return the value of the named header field. name should not include the colon field separator. If the header is missing, None is returned; a KeyError is never raised.

Note that if the named field appears more than once in the message's headers, exactly which of those field values will be returned is undefined. Use the get_all() method to get the values of all the extant named headers.

__setitem__(name, val)  
Add a header to the message with field name name and value val. The field is appended to the end of the message's existing
fields.

Note that this does not overwrite or delete any existing header with the same name. If you want to ensure that the new header is the only one present in the message with field name `name`, delete the field first, e.g.:

```python
del msg['subject']
msg['subject'] = 'Python roolz!'```

`__delitem__(name)`
Delete all occurrences of the field with name `name` from the message's headers. No exception is raised if the named field isn't present in the headers.

`keys()`
Return a list of all the message's header field names.

`values()`
Return a list of all the message's field values.

`items()`
Return a list of 2-tuples containing all the message's field headers and values.

`get(name, failobj=None)`
Return the value of the named header field. This is identical to `__getitem__()`, except that optional `failobj` is returned if the named header is missing (defaults to `None`).

Here are some additional useful methods:

`get_all(name, failobj=None)`
Return a list of all the values for the field named name. If there are no such named headers in the message, failobj is returned (defaults to None).

**add_header**(_name, _value, **_params)

Extended header setting. This method is similar to **__setitem__()** except that additional header parameters can be provided as keyword arguments. _name is the header field to add and _value is the primary value for the header.

For each item in the keyword argument dictionary _params, the key is taken as the parameter name, with underscores converted to dashes (since dashes are illegal in Python identifiers). Normally, the parameter will be added as key="value" unless the value is None, in which case only the key will be added. If the value contains non-ASCII characters, it can be specified as a three tuple in the format (CHARSET, LANGUAGE, VALUE), where CHARSET is a string naming the charset to be used to encode the value, LANGUAGE can usually be set to None or the empty string (see RFC 2231 for other possibilities), and VALUE is the string value containing non-ASCII code points. If a three tuple is not passed and the value contains non-ASCII characters, it is automatically encoded in RFC 2231 format using a CHARSET of utf-8 and a LANGUAGE of None.

Here's an example:

```python
code
msg.add_header('Content-Disposition', 'attachment')
```

This will add a header that looks like
An example with non-ASCII characters:

```python
msg.add_header('Content-Disposition', 'attachment',
               filename=('iso-8859-1', '', 'Fußballer.ppt'))
```

Which produces

```plaintext
Content-Disposition: attachment; filename*="iso-8859-1''Fu%DFballer.ppt"
```

**replace_header(_name, _value)**

Replace a header. Replace the first header found in the message that matches _name, retaining header order and field name case. If no matching header was found, a `KeyError` is raised.

**get_content_type()**

Return the message's content type. The returned string is coerced to lower case of the form `maintype/subtype`. If there was no `Content-Type` header in the message the default type as given by `get_default_type()` will be returned. Since according to **RFC 2045**, messages always have a default type, `get_content_type()` will always return a value.

**RFC 2045** defines a message's default type to be `text/plain` unless it appears inside a `multipart/digest` container, in which case it would be `message/rfc822`. If the `Content-Type` header has an invalid type specification, **RFC 2045** mandates that the default type be `text/plain`. 
get_content_maintype()
    Return the message's main content type. This is the maintype part of the string returned by get_content_type().

get_content_subtype()
    Return the message's sub-content type. This is the subtype part of the string returned by get_content_type().

get_default_type()
    Return the default content type. Most messages have a default content type of text/plain, except for messages that are subparts of multipart/digest containers. Such subparts have a default content type of message/rfc822.

set_default_type(ctype)
    Set the default content type. ctype should either be text/plain or message/rfc822, although this is not enforced. The default content type is not stored in the Content-Type header.

get_params(failobj=None, header='content-type', unquote=True)
    Return the message's Content-Type parameters, as a list. The elements of the returned list are 2-tuples of key/value pairs, as split on the '=' sign. The left hand side of the '=' is the key, while the right hand side is the value. If there is no '=' sign in the parameter the value is the empty string, otherwise the value is as described in get_param() and is unquoted if optional unquote is True (the default).

    Optional failobj is the object to return if there is no Content-Type header. Optional header is the header to search instead of Content-Type.
get_param(param, failobj=None, header='content-type', unquote=True)

Return the value of the Content-Type header’s parameter param as a string. If the message has no Content-Type header or if there is no such parameter, then failobj is returned (defaults to None).

Optional header if given, specifies the message header to use instead of Content-Type.

Parameter keys are always compared case insensitively. The return value can either be a string, or a 3-tuple if the parameter was RFC 2231 encoded. When it’s a 3-tuple, the elements of the value are of the form (CHARSET, LANGUAGE, VALUE). Note that both CHARSET and LANGUAGE can be None, in which case you should consider VALUE to be encoded in the us-ascii charset. You can usually ignore LANGUAGE.

If your application doesn’t care whether the parameter was encoded as in RFC 2231, you can collapse the parameter value by calling email.utils.collapse_rfc2231_value(), passing in the return value from get_param(). This will return a suitably decoded Unicode string when the value is a tuple, or the original string unquoted if it isn’t. For example:

