if (PyObject_SetItem(dict, key, incremented_item)
    goto error;
rv = 0; /* Success */
/* Continue with cleanup code */

error:
/* Cleanup code, shared by success and failure paths */

/* Use Py_XDECREF() to ignore NULL references */
Py_XDECREF(item);
Py_XDECREF(const_one);
Py_XDECREF(incremented_item);

return rv; /* -1 for error, 0 for success */
}

This example represents an endorsed use of the goto statement in C!
It illustrates the use of PyErr_ExceptionMatches() and PyErr_Clear() to handle specific exceptions, and the use of Py_XDECREF() to dispose of owned references that may be NULL (note the 'X' in the name; Py_DECREF() would crash when confronted with a NULL reference). It is important that the variables used to hold owned references are initialized to NULL for this to work; likewise, the proposed return value is initialized to -1 (failure) and only set to success after the final call made is successful.
Embedding Python

The one important task that only embedders (as opposed to extension writers) of the Python interpreter have to worry about is the initialization, and possibly the finalization, of the Python interpreter. Most functionality of the interpreter can only be used after the interpreter has been initialized.

The basic initialization function is `Py_Initialize()`. This initializes the table of loaded modules, and creates the fundamental modules `builtins`, `__main__`, and `sys`. It also initializes the module search path (`sys.path`).

`Py_Initialize()` does not set the “script argument list” (`sys.argv`). If this variable is needed by Python code that will be executed later, it must be set explicitly with a call to `PySys_SetArgvEx(argc, argv, updatepath)` after the call to `Py_Initialize()`.

On most systems (in particular, on Unix and Windows, although the details are slightly different), `Py_Initialize()` calculates the module search path based upon its best guess for the location of the standard Python interpreter executable, assuming that the Python library is found in a fixed location relative to the Python interpreter executable. In particular, it looks for a directory named `lib/pythonX.Y` relative to the parent directory where the executable named `python` is found on the shell command search path (the environment variable `PATH`).

For instance, if the Python executable is found in `/usr/local/bin/python`, it will assume that the libraries are in
/usr/local/lib/pythonX.Y. (In fact, this particular path is also the “fallback” location, used when no executable file named python is found along PATH.) The user can override this behavior by setting the environment variable PYTHONHOME, or insert additional directories in front of the standard path by setting PYTHONPATH.

The embedding application can steer the search by calling Py_SetProgramName(file) before calling Py_Initialize(). Note that PYTHONHOME still overrides this and PYTHONPATH is still inserted in front of the standard path. An application that requires total control has to provide its own implementation of Py_GetPath(), Py_GetPrefix(), Py_GetExecPrefix(), and Py_GetProgramFullPath() (all defined in Modules/getpath.c).

Sometimes, it is desirable to “uninitialize” Python. For instance, the application may want to start over (make another call to Py_Initialize()) or the application is simply done with its use of Python and wants to free memory allocated by Python. This can be accomplished by calling Py_Finalize(). The function Py_IsInitialized() returns true if Python is currently in the initialized state. More information about these functions is given in a later chapter. Notice that Py_Finalize() does not free all memory allocated by the Python interpreter, e.g. memory allocated by extension modules currently cannot be released.
Debugging Builds

Python can be built with several macros to enable extra checks of the interpreter and extension modules. These checks tend to add a large amount of overhead to the runtime so they are not enabled by default.

A full list of the various types of debugging builds is in the file `Misc/SpecialBuilds.txt` in the Python source distribution. Builds are available that support tracing of reference counts, debugging the memory allocator, or low-level profiling of the main interpreter loop. Only the most frequently-used builds will be described in the remainder of this section.

Compiling the interpreter with the Py_DEBUG macro defined produces what is generally meant by “a debug build” of Python. Py_DEBUG is enabled in the Unix build by adding `--with-pydebug` to the `./configure` command. It is also implied by the presence of the not-Python-specific _DEBUG macro. When Py_DEBUG is enabled in the Unix build, compiler optimization is disabled.

In addition to the reference count debugging described below, the following extra checks are performed:

- Extra checks are added to the object allocator.
- Extra checks are added to the parser and compiler.
- Downcasts from wide types to narrow types are checked for loss of information.
- A number of assertions are added to the dictionary and set implementations. In addition, the set object acquires a `test_c_api()` method.
- Sanity checks of the input arguments are added to frame creation.
- The storage for ints is initialized with a known invalid pattern to
catch reference to uninitialized digits.
- Low-level tracing and extra exception checking are added to the runtime virtual machine.
- Extra checks are added to the memory arena implementation.
- Extra debugging is added to the thread module.

There may be additional checks not mentioned here.

Defining `Py_TRACE_REFS` enables reference tracing. When defined, a circular doubly linked list of active objects is maintained by adding two extra fields to every `PyObject`. Total allocations are tracked as well. Upon exit, all existing references are printed. (In interactive mode this happens after every statement run by the interpreter.) Implied by `Py_DEBUG`.

Please refer to `Misc/SpecialBuilds.txt` in the Python source distribution for more detailed information.
Stable Application Binary Interface

Traditionally, the C API of Python will change with every release. Most changes will be source-compatible, typically by only adding API, rather than changing existing API or removing API (although some interfaces do get removed after being deprecated first).

Unfortunately, the API compatibility does not extend to binary compatibility (the ABI). The reason is primarily the evolution of struct definitions, where addition of a new field, or changing the type of a field, might not break the API, but can break the ABI. As a consequence, extension modules need to be recompiled for every Python release (although an exception is possible on Unix when none of the affected interfaces are used). In addition, on Windows, extension modules link with a specific pythonXY.dll and need to be recompiled to link with a newer one.

Since Python 3.2, a subset of the API has been declared to guarantee a stable ABI. Extension modules wishing to use this API (called “limited API”) need to define Py_LIMITED_API. A number of interpreter details then become hidden from the extension module; in return, a module is built that works on any 3.x version (x>=2) without recompilation.

In some cases, the stable ABI needs to be extended with new functions. Extension modules wishing to use these new APIs need to set Py_LIMITED_API to the PY_VERSION_HEX value (see API and ABI Versioning) of the minimum Python version they want to support (e.g. 0x03030000 for Python 3.3). Such modules will work on all subsequent Python releases, but fail to load (because of missing symbols) on the older releases.
As of Python 3.2, the set of functions available to the limited API is documented in PEP 384. In the C API documentation, API elements that are not part of the limited API are marked as “Not part of the limited API.”
The Very High Level Layer

The functions in this chapter will let you execute Python source code given in a file or a buffer, but they will not let you interact in a more detailed way with the interpreter.

Several of these functions accept a start symbol from the grammar as a parameter. The available start symbols are `Py_eval_input`, `Py_file_input`, and `Py_single_input`. These are described following the functions which accept them as parameters.

Note also that several of these functions take `FILE*` parameters. One particular issue which needs to be handled carefully is that the `FILE` structure for different C libraries can be different and incompatible. Under Windows (at least), it is possible for dynamically linked extensions to actually use different libraries, so care should be taken that `FILE*` parameters are only passed to these functions if it is certain that they were created by the same library that the Python runtime is using.

```c
int Py_Main(int argc, wchar_t **argv)
```

The main program for the standard interpreter. This is made available for programs which embed Python. The `argc` and `argv` parameters should be prepared exactly as those which are passed to a C program’s `main()` function (converted to `wchar_t` according to the user’s locale). It is important to note that the argument list may be modified (but the contents of the strings pointed to by the argument list are not). The return value will be 0 if the interpreter exits normally (i.e., without an exception), 1 if the interpreter exits due to an exception, or 2 if the parameter list does not represent a
valid Python command line.

Note that if an otherwise unhandled `SystemExit` is raised, this function will not return 1, but exit the process, as long as `Py_InspectFlag` is not set.

```c
int PyRun_AnyFile(FILE *fp, const char *filename)
```
This is a simplified interface to `PyRun_AnyFileExFlags()` below, leaving `closeit` set to 0 and `flags` set to NULL.

```c
int PyRun_AnyFileFlags(FILE *fp, const char *filename, PyCompilerFlags *flags)
```
This is a simplified interface to `PyRun_AnyFileExFlags()` below, leaving the `closeit` argument set to 0.

```c
int PyRun_AnyFileEx(FILE *fp, const char *filename, int closeit)
```
This is a simplified interface to `PyRun_AnyFileExFlags()` below, leaving the `flags` argument set to NULL.

```c
int PyRun_AnyFileExFlags(FILE *fp, const char *filename, int closeit, PyCompilerFlags *flags)
```
If `fp` refers to a file associated with an interactive device (console or terminal input or Unix pseudo-terminal), return the value of `PyRun_InteractiveLoop()`, otherwise return the result of `PyRun_SimpleFile()`. `filename` is decoded from the filesystem encoding (`.getfilesystemencoding()`). If `filename` is NULL, this function uses "????" as the filename.

```c
int PyRun_SimpleString(const char *command)
```
This is a simplified interface to `PyRun_SimpleStringFlags()` below, leaving the `PyCompilerFlags*` argument set to NULL.
int PyRun_SimpleStringFlags(const char *command, PyCompilerFlags *flags)

Executes the Python source code from command in the __main__ module according to the flags argument. If __main__ does not already exist, it is created. Returns 0 on success or -1 if an exception was raised. If there was an error, there is no way to get the exception information. For the meaning of flags, see below.

Note that if an otherwise unhandled SystemExit is raised, this function will not return -1, but exit the process, as long as Py_InspectFlag is not set.

int PyRun_SimpleFile(FILE *fp, const char *filename)

This is a simplified interface to PyRun_SimpleFileExFlags() below, leaving closeit set to 0 and flags set to NULL.

int PyRun_SimpleFileEx(FILE *fp, const char *filename, int closeit)

This is a simplified interface to PyRun_SimpleFileExFlags() below, leaving flags set to NULL.

int PyRun_SimpleFileExFlags(FILE *fp, const char *filename, int closeit, PyCompilerFlags *flags)

Similar to PyRun_SimpleStringFlags(), but the Python source code is read from fp instead of an in-memory string. filename should be the name of the file, it is decoded from the filesystem encoding (sys.getfilesystemencoding()). If closeit is true, the file is closed before PyRun_SimpleFileExFlags returns.

int PyRun_InteractiveOne(FILE *fp, const char *filename)

This is a simplified interface to
PyRun_InteractiveOneFlags() below, leaving flags set to NULL.

int PyRun_InteractiveOneFlags(FILE *fp, const char *filename, PyCompilerFlags *flags)
Read and execute a single statement from a file associated with an interactive device according to the flags argument. The user will be prompted using sys.ps1 and sys.ps2. filename is decoded from the filesystem encoding (sys.getfilesystemencoding()).

Returns 0 when the input was executed successfully, -1 if there was an exception, or an error code from the errcode.h include file distributed as part of Python if there was a parse error. (Note that errcode.h is not included by Python.h, so must be included specifically if needed.)

int PyRun_InteractiveLoop(FILE *fp, const char *filename)
This is a simplified interface to PyRun_InteractiveLoopFlags() below, leaving flags set to NULL.

int PyRun_InteractiveLoopFlags(FILE *fp, const char *filename, PyCompilerFlags *flags)
Read and execute statements from a file associated with an interactive device until EOF is reached. The user will be prompted using sys.ps1 and sys.ps2. filename is decoded from the filesystem encoding (sys.getfilesystemencoding()). Returns 0 at EOF.

int (*PyOS_InputHook)(void)
Can be set to point to a function with the prototype int func(void). The function will be called when Python's interpreter
prompt is about to become idle and wait for user input from the terminal. The return value is ignored. Overriding this hook can be used to integrate the interpreter’s prompt with other event loops, as done in the Modules/_tkinter.c in the Python source code.

```c
char* (*PyOS_ReadlineFunctionPointer)(FILE *, FILE *, const char *)
```

Can be set to point to a function with the prototype `char *func(FILE *stdin, FILE *stdout, char *prompt)`, overriding the default function used to read a single line of input at the interpreter’s prompt. The function is expected to output the string `prompt` if it’s not `NULL`, and then read a line of input from the provided standard input file, returning the resulting string. For example, The `readline` module sets this hook to provide line-editing and tab-completion features.

The result must be a string allocated by `PyMem_RawMalloc()` or `PyMem_RawRealloc()`, or `NULL` if an error occurred.

*Changed in version 3.4:* The result must be allocated by `PyMem_RawMalloc()` or `PyMem_RawRealloc()`, instead of being allocated by `PyMem_Malloc()` or `PyMem_Realloc()`.

```c
struct _node* PyParser_SimpleParseString(const char *str, int start)
```

This is a simplified interface to `PyParser_SimpleParseStringFlagsFilename()` below, leaving `filename` set to `NULL` and `flags` set to `0`.

```c
struct _node* PyParser_SimpleParseStringFlags(const char *str, int start, int flags)
```

This is a simplified interface to
PyParser_SimpleParseStringFlagsFilename() below, leaving filename set to NULL.

struct _node* PyParser_SimpleParseStringFlagsFilename(const char *str, const char *filename, int start, int flags)

Parse Python source code from str using the start token start according to the flags argument. The result can be used to create a code object which can be evaluated efficiently. This is useful if a code fragment must be evaluated many times. filename is decoded from the filesystem encoding (sys.getfilesystemencoding()).

struct _node* PyParser_SimpleParseFile(FILE *fp, const char *filename, int start)

This is a simplified interface to PyParser_SimpleParseFileFlags() below, leaving flags set to 0.

struct _node* PyParser_SimpleParseFileFlags(FILE *fp, const char *filename, int start, int flags)

Similar to PyParser_SimpleParseStringFlagsFilename(), but the Python source code is read from fp instead of an in-memory string.

PyObject* PyRun_String(const char *str, int start, PyObject *globals, PyObject *locals)

This is a simplified interface to PyRun_StringFlags() below, leaving flags set to NULL.

PyObject* PyRun_StringFlags(const char *str, int start,
PyObject *globals, PyObject *locals, PyCompilerFlags *flags)

    Execute Python source code from str in the context specified by
    the dictionaries globals and locals with the compiler flags specified
    by flags. The parameter start specifies the start token that should
    be used to parse the source code.

    Returns the result of executing the code as a Python object, or
    NULL if an exception was raised.

PyObject* PyRun_File(FILE *fp, const char *filename, int start,
PyObject *globals, PyObject *locals)

    This is a simplified interface to PyRun_FileExFlags() below, leaving
    closeit set to 0 and flags set to NULL.

PyObject* PyRun_FileEx(FILE *fp, const char *filename, int start,
PyObject *globals, PyObject *locals, int closeit)

    This is a simplified interface to PyRun_FileExFlags() below, leaving
    flags set to NULL.

PyObject* PyRun_FileFlags(FILE *fp, const char *filename,
int start, PyObject *globals, PyObject *locals, PyCompilerFlags *flags)

    This is a simplified interface to PyRun_FileExFlags() below, leaving
    closeit set to 0.

PyObject* PyRun_FileExFlags(FILE *fp, const char *filename,
int start, PyObject *globals, PyObject *locals, int closeit,
PyCompilerFlags *flags)

    Similar to PyRun_StringFlags(), but the Python source code is
read from `fp` instead of an in-memory string. `filename` should be the
name of the file, it is decoded from the filesystem encoding
(`sys.getfilesystemencoding()`). If `closeit` is true, the file is
closed before `PyRun_FileExFlags()` returns.

**PyObject** `Py_CompileString` (const char *str, const
char *filename, int start)

*Return value: New reference.*
This is a simplified interface to `Py_CompileStringFlags()` below, leaving `flags` set to `NULL`.

**PyObject** `Py_CompileStringFlags` (const char *str, const
char *filename, int start, PyCompilerFlags *flags)

*Return value: New reference.*
This is a simplified interface to `Py_CompileStringExFlags()` below, with `optimize` set to `-1`.

**PyObject** `Py_CompileStringObject` (const char *str,
PyObject *filename, int start, PyCompilerFlags *flags, int optimize)

Parse and compile the Python source code in `str`, returning the
resulting code object. The start token is given by `start`; this can be
used to constrain the code which can be compiled and should be
`Py_eval_input`, `Py_file_input`, or `Py_single_input`. The
filename specified by `filename` is used to construct the code object
and may appear in tracebacks or `SyntaxError` exception
messages. This returns `NULL` if the code cannot be parsed or
compiled.

The integer `optimize` specifies the optimization level of the
compiler; a value of `-1` selects the optimization level of the
interpreter as given by `-O` options. Explicit levels are 0 (no
optimization; `__debug__` is true), 1 (asserts are removed,
__debug__ is false) or 2 (docstrings are removed too).

*New in version 3.4.*

**PyObject** `Py_CompileStringExFlags` (const char *str, const char *filename, int start, PyCompilerFlags *flags, int optimize)

Like `Py_CompileStringExFlags()`, but `filename` is a byte string decoded from the filesystem encoding (`os.fsdecode()`).

*New in version 3.2.*

**PyObject** `PyEval_EvalCode` (PyObject *co, PyObject *globals, PyObject *locals)

*Return value: New reference.*

This is a simplified interface to `PyEval_EvalCodeEx()`, with just the code object, and the dictionaries of global and local variables. The other arguments are set to `NULL`.

**PyObject** `PyEval_EvalCodeEx` (PyObject *co, PyObject *globals, PyObject *locals, PyObject **args, int argcount, PyObject **kws, int kwcount, PyObject **defs, int defcount, PyObject *closure)

Evaluate a precompiled code object, given a particular environment for its evaluation. This environment consists of dictionaries of global and local variables, arrays of arguments, keywords and defaults, and a closure tuple of cells.

**PyObject** `PyEval_EvalFrame` (PyFrameObject *f)

Evaluate an execution frame. This is a simplified interface to `PyEval_EvalFrameEx`, for backward compatibility.

**PyObject** `PyEval_EvalFrameEx` (PyFrameObject *f, int throwflag)
This is the main, unvarnished function of Python interpretation. It is literally 2000 lines long. The code object associated with the execution frame $f$ is executed, interpreting bytecode and executing calls as needed. The additional throwflag parameter can mostly be ignored - if true, then it causes an exception to immediately be thrown; this is used for the throw() methods of generator objects.

*Changed in version 3.4:* This function now includes a debug assertion to help ensure that it does not silently discard an active exception.

```
int PyEval_MergeCompilerFlags(PyCompilerFlags *cf)
```

This function changes the flags of the current evaluation frame, and returns true on success, false on failure.

```
int Py_eval_input
```

The start symbol from the Python grammar for isolated expressions; for use with Py_CompileString().

```
int Py_file_input
```

The start symbol from the Python grammar for sequences of statements as read from a file or other source; for use with Py_CompileString(). This is the symbol to use when compiling arbitrarily long Python source code.

```
int Py_single_input
```

The start symbol from the Python grammar for a single statement; for use with Py_CompileString(). This is the symbol used for the interactive interpreter loop.

```
struct PyCompilerFlags
```

This is the structure used to hold compiler flags. In cases where code is only being compiled, it is passed as int flags, and in
cases where code is being executed, it is passed as `PyCompilerFlags *flags`. In this case, `from __future__ import` can modify `flags`.