```python
rawparam = msg.get_param('foo')
param = email.utils.collapse_rfc2231_value(rawparam)
```

In any case, the parameter value (either the returned string, or the VALUE item in the 3-tuple) is always unquoted, unless unquote is set to False.
**set_param**(*param*, *value*, *header='Content-Type'*, *requote=True, charset=None, language='', replace=False*)

Set a parameter in the **Content-Type** header. If the parameter already exists in the header, its value will be replaced with *value*. If the **Content-Type** header as not yet been defined for this message, it will be set to *text/plain* and the new parameter value will be appended as per **RFC 2045**.

Optional *header* specifies an alternative header to **Content-Type**, and all parameters will be quoted as necessary unless optional *requote* is **False** (the default is **True**).

If optional *charset* is specified, the parameter will be encoded according to **RFC 2231**. Optional *language* specifies the RFC 2231 language, defaulting to the empty string. Both *charset* and *language* should be strings.

If *replace* is **False** (the default) the header is moved to the end of the list of headers. If *replacement* is **True**, the header will be updated in place.

*Changed in version 3.4:* *replace* keyword was added.

**del_param**(*param*, *header='content-type'*, *requote=True*)

Remove the given parameter completely from the **Content-Type** header. The header will be re-written in place without the parameter or its value. All values will be quoted as necessary unless *requote* is **False** (the default is **True**). Optional *header* specifies an alternative to **Content-Type**.

**set_type**(*type*, *header='Content-Type'*, *requote=True*)

Set the main type and subtype for the **Content-Type** header. *type* must be a string in the form *maintype/subtype*, otherwise a
ValueError is raised.

This method replaces the Content-Type header, keeping all the parameters in place. If requote is False, this leaves the existing header’s quoting as is, otherwise the parameters will be quoted (the default).

An alternative header can be specified in the header argument. When the Content-Type header is set a MIME-Version header is also added.

get_filename(failobj=None)
Return the value of the filename parameter of the Content-Disposition header of the message. If the header does not have a filename parameter, this method falls back to looking for the name parameter on the Content-Type header. If neither is found, or the header is missing, then failobj is returned. The returned string will always be unquoted as per email.utils.unquote().

get_boundary(failobj=None)
Return the value of the boundary parameter of the Content-Type header of the message, or failobj if either the header is missing, or has no boundary parameter. The returned string will always be unquoted as per email.utils.unquote().

set_boundary(boundary)
Set the boundary parameter of the Content-Type header to boundary. set_boundary() will always quote boundary if necessary. A HeaderParseError is raised if the message object has no Content-Type header.
Note that using this method is subtly different than deleting the old Content-Type header and adding a new one with the new boundary via add_header(), because set_boundary() preserves the order of the Content-Type header in the list of headers. However, it does *not* preserve any continuation lines which may have been present in the original Content-Type header.

**get_content_charset** *(failobj=None)*

Return the charset parameter of the Content-Type header, coerced to lower case. If there is no Content-Type header, or if that header has no charset parameter, failobj is returned.

Note that this method differs from get_charset() which returns the Charset instance for the default encoding of the message body.

**get_charsets** *(failobj=None)*

Return a list containing the character set names in the message. If the message is a *multipart*, then the list will contain one element for each subpart in the payload, otherwise, it will be a list of length 1.

Each item in the list will be a string which is the value of the charset parameter in the Content-Type header for the represented subpart. However, if the subpart has no Content-Type header, no charset parameter, or is not of the *text* main MIME type, then that item in the returned list will be failobj.

**walk()**

The walk() method is an all-purpose generator which can be used to iterate over all the parts and subparts of a message.
object tree, in depth-first traversal order. You will typically use `walk()` as the iterator in a `for` loop; each iteration returns the next subpart.

Here's an example that prints the MIME type of every part of a multipart message structure:

```python
>>> for part in msg.walk():
    ...   print(part.get_content_type())
multipart/report
text/plain
message/delivery-status
text/plain
text/plain
message/rfc822
text/plain
```

Message objects can also optionally contain two instance attributes, which can be used when generating the plain text of a MIME message.

**preamble**

The format of a MIME document allows for some text between the blank line following the headers, and the first multipart boundary string. Normally, this text is never visible in a MIME-aware mail reader because it falls outside the standard MIME armor. However, when viewing the raw text of the message, or when viewing the message in a non-MIME aware reader, this text can become visible.

The `preamble` attribute contains this leading extra-armor text for MIME documents. When the `Parser` discovers some text after the headers but before the first boundary string, it assigns this text to the message's `preamble` attribute. When the
Generator is writing out the plain text representation of a MIME message, and it finds the message has a preamble attribute, it will write this text in the area between the headers and the first boundary. See email.parser and email.generator for details.

Note that if the message object has no preamble, the preamble attribute will be None.

epilogue

The epilogue attribute acts the same way as the preamble attribute, except that it contains text that appears between the last boundary and the end of the message.

You do not need to set the epilogue to the empty string in order for the Generator to print a newline at the end of the file.

defects

The defects attribute contains a list of all the problems found when parsing this message. See email.errors for a detailed description of the possible parsing defects.
19.1.2. email.parser: Parsing email messages

Message object structures can be created in one of two ways: they can be created from whole cloth by instantiating `Message` objects and stringing them together via `attach()` and `set_payload()` calls, or they can be created by parsing a flat text representation of the email message.

The `email` package provides a standard parser that understands most email document structures, including MIME documents. You can pass the parser a string or a file object, and the parser will return to you the root `Message` instance of the object structure. For simple, non-MIME messages the payload of this root object will likely be a string containing the text of the message. For MIME messages, the root object will return `True` from its `is_multipart()` method, and the subparts can be accessed via the `get_payload()` and `walk()` methods.

There are actually two parser interfaces available for use, the classic `Parser` API and the incremental `FeedParser` API. The classic `Parser` API is fine if you have the entire text of the message in memory as a string, or if the entire message lives in a file on the file system. `FeedParser` is more appropriate for when you're reading the message from a stream which might block waiting for more input (e.g. reading an email message from a socket). The `FeedParser` can consume and parse the message incrementally, and only returns the root object when you close the parser [1].

Note that the parser can be extended in limited ways, and of course
you can implement your own parser completely from scratch. There is no magical connection between the `email` package's bundled parser and the `Message` class, so your custom parser can create message object trees any way it finds necessary.
19.1.2.1. FeedParser API

The FeedParser, imported from the email.feedparser module, provides an API that is conducive to incremental parsing of email messages, such as would be necessary when reading the text of an email message from a source that can block (e.g. a socket). The FeedParser can of course be used to parse an email message fully contained in a string or a file, but the classic Parser API may be more convenient for such use cases. The semantics and results of the two parser APIs are identical.

The FeedParser's API is simple; you create an instance, feed it a bunch of text until there's no more to feed it, then close the parser to retrieve the root message object. The FeedParser is extremely accurate when parsing standards-compliant messages, and it does a very good job of parsing non-compliant messages, providing information about how a message was deemed broken. It will populate a message object's defects attribute with a list of any problems it found in a message. See the email.errors module for the list of defects that it can find.

Here is the API for the FeedParser:

class email.parser.FeedParser(_factory=email.message.Message, *, policy=policy.default)

Create a FeedParser instance. Optional _factory is a no-argument callable that will be called whenever a new message object is needed. It defaults to the email.message.Message class.
The *policy* keyword specifies a *policy* object that controls a number of aspects of the parser’s operation. The default policy maintains backward compatibility.

*Changed in version 3.3: Added the policy keyword.*

**feed**(data)

Feed the *FeedParser* some more data. *data* should be a string containing one or more lines. The lines can be partial and the *FeedParser* will stitch such partial lines together properly. The lines in the string can have any of the common three line endings, carriage return, newline, or carriage return and newline (they can even be mixed).

**close()**

Closing a *FeedParser* completes the parsing of all previously fed data, and returns the root message object. It is undefined what happens if you feed more data to a closed *FeedParser*.

```python
class email.parser.BytesFeedParser(_factory=email.message.Message)
    Works exactly like *FeedParser* except that the input to the *feed()* method must be bytes and not string.
```

*New in version 3.2.*
19.1.2.2. Parser class API

The **Parser** class, imported from the `email.parser` module, provides an API that can be used to parse a message when the complete contents of the message are available in a string or file. The `email.parser` module also provides header-only parsers, called `HeaderParser` and `BytesHeaderParser`, which can be used if you're only interested in the headers of the message. `HeaderParser` and `BytesHeaderParser` can be much faster in these situations, since they do not attempt to parse the message body, instead setting the payload to the raw body as a string. They have the same API as the **Parser** and **BytesParser** classes.

*New in version 3.3:* The `BytesHeaderParser` class.

```python
class email.parser.Parser(_class=email.message.Message, *, policy=policy.default)
```

The constructor for the **Parser** class takes an optional argument `_class`. This must be a callable factory (such as a function or a class), and it is used whenever a sub-message object needs to be created. It defaults to `Message` (see `email.message`). The factory will be called without arguments.

The `policy` keyword specifies a `policy` object that controls a number of aspects of the parser's operation. The default policy maintains backward compatibility.

*Changed in version 3.3:* Removed the `strict` argument that was deprecated in 2.4. Added the `policy` keyword.

The other public **Parser** methods are:
**parse**(*fp*, *headersonly=False*)

Read all the data from the file-like object *fp*, parse the resulting text, and return the root message object. *fp* must support both the `readline()` and the `read()` methods on file-like objects.

The text contained in *fp* must be formatted as a block of RFC 2822 style headers and header continuation lines, optionally preceded by an envelope header. The header block is terminated either by the end of the data or by a blank line. Following the header block is the body of the message (which may contain MIME-encoded subparts).

Optional *headersonly* is a flag specifying whether to stop parsing after reading the headers or not. The default is `False`, meaning it parses the entire contents of the file.

**parsestr**(*text*, *headersonly=False*)

Similar to the `parse()` method, except it takes a string object instead of a file-like object. Calling this method on a string is exactly equivalent to wrapping *text* in a `StringIO` instance first and calling `parse()`.

Optional *headersonly* is as with the `parse()` method.

class email.parser.BytesParser(_class=email.message.Message, *, policy=policy.default)

This class is exactly parallel to `Parser`, but handles bytes input. The `_class` and `strict` arguments are interpreted in the same way as for the `Parser` constructor.

The `policy` keyword specifies a `policy` object that controls a number of aspects of the parser’s operation. The default policy.
maintains backward compatibility.

Changed in version 3.3: Removed the strict argument. Added the policy keyword.

**parse**(fp, headeronly=False)
Read all the data from the binary file-like object fp, parse the resulting bytes, and return the message object. fp must support both the readline() and the read() methods on file-like objects.

The bytes contained in fp must be formatted as a block of RFC 2822 style headers and header continuation lines, optionally preceded by a envelope header. The header block is terminated either by the end of the data or by a blank line. Following the header block is the body of the message (which may contain MIME-encoded subparts, including subparts with a Content-Transfer-Encoding of 8bit).

Optional headersonly is a flag specifying whether to stop parsing after reading the headers or not. The default is False, meaning it parses the entire contents of the file.

**parsebytes**(bytes, headersonly=False)
Similar to the parse() method, except it takes a byte string object instead of a file-like object. Calling this method on a byte string is exactly equivalent to wrapping text in a BytesIO instance first and calling parse().

Optional headersonly is as with the parse() method.

New in version 3.2.
Since creating a message object structure from a string or a file object is such a common task, four functions are provided as a convenience. They are available in the top-level `email` package namespace.