Whenever `PyCompilerFlags *flags` is `NULL`, `cf_flags` is treated as equal to `0`, and any modification due to `from __future__ import` is discarded.

```c
struct PyCompilerFlags {
    int cf_flags;
}
```

`int CO_FUTURE_DIVISION`

This bit can be set in `flags` to cause division operator `/` to be interpreted as “true division” according to [PEP 238](https://www.python.org/dev/peps/pep-0238/).
Reference Counting

The macros in this section are used for managing reference counts of Python objects.

void **Py_INCREF**(PyObject *o)

Increment the reference count for object o. The object must not be NULL; if you aren’t sure that it isn’t NULL, use **Py_XINCREF( )**.

void **Py_XINCREF**(PyObject *o)

Increment the reference count for object o. The object may be NULL, in which case the macro has no effect.

void **Py_DECREF**(PyObject *o)

Decrement the reference count for object o. The object must not be NULL; if you aren’t sure that it isn’t NULL, use **Py_XDECREF( )**. If the reference count reaches zero, the object’s type’s deallocation function (which must not be NULL) is invoked.

**Warning:** The deallocation function can cause arbitrary Python code to be invoked (e.g. when a class instance with a __del__() method is deallocated). While exceptions in such code are not propagated, the executed code has free access to all Python global variables. This means that any object that is reachable from a global variable should be in a consistent state before **Py_DECREF( )** is invoked. For example, code to delete an object from a list should copy a reference to the deleted object in a temporary variable, update the list data structure, and then call **Py_DECREF( )** for the temporary variable.
void **Py_XDECREF**(PyObject *o)

Decrement the reference count for object o. The object may be `NULL`, in which case the macro has no effect; otherwise the effect is the same as for **Py_DECREF()**, and the same warning applies.

void **Py_CLEAR**(PyObject *o)

Decrement the reference count for object o. The object may be `NULL`, in which case the macro has no effect; otherwise the effect is the same as for **Py_DECREF()**, except that the argument is also set to `NULL`. The warning for **Py_DECREF()** does not apply with respect to the object passed because the macro carefully uses a temporary variable and sets the argument to `NULL` before decrementing its reference count.

It is a good idea to use this macro whenever decrementing the value of a variable that might be traversed during garbage collection.

The following functions are for runtime dynamic embedding of Python: **Py_IncRef**(PyObject *o), **Py_DecRef**(PyObject *o). They are simply exported function versions of **Py_XINCREF()** and **Py_XDECREF()**, respectively.

The following functions or macros are only for use within the interpreter core: _Py_Dealloc(), _Py_ForgetReference(), _Py_NewReference(), as well as the global variable _Py_RefTotal.
Last updated on Mar 16, 2014. Found a bug?
Created using Sphinx 1.2.
Exception Handling

The functions described in this chapter will let you handle and raise Python exceptions. It is important to understand some of the basics of Python exception handling. It works somewhat like the Unix errno variable: there is a global indicator (per thread) of the last error that occurred. Most functions don’t clear this on success, but will set it to indicate the cause of the error on failure. Most functions also return an error indicator, usually NULL if they are supposed to return a pointer, or -1 if they return an integer (exception: the PyArg_*() functions return 1 for success and 0 for failure).

When a function must fail because some function it called failed, it generally doesn’t set the error indicator; the function it called already set it. It is responsible for either handling the error and clearing the exception or returning after cleaning up any resources it holds (such as object references or memory allocations); it should not continue normally if it is not prepared to handle the error. If returning due to an error, it is important to indicate to the caller that an error has been set. If the error is not handled or carefully propagated, additional calls into the Python/C API may not behave as intended and may fail in mysterious ways.

The error indicator consists of three Python objects corresponding to the result of sys.exc_info(). API functions exist to interact with the error indicator in various ways. There is a separate error indicator for each thread.

void PyErr_PrintEx(int set_sys_last_vars)

Print a standard traceback to sys.stderr and clear the error indicator. Call this function only when the error indicator is set.
(Otherwise it will cause a fatal error!)

If \texttt{set\_sys\_last\_vars} is nonzero, the variables \texttt{sys\_last\_type}, \texttt{sys\_last\_value} and \texttt{sys\_last\_traceback} will be set to the type, value and traceback of the printed exception, respectively.

\begin{verbatim}
void \textbf{PyErr\_Print}()
    Alias for \textbf{PyErr\_PrintEx}(1).
\end{verbatim}

\begin{verbatim}
\textbf{PyObject\ *} \textbf{PyErr\_Occurred}()
    \textit{Return value: Borrowed reference.}
    Test whether the error indicator is set. If set, return the exception type (the first argument to the last call to one of the \textbf{PyErr\_Set\*} () functions or to \textbf{PyErr\_Restore}()). If not set, return \texttt{NULL}. You do not own a reference to the return value, so you do not need to \textbf{Py\_DECREF}() it.
\end{verbatim}

\begin{ Vigtor}
\textbf{Note:} Do not compare the return value to a specific exception; use \textbf{PyErr\_ExceptionMatches()} instead, shown below. (The comparison could easily fail since the exception may be an instance instead of a class, in the case of a class exception, or it may be a subclass of the expected exception.)
\end{Vigtor}

\begin{verbatim}
int \textbf{PyErr\_ExceptionMatches}(\textbf{PyObject \ *}exc)
    Equivalent to \textbf{PyErr\_GivenExceptionMatches}\textbf{(PyErr\_Occurred()}, exc). This should only be called when an exception is actually set; a memory access violation will occur if no exception has been raised.
\end{verbatim}

\begin{verbatim}
int \textbf{PyErr\_GivenExceptionMatches}(\textbf{PyObject \ *}given, \\
\textbf{PyObject \ *}exc)
\end{verbatim}
Return true if the *given* exception matches the exception in *exc*. If *exc* is a class object, this also returns true when *given* is an instance of a subclass. If *exc* is a tuple, all exceptions in the tuple (and recursively in subtuples) are searched for a match.

```c
#define PyErr_NormalizeException (PyObject** exc, PyObject** val, PyObject** tb)
```

Under certain circumstances, the values returned by PyErr_Fetch() below can be “unnormalized”, meaning that *exc* is a class object but *val* is not an instance of the same class. This function can be used to instantiate the class in that case. If the values are already normalized, nothing happens. The delayed normalization is implemented to improve performance.

**Note:** This function does not implicitly set the __traceback__ attribute on the exception value. If setting the traceback appropriately is desired, the following additional snippet is needed:

```c
if (tb != NULL) {
    PyErr_SetTraceback(val, tb);
}
```

```c
#define PyErr_Clear ()
```

Clear the error indicator. If the error indicator is not set, there is no effect.

```c
#define PyErr_Fetch (PyObject **ptype, PyObject **pvalue, PyObject **ptraceback)
```

Retrieve the error indicator into three variables whose addresses are passed. If the error indicator is not set, set all three variables to NULL. If it is set, it will be cleared and you own a reference to each
object retrieved. The value and traceback object may be `NULL` even when the type object is not.

**Note:** This function is normally only used by code that needs to handle exceptions or by code that needs to save and restore the error indicator temporarily.

```c
void PyErr_Restore(PyObject *type, PyObject *value, PyObject *traceback)
```

Set the error indicator from the three objects. If the error indicator is already set, it is cleared first. If the objects are `NULL`, the error indicator is cleared. Do not pass a `NULL` type and non-`NULL` value or traceback. The exception type should be a class. Do not pass an invalid exception type or value. (Violating these rules will cause subtle problems later.) This call takes away a reference to each object: you must own a reference to each object before the call and after the call you no longer own these references. (If you don’t understand this, don’t use this function. I warned you.)

**Note:** This function is normally only used by code that needs to save and restore the error indicator temporarily; use `PyErr_Fetch()` to save the current exception state.

```c
void PyErr_GetExcInfo(PyObject **ptype, PyObject **pvalue, PyObject **ptraceback)
```

Retrieve the exception info, as known from `sys.exc_info()`. This refers to an exception that was already caught, not to an exception that was freshly raised. Returns new references for the three objects, any of which may be `NULL`. Does not modify the exception info state.
Note: This function is not normally used by code that wants to handle exceptions. Rather, it can be used when code needs to save and restore the exception state temporarily. Use `PyErr_SetExcInfo()` to restore or clear the exception state.

New in version 3.3.

```c
void PyErr_SetExcInfo(PyObject *type, PyObject *value, PyObject *traceback)
```

Set the exception info, as known from `sys.exc_info()`. This refers to an exception that was already caught, not to an exception that was freshly raised. This function steals the references of the arguments. To clear the exception state, pass `NULL` for all three arguments. For general rules about the three arguments, see `PyErr_Restore()`.

Note: This function is not normally used by code that wants to handle exceptions. Rather, it can be used when code needs to save and restore the exception state temporarily. Use `PyErr_GetExcInfo()` to read the exception state.

New in version 3.3.

```c
void PyErr_SetString(PyObject *type, const char *message)
```

This is the most common way to set the error indicator. The first argument specifies the exception type; it is normally one of the standard exceptions, e.g. `PyExc_RuntimeError`. You need not increment its reference count. The second argument is an error message; it is decoded from 'utf-8'.

```c
void PyErr_SetObject(PyObject *type, PyObject *value)
```

This function is similar to `PyErr_SetString()` but lets you
specify an arbitrary Python object for the “value” of the exception.

```c
PyObject* PyErr_Format(PyObject *exception, const char *format, ...)  
Return value: Always NULL.
```
This function sets the error indicator and returns NULL. `exception` should be a Python exception class. The `format` and subsequent parameters help format the error message; they have the same meaning and values as in `PyUnicode_FromFormat()`. `format` is an ASCII-encoded string.

```c
void PyErr_SetNone(PyObject *type)
```
This is a shorthand for `PyErr_SetObject(type, Py_None)`.

```c
int PyErr_BadArgument()
```
This is a shorthand for `PyErr_SetString(PyExc_TypeError, message)`, where `message` indicates that a built-in operation was invoked with an illegal argument. It is mostly for internal use.

```c
PyObject* PyErr_NoMemory()
```
Return value: Always NULL.
This is a shorthand for `PyErr_SetNone(PyExc_MemoryError);` it returns NULL so an object allocation function can write return `PyErr_NoMemory();` when it runs out of memory.

```c
PyObject* PyErr_SetFromErrno(PyObject *type)
```
Return value: Always NULL.
This is a convenience function to raise an exception when a C library function has returned an error and set the C variable `errno`. It constructs a tuple object whose first item is the integer `errno` value and whose second item is the corresponding error message (gotten from `strerror()`), and then calls
PyErr_SetObject(type, object). On Unix, when the errno value is EINTR, indicating an interrupted system call, this calls PyErr_CheckSignals(), and if that set the error indicator, leaves it set to that. The function always returns NULL, so a wrapper function around a system call can write return PyErr_SetFromErrno(type); when the system call returns an error.

PyObject*
PyErr_SetFromErrnoWithFilenameObject(PyObject *typ, PyObject *filenameObject)

Similar to PyErr_SetFromErrno(), with the additional behavior that if filenameObject is not NULL, it is passed to the constructor of type as a third parameter. In the case of exceptions such as IOError and OSError, this is used to define the filename attribute of the exception instance.

PyObject*
PyErr_SetFromErrnoWithFilenameObjects(PyObject *typ, PyObject *filenameObject, PyObject *filenameObject2)

Similar to PyErr_SetFromErrnoWithFilenameObject(), but takes a second filename object, for raising errors when a function that takes two filenames fails.

New in version 3.4.

PyObject*
PyErr_SetFromErrnoWithFilename(PyObject *type, const char *filename)

Return value: Always NULL.

Similar to PyErr_SetFromErrnoWithFilenameObject(), but the filename is given as a C string. filename is decoded from the
filesystem encoding (\texttt{os.fsdecode()}).

\textbf{PyObject* \texttt{PyErr_SetFromWindowsErr}(int \textit{ierr})}

\textit{Return value: Always NULL.}\n
This is a convenience function to raise \texttt{WindowsError}. If called with \textit{ierr} of 0, the error code returned by a call to \texttt{GetLastError()} is used instead. It calls the Win32 function \texttt{FormatMessage()} to retrieve the Windows description of error code given by \textit{ierr} or \texttt{GetLastError()}, then it constructs a tuple object whose first item is the \textit{ierr} value and whose second item is the corresponding error message (gotten from \texttt{FormatMessage()}); and then calls \texttt{PyErr_SetObject(PyExc_WindowsError, object)}. This function always returns \texttt{NULL}. Availability: Windows.

\textbf{PyObject* \texttt{PyErr_SetExcFromWindowsErr}(PyObject *\textit{type}, int \textit{ierr})}

\textit{Return value: Always NULL.}\n
Similar to \texttt{PyErr_SetFromWindowsErr()}, with an additional parameter specifying the exception type to be raised. Availability: Windows.

\textbf{PyObject* \texttt{PyErr_SetFromWindowsErrWithFilename}(int \textit{ierr}, const char *\textit{filename})}

\textit{Return value: Always NULL.}\n
Similar to \texttt{PyErr_SetFromWindowsErrWithFilenameObject()}, but the filename is given as a C string. \textit{filename} is decoded from the filesystem encoding (\texttt{os.fsdecode()}). Availability: Windows.
**PyErr_SetExcFromWindowsErrWithFilenameObject**

```python
int ierr, PyObject *filename)
```

Similar to **PyErr_SetFromWindowsErrWithFilenameObject()**, with an additional parameter specifying the exception type to be raised. Availability: Windows.

**PyErr_SetExcFromWindowsErrWithFilenameObjects**

```python
int ierr, PyObject *filename, PyObject *filename2)
```

Similar to **PyErr_SetExcFromWindowsErrWithFilenameObject()**, but accepts a second filename object. Availability: Windows.

*New in version 3.4.*

**PyErr_SetImportError**

```python
PyObject *msg, PyObject *name, PyObject *path)
```

This is a convenience function to raise `ImportError`. `msg` will be set as the exception’s message string. `name` and `path`, both of which can be `NULL`, will be set as the `ImportError`’s respective name and path attributes.

*New in version 3.3.*
void **PyErr_SyntaxLocationObject**(*PyObject* filename, int lineno, int col_offset)

Set file, line, and offset information for the current exception. If the current exception is not a **SyntaxError**, then it sets additional attributes, which make the exception printing subsystem think the exception is a **SyntaxError**.

*New in version 3.4.*

void **PyErr_SyntaxLocationEx**(*char* filename, int lineno, int col_offset)

Like **PyErr_SyntaxLocationObject()**, but *filename* is a byte string decoded from the filesystem encoding (**os.fsdecode()**).

*New in version 3.2.*

void **PyErr_SyntaxLocation**(*char* filename, int lineno)

Like **PyErr_SyntaxLocationEx()**, but the col_offset parameter is omitted.

void **PyErr_BadInternalCall()**

This is a shorthand for **PyErr_SetString(PyExc_SystemError, message)**, where *message* indicates that an internal operation (e.g. a Python/C API function) was invoked with an illegal argument. It is mostly for internal use.

int **PyErr_WarnEx**(*PyObject* category, char *message, int stack_level)

Issue a warning message. The *category* argument is a warning category (see below) or **NULL**; the *message* argument is an UTF-8 encoded string. *stack_level* is a positive number giving a number of
stack frames; the warning will be issued from the currently executing line of code in that stack frame. A stack_level of 1 is the function calling PyErr_WarnEx(), 2 is the function above that, and so forth.

This function normally prints a warning message to sys.stderr; however, it is also possible that the user has specified that warnings are to be turned into errors, and in that case this will raise an exception. It is also possible that the function raises an exception because of a problem with the warning machinery (the implementation imports the warnings module to do the heavy lifting). The return value is 0 if no exception is raised, or -1 if an exception is raised. (It is not possible to determine whether a warning message is actually printed, nor what the reason is for the exception; this is intentional.) If an exception is raised, the caller should do its normal exception handling (for example, Py_DECREF() owned references and return an error value).

Warning categories must be subclasses of Warning; the default warning category is RuntimeWarning. The standard Python warning categories are available as global variables whose names are PyExc_ followed by the Python exception name. These have the type PyObject*; they are all class objects. Their names are PyExc_Warning, PyExc_UserWarning, PyExc_UnicodeWarning, PyExc_DeprecationWarning, PyExc_SyntaxWarning, PyExc_RuntimeWarning, and PyExc_FutureWarning. PyExc_Warning is a subclass of PyExc_Exception; the other warning categories are subclasses of PyExc_Warning.

For information about warning control, see the documentation for
the `warnings` module and the `-W` option in the command line documentation. There is no C API for warning control.

```c
int PyErr_WarnExplicitObject(PyObject *category, PyObject *message, PyObject *filename, int lineno, PyObject *module, PyObject *registry)
```

Issue a warning message with explicit control over all warning attributes. This is a straightforward wrapper around the Python function `warnings.warn_explicit()`, see there for more information. The `module` and `registry` arguments may be set to `NULL` to get the default effect described there.

*New in version 3.4.*

```c
int PyErr_WarnExplicit(PyObject *category, const char *message, const char *filename, int lineno, const char *module, PyObject *registry)
```

Similar to `PyErr_WarnExplicitObject()` except that `message` and `module` are UTF-8 encoded strings, and `filename` is decoded from the filesystem encoding (`os.fsdecode()`).

```c
int PyErr_WarnFormat(PyObject *category, Py_ssize_t stack_level, const char *format, ...)
```

Function similar to `PyErr_WarnEx()`, but use `PyUnicode_FromFormat()` to format the warning message. `format` is an ASCII-encoded string.

*New in version 3.2.*

```c
int PyErr_CheckSignals()
```

This function interacts with Python’s signal handling. It checks whether a signal has been sent to the processes and if so, invokes the corresponding signal handler. If the `signal` module is...
supported, this can invoke a signal handler written in Python. In all cases, the default effect for SIGINT is to raise the 
**KeyboardInterrupt** exception. If an exception is raised the error indicator is set and the function returns -1; otherwise the function returns 0. The error indicator may or may not be cleared if it was previously set.

**void PyErr_SetInterrupt()**

This function simulates the effect of a SIGINT signal arriving — the next time PyErr_CheckSignals() is called, **KeyboardInterrupt** will be raised. It may be called without holding the interpreter lock.