```python
eemail.message_from_string(s, _class=email.message.Message, *, policy=policy.default)
```

Return a message object structure from a string. This is exactly equivalent to `Parser().parsestr(s)`. `_class` and `policy` are interpreted as with the `Parser` class constructor.

*Changed in version 3.3:* Removed the `strict` argument. Added the `policy` keyword.

```python
eemail.message_from_bytes(s, _class=email.message.Message, *, policy=policy.default)
```

Return a message object structure from a byte string. This is exactly equivalent to `BytesParser().parsebytes(s)`. Optional `_class` and `strict` are interpreted as with the `Parser` class constructor.

*New in version 3.2.*

*Changed in version 3.3:* Removed the `strict` argument. Added the `policy` keyword.

```python
eemail.message_from_file(fp, _class=email.message.Message, *, policy=policy.default)
```

Return a message object structure tree from an open file object. This is exactly equivalent to `Parser().parse(fp)`. `_class` and `policy` are interpreted as with the `Parser` class constructor.

*Changed in version Removed:* the `strict` argument. Added the `policy` keyword.
email.message_from_binary_file(fp, _class=email.message.Message, *, policy=policy.default)

Return a message object structure tree from an open binary file object. This is exactly equivalent to BytesParser().parse(fp). _class and policy are interpreted as with the Parser class constructor.

New in version 3.2.

Changed in version 3.3: Removed the strict argument. Added the policy keyword.

Here's an example of how you might use this at an interactive Python prompt:

```python
>>> import email
>>> msg = email.message_from_string(myString)
```
19.1.2.3. Additional notes

Here are some notes on the parsing semantics:

- Most non-
  multipart type messages are parsed as a single message object with a string payload. These objects will return False for is_multipart(). Their get_payload() method will return a string object.
- All multipart type messages will be parsed as a container message object with a list of sub-message objects for their payload. The outer container message will return True for is_multipart() and their get_payload() method will return the list of Message subparts.
- Most messages with a content type of message/* (e.g. message/delivery-status and message/rfc822) will also be parsed as container object containing a list payload of length 1. Their is_multipart() method will return True. The single element in the list payload will be a sub-message object.
- Some non-standards compliant messages may not be internally consistent about their multipart-edness. Such messages may have a Content-Type header of type multipart, but their is_multipart() method may return False. If such messages were parsed with the FeedParser, they will have an instance of the MultipartInvariantViolationDefect class in their defects attribute list. See email.errors for details.

Footnotes

[1] As of email package version 3.0, introduced in Python 2.4, the classic Parser was re-implemented in terms of the FeedParser, so the semantics and results are identical between the two parsers.
19.1.3. 

Generating MIME documents

One of the most common tasks is to generate the flat text of the email message represented by a message object structure. You will need to do this if you want to send your message via the `smtplib` module or the `nntplib` module, or print the message on the console. Taking a message object structure and producing a flat text document is the job of the `Generator` class.

Again, as with the `email.parser` module, you aren’t limited to the functionality of the bundled generator; you could write one from scratch yourself. However the bundled generator knows how to generate most email in a standards-compliant way, should handle MIME and non-MIME email messages just fine, and is designed so that the transformation from flat text, to a message structure via the `Parser` class, and back to flat text, is idempotent (the input is identical to the output) [1]. On the other hand, using the Generator on a `Message` constructed by program may result in changes to the `Message` object as defaults are filled in.

`bytes` output can be generated using the `BytesGenerator` class. If the message object structure contains non-ASCII bytes, this generator’s `flatten()` method will emit the original bytes. Parsing a binary message and then flattening it with `BytesGenerator` should be idempotent for standards compliant messages.

Here are the public methods of the `Generator` class, imported from the `email.generator` module:
class email.generator.**Generator**(*outfp*, *mangle_from_=True, maxheaderlen=78, *, *policy=None*)

The constructor for the Generator class takes a file-like object called *outfp* for an argument. *outfp* must support the `write()` method and be usable as the output file for the `print()` function.

Optional *mangle_from_* is a flag that, when True, puts a > character in front of any line in the body that starts exactly as From, i.e. From followed by a space at the beginning of the line. This is the only guaranteed portable way to avoid having such lines be mistaken for a Unix mailbox format envelope header separator (see WHY THE CONTENT-LENGTH FORMAT IS BAD for details). *mangle_from_* defaults to True, but you might want to set this to False if you are not writing Unix mailbox format files.

Optional *maxheaderlen* specifies the longest length for a non-continued header. When a header line is longer than *maxheaderlen* (in characters, with tabs expanded to 8 spaces), the header will be split as defined in the Header class. Set to zero to disable header wrapping. The default is 78, as recommended (but not required) by RFC 2822.

The *policy* keyword specifies a policy object that controls a number of aspects of the generator’s operation. If no *policy* is specified, then the *policy* attached to the message object passed to flatten is used.

*Changed in version 3.3:* Added the *policy* keyword.

The other public Generator methods are:

**flatten**(msg, unixfrom=False, linesep=None)
Print the textual representation of the message object structure rooted at `msg` to the output file specified when the Generator instance was created. Subparts are visited depth-first and the resulting text will be properly MIME encoded.

Optional `unixfrom` is a flag that forces the printing of the envelope header delimiter before the first RFC 2822 header of the root message object. If the root object has no envelope header, a standard one is crafted. By default, this is set to `False` to inhibit the printing of the envelope delimiter.

Note that for subparts, no envelope header is ever printed.

Optional `linesep` specifies the line separator character used to terminate lines in the output. If specified it overrides the value specified by the `msg`'s or Generator's policy.

Because strings cannot represent non-ASCII bytes, if the policy that applies when `flatten` is run has `cte_type` set to 8bit, Generator will operate as if it were set to 7bit. This means that messages parsed with a Bytes parser that have a `Content-Transfer-Encoding` of 8bit will be converted to use a 7bit Content-Transfer-Encoding. Non-ASCII bytes in the headers will be RFC 2047 encoded with a charset of unknown-8bit.

*Changed in version 3.2*: Added support for re-encoding 8bit message bodies, and the `linesep` argument.

`clone(fp)`

Return an independent clone of this Generator instance with the exact same options.

`write(s)`
Write the string \( s \) to the underlying file object, i.e. `outfp` passed to `Generator`'s constructor. This provides just enough file-like API for `Generator` instances to be used in the `print()` function.

As a convenience, see the `Message` methods `as_string()` and `str(aMessage)`, a.k.a. `__str__()`, which simplify the generation of a formatted string representation of a message object. For more detail, see `email.message`.

```python
class email.generator.BytesGenerator(outfp, mangle_from_=True, maxheaderlen=78, *, policy=policy.default)
```

The constructor for the `BytesGenerator` class takes a binary file-like object called `outfp` for an argument. `outfp` must support a `write()` method that accepts binary data.

Optional `mangle_from_` is a flag that, when `True`, puts a `>` character in front of any line in the body that starts exactly as `From`, i.e. `From` followed by a space at the beginning of the line. This is the only guaranteed portable way to avoid having such lines be mistaken for a Unix mailbox format envelope header separator (see [WHY THE CONTENT-LENGTH FORMAT IS BAD](#) for details). `mangle_from_` defaults to `True`, but you might want to set this to `False` if you are not writing Unix mailbox format files.

Optional `maxheaderlen` specifies the longest length for a non-continued header. When a header line is longer than `maxheaderlen` (in characters, with tabs expanded to 8 spaces), the header will be split as defined in the `Header` class. Set to zero to disable header wrapping. The default is 78, as recommended (but not required) by [RFC 2822](https://tools.ietf.org/html/rfc2822).
The *policy* keyword specifies a *policy* object that controls a number of aspects of the generator’s operation. The default policy maintains backward compatibility.

*Changed in version 3.3:* Added the *policy* keyword.

The other public *BytesGenerator* methods are:

**flatten**(*msg*, *unixfrom=False*, *linesep=None*)

Print the textual representation of the message object structure rooted at *msg* to the output file specified when the *BytesGenerator* instance was created. Subparts are visited depth-first and the resulting text will be properly MIME encoded. If the *policy* option *cte_type* is 8bit (the default), then any bytes with the high bit set in the original parsed message that have not been modified will be copied faithfully to the output. If *cte_type* is 7bit, the bytes will be converted as needed using an ASCII-compatible Content-Transfer-Encoding. In particular, RFC-invalid non-ASCII bytes in headers will be encoded using the MIME unknown-8bit character set, thus rendering them RFC-compliant.

Messages parsed with a Bytes parser that have a *Content-Transfer-Encoding* of 8bit will be reconstructed as 8bit if they have not been modified.

Optional *unixfrom* is a flag that forces the printing of the envelope header delimiter before the first RFC 2822 header of the root message object. If the root object has no envelope header, a standard one is crafted. By default, this is set to False to inhibit the printing of the envelope delimiter.

Note that for subparts, no envelope header is ever printed.
Optional *linesep* specifies the line separator character used to terminate lines in the output. If specified it overrides the value specified by the `Generator`'s policy.

**clone**(*fp*)

Return an independent clone of this `BytesGenerator` instance with the exact same options.

**write**(*s*)

Write the string *s* to the underlying file object. *s* is encoded using the ASCII codec and written to the `write` method of the `outfp` passed to the `BytesGenerator`'s constructor. This provides just enough file-like API for `BytesGenerator` instances to be used in the `print()` function.

*New in version 3.2.*

The `email.generator` module also provides a derived class, called `DecodedGenerator` which is like the `Generator` base class, except that non-text parts are substituted with a format string representing the part.

**class** `email.generator.**DecodedGenerator**`(*outfp, mangle_from_=True, maxheaderlen=78, fmt=None*)

This class, derived from `Generator` walks through all the subparts of a message. If the subpart is of main type `text`, then it prints the decoded payload of the subpart. Optional `_mangle_from_` and `maxheaderlen` are as with the `Generator` base class.

If the subpart is not of main type `text`, optional `fmt` is a format string that is used instead of the message payload. `fmt` is expanded with
the following keywords, \%(keyword)s format:

- **type** – Full MIME type of the non-text part
- **maintype** – Main MIME type of the non-text part
- **subtype** – Sub-MIME type of the non-text part
- **filename** – Filename of the non-text part
- **description** – Description associated with the non-text part
- **encoding** – Content transfer encoding of the non-text part

The default value for *fmt* is *None*, meaning