**int PySignal_SetWakeupFd(int fd)**

This utility function specifies a file descriptor to which a '0' byte will be written whenever a signal is received. It returns the previous such file descriptor. The value -1 disables the feature; this is the initial state. This is equivalent to signal.set_wakeup_fd() in Python, but without any error checking. *fd* should be a valid file descriptor. The function should only be called from the main thread.

**PyObject* PyErr_NewException(char *name, PyObject *base, PyObject *dict)**

*Return value: New reference.*

This utility function creates and returns a new exception class. The *name* argument must be the name of the new exception, a C string of the form module\.classname. The *base* and *dict* arguments are normally NULL. This creates a class object derived from **Exception** (accessible in C as PyExc_Exception).

The **module** attribute of the new class is set to the first part (up to the last dot) of the *name* argument, and the class name is
set to the last part (after the last dot). The base argument can be used to specify alternate base classes; it can either be only one class or a tuple of classes. The dict argument can be used to specify a dictionary of class variables and methods.

PyObject* PyErr_NewExceptionWithDoc(char *name, char *doc, PyObject *base, PyObject *dict)

Same as PyErr_NewException(), except that the new exception class can easily be given a docstring: If doc is non-NULL, it will be used as the docstring for the exception class.

New in version 3.2.

void PyErr_WriteUnraisable(PyObject *obj)

This utility function prints a warning message to sys.stderr when an exception has been set but it is impossible for the interpreter to actually raise the exception. It is used, for example, when an exception occurs in an __del__() method.

The function is called with a single argument obj that identifies the context in which the unraisable exception occurred. The repr of obj will be printed in the warning message.
Exception Objects

PyObject* PyException_GetTraceback(PyObject *ex)

*Return value: New reference.*
Return the traceback associated with the exception as a new reference, as accessible from Python through __traceback__. If there is no traceback associated, this returns NULL.

int PyException_SetTraceback(PyObject *ex, PyObject *tb)
Set the traceback associated with the exception to tb. Use Py_None to clear it.

PyObject* PyException_GetContext(PyObject *ex)
Return the context (another exception instance during whose handling ex was raised) associated with the exception as a new reference, as accessible from Python through __context__. If there is no context associated, this returns NULL.

void PyException_SetContext(PyObject *ex, PyObject *ctx)
Set the context associated with the exception to ctx. Use NULL to clear it. There is no type check to make sure that ctx is an exception instance. This steals a reference to ctx.

PyObject* PyException_GetCause(PyObject *ex)
Return the cause (either an exception instance, or None, set by raise ... from ...) associated with the exception as a new reference, as accessible from Python through __cause__.

void PyException_SetCause(PyObject *ex, PyObject *cause)
Set the cause associated with the exception to cause. Use NULL to clear it. There is no type check to make sure that cause is either an
exception instance or None. This steals a reference to cause.

__suppress_context__ is implicitly set to True by this function.
Unicode Exception Objects

The following functions are used to create and modify Unicode exceptions from C.

**PyObject** `PyUnicodeDecodeError_Create(const char *encoding, const char *object, Py_ssize_t length, Py_ssize_t start, Py_ssize_t end, const char *reason)`

Create a `UnicodeDecodeError` object with the attributes `encoding, object, length, start, end` and `reason`. `encoding` and `reason` are UTF-8 encoded strings.

**PyObject** `PyUnicodeEncodeError_Create(const char *encoding, const Py_UNICODE *object, Py_ssize_t length, Py_ssize_t start, Py_ssize_t end, const char *reason)`

Create a `UnicodeEncodeError` object with the attributes `encoding, object, length, start, end` and `reason`. `encoding` and `reason` are UTF-8 encoded strings.

**PyObject** `PyUnicodeTranslateError_Create(const Py_UNICODE *object, Py_ssize_t length, Py_ssize_t start, Py_ssize_t end, const char *reason)`

Create a `UnicodeTranslateError` object with the attributes `object, length, start, end` and `reason`. `reason` is an UTF-8 encoded string.

**PyObject**

`PyUnicodeDecodeError_GetEncoding(PyObject *exc)`

**PyObject**

`PyUnicodeEncodeError_GetEncoding(PyObject *exc)`

Return the `encoding` attribute of the given exception object.
PyUnicodeDecodeError_GetObject(PyObject *exc)
PyObject*
PyUnicodeEncodeError_GetObject(PyObject *exc)
PyObject*
PyUnicodeTranslateError_GetObject(PyObject *exc)
  Return the object attribute of the given exception object.

int PyUnicodeDecodeError_GetStart(PyObject *exc, Py_ssize_t *start)
int PyUnicodeEncodeError_GetStart(PyObject *exc, Py_ssize_t *start)
int PyUnicodeTranslateError_GetStart(PyObject *exc, Py_ssize_t *start)
  Get the start attribute of the given exception object and place it into *start. start must not be NULL. Return 0 on success, -1 on failure.

int PyUnicodeDecodeError_SetStart(PyObject *exc, Py_ssize_t start)
int PyUnicodeEncodeError_SetStart(PyObject *exc, Py_ssize_t start)
int PyUnicodeTranslateError_SetStart(PyObject *exc, Py_ssize_t start)
  Set the start attribute of the given exception object to start. Return 0 on success, -1 on failure.

int PyUnicodeDecodeError_GetEnd(PyObject *exc, Py_ssize_t *end)
int PyUnicodeEncodeError_GetEnd(PyObject *exc, Py_ssize_t *end)
int PyUnicodeTranslateError_GetEnd(PyObject *exc, Py_ssize_t *end)
  Get the end attribute of the given exception object and place it into
*end. end must not be NULL. Return 0 on success, -1 on failure.

int PyUnicodeDecodeError_SetEnd(PyObject *exc, Py_ssize_t end)
int PyUnicodeEncodeError_SetEnd(PyObject *exc, Py_ssize_t end)
int PyUnicodeTranslateError_SetEnd(PyObject *exc, Py_ssize_t end)
    Set the end attribute of the given exception object to end. Return 0 on success, -1 on failure.

PyObject*
PyUnicodeDecodeError_GetReason(PyObject *exc)
PyObject*
PyUnicodeEncodeError_GetReason(PyObject *exc)
PyObject*
PyUnicodeTranslateError_GetReason(PyObject *exc)
    Return the reason attribute of the given exception object.

int PyUnicodeDecodeError_SetReason(PyObject *exc, const char *reason)
int PyUnicodeEncodeError_SetReason(PyObject *exc, const char *reason)
int PyUnicodeTranslateError_SetReason(PyObject *exc, const char *reason)
    Set the reason attribute of the given exception object to reason. Return 0 on success, -1 on failure.
Recursion Control

These two functions provide a way to perform safe recursive calls at the C level, both in the core and in extension modules. They are needed if the recursive code does not necessarily invoke Python code (which tracks its recursion depth automatically).

int Py_EnterRecursiveCall(char *where)

Marks a point where a recursive C-level call is about to be performed.

If USE_STACKCHECK is defined, this function checks if the OS stack overflowed using PyOS_CheckStack(). In this case, it sets a MemoryError and returns a nonzero value.

The function then checks if the recursion limit is reached. If this is the case, a RuntimeError is set and a nonzero value is returned. Otherwise, zero is returned.

where should be a string such as " in instance check" to be concatenated to the RuntimeError message caused by the recursion depth limit.

void Py_LeaveRecursiveCall()

Ends a Py_EnterRecursiveCall(). Must be called once for each successful invocation of Py_EnterRecursiveCall().

Properly implementing tp_repr for container types requires special recursion handling. In addition to protecting the stack, tp_repr also needs to track objects to prevent cycles. The following two functions facilitate this functionality. Effectively, these are the C equivalent to
reprlib.recursive_repr().

int Py_ReprEnter(PyObject *object)
    Called at the beginning of the tp_repr implementation to detect cycles.

    If the object has already been processed, the function returns a positive integer. In that case the tp_repr implementation should return a string object indicating a cycle. As examples, dict objects return {...} and list objects return [...].

    The function will return a negative integer if the recursion limit is reached. In that case the tp_repr implementation should typically return NULL.

    Otherwise, the function returns zero and the tp_repr implementation can continue normally.

void Py_ReprLeave(PyObject *object)
    Ends a Py_ReprEnter(). Must be called once for each invocation of Py_ReprEnter() that returns zero.
Standard Exceptions

All standard Python exceptions are available as global variables whose names are `PyExc_` followed by the Python exception name. These have the type `PyObject*`; they are all class objects. For completeness, here are all the variables:

<table>
<thead>
<tr>
<th>C Name</th>
<th>Python Name</th>
</tr>
</thead>
<tbody>
<tr>
<td>PyExc_BaseException</td>
<td>BaseException</td>
</tr>
<tr>
<td>PyExc_Exception</td>
<td>Exception</td>
</tr>
<tr>

</tbody>
</table>

*New in version 3.3:* PyExc_BlockingIOError, PyExc_BrokenPipeError, PyExc_ChildProcessError,
PyExc_ConnectionError, PyExc_ConnectionAbortedError, PyExc_ConnectionRefusedError, PyExc_ConnectionResetError, PyExc_FileExistsError, PyExc_FileNotFoundError, PyExc_IsADirectoryError, PyExc_NotADirectoryError, PyExc_PermissionError, PyExc_ProcessLookupError and PyExc_TimeoutError were introduced following PEP 3151.

These are compatibility aliases to PyExc_OSError:

<table>
<thead>
<tr>
<th>C Name</th>
<th>Notes</th>
</tr>
</thead>
<tbody>
<tr>
<td>PyExc_EnvironmentError</td>
<td></td>
</tr>
<tr>
<td>PyExc_IOError</td>
<td></td>
</tr>
<tr>
<td>PyExc_WindowsError</td>
<td>(3)</td>
</tr>
</tbody>
</table>

*Changed in version 3.3:* These aliases used to be separate exception types.

**Notes:**

1. This is a base class for other standard exceptions.
2. This is the same as `weakref.ReferenceError`.
3. Only defined on Windows; protect code that uses this by testing that the preprocessor macro `MS_WINDOWS` is defined.
Utilities

The functions in this chapter perform various utility tasks, ranging from helping C code be more portable across platforms, using Python modules from C, and parsing function arguments and constructing Python values from C values.

- Operating System Utilities
- System Functions
- Process Control
- Importing Modules
- Data marshalling support
- Parsing arguments and building values
  - Parsing arguments
    - Strings and buffers
    - Numbers
    - Other objects
    - API Functions
  - Building values
- String conversion and formatting
- Reflection
- Codec registry and support functions
  - Codec lookup API
  - Registry API for Unicode encoding error handlers
Operating System Utilities

int Py_FdIsInteractive(FILE *fp, const char *filename)

Return true (nonzero) if the standard I/O file fp with name filename is deemed interactive. This is the case for files for which isatty(fileno(fp)) is true. If the global flag Py_InteractiveFlag is true, this function also returns true if the filename pointer is NULL or if the name is equal to one of the strings '<stdin>' or '?'?

void PyOS_AfterFork()

Function to update some internal state after a process fork; this should be called in the new process if the Python interpreter will continue to be used. If a new executable is loaded into the new process, this function does not need to be called.

int PyOS_CheckStack()

Return true when the interpreter runs out of stack space. This is a reliable check, but is only available when USE_STACKCHECK is defined (currently on Windows using the Microsoft Visual C++ compiler). USE_STACKCHECK will be defined automatically; you should never change the definition in your own code.

PyOS_sighandler_t PyOS_getsig(int i)

Return the current signal handler for signal i. This is a thin wrapper around either sigaction() or signal(). Do not call those functions directly! PyOS_sighandler_t is a typedef alias for void (*)(int).

PyOS_sighandler_t PyOS_setsig(int i, PyOS_sighandler_t h)
Set the signal handler for signal \( i \) to be \( h \); return the old signal handler. This is a thin wrapper around either \texttt{sigaction()} or \texttt{signal()}. Do not call those functions directly! \texttt{PyOS\_sighandler\_t} is a typedef alias for \texttt{void (*)(int)}.
System Functions

These are utility functions that make functionality from the `sys` module accessible to C code. They all work with the current interpreter thread's `sys` module's dict, which is contained in the internal thread state structure.

**PyObject PySysGetObject(char *name)**

*Return value: Borrowed reference.*

Return the object `name` from the `sys` module or `NULL` if it does not exist, without setting an exception.

**int PySys_SetObject(char *name, PyObject *v)**

Set `name` in the `sys` module to `v` unless `v` is `NULL`, in which case `name` is deleted from the `sys` module. Returns 0 on success, -1 on error.

**void PySys_ResetWarnOptions()**

Reset `sys.warnoptions` to an empty list.

**void PySys_AddWarnOption(wchar_t *s)**

Append `s` to `sys.warnoptions`.

**void PySys_AddWarnOptionUnicode(PyObject *unicode)**

Append `unicode` to `sys.warnoptions`.

**void PySys_SetPath(wchar_t *path)**

Set `sys.path` to a list object of paths found in `path` which should be a list of paths separated with the platform's search path delimiter (`:` on Unix, `;` on Windows).
void **PySys_WriteStdout**(const char *format, ...)  
Write the output string described by format to **sys.stdout**. No exceptions are raised, even if truncation occurs (see below).

format should limit the total size of the formatted output string to 1000 bytes or less – after 1000 bytes, the output string is truncated. In particular, this means that no unrestricted “%s” formats should occur; these should be limited using “%.<N>s” where <N> is a decimal number calculated so that <N> plus the maximum size of other formatted text does not exceed 1000 bytes. Also watch out for “%f”, which can print hundreds of digits for very large numbers.

If a problem occurs, or **sys.stdout** is unset, the formatted message is written to the real (C level) **stdout**.

void **PySys_WriteStderr**(const char *format, ...)  
As **PySys_WriteStdout()**, but write to **sys.stderr** or stderr instead.

void **PySys_FormatStdout**(const char *format, ...)  
Function similar to **PySys_WriteStdout()** but format the message using **PyUnicode_FromFormatV()** and don’t truncate the message to an arbitrary length.

*New in version 3.2.*

void **PySys_FormatStderr**(const char *format, ...)  
As **PySys_FormatStdout()**, but write to **sys.stderr** or stderr instead.

*New in version 3.2.*
void PySys_AddXOption(const wchar_t *s)
    Parse s as a set of -X options and add them to the current options mapping as returned by PySys_GetXOptions().

    New in version 3.2.

PyObject *PySys_GetXOptions()
    Return value: Borrowed reference.
    Return the current dictionary of -X options, similarly to sys._xoptions. On error, NULL is returned and an exception is set.

    New in version 3.2.
Process Control

void **Py_FatalError**(const char *\textit{message})

Print a fatal error message and kill the process. No cleanup is performed. This function should only be invoked when a condition is detected that would make it dangerous to continue using the Python interpreter; e.g., when the object administration appears to be corrupted. On Unix, the standard C library function \texttt{abort()} is called which will attempt to produce a core file.

void **Py_Exit**(int \textit{status})

Exit the current process. This calls \texttt{Py_Finalize()} and then calls the standard C library function \texttt{exit(status)}.

int **Py_AtExit**(void (*\textit{func})())

Register a cleanup function to be called by \texttt{Py_Finalize()}. The cleanup function will be called with no arguments and should return no value. At most 32 cleanup functions can be registered. When the registration is successful, \texttt{Py_AtExit()} returns 0; on failure, it returns -1. The cleanup function registered last is called first. Each cleanup function will be called at most once. Since Python's internal finalization will have completed before the cleanup function, no Python APIs should be called by \textit{func}.
Importing Modules

PyObject* PyImport_ImportModule(const char *name)

*Return value: New reference.*

This is a simplified interface to PyImport_ImportModuleEx() below, leaving the `globals` and `locals` arguments set to `NULL` and `level` set to 0. When the `name` argument contains a dot (when it specifies a submodule of a package), the `fromlist` argument is set to the list `['*']` so that the return value is the named module rather than the top-level package containing it as would otherwise be the case. (Unfortunately, this has an additional side effect when `name` in fact specifies a subpackage instead of a submodule: the submodules specified in the package’s `__all__` variable are loaded.) Return a new reference to the imported module, or `NULL` with an exception set on failure. A failing import of a module doesn’t leave the module in `sys.modules`.

This function always uses absolute imports.

PyObject* PyImport_ImportModuleNoBlock(const char *name)

This function is a deprecated alias of PyImport_ImportModule().

*Changed in version 3.3:* This function used to fail immediately when the import lock was held by another thread. In Python 3.3 though, the locking scheme switched to per-module locks for most purposes, so this function’s special behaviour isn’t needed anymore.

PyObject* PyImport_ImportModuleEx(char *name,
PyObject *globals, PyObject *locals, PyObject *fromlist)

Import a module. This is best described by referring to the built-in Python function __import__().

The return value is a new reference to the imported module or top-level package, or NULL with an exception set on failure. Like for __import__(), the return value when a submodule of a package was requested is normally the top-level package, unless a non-empty fromlist was given.

Failing imports remove incomplete module objects, like with PyImport_ImportModule().

PyObject *
PyImport_ImportModuleLevelObject(PyObject *name, PyObject *globals, PyObject *locals, PyObject *fromlist, int level)

Import a module. This is best described by referring to the built-in Python function __import__(), as the standard __import__() function calls this function directly.

The return value is a new reference to the imported module or top-level package, or NULL with an exception set on failure. Like for __import__(), the return value when a submodule of a package was requested is normally the top-level package, unless a non-empty fromlist was given.

New in version 3.3.

PyObject * PyImport_ImportModuleLevel(char *name, PyObject *globals, PyObject *locals, PyObject *fromlist, int level)

Similar to PyImport_ImportModuleLevelObject(), but the
name is an UTF-8 encoded string instead of a Unicode object.

*Changed in version 3.3*: Negative values for *level* are no longer accepted.

**PyObject** `PyImport_Import(PyObject *name)`  
*Return value: New reference.*  
This is a higher-level interface that calls the current “import hook function” (with an explicit *level* of 0, meaning absolute import). It invokes the `__import__()` function from the `__builtins__` of the current globals. This means that the import is done using whatever import hooks are installed in the current environment.

This function always uses absolute imports.

**PyObject** `PyImport_ReloadModule(PyObject *m)`  
*Return value: New reference.*  
Reload a module. Return a new reference to the reloaded module, or NULL with an exception set on failure (the module still exists in this case).

**PyObject** `PyImport_AddModuleObject(PyObject *name)`  
Return the module object corresponding to a module name. The *name* argument may be of the form `package.module`. First check the modules dictionary if there’s one there, and if not, create a new one and insert it in the modules dictionary. Return NULL with an exception set on failure.

**Note:** This function does not load or import the module; if the module wasn’t already loaded, you will get an empty module object. Use `PyImport_ImportModule()` or one of its variants to import a module. Package structures implied by a dotted name for *name* are not created if not already present.
New in version 3.3.