```python
[Non-text \%(type)s) part of message omitted, fil
```

---

**Footnotes**

This statement assumes that you use the appropriate setting for the `unixfrom` argument, and that you set `maxheaderlen=0` (which will preserve whatever the input line lengths were). It is also not strictly true, since in many cases runs of whitespace in headers are collapsed into single blanks. The latter is a bug that will eventually be fixed.

[1]
19.1. **email** — An email and MIME handling package
19.1.4. email.policy: Policy Objects

New in version 3.3.

The email package's prime focus is the handling of email messages as described by the various email and MIME RFCs. However, the general format of email messages (a block of header fields each consisting of a name followed by a colon followed by a value, the whole block followed by a blank line and an arbitrary ‘body’), is a format that has found utility outside of the realm of email. Some of these uses conform fairly closely to the main RFCs, some do not. And even when working with email, there are times when it is desirable to break strict compliance with the RFCs.

Policy objects give the email package the flexibility to handle all these disparate use cases.

A Policy object encapsulates a set of attributes and methods that control the behavior of various components of the email package during use. Policy instances can be passed to various classes and methods in the email package to alter the default behavior. The settable values and their defaults are described below.

There is a default policy used by all classes in the email package. This policy is named Compat32, with a corresponding pre-defined instance named compat32. It provides for complete backward compatibility (in some cases, including bug compatibility) with the pre-Python3.3 version of the email package.

The first part of this documentation covers the features of Policy, an
**abstract base class** that defines the features that are common to all policy objects, including compat32. This includes certain hook methods that are called internally by the email package, which a custom policy could override to obtain different behavior.

When a Message object is created, it acquires a policy. By default this will be compat32, but a different policy can be specified. If the Message is created by a parser, a policy passed to the parser will be the policy used by the Message it creates. If the Message is created by the program, then the policy can be specified when it is created. When a Message is passed to a generator, the generator uses the policy from the Message by default, but you can also pass a specific policy to the generator that will override the one stored on the Message object.

Policy instances are immutable, but they can be cloned, accepting the same keyword arguments as the class constructor and returning a new Policy instance that is a copy of the original but with the specified attributes values changed.

As an example, the following code could be used to read an email message from a file on disk and pass it to the system sendmail program on a Unix system:

```python
>>> from email import message_from_binary_file
>>> from email.generator import BytesGenerator
>>> from email import policy
>>> from subprocess import Popen, PIPE
>>> with open('mymsg.txt', 'rb') as f:
...     msg = message_from_binary_file(f, policy=policy)
>>> p = Popen(['sendmail', msg['To'].addresses[0]],
>>> g = BytesGenerator(p.stdin, policy=msg.policy.clone)
>>> g.flatten(msg)
```
Here we are telling BytesGenerator to use the RFC correct line separator characters when creating the binary string to feed into sendmail's stdin, where the default policy would use \n line separators.

Some email package methods accept a policy keyword argument, allowing the policy to be overridden for that method. For example, the following code uses the as_string() method of the msg object from the previous example and writes the message to a file using the native line separators for the platform on which it is running:

Policy objects can also be combined using the addition operator, producing a policy object whose settings are a combination of the non-default values of the summed objects:

This operation is not commutative; that is, the order in which the objects are added matters. To illustrate:
class email.policy.\texttt{Policy}(**kw)

This is the \textit{abstract base class} for all policy classes. It provides
default implementations for a couple of trivial methods, as well as
the implementation of the immutability property, the \texttt{clone()} method, and the constructor semantics.

The constructor of a policy class can be passed various keyword arguments. The arguments that may be specified are any non-
method properties on this class, plus any additional non-method properties on the concrete class. A value specified in the
constructor will override the default value for the corresponding attribute.

This class defines the following properties, and thus values for the following may be passed in the constructor of any policy class:

\textbf{max\_line\_length}

The maximum length of any line in the serialized output, not
counting the end of line character(s). Default is 78, per \texttt{RFC 5322}. A value of \texttt{0} or \texttt{None} indicates that no line wrapping
should be done at all.

\textbf{linesep}

The string to be used to terminate lines in serialized output. The
default is \texttt{\n} because that’s the internal end-of-line discipline
used by Python, though \texttt{\r\n} is required by the RFCs.
**cte_type**

Controls the type of Content Transfer Encodings that may be or are required to be used. The possible values are:

<table>
<thead>
<tr>
<th>cte_type</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>7bit</td>
<td>All data must be “7 bit clean” (ASCII-only). This means that where necessary data will be encoded using either quoted-printable or base64 encoding.</td>
</tr>
<tr>
<td>8bit</td>
<td>Data is not constrained to be 7 bit clean. Data in headers is still required to be ASCII-only and so will be encoded (see ‘binary_fold’ below for an exception), but body parts may use the 8bit CTE.</td>
</tr>
</tbody>
</table>

A cte_type value of 8bit only works with BytesGenerator, not Generator, because strings cannot contain binary data. If a Generator is operating under a policy that specifies cte_type=8bit, it will act as if cte_type is 7bit.

**raise_on_defect**

If True, any defects encountered will be raised as errors. If False (the default), defects will be passed to the register_defect() method.

The following Policy method is intended to be called by code using the email library to create policy instances with custom settings:

**clone(**kw**)

Return a new Policy instance whose attributes have the same values as the current instance, except where those attributes are given new values by the keyword arguments.

The remaining Policy methods are called by the email package...
code, and are not intended to be called by an application using the email package. A custom policy must implement all of these methods.

**handle_defect**(obj, defect)

Handle a defect found on obj. When the email package calls this method, defect will always be a subclass of Defect.

The default implementation checks the raise_on_defect flag. If it is True, defect is raised as an exception. If it is False (the default), obj and defect are passed to register_defect().

**register_defect**(obj, defect)

Register a defect on obj. In the email package, defect will always be a subclass of Defect.

The default implementation calls the append method of the defects attribute of obj. When the email package calls handle_defect, obj will normally have a defects attribute that has an append method. Custom object types used with the email package (for example, custom Message objects) should also provide such an attribute, otherwise defects in parsed messages will raise unexpected errors.

**header_max_count**(name)

Return the maximum allowed number of headers named name.

Called when a header is added to a Message object. If the returned value is not 0 or None, and there are already a number of headers with the name name equal to the value returned, a ValueError is raised.
Because the default behavior of `Message.__setitem__` is to append the value to the list of headers, it is easy to create duplicate headers without realizing it. This method allows certain headers to be limited in the number of instances of that header that may be added to a `Message` programmatically. (The limit is not observed by the parser, which will faithfully produce as many headers as exist in the message being parsed.)

The default implementation returns `None` for all header names.

**header_source_parse**(*sourcelines*)

The email package calls this method with a list of strings, each string ending with the line separation characters found in the source being parsed. The first line includes the field header name and separator. All whitespace in the source is preserved. The method should return the `(name, value)` tuple that is to be stored in the `Message` to represent the parsed header.

If an implementation wishes to retain compatibility with the existing email package policies, `name` should be the case preserved name (all characters up to the `:` separator), while `value` should be the unfolded value (all line separator characters removed, but whitespace kept intact), stripped of leading whitespace.

*sourcelines* may contain surrogateescaped binary data.

There is no default implementation

**header_store_parse**(*name, value*)

The email package calls this method with the name and value provided by the application program when the application
program is modifying a `Message` programmatically (as opposed to a `Message` created by a parser). The method should return the `(name, value)` tuple that is to be stored in the `Message` to represent the header.

If an implementation wishes to retain compatibility with the existing email package policies, the `name` and `value` should be strings or string subclasses that do not change the content of the passed in arguments.

There is no default implementation

**header_fetch_parse**(*name*, *value*)

The email package calls this method with the `name` and `value` currently stored in the `Message` when that header is requested by the application program, and whatever the method returns is what is passed back to the application as the value of the header being retrieved. Note that there may be more than one header with the same name stored in the `Message`; the method is passed the specific name and value of the header destined to be returned to the application.

`value` may contain surrogateescaped binary data. There should be no surrogateescaped binary data in the value returned by the method.

There is no default implementation

**fold**(*name*, *value*)

The email package calls this method with the `name` and `value` currently stored in the `Message` for a given header. The method should return a string that represents that header “folded” correctly (according to the policy settings) by
composing the name with the value and inserting linesep characters at the appropriate places. See RFC 5322 for a discussion of the rules for folding email headers.

value may contain surrogateescaped binary data. There should be no surrogateescaped binary data in the string returned by the method.

fold_binary(name, value)
The same as fold(), except that the returned value should be a bytes object rather than a string.