PyObject* PyImport_AddModule(const char *name)

*Return value: Borrowed reference.*
Similar to PyImport_AddModuleObject(), but the name is a UTF-8 encoded string instead of a Unicode object.

PyObject* PyImport_ExecCodeModule(const char *name, PyObject *co)

*Return value: New reference.*
Given a module name (possibly of the form package.module) and a code object read from a Python bytecode file or obtained from the built-in function compile(), load the module. Return a new reference to the module object, or NULL with an exception set if an error occurred. name is removed from sys.modules in error cases, even if name was already in sys.modules on entry to PyImport_ExecCodeModule(). Leaving incompletely initialized modules in sys.modules is dangerous, as imports of such modules have no way to know that the module object is an unknown (and probably damaged with respect to the module author’s intents) state.

The module’s __file__ attribute will be set to the code object’s co_filename.

This function will reload the module if it was already imported. See PyImport_ReloadModule() for the intended way to reload a module.

If name points to a dotted name of the form package.module, any package structures not already created will still not be created.
See also `PyImport_ExecCodeModuleEx()` and `PyImport_ExecCodeModuleWithPathnames()`.

**PyObject**

**PyImport_ExecCodeModuleEx**(const char *name, PyObject *co, const char *pathname)

*Return value: New reference.*

Like `PyImport_ExecCodeModule()`, but the __file__ attribute of the module object is set to *pathname* if it is non-NULL.

See also `PyImport_ExecCodeModuleWithPathnames()`.

**PyObject**

**PyImport_ExecCodeModuleObject**(PyObject *name, PyObject *co, PyObject *pathname, PyObject *cpathname)

Like `PyImport_ExecCodeModuleEx()`, but the __cached__ attribute of the module object is set to *cpathname* if it is non-NULL.

Of the three functions, this is the preferred one to use.

*New in version 3.3.*

**PyObject**

**PyImport_ExecCodeModuleWithPathnames**(const char *name, PyObject *co, const char *pathname, const char *cpathname)

Like `PyImport_ExecCodeModuleObject()`, but *name*, *pathname* and *cpathname* are UTF-8 encoded strings. Attempts are also made to figure out what the value for *pathname* should be from *cpathname* if the former is set to NULL.

*New in version 3.2.*

*Changed in version 3.3:* Uses `imp.source_from_cache()` in calculating the source path if only the bytecode path is provided.
long PyImport_GetMagicNumber()

Return the magic number for Python bytecode files (a.k.a. .pyc and .pyo files). The magic number should be present in the first four bytes of the bytecode file, in little-endian byte order. Returns -1 on error.

*Changed in version 3.3:* Return value of -1 upon failure.

const char * PyImport_GetMagicTag()

Return the magic tag string for PEP 3147 format Python bytecode file names. Keep in mind that the value at sys.implementation.cache_tag is authoritative and should be used instead of this function.

*New in version 3.2.*

PyObject* PyImport_GetModuleDict()

*Return value: Borrowed reference.*

Return the dictionary used for the module administration (a.k.a. sys.modules). Note that this is a per-interpreter variable.

PyObject* PyImport_GetImporter(PyObject *path)

Return an importer object for a sys.path/pkg.__path__ item path, possibly by fetching it from the sys.path_importer_cache dict. If it wasn’t yet cached, traverse sys.path_hooks until a hook is found that can handle the path item. Return None if no hook could; this tells our caller it should fall back to the built-in import mechanism. Cache the result in sys.path_importer_cache. Return a new reference to the importer object.

void _PyImport_Init()
Initialize the import mechanism. For internal use only.

```c
void PyImport_Cleanup()
```
Empty the module table. For internal use only.

```c
void _PyImport_Fini()
```
Finalize the import mechanism. For internal use only.

```c
PyObject* _PyImport_FindExtension(char *, char *)
```
For internal use only.

```c
PyObject* _PyImport_FixupExtension(char *, char *)
```
For internal use only.

```c
int PyImport_ImportFrozenModuleObject(PyObject *name)
```
Load a frozen module named `name`. Return 1 for success, 0 if the module is not found, and -1 with an exception set if the initialization failed. To access the imported module on a successful load, use `PyImport_ImportModule()`. (Note the misnomer — this function would reload the module if it was already imported.)

New in version 3.3.

```c
int PyImport_ImportFrozenModule(const char *name)
```
Similar to `PyImport_ImportFrozenModuleObject()`, but the name is a UTF-8 encoded string instead of a Unicode object.

```c
struct _frozen
```
This is the structure type definition for frozen module descriptors, as generated by the `freeze` utility (see `Tools/freeze/` in the Python source distribution). Its definition, found in `Include/import.h`, is:
struct _frozen {
    char *name;
    unsigned char *code;
    int size;
};

struct _frozen* PyImport_FrozenModules
This pointer is initialized to point to an array of struct _frozen records, terminated by one whose members are all NULL or zero. When a frozen module is imported, it is searched in this table. Third-party code could play tricks with this to provide a dynamically created collection of frozen modules.

int PyImport_AppendInitTab(const char *name, PyObject* (*initfunc)(void))
Add a single module to the existing table of built-in modules. This is a convenience wrapper around PyImport_ExtendInitTab(), returning -1 if the table could not be extended. The new module can be imported by the name name, and uses the function initfunc as the initialization function called on the first attempted import. This should be called before Py_Initialize().

struct _inittab
Structure describing a single entry in the list of built-in modules. Each of these structures gives the name and initialization function for a module built into the interpreter. The name is an ASCII encoded string. Programs which embed Python may use an array of these structures in conjunction with PyImport_ExtendInitTab() to provide additional built-in modules. The structure is defined in Include/import.h as:

struct _inittab {

int PyImport_ExtendInittab(struct _inittab *newtab)

Add a collection of modules to the table of built-in modules. The newtab array must end with a sentinel entry which contains NULL for the name field; failure to provide the sentinel value can result in a memory fault. Returns 0 on success or -1 if insufficient memory could be allocated to extend the internal table. In the event of failure, no modules are added to the internal table. This should be called before Py_Initialize().
Data marshalling support

These routines allow C code to work with serialized objects using the same data format as the `marshal` module. There are functions to write data into the serialization format, and additional functions that can be used to read the data back. Files used to store marshalled data must be opened in binary mode.

Numeric values are stored with the least significant byte first.

The module supports two versions of the data format: version 0 is the historical version, version 1 shares interned strings in the file, and upon unmarshalling. Version 2 uses a binary format for floating point numbers. `Py_MARSHAL_VERSION` indicates the current file format (currently 2).

```c
void PyMarshal_WriteLongToFile(long value, FILE *file, int version)
    Marshal a long integer, value, to file. This will only write the least-significant 32 bits of value; regardless of the size of the native long type. version indicates the file format.

void PyMarshal_WriteObjectToFile(PyObject *value, FILE *file, int version)
    Marshal a Python object, value, to file. version indicates the file format.

PyObject*
PyMarshal_WriteObjectToString(PyObject *value, int version)
    Return a string object containing the marshalled representation of
value. version indicates the file format.

The following functions allow marshalled values to be read back in.

XXX What about error detection? It appears that reading past the end of the file will always result in a negative numeric value (where that's relevant), but it's not clear that negative values won't be handled properly when there's no error. What's the right way to tell? Should only non-negative values be written using these routines?

long PyMarshal_ReadLongFromFile(FILE *file)
    Return a C long from the data stream in a FILE* opened for reading. Only a 32-bit value can be read in using this function, regardless of the native size of long.

int PyMarshal_ReadShortFromFile(FILE *file)
    Return a C short from the data stream in a FILE* opened for reading. Only a 16-bit value can be read in using this function, regardless of the native size of short.

PyObject* PyMarshal_ReadObjectFromFile(FILE *file)
    Return a Python object from the data stream in a FILE* opened for reading. On error, sets the appropriate exception (EOFError or TypeError) and returns NULL.

PyObject*
PyMarshal_ReadLastObjectFromFile(FILE *file)
    Return a Python object from the data stream in a FILE* opened for reading. Unlike PyMarshal_ReadObjectFromFile(), this function assumes that no further objects will be read from the file,
allowing it to aggressively load file data into memory so that the de-
serialization can operate from data in memory rather than reading
a byte at a time from the file. Only use these variant if you are
certain that you won’t be reading anything else from the file. On
error, sets the appropriate exception (EOFError or TypeError)
and returns NULL.

PyObject* PyMarshal_ReadObjectFromStream(char *string,
Py_ssize_t len)

Return a Python object from the data stream in a character buffer
containing len bytes pointed to by string. On error, sets the
appropriate exception (EOFError or TypeError) and returns
NULL.
Parsing arguments and building values

These functions are useful when creating your own extensions functions and methods. Additional information and examples are available in *Extending and Embedding the Python Interpreter*.

The first three of these functions described, `PyArg_ParseTuple()`, `PyArg_ParseTupleAndKeywords()`, and `PyArg_Parse()`, all use *format strings* which are used to tell the function about the expected arguments. The format strings use the same syntax for each of these functions.
Parsing arguments

A format string consists of zero or more “format units.” A format unit describes one Python object; it is usually a single character or a parenthesized sequence of format units. With a few exceptions, a format unit that is not a parenthesized sequence normally corresponds to a single address argument to these functions. In the following description, the quoted form is the format unit; the entry in (round) parentheses is the Python object type that matches the format unit; and the entry in [square] brackets is the type of the C variable(s) whose address should be passed.

Strings and buffers

These formats allow to access an object as a contiguous chunk of memory. You don’t have to provide raw storage for the returned unicode or bytes area. Also, you won’t have to release any memory yourself, except with the es, es#, et and et# formats.

However, when a Py_buffer structure gets filled, the underlying buffer is locked so that the caller can subsequently use the buffer even inside a Py_BEGIN_ALLOW_THREADS block without the risk of mutable data being resized or destroyed. As a result, you have to call PyBuffer_Release() after you have finished processing the data (or in any early abort case).

Unless otherwise stated, buffers are not NUL-terminated.

Note: For all # variants of formats (s#, y#, etc.), the type of the length argument (int or Py_ssize_t) is controlled by defining the macro PY_SSIZE_T_CLEAN before including Python.h. If the
Macro was defined, length is a Py_ssize_t rather than an int. This behavior will change in a future Python version to only support Py_ssize_t and drop int support. It is best to always define PY_SSIZE_T_CLEAN.

`s (str) [const char *]`
Convert a Unicode object to a C pointer to a character string. A pointer to an existing string is stored in the character pointer variable whose address you pass. The C string is NUL-terminated. The Python string must not contain embedded NUL bytes; if it does, a TypeError exception is raised. Unicode objects are converted to C strings using 'utf-8' encoding. If this conversion fails, a UnicodeError is raised.

**Note:** This format does not accept bytes-like objects. If you want to accept filesystem paths and convert them to C character strings, it is preferable to use the 0& format with `PyUnicode_FSConverter()` as converter.

`s* (str, bytes, bytearray or buffer compatible object) [Py_buffer]`
This format accepts Unicode objects as well as bytes-like objects. It fills a Py_buffer structure provided by the caller. In this case the resulting C string may contain embedded NUL bytes. Unicode objects are converted to C strings using 'utf-8' encoding.

`s# (str, bytes or read-only buffer compatible object) [const char *, int or Py_ssize_t]`
Like s*, except that it doesn’t accept mutable buffer-like objects such as bytearray. The result is stored into two C variables, the first one a pointer to a C string, the second one its length. The string may contain embedded null bytes. Unicode objects are converted to C strings using 'utf-8' encoding.

\[\text{z (str or None) [const char *]}\]
Like \text{s}, but the Python object may also be \text{None}, in which case the C pointer is set to \text{NULL}.

\[\text{z* (str, bytes, bytearray, buffer compatible object or None) [Py_buffer]}\]
Like \text{s*}, but the Python object may also be \text{None}, in which case the \text{buf} member of the \text{Py_buffer} structure is set to \text{NULL}.

\[\text{z# (str, bytes, read-only buffer compatible object or None) [const char *, int]}\]
Like \text{s#}, but the Python object may also be \text{None}, in which case the C pointer is set to \text{NULL}.

\[\text{y (bytes) [const char *]}\]
This format converts a bytes-like object to a C pointer to a character string; it does not accept Unicode objects. The bytes buffer must not contain embedded NUL bytes; if it does, a \text{TypeError} exception is raised.

\[\text{y* (bytes, bytearray or bytes-like object) [Py_buffer]}\]
This variant on \text{s*} doesn’t accept Unicode objects, only \text{bytes-like objects}. \textbf{This is the recommended way to accept binary data.}

\[\text{y# (bytes) [const char *, int]}\]
This variant on \text{s#} doesn’t accept Unicode objects, only \text{bytes-like objects}.

\[\text{S (bytes) [PyBytesObject *]}\]
Requires that the Python object is a \text{bytes} object, without attempting any conversion. Raises \text{TypeError} if the object is not a bytes object. The C variable may also be declared as \text{PyObject*}.

\[\text{Y (bytearray) [PyByteArrayObject *]}\]
Requires that the Python object is a \text{bytearray} object, without attempting any conversion. Raises \text{TypeError} if the object is not
a `bytearray` object. The C variable may also be declared as `PyObject*`.

\[u\text{(str)}\text{[Py\_UNICODE \*]}\]

Convert a Python Unicode object to a C pointer to a NUL-terminated buffer of Unicode characters. You must pass the address of a `Py\_UNICODE` pointer variable, which will be filled with the pointer to an existing Unicode buffer. Please note that the width of a `Py\_UNICODE` character depends on compilation options (it is either 16 or 32 bits). The Python string must not contain embedded NUL characters; if it does, a `TypeError` exception is raised.

**Note:** Since `u` doesn't give you back the length of the string, and it may contain embedded NUL characters, it is recommended to use `u#` or `U` instead.

\[u\#\text{(str)}\text{[Py\_UNICODE \*, int]}\]

This variant on `u` stores into two C variables, the first one a pointer to a Unicode data buffer, the second one its length.

\[Z\text{(str or None)}\text{[Py\_UNICODE \*]}\]

Like `u`, but the Python object may also be `None`, in which case the `Py\_UNICODE` pointer is set to `NULL`.

\[Z\#\text{(str or None)}\text{[Py\_UNICODE \*, int]}\]

Like `u#`, but the Python object may also be `None`, in which case the `Py\_UNICODE` pointer is set to `NULL`.

\[U\text{(str)}\text{[PyObject \*]}\]

Requires that the Python object is a Unicode object, without attempting any conversion. Raises `TypeError` if the object is not a Unicode object. The C variable may also be declared as `PyObject*`.

\[w\text{* (bytearray or read-write byte-oriented buffer)}\text{[Py\_buffer]}\]
This format accepts any object which implements the read-write buffer interface. It fills a Py_buffer structure provided by the caller. The buffer may contain embedded null bytes. The caller have to call PyBuffer_Release() when it is done with the buffer.

es (str) [const char *encoding, char **buffer]

This variant on s is used for encoding Unicode into a character buffer. It only works for encoded data without embedded NUL bytes.

This format requires two arguments. The first is only used as input, and must be a const char* which points to the name of an encoding as a NUL-terminated string, or NULL, in which case 'utf-8' encoding is used. An exception is raised if the named encoding is not known to Python. The second argument must be a char**; the value of the pointer it references will be set to a buffer with the contents of the argument text. The text will be encoded in the encoding specified by the first argument.

PyArg_ParseTuple() will allocate a buffer of the needed size, copy the encoded data into this buffer and adjust *buffer to reference the newly allocated storage. The caller is responsible for calling PyMem_Free() to free the allocated buffer after use.

et (str, bytes or bytearray) [const char *encoding, char **buffer]

Same as es except that byte string objects are passed through without recoding them. Instead, the implementation assumes that the byte string object uses the encoding passed in as parameter.

es# (str) [const char *encoding, char **buffer, int *buffer_length]

This variant on s# is used for encoding Unicode into a character buffer. Unlike the es format, this variant allows input data which contains NUL characters.
It requires three arguments. The first is only used as input, and must be a `const char*` which points to the name of an encoding as a NUL-terminated string, or `NULL`, in which case `utf-8` encoding is used. An exception is raised if the named encoding is not known to Python. The second argument must be a `char**`; the value of the pointer it references will be set to a buffer with the contents of the argument text. The text will be encoded in the encoding specified by the first argument. The third argument must be a pointer to an integer; the referenced integer will be set to the number of bytes in the output buffer.

There are two modes of operation:

If `*buffer` points a `NULL` pointer, the function will allocate a buffer of the needed size, copy the encoded data into this buffer and set `*buffer` to reference the newly allocated storage. The caller is responsible for calling `PyMem_Free()` to free the allocated buffer after usage.

If `*buffer` points to a non-`NULL` pointer (an already allocated buffer), `PyArg_ParseTuple()` will use this location as the buffer and interpret the initial value of `*buffer_length` as the buffer size. It will then copy the encoded data into the buffer and NUL-terminate it. If the buffer is not large enough, a `ValueError` will be set.

In both cases, `*buffer_length` is set to the length of the encoded data without the trailing NUL byte.

```
( str, bytes or bytearray ) [const char *encoding, char **buffer, int *buffer_length]
```

Same as `es#` except that byte string objects are passed through without recoding them. Instead, the implementation assumes that the byte string object uses the encoding passed in as parameter.
Numbers

\(b\) (int) [unsigned char]
  Convert a nonnegative Python integer to an unsigned tiny int, stored in a C unsigned char.

\(B\) (int) [unsigned char]
  Convert a Python integer to a tiny int without overflow checking, stored in a C unsigned char.

\(h\) (int) [short int]
  Convert a Python integer to a C short int.

\(H\) (int) [unsigned short int]
  Convert a Python integer to a C unsigned short int, without overflow checking.

\(i\) (int) [int]
  Convert a Python integer to a plain C int.

\(I\) (int) [unsigned int]
  Convert a Python integer to a C unsigned int, without overflow checking.

\(l\) (int) [long int]
  Convert a Python integer to a C long int.

\(k\) (int) [unsigned long]
  Convert a Python integer to a C unsigned long without overflow checking.

\(L\) (int) [PY_LONG_LONG]
  Convert a Python integer to a C long long. This format is only available on platforms that support long long (or _int64 on Windows).

\(K\) (int) [unsigned PY_LONG_LONG]
  Convert a Python integer to a C unsigned long long without
overflow checking. This format is only available on platforms that support unsigned `long long` (or unsigned `__int64` on Windows).

```
 n (int) [Py_ssize_t]
    Convert a Python integer to a C Py_ssize_t.

c (bytes or bytearray of length 1) [char]
    Convert a Python byte, represented as a bytes or bytearray object of length 1, to a C char.

    Changed in version 3.3: Allow bytearray objects.