value may contain surrogateescaped binary data. These could be converted back into binary data in the returned bytes object.

class email.policy.Compat32(**kw)
This concrete Policy is the backward compatibility policy. It replicates the behavior of the email package in Python 3.2. The policy module also defines an instance of this class, compat32, that is used as the default policy. Thus the default behavior of the email package is to maintain compatibility with Python 3.2.

The class provides the following concrete implementations of the abstract methods of Policy:

header_source_parse(sourcelines)
The name is parsed as everything up to the ‘:’ and returned unmodified. The value is determined by stripping leading whitespace off the remainder of the first line, joining all subsequent lines together, and stripping any trailing carriage return or linefeed characters.

header_store_parse(name, value)
The name and value are returned unmodified.

**header_fetch_parse**(*name, value*)

If the value contains binary data, it is converted into a `Header` object using the `unknown-8bit` charset. Otherwise it is returned unmodified.

**fold**(*name, value*)

Headers are folded using the `Header` folding algorithm, which preserves existing line breaks in the value, and wraps each resulting line to the `max_line_length`. Non-ASCII binary data are CTE encoded using the `unknown-8bit` charset.

**fold_binary**(*name, value*)

Headers are folded using the `Header` folding algorithm, which preserves existing line breaks in the value, and wraps each resulting line to the `max_line_length`. If `cte_type` is 7bit, non-ascii binary data is CTE encoded using the `unknown-8bit` charset. Otherwise the original source header is used, with its existing line breaks and any (RFC invalid) binary data it may contain.

**Note:** The documentation below describes new policies that are included in the standard library on a *provisional basis*. Backwards incompatible changes (up to and including removal of the feature) may occur if deemed necessary by the core developers.

**class** `email.policy.EmailPolicy(**kw)`

This concrete `Policy` provides behavior that is intended to be fully compliant with the current email RFCs. These include (but are not limited to) `RFC 5322`, `RFC 2047`, and the current MIME RFCs.
This policy adds new header parsing and folding algorithms. Instead of simple strings, headers are \texttt{str} subclasses with attributes that depend on the type of the field. The parsing and folding algorithm fully implement \texttt{RFC 2047} and \texttt{RFC 5322}.

In addition to the settable attributes listed above that apply to all policies, this policy adds the following additional attributes:

\textbf{refold\_source}

If the value for a header in the \texttt{Message} object originated from a \texttt{parser} (as opposed to being set by a program), this attribute indicates whether or not a generator should refold that value when transforming the message back into stream form. The possible values are:

<table>
<thead>
<tr>
<th>Attribute</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>\texttt{none}</td>
<td>all source values use original folding</td>
</tr>
<tr>
<td>\texttt{long}</td>
<td>source values that have any line that is longer than \texttt{max_line_length} will be refolded</td>
</tr>
<tr>
<td>\texttt{all}</td>
<td>all values are refolded</td>
</tr>
</tbody>
</table>

The default is \texttt{long}.

\textbf{header\_factory}

A callable that takes two arguments, \texttt{name} and \texttt{value}, where \texttt{name} is a header field name and \texttt{value} is an unfolded header field value, and returns a string subclass that represents that header. A default \texttt{header\_factory} (see \texttt{headerregistry}) is provided that understands some of the \texttt{RFC 5322} header field types. (Currently address fields and date fields have special treatment, while all other fields are treated as unstructured. This list will be completed before the extension is marked stable.)
content_manager

An object with at least two methods: `get_content` and `set_content`. When the `get_content()` or `set_content()` method of a `Message` object is called, it calls the corresponding method of this object, passing it the message object as its first argument, and any arguments or keywords that were passed to it as additional arguments. By default `content_manager` is set to `raw_data_manager`.

New in version 3.4.

The class provides the following concrete implementations of the abstract methods of `Policy`:

**header_max_count** (*name*)

Returns the value of the `max_count` attribute of the specialized class used to represent the header with the given name.

**header_source_parse** (*sourcelines*)

The implementation of this method is the same as that for the `Compat32` policy.

**header_store_parse** (*name*, *value*)

The name is returned unchanged. If the input value has a `name` attribute and it matches `name` ignoring case, the value is returned unchanged. Otherwise the `name` and `value` are passed to `header_factory`, and the resulting header object is returned as the value. In this case a `ValueError` is raised if the input value contains CR or LF characters.

**header_fetch_parse** (*name*, *value*)

If the value has a `name` attribute, it is returned to unmodified.
Otherwise the name, and the value with any CR or LF characters removed, are passed to the header_factory, and the resulting header object is returned. Any surrogateescaped bytes get turned into the unicode unknown-character glyph.

fold(name, value)

Header folding is controlled by the refold_source policy setting. A value is considered to be a 'source value' if and only if it does not have a name attribute (having a name attribute means it is a header object of some sort). If a source value needs to be refolded according to the policy, it is converted into a header object by passing the name and the value with any CR and LF characters removed to the header_factory. Folding of a header object is done by calling its fold method with the current policy.

Source values are split into lines using splitlines(). If the value is not to be refolded, the lines are rejoined using the linesep from the policy and returned. The exception is lines containing non-ascii binary data. In that case the value is refolded regardless of the refold_source setting, which causes the binary data to be CTE encoded using the unknown-8bit charset.

fold_binary(name, value)

The same as fold() if cte_type is 7bit, except that the returned value is bytes.

If cte_type is 8bit, non-ASCII binary data is converted back into bytes. Headers with binary data are not refolded, regardless of the refold_header setting, since there is no way to know whether the binary data consists of single byte
characters or multibyte characters.

The following instances of EmailPolicy provide defaults suitable for specific application domains. Note that in the future the behavior of these instances (in particular the HTTP instance) may be adjusted to conform even more closely to the RFCs relevant to their domains.

email.policy.default
An instance of EmailPolicy with all defaults unchanged. This policy uses the standard Python \n line endings rather than the RFC-correct \r\n.

email.policy.SMTP
Suitable for serializing messages in conformance with the email RFCs. Like default, but with linesep set to \r\n, which is RFC compliant.

email.policy.HTTP
Suitable for serializing headers with for use in HTTP traffic. Like SMTP except that max_line_length is set to None (unlimited).

email.policy.strict
Convenience instance. The same as default except that raise_on_defect is set to True. This allows any policy to be made strict by writing:

somepolicy + policy.strict

With all of these EmailPolicies, the effective API of the email package is changed from the Python 3.2 API in the following ways:

- Setting a header on a Message results in that header being parsed and a header object created.
• Fetching a header value from a `Message` results in that header being parsed and a header object created and returned.

• Any header object, or any header that is refolded due to the policy settings, is folded using an algorithm that fully implements the RFC folding algorithms, including knowing where encoded words are required and allowed.