C (str of length 1) [int]
    Convert a Python character, represented as a str object of length 1, to a C int.

f (float) [float]
    Convert a Python floating point number to a C float.

d (float) [double]
    Convert a Python floating point number to a C double.

D (complex) [Py_complex]
    Convert a Python complex number to a C Py_complex structure.
```

**Other objects**

```
0 (object) [PyObject *]
    Store a Python object (without any conversion) in a C object pointer. The C program thus receives the actual object that was passed. The object's reference count is not increased. The pointer stored is not NULL.

0! (object) [typeobject, PyObject *]
    Store a Python object in a C object pointer. This is similar to 0, but takes two C arguments: the first is the address of a Python type
object, the second is the address of the C variable (of type \texttt{PyObject*}) into which the object pointer is stored. If the Python object does not have the required type, \texttt{TypeError} is raised.

\texttt{O-& (object) [converter, anything]}

Convert a Python object to a C variable through a \texttt{converter} function. This takes two arguments: the first is a function, the second is the address of a C variable (of arbitrary type), converted to \texttt{void*}. The \texttt{converter} function in turn is called as follows:

\begin{verbatim}
status = converter(object, address);
\end{verbatim}

where \texttt{object} is the Python object to be converted and \texttt{address} is the \texttt{void*} argument that was passed to the \texttt{PyArg_Parse*()} function. The returned \texttt{status} should be \texttt{1} for a successful conversion and \texttt{0} if the conversion has failed. When the conversion fails, the \texttt{converter} function should raise an exception and leave the content of \texttt{address} unmodified.

If the \texttt{converter} returns \texttt{Py\_CLEANUP\_SUPPORTED}, it may get called a second time if the argument parsing eventually fails, giving the converter a chance to release any memory that it had already allocated. In this second call, the \texttt{object} parameter will be \texttt{NULL}; \texttt{address} will have the same value as in the original call.

\textit{Changed in version 3.1:} \texttt{Py\_CLEANUP\_SUPPORTED} was added.

\texttt{p (bool) \[int\]}

Tests the value passed in for truth (a boolean \texttt{predicate}) and converts the result to its equivalent C true/false integer value. Sets the \texttt{int} to \texttt{1} if the expression was true and \texttt{0} if it was false. This accepts any valid Python value. See \textit{Truth Value Testing} for more information about how Python tests values for truth.
New in version 3.3.

(items) (tuple) [matching-items]

The object must be a Python sequence whose length is the number of format units in items. The C arguments must correspond to the individual format units in items. Format units for sequences may be nested.

It is possible to pass “long” integers (integers whose value exceeds the platform’s LONG_MAX) however no proper range checking is done — the most significant bits are silently truncated when the receiving field is too small to receive the value (actually, the semantics are inherited from downcasts in C — your mileage may vary).

A few other characters have a meaning in a format string. These may not occur inside nested parentheses. They are:

\ | Indicates that the remaining arguments in the Python argument list are optional. The C variables corresponding to optional arguments should be initialized to their default value — when an optional argument is not specified, PyArg_ParseTuple() does not touch the contents of the corresponding C variable(s).

\$ PyArg_ParseTupleAndKeywords() only: Indicates that the remaining arguments in the Python argument list are keyword-only. Currently, all keyword-only arguments must also be optional arguments, so | must always be specified before $ in the format string.

New in version 3.3.

: The list of format units ends here; the string after the colon is used
as the function name in error messages (the “associated value” of the exception that `PyArg_ParseTuple()` raises).

;

The list of format units ends here; the string after the semicolon is used as the error message *instead* of the default error message. ; and ; mutually exclude each other.

Note that any Python object references which are provided to the caller are *borrowed* references; do not decrement their reference count!

Additional arguments passed to these functions must be addresses of variables whose type is determined by the format string; these are used to store values from the input tuple. There are a few cases, as described in the list of format units above, where these parameters are used as input values; they should match what is specified for the corresponding format unit in that case.

For the conversion to succeed, the *arg* object must match the format and the format must be exhausted. On success, the `PyArg_Parse*()` functions return true, otherwise they return false and raise an appropriate exception. When the `PyArg_Parse*()` functions fail due to conversion failure in one of the format units, the variables at the addresses corresponding to that and the following format units are left untouched.

**API Functions**

```c
int PyArg_ParseTuple(PyObject *args, const char *format, ...)  
```

Parse the parameters of a function that takes only positional parameters into local variables. Returns true on success; on failure, it returns false and raises the appropriate exception.
int PyArg_VaParse(PyObject *args, const char *format, va_list vargs)
    Identical to PyArg_ParseTuple(), except that it accepts a va_list rather than a variable number of arguments.

int PyArg_ParseTupleAndKeywords(PyObject *args, PyObject *kw, const char *format, char *keywords[], ...) Parse the parameters of a function that takes both positional and keyword parameters into local variables. Returns true on success; on failure, it returns false and raises the appropriate exception.

int PyArg_VaParseTupleAndKeywords(PyObject *args, PyObject *kw, const char *format, char *keywords[], va_list vargs) Identical to PyArg_ParseTupleAndKeywords(), except that it accepts a va_list rather than a variable number of arguments.

int PyArg_ValidateKeywordArguments(PyObject *) Ensure that the keys in the keywords argument dictionary are strings. This is only needed if PyArg_ParseTupleAndKeywords() is not used, since the latter already does this check.

*New in version 3.2.*

int PyArg_Parse(PyObject *args, const char *format, ...) Function used to deconstruct the argument lists of “old-style” functions — these are functions which use the METH_OLDARGS parameter parsing method. This is not recommended for use in parameter parsing in new code, and most code in the standard interpreter has been modified to no longer use this for that purpose. It does remain a convenient way to decompose other tuples, however, and may continue to be used for that purpose.
int PyArg_UnpackTuple(PyObject *args, const char *name,
Py_ssize_t min, Py_ssize_t max, ...)

A simpler form of parameter retrieval which does not use a format
string to specify the types of the arguments. Functions which use
this method to retrieve their parameters should be declared as
METH_VARARGS in function or method tables. The tuple containing
the actual parameters should be passed as args; it must actually
be a tuple. The length of the tuple must be at least min and no
more than max; min and max may be equal. Additional arguments
must be passed to the function, each of which should be a pointer
to a PyObject* variable; these will be filled in with the values
from args; they will contain borrowed references. The variables
which correspond to optional parameters not given by args will not
be filled in; these should be initialized by the caller. This function
returns true on success and false if args is not a tuple or contains
the wrong number of elements; an exception will be set if there was
a failure.

This is an example of the use of this function, taken from the
sources for the _weakref helper module for weak references:

```c
static PyObject *
weakref_ref(PyObject *self, PyObject *args)
{
    PyObject *object;
    PyObject *callback = NULL;
    PyObject *result = NULL;

    if (PyArg_UnpackTuple(args, "ref", 1, 2, &object,
                    result = PyWeakref_NewRef(object, callback)
    }
    return result;
}
```
The call to `PyArg_UnpackTuple()` in this example is entirely equivalent to this call to `PyArg_ParseTuple()`:

```c
PyArg_ParseTuple(args, "O|O:ref", &object, &callback)
```
Building values

**PyObject**\* Py\_BuildValue(const char \*format, ...)

*Return value: New reference.*

Create a new value based on a format string similar to those accepted by the PyArg\_Parse\*() family of functions and a sequence of values. Returns the value or NULL in the case of an error; an exception will be raised if NULL is returned.

Py\_BuildValue() does not always build a tuple. It builds a tuple only if its format string contains two or more format units. If the format string is empty, it returns None; if it contains exactly one format unit, it returns whatever object is described by that format unit. To force it to return a tuple of size 0 or one, parenthesize the format string.

When memory buffers are passed as parameters to supply data to build objects, as for the s and s# formats, the required data is copied. Buffers provided by the caller are never referenced by the objects created by Py\_BuildValue(). In other words, if your code invokes malloc() and passes the allocated memory to Py\_BuildValue(), your code is responsible for calling free() for that memory once Py\_BuildValue() returns.

In the following description, the quoted form is the format unit; the entry in (round) parentheses is the Python object type that the format unit will return; and the entry in [square] brackets is the type of the C value(s) to be passed.

The characters space, tab, colon and comma are ignored in format strings (but not within format units such as s#). This can be used
to make long format strings a tad more readable.

s (str or None) [char *]
Convert a null-terminated C string to a Python str object using 'utf-8' encoding. If the C string pointer is NULL, None is used.

s# (str or None) [char *, int]
Convert a C string and its length to a Python str object using 'utf-8' encoding. If the C string pointer is NULL, the length is ignored and None is returned.

y (bytes) [char *]
This converts a C string to a Python bytes object. If the C string pointer is NULL, None is returned.

y# (bytes) [char *, int]
This converts a C string and its length to a Python object. If the C string pointer is NULL, None is returned.

z (str or None) [char *]
Same as s.

z# (str or None) [char *, int]
Same as s#.

u (str) [Py_UNICODE *]
Convert a null-terminated buffer of Unicode (UCS-2 or UCS-4) data to a Python Unicode object. If the Unicode buffer pointer is NULL, None is returned.

u# (str) [Py_UNICODE *, int]
Convert a Unicode (UCS-2 or UCS-4) data buffer and its length to a Python Unicode object. If the Unicode buffer pointer is NULL, the length is ignored and None is returned.

U (str or None) [char *]
Same as s.

U# (str or None) [char *, int]
   Same as s#.

i (int) [int]
   Convert a plain C int to a Python integer object.

b (int) [char]
   Convert a plain C char to a Python integer object.

h (int) [short int]
   Convert a plain C short int to a Python integer object.

l (int) [long int]
   Convert a C long int to a Python integer object.

B (int) [unsigned char]
   Convert a C unsigned char to a Python integer object.

H (int) [unsigned short int]
   Convert a C unsigned short int to a Python integer object.

I (int) [unsigned int]
   Convert a C unsigned int to a Python integer object.

k (int) [unsigned long]
   Convert a C unsigned long to a Python integer object.

L (int) [PY_LONG_LONG]
   Convert a C long long to a Python integer object. Only available on platforms that support long long (or _int64 on Windows).

K (int) [unsigned PY_LONG_LONG]
   Convert a C unsigned long long to a Python integer object. Only available on platforms that support unsigned
long long (or unsigned _int64 on Windows).

n (int)[Py_ssize_t]
  Convert a C Py_ssize_t to a Python integer.

c (bytes of length 1)[char]
  Convert a C int representing a byte to a Python bytes object of length 1.

C (str of length 1)[int]
  Convert a C int representing a character to Python str object of length 1.

d (float)[double]
  Convert a C double to a Python floating point number.

f (float)[float]
  Convert a C float to a Python floating point number.

D (complex)[Py_complex *]
  Convert a C Py_complex structure to a Python complex number.

O (object)[PyObject *]
  Pass a Python object untouched (except for its reference count, which is incremented by one). If the object passed in is a NULL pointer, it is assumed that this was caused because the call producing the argument found an error and set an exception. Therefore, Py_BuildValue() will return NULL but won’t raise an exception. If no exception has been raised yet, SystemError is set.

S (object)[PyObject *]
  Same as O.

N (object)[PyObject *]
  Same as O, except it doesn’t increment the reference count on
the object. Useful when the object is created by a call to an object constructor in the argument list.

0& (object) [converter, anything]
Convert anything to a Python object through a converter function. The function is called with anything (which should be compatible with void *) as its argument and should return a “new” Python object, or NULL if an error occurred.

(items) (tuple) [matching-items]
Convert a sequence of C values to a Python tuple with the same number of items.

[items] (list) [matching-items]
Convert a sequence of C values to a Python list with the same number of items.

{items} (dict) [matching-items]
Convert a sequence of C values to a Python dictionary. Each pair of consecutive C values adds one item to the dictionary, serving as key and value, respectively.

If there is an error in the format string, the SystemError exception is set and NULL returned.

PyObject* Py_VaBuildValue(const char *format, va_list vargs)
Identical to Py_BuildValue(), except that it accepts a va_list rather than a variable number of arguments.
String conversion and formatting

Functions for number conversion and formatted string output.

```c
int PyOS_snprintf(char *str, size_t size, const char *format, ...)  
```

Output not more than `size` bytes to `str` according to the format string `format` and the extra arguments. See the Unix man page `snprintf(2)`.

```c
int PyOS_vsnprintf(char *str, size_t size, const char *format, va_list va)  
```

Output not more than `size` bytes to `str` according to the format string `format` and the variable argument list `va`. Unix man page `vsnprintf(2)`.

`PyOS_snprintf()` and `PyOS_vsnprintf()` wrap the Standard C library functions `snprintf()` and `vsnprintf()`. Their purpose is to guarantee consistent behavior in corner cases, which the Standard C functions do not.

The wrappers ensure that `str[\*size-1]` is always `\0` upon return. They never write more than `size` bytes (including the trailing `\0`) into `str`. Both functions require that `str` != NULL, `size` > 0 and `format` != NULL.

If the platform doesn’t have `vsnprintf()` and the buffer size needed to avoid truncation exceeds `size` by more than 512 bytes, Python aborts with a `Py_FatalError`.

The return value (`rv`) for these functions should be interpreted as follows:
- When \( 0 \leq rv < size \), the output conversion was successful and \( rv \) characters were written to \( str \) (excluding the trailing '0' byte at \( str[*rv] \)).
- When \( rv \geq size \), the output conversion was truncated and a buffer with \( rv + 1 \) bytes would have been needed to succeed. \( str[*size-1] \) is '0' in this case.
- When \( rv < 0 \), “something bad happened.” \( str[*size-1] \) is '0' in this case too, but the rest of \( str \) is undefined. The exact cause of the error depends on the underlying platform.

The following functions provide locale-independent string to number conversions.

```c
double PyOS_string_to_double(const char *s, char **endptr, PyObject *overflow_exception)
```
Convert a string \( s \) to a double, raising a Python exception on failure. The set of accepted strings corresponds to the set of strings accepted by Python’s `float()` constructor, except that \( s \) must not have leading or trailing whitespace. The conversion is independent of the current locale.

If \( endptr \) is NULL, convert the whole string. Raise ValueError and return \(-1.0\) if the string is not a valid representation of a floating-point number.

If \( endptr \) is not NULL, convert as much of the string as possible and set \(*endptr\) to point to the first unconverted character. If no initial segment of the string is the valid representation of a floating-point number, set \(*endptr\) to point to the beginning of the string, raise ValueError, and return \(-1.0\).

If \( s \) represents a value that is too large to store in a float (for
example, "1e500" is such a string on many platforms) then if
overflow_exception is NULL return Py_HUGE_VAL (with an
appropriate sign) and don’t set any exception. Otherwise,
overflow_exception must point to a Python exception object;
raise that exception and return -1.0. In both cases, set *endptr
to point to the first character after the converted value.

If any other error occurs during the conversion (for example an out-
of-memory error), set the appropriate Python exception and return
-1.0.

New in version 3.1.

char* PyOS_double_to_string(double val, char format_code,
int precision, int flags, int *ptype)
Convert a double val to a string using supplied format_code,
precision, and flags.

format_code must be one of 'e', 'E', 'f', 'F', 'g', 'G' or
'r'. For 'r', the supplied precision must be 0 and is ignored.
The 'r' format code specifies the standard repr() format.

flags can be zero or more of the values Py_DTSF_SIGN,
Py_DTSF_ADD_DOT_0, or Py_DTSF_ALT, or-ed together:

- Py_DTSF_SIGN means to always precede the returned string
  with a sign character, even if val is non-negative.
- Py_DTSF_ADD_DOT_0 means to ensure that the returned
  string will not look like an integer.
- Py_DTSF_ALT means to apply “alternate” formatting rules.
  See the documentation for the PyOS_snprintf() '#'
specifier for details.

If ptype is non-NULL, then the value it points to will be set to one of
Py_DTST_FINITE, Py_DTST_INFINITY, or Py_DTST_NAN, signifying that val is a finite number, an infinite number, or not a number, respectively.

The return value is a pointer to buffer with the converted string or NULL if the conversion failed. The caller is responsible for freeing the returned string by calling PyMem_Free().

New in version 3.1.

int PyOS_stricmp(char *s1, char *s2)

Case insensitive comparison of strings. The function works almost identically to strcmp() except that it ignores the case.

int PyOS_strnicmp(char *s1, char *s2, Py_ssize_t size)

Case insensitive comparison of strings. The function works almost identically to strncmp() except that it ignores the case.
Reflection

**PyObject* **PyEval_GetBuiltin**s()
*Return value: Borrowed reference.*
Return a dictionary of the builtins in the current execution frame, or the interpreter of the thread state if no frame is currently executing.

**PyObject* **PyEval_GetLocals**()
*Return value: Borrowed reference.*
Return a dictionary of the local variables in the current execution frame, or *NULL* if no frame is currently executing.

**PyObject* **PyEval_GetGlobals**()
*Return value: Borrowed reference.*
Return a dictionary of the global variables in the current execution frame, or *NULL* if no frame is currently executing.

**PyFrameObject** *PyEval_GetFrame**()
*Return value: Borrowed reference.*
Return the current thread state's frame, which is *NULL* if no frame is currently executing.

**int** **PyFrame_GetLineNumber** *(PyFrameObject *frame)*
Return the line number that *frame* is currently executing.

**const char** *PyEval_GetFuncName***(PyObject *func)*
Return the name of *func* if it is a function, class or instance object, else the name of *funcs* type.

**const char** *PyEval_GetFuncDesc***(PyObject *func)*
Return a description string, depending on the type of *func*. Return
values include “()” for functions and methods, ” constructor”, " instance”, and ” object”. Concatenated with the result of `PyEval_GetFuncName()` , the result will be a description of `func`. 
Codec registry and support functions

int **PyCodec_Register**(PyObject *search_function)

Register a new codec search function.

As side effect, this tries to load the encodings package, if not yet done, to make sure that it is always first in the list of search functions.

int **PyCodec_KnownEncoding**(const char *encoding)

Return 1 or 0 depending on whether there is a registered codec for the given *encoding*.

PyObject* **PyCodec_Encode**(PyObject *object, const char *encoding, const char *errors)

Generic codec based encoding API.

*object* is passed through the encoder function found for the given *encoding* using the error handling method defined by *errors*. *errors* may be NULL to use the default method defined for the codec. Raises a **LookupError** if no encoder can be found.

PyObject* **PyCodec_Decode**(PyObject *object, const char *encoding, const char *errors)

Generic codec based decoding API.

*object* is passed through the decoder function found for the given *encoding* using the error handling method defined by *errors*. *errors* may be NULL to use the default method defined for the codec. Raises a **LookupError** if no encoder can be found.
Codec lookup API

In the following functions, the *encoding* string is looked up converted to all lower-case characters, which makes encodings looked up through this mechanism effectively case-insensitive. If no codec is found, a *KeyError* is set and *NULL* returned.

**PyObject**\* **PyCodec.Encoder**(const char\* *encoding*)

- Get an encoder function for the given *encoding*.

**PyObject**\* **PyCodec.Decoder**(const char\* *encoding*)

- Get a decoder function for the given *encoding*.

**PyObject**\* **PyCodec.IncrementalEncoder**(const char\* *encoding*, const char\* *errors*)

- Get an IncrementalEncoder object for the given *encoding*.

**PyObject**\* **PyCodec.IncrementalDecoder**(const char\* *encoding*, const char\* *errors*)

- Get an IncrementalDecoder object for the given *encoding*.

**PyObject**\* **PyCodec.StreamReader**(const char\* *encoding*, PyObject* *stream*, const char\* *errors*)

- Get a StreamReader factory function for the given *encoding*.

**PyObject**\* **PyCodec.StreamWriter**(const char\* *encoding*, PyObject* *stream*, const char\* *errors*)

- Get a StreamWriter factory function for the given *encoding*. 
Registry API for Unicode encoding error handlers

```c
int PyCodec_RegisterError(const char *name, PyObject *error)
```

Register the error handling callback function `error` under the given `name`. This callback function will be called by a codec when it encounters unencodable characters/undecodable bytes and `name` is specified as the error parameter in the call to the encode/decode function.

The callback gets a single argument, an instance of `UnicodeEncodeError`, `UnicodeDecodeError` or `UnicodeTranslateError` that holds information about the problematic sequence of characters or bytes and their offset in the original string (see *Unicode Exception Objects* for functions to extract this information). The callback must either raise the given exception, or return a two-item tuple containing the replacement for the problematic sequence, and an integer giving the offset in the original string at which encoding/decoding should be resumed.

Return 0 on success, -1 on error.

```c
PyObject* PyCodec_LookupError(const char *name)
```

Lookup the error handling callback function registered under `name`. As a special case `NULL` can be passed, in which case the error handling callback for “strict” will be returned.

```c
PyObject* PyCodec_StrictErrors(PyObject *exc)
```

Raise `exc` as an exception.
PyObject* PyCodec_IgnoreErrors(PyObject *exc)
    Ignore the unicode error, skipping the faulty input.

PyObject* PyCodec_ReplacErrors(PyObject *exc)
    Replace the unicode encode error with ? or U+FFFD.

PyObject*
PyCodec_XMLCharRefReplaceErrors(PyObject *exc)
    Replace the unicode encode error with XML character references.

PyObject*
PyCodec_BackslashReplaceErrors(PyObject *exc)
    Replace the unicode encode error with backslash escapes (\x, \u and \U).
Abstract Objects Layer

The functions in this chapter interact with Python objects regardless of their type, or with wide classes of object types (e.g. all numerical types, or all sequence types). When used on object types for which they do not apply, they will raise a Python exception.

It is not possible to use these functions on objects that are not properly initialized, such as a list object that has been created by `PyList_New()`, but whose items have not been set to some non-NULL value yet.

- Object Protocol
- Number Protocol
- Sequence Protocol
- Mapping Protocol
- Iterator Protocol
- Buffer Protocol
  - Buffer structure
  - Buffer request types
    - request-independent fields
    - readonly, format
    - shape, strides, suboffsets
    - contiguity requests
    - compound requests
  - Complex arrays
    - NumPy-style: shape and strides
    - PIL-style: shape, strides and suboffsets
  - Buffer-related functions
- Old Buffer Protocol
Object Protocol

PyObject* `Py_NotImplemented`

The `NotImplemented` singleton, used to signal that an operation is not implemented for the given type combination.

`Py_RETURN_NOTIMPLEMENTED`

Properly handle returning `Py_NotImplemented` from within a C function (that is, increment the reference count of `NotImplemented` and return it).

```c
int PyObject_Print(PyObject *o, FILE *fp, int flags)
```

Print an object `o`, on file `fp`. Returns `-1` on error. The flags argument is used to enable certain printing options. The only option currently supported is `Py_PRINT_RAW`; if given, the `str()` of the object is written instead of the `repr()`.

```c
int PyObject_HasAttr(PyObject *o, PyObject *attr_name)
```

Returns `1` if `o` has the attribute `attr_name`, and `0` otherwise. This is equivalent to the Python expression `hasattr(o, attr_name)`. This function always succeeds.

```c
int PyObject_HasAttrString(PyObject *o, const char *attr_name)
```

Returns `1` if `o` has the attribute `attr_name`, and `0` otherwise. This is equivalent to the Python expression `hasattr(o, attr_name)`. This function always succeeds.

```c
PyObject* PyObject_GetAttr(PyObject *o, PyObject *attr_name)
```

*Return value: New reference.*

Retrieve an attribute named \textit{attr\_name} from object \textit{o}. Returns the attribute value on success, or \textit{NULL} on failure. This is the equivalent of the Python expression \texttt{o.attr\_name}.

\texttt{PyObject* \textbf{PyObject\_GetAttrString}(PyObject \*o, const char \*\textit{attr\_name})}

\textit{Return value: New reference.}
Retrieve an attribute named \textit{attr\_name} from object \textit{o}. Returns the attribute value on success, or \textit{NULL} on failure. This is the equivalent of the Python expression \texttt{o.attr\_name}.

\texttt{PyObject* \textbf{PyObject\_GenericGetAttr}(PyObject \*o, PyObject \*\textit{name})}

Generic attribute getter function that is meant to be put into a type object's \texttt{tp\_getattro} slot. It looks for a descriptor in the dictionary of classes in the object's MRO as well as an attribute in the object's \texttt{\_dict\_} (if present). As outlined in \textit{Implementing Descriptors}, data descriptors take preference over instance attributes, while non-data descriptors don't. Otherwise, an \texttt{AttributeError} is raised.

\texttt{int \textbf{PyObject\_SetAttr}(PyObject \*o, PyObject \*\textit{attr\_name}, PyObject \*\textit{v})}

Set the value of the attribute named \textit{attr\_name}, for object \textit{o}, to the value \textit{v}. Returns \texttt{-1} on failure. This is the equivalent of the Python statement \texttt{o.attr\_name\ = \ v}.

\texttt{int \textbf{PyObject\_SetAttrString}(PyObject \*o, const char \*\textit{attr\_name}, PyObject \*\textit{v})}

Set the value of the attribute named \textit{attr\_name}, for object \textit{o}, to the value \textit{v}. Returns \texttt{-1} on failure. This is the equivalent of the Python statement \texttt{o.attr\_name\ = \ v}.
int PyObject_GenericSetAttr(PyObject *o, PyObject *name, PyObject *value)
    Generic attribute setter function that is meant to be put into a type object's `tp_setattro` slot. It looks for a data descriptor in the dictionary of classes in the object's MRO, and if found it takes preference over setting the attribute in the instance dictionary. Otherwise, the attribute is set in the object's `__dict__` (if present). Otherwise, an `AttributeError` is raised and `-1` is returned.

int PyObject_DelAttr(PyObject *o, PyObject *attr_name)
    Delete attribute named `attr_name`, for object `o`. Returns `-1` on failure. This is the equivalent of the Python statement `del o.attr_name`.

int PyObject_DelAttrString(PyObject *o, const char *attr_name)
    Delete attribute named `attr_name`, for object `o`. Returns `-1` on failure. This is the equivalent of the Python statement `del o.attr_name`.

PyObject* PyType_GenericGetDict(PyObject *o, void *context)
    A generic implementation for the getter of a `__dict__` descriptor. It creates the dictionary if necessary.

    *New in version 3.3.*

int PyType_GenericSetDict(PyObject *o, void *context)
    A generic implementation for the setter of a `__dict__` descriptor. This implementation does not allow the dictionary to be deleted.
New in version 3.3.

**PyObject** \* **PyObject** \_RichCompare**(PyObject \*o1, PyObject \*o2, int opid)**

*Return value: New reference.*

Compare the values of o1 and o2 using the operation specified by *opid*, which must be one of Py_LT, Py_LE, Py_EQ, Py_NE, Py_GT, or Py_GE, corresponding to <, <=, ==, !=, >, or >= respectively. This is the equivalent of the Python expression o1 op o2, where op is the operator corresponding to *opid*. Returns the value of the comparison on success, or *NULL* on failure.

**int** **PyObject** \_RichCompareBool**(PyObject \*o1, PyObject \*o2, int opid)**

Compare the values of o1 and o2 using the operation specified by *opid*, which must be one of Py_LT, Py_LE, Py_EQ, Py_NE, Py_GT, or Py_GE, corresponding to <, <=, ==, !=, >, or >= respectively. Returns -1 on error, 0 if the result is false, 1 otherwise. This is the equivalent of the Python expression o1 op o2, where op is the operator corresponding to *opid*.

**Note:** If o1 and o2 are the same object, **PyObject** \_RichCompareBool() will always return 1 for Py_EQ and 0 for Py_NE.

**PyObject** \* **PyObject** \_Repr**(PyObject \*o)**

*Return value: New reference.*

Compute a string representation of object o. Returns the string representation on success, *NULL* on failure. This is the equivalent of the Python expression \texttt{repr(o)}. Called by the \texttt{repr()} built-in function.
Changed in version 3.4: This function now includes a debug assertion to help ensure that it does not silently discard an active exception.

**PyObject** *PyObject_ASCII(PyObject *o)*

As **PyObject_Repr()**, compute a string representation of object o, but escape the non-ASCII characters in the string returned by **PyObject_Repr()** with \x, \u or \U escapes. This generates a string similar to that returned by **PyObject_Repr()** in Python 2. Called by the **ascii()** built-in function.

**PyObject** *PyObject_Str(PyObject *o)*

*Return value: New reference.*

Compute a string representation of object o. Returns the string representation on success, **NULL** on failure. This is the equivalent of the Python expression str(o). Called by the **str()** built-in function and, therefore, by the **print()** function.

*Changed in version 3.4:* This function now includes a debug assertion to help ensure that it does not silently discard an active exception.

**PyObject** *PyObject_Bytes(PyObject *o)*

Compute a bytes representation of object o. **NULL** is returned on failure and a bytes object on success. This is equivalent to the Python expression bytes(o), when o is not an integer. Unlike bytes(o), a TypeError is raised when o is an integer instead of a zero-initialized bytes object.

**int** *PyObject_IsInstance(PyObject *inst, PyObject *cls)*

Returns 1 if inst is an instance of the class cls or a subclass of cls, or 0 if not. On error, returns -1 and sets an exception. If cls is a
type object rather than a class object, \texttt{PyObject\_IsInstance()} returns 1 if \textit{inst} is of type \textit{cls}. If \textit{cls} is a tuple, the check will be done against every entry in \textit{cls}. The result will be 1 when at least one of the checks returns 1, otherwise it will be 0. If \textit{inst} is not a class instance and \textit{cls} is neither a type object, nor a class object, nor a tuple, \textit{inst} must have a \texttt{\_\_class\_\_} attribute — the class relationship of the value of that attribute with \textit{cls} will be used to determine the result of this function.

Subclass determination is done in a fairly straightforward way, but includes a wrinkle that implementors of extensions to the class system may want to be aware of. If \texttt{A} and \texttt{B} are class objects, \texttt{B} is a subclass of \texttt{A} if it inherits from \texttt{A} either directly or indirectly. If either is not a class object, a more general mechanism is used to determine the class relationship of the two objects. When testing if \texttt{B} is a subclass of \texttt{A}, if \texttt{A} is \texttt{B}, \texttt{PyObject\_IsSubclass()} returns true. If \texttt{A} and \texttt{B} are different objects, \texttt{B}'s \texttt{\_\_bases\_\_} attribute is searched in a depth-first fashion for \texttt{A} — the presence of the \texttt{\_\_bases\_\_} attribute is considered sufficient for this determination.

\begin{verbatim}
int PyObject\_IsSubclass(PyObject *derived, PyObject *cls)
    Returns 1 if the class \texttt{derived} is identical to or derived from the class \texttt{cls}, otherwise returns 0. In case of an error, returns -1. If \texttt{cls} is a tuple, the check will be done against every entry in \texttt{cls}. The result will be 1 when at least one of the checks returns 1, otherwise it will be 0. If either \texttt{derived} or \texttt{cls} is not an actual class object (or tuple), this function uses the generic algorithm described above.

int PyCallable\_Check(PyObject *o)
    Determine if the object \texttt{o} is callable. Return 1 if the object is
\end{verbatim}
callable and 0 otherwise. This function always succeeds.

```c
PyObject* PyObject_Call(PyObject *callable_object, PyObject *args, PyObject *kw)
```

**Return value:** New reference.

Call a callable Python object `callable_object`, with arguments given by the tuple `args`, and named arguments given by the dictionary `kw`. If no named arguments are needed, `kw` may be `NULL`. `args` must not be `NULL`, use an empty tuple if no arguments are needed. Returns the result of the call on success, or `NULL` on failure. This is the equivalent of the Python expression `callable_object(*args, **kw)`.

```c
PyObject* PyObject_CallObject(PyObject *callable_object, PyObject *args)
```

**Return value:** New reference.

Call a callable Python object `callable_object`, with arguments given by the tuple `args`. If no arguments are needed, then `args` may be `NULL`. Returns the result of the call on success, or `NULL` on failure. This is the equivalent of the Python expression `callable_object(*args)`.

```c
PyObject* PyObject_CallFunction(PyObject *callable, const char *format, ...)
```

**Return value:** New reference.

Call a callable Python object `callable`, with a variable number of C arguments. The C arguments are described using a `Py_BuildValue()` style format string. The format may be `NULL`, indicating that no arguments are provided. Returns the result of the call on success, or `NULL` on failure. This is the equivalent of the Python expression `callable(*args)`. Note that if you only pass `PyObject * args`, `PyObject_CallFunctionObjArgs()` is a
faster alternative.

* Changed in version 3.4: The type of *format* was changed from `char *`.

`PyObject* PyObject_CallMethod(PyObject *o, const char *method, const char *format, ...)`

*Return value: New reference.*

Call the method named *method* of object *o* with a variable number of C arguments. The C arguments are described by a `Py_BuildValue()` format string that should produce a tuple. The format may be `NULL`, indicating that no arguments are provided. Returns the result of the call on success, or `NULL` on failure. This is the equivalent of the Python expression `o.method(args)`. Note that if you only pass `PyObject * args, PyObject_CallMethodObjArgs()` is a faster alternative.

* Changed in version 3.4: The types of *method* and *format* were changed from `char *`.

`PyObject* PyObject_CallFunctionObjArgs(PyObject *callable, ..., NULL)`

*Return value: New reference.*

Call a callable Python object *callable*, with a variable number of `PyObject*` arguments. The arguments are provided as a variable number of parameters followed by `NULL`. Returns the result of the call on success, or `NULL` on failure.

`PyObject* PyObject_CallMethodObjArgs(PyObject *o, PyObject *name, ..., NULL)`

*Return value: New reference.*

Calls a method of the object *o*, where the name of the method is
given as a Python string object in name. It is called with a variable number of PyObject* arguments. The arguments are provided as a variable number of parameters followed by NULL. Returns the result of the call on success, or NULL on failure.

Py_hash_t **PyObject** _**Hash***(PyObject *o)
Compute and return the hash value of an object o. On failure, return -1. This is the equivalent of the Python expression hash(o).

.changed in version 3.2: The return type is now Py_hash_t. This is a signed integer the same size as Py_ssize_t.

Py_hash_t **PyObject** _**HashNotImplemented***(PyObject *o)
Set a TypeError indicating that type(o) is not hashable and return -1. This function receives special treatment when stored in a tp_hash slot, allowing a type to explicitly indicate to the interpreter that it is not hashable.

.int **PyObject** _**IsTrue***(PyObject *o)
Returns 1 if the object o is considered to be true, and 0 otherwise. This is equivalent to the Python expression not not o. On failure, return -1.

.int **PyObject** _**Not***(PyObject *o)
Returns 0 if the object o is considered to be true, and 1 otherwise. This is equivalent to the Python expression not o. On failure, return -1.

PyObject* **PyObject** _**Type***(PyObject *o)
When o is non-NULL, returns a type object corresponding to the
object type of object o. On failure, raises SystemError and returns NULL. This is equivalent to the Python expression type(o). This function increments the reference count of the return value. There's really no reason to use this function instead of the common expression o->ob_type, which returns a pointer of type PyTypeObject*, except when the incremented reference count is needed.

```c
int PyObject_TypeCheck(PyObject *o, PyTypeObject *type)
```
Return true if the object o is of type type or a subtype of type. Both parameters must be non-NULL.

```c
Py_ssize_t PyObject_Length(PyObject *o)
Py_ssize_t PyObject_Size(PyObject *o)
```
Return the length of object o. If the object o provides either the sequence and mapping protocols, the sequence length is returned. On error, -1 is returned. This is the equivalent to the Python expression len(o).

```c
Py_ssize_t PyObject_LengthHint(PyObject *o, Py_ssize_t default)
```
Return an estimated length for the object o. First try to return its actual length, then an estimate using __length_hint__(), and finally return the default value. On error return -1. This is the equivalent to the Python expression operator.length_hint(o, default).

*New in version 3.4.*

```c
PyObject* PyObject_GetItem(PyObject *o, PyObject *key)
```
*Return value: New reference.*
Return element of o corresponding to the object key or NULL on
failure. This is the equivalent of the Python expression `o[key].`

```c
int PyObject_SetItem(PyObject *o, PyObject *key, PyObject *v)
```

Map the object `key` to the value `v`. Returns `-1` on failure. This is the equivalent of the Python statement `o[key] = v`.

```c
int PyObject_DelItem(PyObject *o, PyObject *key)
```

Delete the mapping for `key` from `o`. Returns `-1` on failure. This is the equivalent of the Python statement `del o[key]`.

```c
PyObject* PyObject_Dir(PyObject *o)
```

*Return value: New reference.*

This is equivalent to the Python expression `dir(o)`, returning a (possibly empty) list of strings appropriate for the object argument, or `NULL` if there was an error. If the argument is `NULL`, this is like the Python `dir()`, returning the names of the current locals; in this case, if no execution frame is active then `NULL` is returned but `PyErr_Occurred()` will return false.

```c
PyObject* PyObject_GetIter(PyObject *o)
```

*Return value: New reference.*

This is equivalent to the Python expression `iter(o)`. It returns a new iterator for the object argument, or the object itself if the object is already an iterator. Raises `TypeError` and returns `NULL` if the object cannot be iterated.
Number Protocol

int PyNumber_Check(PyObject *o)
Returns 1 if the object o provides numeric protocols, and false otherwise. This function always succeeds.

PyObject* PyNumber_Add(PyObject *o1, PyObject *o2)
Returns the result of adding o1 and o2, or NULL on failure. This is the equivalent of the Python expression o1 + o2.

PyObject* PyNumber_Subtract(PyObject *o1, PyObject *o2)
Returns the result of subtracting o2 from o1, or NULL on failure. This is the equivalent of the Python expression o1 - o2.

PyObject* PyNumber_Multiply(PyObject *o1, PyObject *o2)
Returns the result of multiplying o1 and o2, or NULL on failure. This is the equivalent of the Python expression o1 * o2.

PyObject* PyNumber_FloorDivide(PyObject *o1, PyObject *o2)
Return the floor of o1 divided by o2, or NULL on failure. This is equivalent to the “classic” division of integers.

PyObject* PyNumber_TrueDivide(PyObject *o1, PyObject *o2)
Return a reasonable approximation for the mathematical value of o1 divided by o2, or NULL on failure. The return value is
“approximate” because binary floating point numbers are approximate; it is not possible to represent all real numbers in base two. This function can return a floating point value when passed two integers.

PyObject* PyNumber_Remainder(PyObject *o1, PyObject *o2)

Returns the remainder of dividing o1 by o2, or NULL on failure. This is the equivalent of the Python expression \( o1 \% o2 \).

PyObject* PyNumber_Divmod(PyObject *o1, PyObject *o2)

See the built-in function \( \text{divmod}() \). Returns NULL on failure. This is the equivalent of the Python expression \( \text{divmod}(o1, o2) \).

PyObject* PyNumber_Power(PyObject *o1, PyObject *o2, PyObject *o3)

See the built-in function \( \text{pow}() \). Returns NULL on failure. This is the equivalent of the Python expression \( \text{pow}(o1, o2, o3) \), where o3 is optional. If o3 is to be ignored, pass \( \text{Py_None} \) in its place (passing NULL for o3 would cause an illegal memory access).

PyObject* PyNumber_Negative(PyObject *o)

Returns the negation of o on success, or NULL on failure. This is the equivalent of the Python expression \(-o\).

PyObject* PyNumber_Positive(PyObject *o)

Returns o on success, or NULL on failure. This is the equivalent of
the Python expression +o.

PyObject* PyNumber_Absolute(PyObject *o)
    
    
    Returns the absolute value of o, or NULL on failure. This is the equivalent of the Python expression abs(o).

PyObject* PyNumber_Invert(PyObject *o)
    
    
    Returns the bitwise negation of o on success, or NULL on failure. This is the equivalent of the Python expression ~o.

PyObject* PyNumber_Lshift(PyObject *o1, PyObject *o2)
    
    
    Returns the result of left shifting o1 by o2 on success, or NULL on failure. This is the equivalent of the Python expression o1 << o2.

PyObject* PyNumber_Rshift(PyObject *o1, PyObject *o2)
    
    
    Returns the result of right shifting o1 by o2 on success, or NULL on failure. This is the equivalent of the Python expression o1 >> o2.

PyObject* PyNumber_And(PyObject *o1, PyObject *o2)
    
    
    Returns the “bitwise and” of o1 and o2 on success and NULL on failure. This is the equivalent of the Python expression o1 & o2.

PyObject* PyNumber_Xor(PyObject *o1, PyObject *o2)
    
    
    Returns the “bitwise exclusive or” of o1 by o2 on success, or NULL on failure. This is the equivalent of the Python expression o1 ^ o2.
PyObject* **PyNumber** **_Or** (PyObject *o1, PyObject *o2)

*Return value: New reference.*

Returns the “bitwise or” of o1 and o2 on success, or **NULL** on failure. This is the equivalent of the Python expression `o1 | o2`.

PyObject* **PyNumber** **_InPlaceAdd** (PyObject *o1, PyObject *o2)

*Return value: New reference.*

Returns the result of adding o1 and o2, or **NULL** on failure. The operation is done *in-place* when o1 supports it. This is the equivalent of the Python statement `o1 += o2`.

PyObject* **PyNumber** **_InPlaceSubtract** (PyObject *o1, PyObject *o2)

*Return value: New reference.*

Returns the result of subtracting o2 from o1, or **NULL** on failure. The operation is done *in-place* when o1 supports it. This is the equivalent of the Python statement `o1 -= o2`.

PyObject* **PyNumber** **_InPlaceMultiply** (PyObject *o1, PyObject *o2)

*Return value: New reference.*

Returns the result of multiplying o1 and o2, or **NULL** on failure. The operation is done *in-place* when o1 supports it. This is the equivalent of the Python statement `o1 *= o2`.

PyObject* **PyNumber** **_InPlaceFloorDivide** (PyObject *o1, PyObject *o2)

*Return value: New reference.*

Returns the mathematical floor of dividing o1 by o2, or **NULL** on failure. The operation is done *in-place* when o1 supports it. This is the equivalent of the Python statement `o1 //= o2`. 
PyObject* **PyNumber_InPlaceTrueDivide** (PyObject *o1, PyObject *o2)

*Return value: New reference.*
Return a reasonable approximation for the mathematical value of o1 divided by o2, or NULL on failure. The return value is “approximate” because binary floating point numbers are approximate; it is not possible to represent all real numbers in base two. This function can return a floating point value when passed two integers. The operation is done *in-place* when o1 supports it.

PyObject* **PyNumber_InPlaceRemainder** (PyObject *o1, PyObject *o2)

*Return value: New reference.*
Returns the remainder of dividing o1 by o2, or NULL on failure. The operation is done *in-place* when o1 supports it. This is the equivalent of the Python statement o1 %= o2.

PyObject* **PyNumber_InPlacePower** (PyObject *o1, PyObject *o2, PyObject *o3)

*Return value: New reference.*
See the built-in function pow(). Returns NULL on failure. The operation is done *in-place* when o1 supports it. This is the equivalent of the Python statement o1 **= o2 when o3 is Py_None, or an in-place variant of pow(o1, o2, o3) otherwise. If o3 is to be ignored, pass Py_None in its place (passing NULL for o3 would cause an illegal memory access).

PyObject* **PyNumber_InPlaceLshift** (PyObject *o1, PyObject *o2)

*Return value: New reference.*
Returns the result of left shifting o1 by o2 on success, or NULL on failure. The operation is done *in-place* when o1 supports it. This is
the equivalent of the Python statement $o_1 >>= o_2$.

**PyObject**\(^*\) **PyNumber\_InPlaceRshift**(*PyObject* \(o_1\),
**PyObject** \(o_2\))

*Return value: New reference.*

Returs the result of right shifting \(o_1\) by \(o_2\) on success, or *NULL* on failure. The operation is done *in-place* when \(o_1\) supports it. This is the equivalent of the Python statement $o_1 >>= o_2$.

**PyObject**\(^*\) **PyNumber\_InPlaceAnd**(*PyObject* \(o_1\), **PyObject** \(o_2\))

*Return value: New reference.*

Returs the "bitwise and" of \(o_1\) and \(o_2\) on success and *NULL* on failure. The operation is done *in-place* when \(o_1\) supports it. This is the equivalent of the Python statement $o_1 &= o_2$.

**PyObject**\(^*\) **PyNumber\_InPlaceXor**(*PyObject* \(o_1\), **PyObject** \(o_2\))

*Return value: New reference.*

Returs the "bitwise exclusive or" of \(o_1\) by \(o_2\) on success, or *NULL* on failure. The operation is done *in-place* when \(o_1\) supports it. This is the equivalent of the Python statement $o_1 ^= o_2$.

**PyObject**\(^*\) **PyNumber\_InPlaceOr**(*PyObject* \(o_1\), **PyObject** \(o_2\))

*Return value: New reference.*

Returs the "bitwise or" of \(o_1\) and \(o_2\) on success, or *NULL* on failure. The operation is done *in-place* when \(o_1\) supports it. This is the equivalent of the Python statement $o_1 |= o_2$.

**PyObject**\(^*\) **PyNumber\_Long**(*PyObject* \(o\))

*Return value: New reference.*

Returs the \(o\) converted to an integer object on success, or *NULL* on failure. This is the equivalent of the Python expression $\text{int}(o)$.

**PyObject**\(^*\) **PyNumber\_Float**(*PyObject* \(o\))
Returns the \( o \) converted to a float object on success, or \( NULL \) on failure. This is the equivalent of the Python expression \( \text{float}(o) \).

\textbf{PyObject* \texttt{PyNumber\_Index}(PyObject *o)}

Returns the \( o \) converted to a Python int on success or \( NULL \) with a \texttt{TypeError} exception raised on failure.

\textbf{PyObject* \texttt{PyNumber\_ToBase}(PyObject *n, int base)}

Returns the integer \( n \) converted to base \( base \) as a string. The \texttt{base} argument must be one of 2, 8, 10, or 16. For base 2, 8, or 16, the returned string is prefixed with a base marker of \'0b\', \'0o\', or \'0x\', respectively. If \( n \) is not a Python int, it is converted with \texttt{PyNumber\_Index()} first.

\textbf{Py\_ssize\_t \texttt{PyNumber\_AsSsize\_t}(PyObject *o, PyObject *exc)}

Returns \( o \) converted to a Py\_ssize\_t value if \( o \) can be interpreted as an integer. If the call fails, an exception is raised and -1 is returned.

If \( o \) can be converted to a Python int but the attempt to convert to a Py\_ssize\_t value would raise an \texttt{OverflowError}, then the \texttt{exc} argument is the type of exception that will be raised (usually \texttt{IndexError} or \texttt{OverflowError}). If \texttt{exc} is \texttt{NULL}, then the exception is cleared and the value is clipped to \texttt{PY\_SSIZE\_T\_MIN} for a negative integer or \texttt{PY\_SSIZE\_T\_MAX} for a positive integer.

\textbf{int \texttt{PyIndex\_Check}(PyObject *o)}

Returns True if \( o \) is an index integer (has the \texttt{nb\_index} slot of the \texttt{tp\_as\_number} structure filled in).
Sequence Protocol

int PySequence_Check(PyObject *o)
Return 1 if the object provides sequence protocol, and 0 otherwise. This function always succeeds.

Py_ssize_t PySequence_Size(PyObject *o)
Py_ssize_t PySequence_Length(PyObject *o)
Returns the number of objects in sequence o on success, and -1 on failure. For objects that do not provide sequence protocol, this is equivalent to the Python expression len(o).

PyObject* PySequence_Concat(PyObject *o1, PyObject *o2)
Return the concatenation of o1 and o2 on success, and NULL on failure. This is the equivalent of the Python expression o1 + o2.

PyObject* PySequence_Repeat(PyObject *o, Py_ssize_t count)
Return the result of repeating sequence object o count times, or NULL on failure. This is the equivalent of the Python expression o * count.

PyObject* PySequence_InPlaceConcat(PyObject *o1, PyObject *o2)
Return the concatenation of o1 and o2 on success, and NULL on failure. The operation is done in-place when o1 supports it. This is the equivalent of the Python expression o1 += o2.

PyObject* PySequence_InPlaceRepeat(PyObject *o,
Py_ssize_t count)

*Return value: New reference.*
Return the result of repeating sequence object o count times, or NULL on failure. The operation is done in-place when o supports it. This is the equivalent of the Python expression o *= count.

PyObject* PySequence_GetItem(PyObject *o, Py_ssize_t i)

*Return value: New reference.*
Return the i th element of o, or NULL on failure. This is the equivalent of the Python expression o[i].

PyObject* PySequence_GetSlice(PyObject *o, Py_ssize_t i1, Py_ssize_t i2)

*Return value: New reference.*
Return the slice of sequence object o between i1 and i2, or NULL on failure. This is the equivalent of the Python expression o[i1:i2].

int PySequence_SetItem(PyObject *o, Py_ssize_t i, PyObject *v)

Assign object v to the i th element of o. Returns -1 on failure. This is the equivalent of the Python statement o[i] = v. This function does not steal a reference to v.

int PySequence_DELItem(PyObject *o, Py_ssize_t i)

Delete the i th element of object o. Returns -1 on failure. This is the equivalent of the Python statement del o[i].

int PySequence_SetSlice(PyObject *o, Py_ssize_t i1, Py_ssize_t i2, PyObject *v)

Assign the sequence object v to the slice in sequence object o from i1 to i2. This is the equivalent of the Python statement o[i1:i2]
int PySequence_DelSlice(PyObject *o, Py_ssize_t i1, Py_ssize_t i2)
Delete the slice in sequence object o from i1 to i2. Returns -1 on failure. This is the equivalent of the Python statement del o[i1:i2].

Py_ssize_t PySequence_Count(PyObject *o, PyObject *value)
Return the number of occurrences of value in o, that is, return the number of keys for which o[key] == value. On failure, return -1. This is equivalent to the Python expression o.count(value).

int PySequence_Contains(PyObject *o, PyObject *value)
Determine if o contains value. If an item in o is equal to value, return 1, otherwise return 0. On error, return -1. This is equivalent to the Python expression value in o.

Py_ssize_t PySequence_Index(PyObject *o, PyObject *value)
Return the first index i for which o[i] == value. On error, return -1. This is equivalent to the Python expression o.index(value).

PyObject* PySequence_List(PyObject *o)
Return a list object with the same contents as the arbitrary sequence o. The returned list is guaranteed to be new.

PyObject* PySequence_Tuple(PyObject *o)
Return a tuple object with the same contents as the arbitrary
sequence o or NULL on failure. If o is a tuple, a new reference will be returned, otherwise a tuple will be constructed with the appropriate contents. This is equivalent to the Python expression tuple(o).

PyObject* **PySequence_Fast_ITEMS(PyObject *o)**

Return the underlying array of PyObject pointers. Assumes that o was returned by PySequence_Fast(), o is not NULL, and o is not NULL.

Note, if a list gets resized, the reallocation may relocate the items array. So, only use the underlying array pointer in contexts where the sequence cannot change.

PyObject* **PySequence_ITEM(PyObject *o, Py_ssize_t i)**

Return the ith element of o or NULL on failure. Macro form of PySequence_GetItem() but without checking that PySequence_Check() on o is true and without adjustment for

PyObject* PySequence_Fast(PyObject *o, const char *m)

*Return value: New reference.*

Returns the sequence o as a tuple, unless it is already a tuple or list, in which case o is returned. Use PySequence_Fast_GET_ITEM() to access the members of the result. Returns NULL on failure. If the object is not a sequence, raises TypeError with m as the message text.

PyObject* PySequence_Fast_GET_ITEM(PyObject *o, Py_ssize_t i)

*Return value: Borrowed reference.*

Return the ith element of o, assuming that o was returned by PySequence_Fast(), o is not NULL, and that i is within bounds.

PyObject* PySequence_Fast(GET_ITEM(PyObject *o, Py_ssize_t i))

*Return value: New reference.*

Return the sequence o as a tuple, unless it is already a tuple or list, in which case o is returned. Use PySequence_Fast_GET_ITEM() to access the members of the result. Returns NULL on failure. If the object is not a sequence, raises TypeError with m as the message text.
negative indices.

Pyssize_t PySequence_Fast_GET_SIZE(PyObject *o)

Returns the length of o, assuming that o was returned by PySequence_Fast() and that o is not NULL. The size can also be gotten by calling PySequence_Size() on o, but PySequence_Fast_GET_SIZE() is faster because it can assume o is a list or tuple.
Mapping Protocol

int **PyMapping_Check**(PyObject *o)

    Return 1 if the object provides mapping protocol, and 0 otherwise. This function always succeeds.

Py_ssize_t **PyMapping_Size**(PyObject *o)
Py_ssize_t **PyMapping_Length**(PyObject *o)

    Returns the number of keys in object o on success, and -1 on failure. For objects that do not provide mapping protocol, this is equivalent to the Python expression `len(o)`.

int **PyMapping_DelItemString**(PyObject *o, const char *key)

    Remove the mapping for object key from the object o. Return -1 on failure. This is equivalent to the Python statement `del o[key]`.

int **PyMapping_DelItem**(PyObject *o, PyObject *key)

    Remove the mapping for object key from the object o. Return -1 on failure. This is equivalent to the Python statement `del o[key]`.

int **PyMapping_HasKeyString**(PyObject *o, char *key)

    On success, return 1 if the mapping object has the key key and 0 otherwise. This is equivalent to the Python expression `key in o`. This function always succeeds.

int **PyMapping_HasKey**(PyObject *o, PyObject *key)

    Return 1 if the mapping object has the key key and 0 otherwise. This is equivalent to the Python expression `key in o`. This
function always succeeds.

**PyObject**\* **PyMapping\_Keys**(PyObject \*o)

*Return value: New reference.*
On success, return a list of the keys in object o. On failure, return `NULL`. This is equivalent to the Python expression `list(o.keys())`.

**PyObject**\* **PyMapping\_Values**(PyObject \*o)

*Return value: New reference.*
On success, return a list of the values in object o. On failure, return `NULL`. This is equivalent to the Python expression `list(o.values())`.

**PyObject**\* **PyMapping\_Items**(PyObject \*o)

*Return value: New reference.*
On success, return a list of the items in object o, where each item is a tuple containing a key-value pair. On failure, return `NULL`. This is equivalent to the Python expression `list(o.items())`.

**PyObject**\* **PyMapping\_GetItemString**(PyObject \*o, const char \*key)

*Return value: New reference.*
Return element of o corresponding to the object key or `NULL` on failure. This is the equivalent of the Python expression `o[key]`.

int **PyMapping\_SetItemString**(PyObject \*o, const char \*key, PyObject \*v)

Map the object key to the value v in object o. Returns -1 on failure. This is the equivalent of the Python statement `o[key] = v`.
Iterator Protocol

There are two functions specifically for working with iterators.

```c
int PyIter_Check(PyObject *o)
    Return true if the object o supports the iterator protocol.
```

```c
PyObject* PyIter_Next(PyObject *o)
    Return the next value from the iteration o. The object must be an iterator (it is up to the caller to check this). If there are no remaining values, returns NULL with no exception set. If an error occurs while retrieving the item, returns NULL and passes along the exception.
```

To write a loop which iterates over an iterator, the C code should look something like this:

```c
PyObject *iterator = PyObject_GetIter(obj);
PyObject *item;

if (iterator == NULL) {
    /* propagate error */
}

while (item = PyIter_Next(iterator)) {
    /* do something with item */
    ...
    /* release reference when done */
    Py_DECREF(item);
}

Py_DECREF(iterator);

if (PyErr_Occurred()) {
```
/* propagate error */
}
else {
    /* continue doing useful work */
}
Buffer Protocol

Certain objects available in Python wrap access to an underlying memory array or buffer. Such objects include the built-in bytes and bytearray, and some extension types like array.array. Third-party libraries may define their own types for special purposes, such as image processing or numeric analysis.

While each of these types have their own semantics, they share the common characteristic of being backed by a possibly large memory buffer. It is then desirable, in some situations, to access that buffer directly and without intermediate copying.

Python provides such a facility at the C level in the form of the buffer protocol. This protocol has two sides:

- on the producer side, a type can export a “buffer interface” which allows objects of that type to expose information about their underlying buffer. This interface is described in the section Buffer Object Structures;
- on the consumer side, several means are available to obtain a pointer to the raw underlying data of an object (for example a method parameter).

Simple objects such as bytes and bytearray expose their underlying buffer in byte-oriented form. Other forms are possible; for example, the elements exposed by a array.array can be multi-byte values.

An example consumer of the buffer interface is the write() method of file objects: any object that can export a series of bytes through the buffer interface can be written to a file. While write() only needs
read-only access to the internal contents of the object passed to it, other methods such as `readinto()` need write access to the contents of their argument. The buffer interface allows objects to selectively allow or reject exporting of read-write and read-only buffers.

There are two ways for a consumer of the buffer interface to acquire a buffer over a target object:

- call `PyObject_GetBuffer()` with the right parameters;
- call `PyArg_ParseTuple()` (or one of its siblings) with one of the `y*`, `w*` or `s*` format codes.

In both cases, `PyBuffer_Release()` must be called when the buffer isn't needed anymore. Failure to do so could lead to various issues such as resource leaks.
Buffer structure

Buffer structures (or simply “buffers”) are useful as a way to expose the binary data from another object to the Python programmer. They can also be used as a zero-copy slicing mechanism. Using their ability to reference a block of memory, it is possible to expose any data to the Python programmer quite easily. The memory could be a large, constant array in a C extension, it could be a raw block of memory for manipulation before passing to an operating system library, or it could be used to pass around structured data in its native, in-memory format.

Contrary to most data types exposed by the Python interpreter, buffers are not PyObject pointers but rather simple C structures. This allows them to be created and copied very simply. When a generic wrapper around a buffer is needed, a memoryview object can be created.

For short instructions how to write an exporting object, see Buffer Object Structures. For obtaining a buffer, see PyObject_GetBuffer().

Py_buffer

void *obj

A new reference to the exporting object. The reference is owned by the consumer and automatically decremented and set to NULL by PyBuffer_Release(). The field is the equivalent of the return value of any standard C-API function.

As a special case, for temporary buffers that are wrapped by PyMemoryView_FromBuffer() or PyBuffer_FillInfo() this field is NULL. In general, exporting objects MUST NOT use this scheme.
void *buf

A pointer to the start of the logical structure described by the buffer fields. This can be any location within the underlying physical memory block of the exporter. For example, with negative strides the value may point to the end of the memory block.

For contiguous arrays, the value points to the beginning of the memory block.

Py_ssize_t len

\(\text{product(shape) \times itemsize}\). For contiguous arrays, this is the length of the underlying memory block. For non-contiguous arrays, it is the length that the logical structure would have if it were copied to a contiguous representation.

Accessing \(((\text{char} \ast)\text{buf})[0] \text{ up to } ((\text{char} \ast)\text{buf})[\text{len}-1]\) is only valid if the buffer has been obtained by a request that guarantees contiguity. In most cases such a request will be PyBUF_SIMPLE or PyBUF_WRITABLE.

int readonly

An indicator of whether the buffer is read-only. This field is controlled by the PyBUF_WRITABLE flag.

Py_ssize_t itemsize

Item size in bytes of a single element. Same as the value of struct.calcsize() called on non-NULL format values.

Important exception: If a consumer requests a buffer without the PyBUF_FORMAT flag, format will be set to NULL, but itemsize still has the value for the original format.
If shape is present, the equality \( \text{product}(\text{shape}) \ast \text{itemsize} == \text{len} \) still holds and the consumer can use \text{itemsize} to navigate the buffer.

If shape is \textit{NULL} as a result of a \texttt{PyBUF SIMPL E} or a \texttt{PyBUF WRITABLE} request, the consumer must disregard \text{itemsize} and assume \text{itemsize} == 1.

\textbf{const char *} \texttt{format}

A \textit{NUL} terminated string in \texttt{struct} module style syntax describing the contents of a single item. If this is \textit{NULL}, "B" (unsigned bytes) is assumed.

This field is controlled by the \texttt{PyBUF FORMAT} flag.

\textbf{int} \texttt{ndim}

The number of dimensions the memory represents as an n-dimensional array. If it is 0, \texttt{buf} points to a single item representing a scalar. In this case, \texttt{shape}, \texttt{strides} and \texttt{suboffsets} MUST be \textit{NULL}.

The macro \texttt{PyBUF_MAX_NDIM} limits the maximum number of dimensions to 64. Exporters MUST respect this limit, consumers of multi-dimensional buffers SHOULD be able to handle up to \texttt{PyBUF_MAX_NDIM} dimensions.

\textbf{Py_ssize_t *} \texttt{shape}

An array of \texttt{Py_ssize_t} of length \texttt{ndim} indicating the shape of the memory as an n-dimensional array. Note that \texttt{shape[0]} \ast \ldots \ast \texttt{shape[ndim-1]} \ast \text{itemsize} MUST be equal to \texttt{len}.  

Shape values are restricted to \texttt{shape[n] \geq 0}. The case \texttt{shape[n] == 0} requires special attention. See complex arrays for further information.

The shape array is read-only for the consumer.

\textbf{Py_ssize_t *} \texttt{strides}

An array of \texttt{Py_ssize_t} of length \texttt{ndim} giving the number of bytes to skip to get to a new element in each dimension.

Stride values can be any integer. For regular arrays, strides are usually positive, but a consumer MUST be able to handle the case \texttt{strides[n] \leq 0}. See complex arrays for further information.

The strides array is read-only for the consumer.

\textbf{Py_ssize_t *} \texttt{suboffsets}

An array of \texttt{Py_ssize_t} of length \texttt{ndim}. If \texttt{suboffsets[n] \geq 0}, the values stored along the \texttt{nth} dimension are pointers and the suboffset value dictates how many bytes to add to each pointer after de-referencing. A suboffset value that is negative indicates that no de-referencing should occur (striding in a contiguous memory block).

This type of array representation is used by the Python Imaging Library (PIL). See complex arrays for further information how to access elements of such an array.

The suboffsets array is read-only for the consumer.

\textbf{void *} \texttt{internal}

This is for use internally by the exporting object. For example,
this might be re-cast as an integer by the exporter and used to store flags about whether or not the shape, strides, and suboffsets arrays must be freed when the buffer is released. The consumer MUST NOT alter this value.
Buffer request types

Buffers are usually obtained by sending a buffer request to an exporting object via `PyObject_GetBuffer()`. Since the complexity of the logical structure of the memory can vary drastically, the consumer uses the `flags` argument to specify the exact buffer type it can handle.

All `Py_buffer` fields are unambiguously defined by the request type.

request-independent fields

The following fields are not influenced by `flags` and must always be filled in with the correct values: `obj, buf, len, itemsize, ndim`.

readonly, format

**PyBUF_WRITABLE**

Controls the `readonly` field. If set, the exporter MUST provide a writable buffer or else report failure. Otherwise, the exporter MAY provide either a read-only or writable buffer, but the choice MUST be consistent for all consumers.

**PyBUF_FORMAT**

Controls the `format` field. If set, this field MUST be filled in correctly. Otherwise, this field MUST be `NULL`.

`PyBUF_WRITABLE` can be |d to any of the flags in the next section. Since `PyBUF_SIMPLE` is defined as 0, `PyBUF_WRITABLE` can be used as a stand-alone flag to request a simple writable buffer.
**PyBUF_FORMAT** can be |'d to any of the flags except **PyBUF_SIMPLE**. The latter already implies format B (unsigned bytes).

### shape, strides, suboffsets

The flags that control the logical structure of the memory are listed in decreasing order of complexity. Note that each flag contains all bits of the flags below it.

<table>
<thead>
<tr>
<th>Request</th>
<th>shape</th>
<th>strides</th>
<th>suboffsets</th>
</tr>
</thead>
<tbody>
<tr>
<td><strong>PyBUF_INDIRECT</strong></td>
<td>yes</td>
<td>yes</td>
<td>if needed</td>
</tr>
<tr>
<td><strong>PyBUF_STRIDES</strong></td>
<td>yes</td>
<td>yes</td>
<td>NULL</td>
</tr>
<tr>
<td><strong>PyBUF_ND</strong></td>
<td>yes</td>
<td>NULL</td>
<td>NULL</td>
</tr>
<tr>
<td><strong>PyBUF_SIMPLE</strong></td>
<td>NULL</td>
<td>NULL</td>
<td>NULL</td>
</tr>
</tbody>
</table>

### contiguity requests

C or Fortran contiguity can be explicitly requested, with and without stride information. Without stride information, the buffer must be C-contiguous.

<table>
<thead>
<tr>
<th>Request</th>
<th>shape</th>
<th>strides</th>
<th>suboffsets</th>
<th>cont</th>
</tr>
</thead>
<tbody>
<tr>
<td><strong>PyBUF_C_CONTIGUOUS</strong></td>
<td>yes</td>
<td>yes</td>
<td>NULL</td>
<td>C</td>
</tr>
<tr>
<td><strong>PyBUF_F_CONTIGUOUS</strong></td>
<td>yes</td>
<td>yes</td>
<td>NULL</td>
<td>F</td>
</tr>
<tr>
<td><strong>PyBUF_ANY_CONTIGUOUS</strong></td>
<td>yes</td>
<td>yes</td>
<td>NULL</td>
<td>C c</td>
</tr>
</tbody>
</table>
compound requests

All possible requests are fully defined by some combination of the flags in the previous section. For convenience, the buffer protocol provides frequently used combinations as single flags.

In the following table $U$ stands for undefined contiguity. The consumer would have to call `PyBuffer_IsContiguous()` to determine contiguity.

<table>
<thead>
<tr>
<th>Request</th>
<th>shape</th>
<th>strides</th>
<th>suboffsets</th>
<th>contig</th>
</tr>
</thead>

<td>yes</td>
<td>NULL</td>
<td>NULL</td>
<td>C</td>
</tr>
</tbody>
</table>
Complex arrays

NumPy-style: shape and strides

The logical structure of NumPy-style arrays is defined by `itemsize`, `ndim`, `shape` and `strides`.

If `ndim == 0`, the memory location pointed to by `buf` is interpreted as a scalar of size `itemsize`. In that case, both `shape` and `strides` are `NULL`.

If `strides` is `NULL`, the array is interpreted as a standard n-dimensional C-array. Otherwise, the consumer must access an n-dimensional array as follows:

```
ptr = (char *)buf + indices[0] * strides[0] +
     ... + indices[n-1] * strides[n-1] item = *
     ((typeof(item) *)ptr);
```

As noted above, `buf` can point to any location within the actual memory block. An exporter can check the validity of a buffer with this function:

```python
def verify_structure(memlen, itemsize, ndim, shape, 
                   """Verify that the parameters represent a valid
the bounds of the allocated memory:
  char *mem: start of the physical memory block
  memlen: length of the physical memory block
  offset: (char *)buf - mem"
                   """
    if offset % itemsize:
        return False
    if offset < 0 or offset+itemsize > memlen:
        return False
```
if any(v % itemsize for v in strides):
    return False

if ndim <= 0:
    return ndim == 0 and not shape and not strides
if 0 in shape:
    return True

imin = sum(strides[j]*(shape[j]-1) for j in range(len(strides)) if strides[j] <= 0)
imax = sum(strides[j]*(shape[j]-1) for j in range(len(strides)) if strides[j] > 0)

return 0 <= offset+imin and offset+imax+itemsize

PIL-style: shape, strides and suboffsets

In addition to the regular items, PIL-style arrays can contain pointers that must be followed in order to get to the next element in a dimension. For example, the regular three-dimensional C-array `char v[2][2][3]` can also be viewed as an array of 2 pointers to 2 two-dimensional arrays: `char (*v[2])[2][3]`. In suboffsets representation, those two pointers can be embedded at the start of `buf`, pointing to two `char x[2][3]` arrays that can be located anywhere in memory.

Here is a function that returns a pointer to the element in an N-D array pointed to by an N-dimensional index when there are both non-NULL strides and suboffsets:

```c
void *get_item_pointer(int ndim, void *buf, Py_ssize_t suboffsets, Py_ssize_t offset, char *pointer = (char*)buf;
```
int i;
for (i = 0; i < ndim; i++) {
    pointer += strides[i] * indices[i];
    if (suboffsets[i] >= 0) {
        pointer = *((char**)pointer) + suboffset;
    }
}
return (void*)pointer;
Buffer-related functions

int **PyObject_CheckBuffer**(PyObject *obj)

Return 1 if obj supports the buffer interface otherwise 0. When 1 is returned, it doesn’t guarantee that **PyObject_GetBuffer()** will succeed.

int **PyObject_GetBuffer**(PyObject *exporter, Py_buffer *view, int flags)

Send a request to exporter to fill in view as specified by flags. If the exporter cannot provide a buffer of the exact type, it MUST raise PyExc_BufferError, set view->obj to NULL and return -1.

On success, fill in view, set view->obj to a new reference to exporter and return 0. In the case of chained buffer providers that redirect requests to a single object, view->obj MAY refer to this object instead of exporter (See Buffer Object Structures).

Successful calls to **PyObject_GetBuffer()** must be paired with calls to **PyBuffer_Release()**, similar to malloc() and free(). Thus, after the consumer is done with the buffer, **PyBuffer_Release()** must be called exactly once.

void **PyBuffer_Release**(Py_buffer *view)

Release the buffer view and decrement the reference count for view->obj. This function MUST be called when the buffer is no longer being used, otherwise reference leaks may occur.

It is an error to call this function on a buffer that was not obtained via **PyObject_GetBuffer()**.
Py_ssize_t PyBuffer_SizeFromFormat(const char *)

Return the implied itemsize from format. This function is not yet implemented.

int PyBuffer_IsContiguous(Py_buffer *view, char order)

Return 1 if the memory defined by the view is C-style (order is 'C') or Fortran-style (order is 'F') contiguous or either one (order is 'A'). Return 0 otherwise.

void PyBuffer_FillContiguousStrides(int ndim, Py_ssize_t *shape, Py_ssize_t *strides, Py_ssize_t itemsize, char order)

Fill the strides array with byte-strides of a contiguous (C-style if order is 'C' or Fortran-style if order is 'F') array of the given shape with the given number of bytes per element.

int PyBuffer_FillInfo(Py_buffer *view, PyObject *exporter, void *buf, Py_ssize_t len, int readonly, int flags)

Handle buffer requests for an exporter that wants to expose buf of size len with writability set according to readonly. buf is interpreted as a sequence of unsigned bytes.

The flags argument indicates the request type. This function always fills in view as specified by flags, unless buf has been designated as read-only and PyBUF_WRITABLE is set in flags.

On success, set view->obj to a new reference to exporter and return 0. Otherwise, raise PyExc_BufferError, set view->obj to NULL and return -1;

If this function is used as part of a getbufferproc, exporter MUST be set to the exporting object. Otherwise, exporter MUST be NULL.
Old Buffer Protocol

Deprecated since version 3.0.

These functions were part of the “old buffer protocol” API in Python 2. In Python 3, this protocol doesn’t exist anymore but the functions are still exposed to ease porting 2.x code. They act as a compatibility wrapper around the new buffer protocol, but they don’t give you control over the lifetime of the resources acquired when a buffer is exported.

Therefore, it is recommended that you call PyObject_GetBuffer() (or the \texttt{y*} or \texttt{w*} format codes with the \texttt{PyArg_ParseTuple()} family of functions) to get a buffer view over an object, and PyBuffer_Release() when the buffer view can be released.

```c
int PyObject_AsCharBuffer(PyObject *obj, const char **buffer, Py_ssize_t *buffer_len)
```

Returns a pointer to a read-only memory location usable as character-based input. The \textit{obj} argument must support the single-segment character buffer interface. On success, returns 0, sets \textit{buffer} to the memory location and \textit{buffer_len} to the buffer length. Returns -1 and sets a \texttt{TypeError} on error.

```c
int PyObject_AsReadBuffer(PyObject *obj, const void **buffer, Py_ssize_t *buffer_len)
```

Returns a pointer to a read-only memory location containing arbitrary data. The \textit{obj} argument must support the single-segment readable buffer interface. On success, returns 0, sets \textit{buffer} to the memory location and \textit{buffer_len} to the buffer length. Returns -1 and sets a \texttt{TypeError} on error.
int **PyObject_CheckReadBuffer(PyObject *o)

Returns 1 if o supports the single-segment readable buffer interface. Otherwise returns 0.

intPyObject_AsWriteBuffer(PyObject *obj, void **buffer, Py_ssize_t *buffer_len)

Returns a pointer to a writable memory location. The obj argument must support the single-segment, character buffer interface. On success, returns 0, sets buffer to the memory location and buffer_len to the buffer length. Returns -1 and sets a TypeError on error.
Concrete Objects Layer

The functions in this chapter are specific to certain Python object types. Passing them an object of the wrong type is not a good idea; if you receive an object from a Python program and you are not sure that it has the right type, you must perform a type check first; for example, to check that an object is a dictionary, use `PyDict_Check()`. The chapter is structured like the “family tree” of Python object types.

**Warning:** While the functions described in this chapter carefully check the type of the objects which are passed in, many of them do not check for *NULL* being passed instead of a valid object. Allowing *NULL* to be passed in can cause memory access violations and immediate termination of the interpreter.
Fundamental Objects

This section describes Python type objects and the singleton object None.

- Type Objects
- The None Object
Numeric Objects

- Integer Objects
- Boolean Objects
- Floating Point Objects
- Complex Number Objects
  - Complex Numbers as C Structures
  - Complex Numbers as Python Objects
Sequence Objects

Generic operations on sequence objects were discussed in the previous chapter; this section deals with the specific kinds of sequence objects that are intrinsic to the Python language.

Type Objects

**PyTypeObject**

The C structure of the objects used to describe built-in types.

**PyObject**

* PyType_Type

This is the type object for type objects; it is the same object as `type` in the Python layer.

`int PyType_Check(PyObject *o)`

Return true if the object `o` is a type object, including instances of types derived from the standard type object. Return false in all other cases.

`int PyType_CheckExact(PyObject *o)`

Return true if the object `o` is a type object, but not a subtype of the standard type object. Return false in all other cases.

`unsigned int PyType_ClearCache()`

Clear the internal lookup cache. Return the current version tag.

`long PyType_GetFlags(PyTypeObject *type)`

Return the `tp_flags` member of `type`. This function is primarily meant for use with `Py_LIMITED_API`; the individual flag bits are guaranteed to be stable across Python releases, but access to `tp_flags` itself is not part of the limited API.

*New in version 3.2.*

`void PyType_Modified(PyTypeObject *type)`

Invalidate the internal lookup cache for the type and all of its
subtypes. This function must be called after any manual modification of the attributes or base classes of the type.

```c
int PyType_HasFeature(PyTypeObject *o, int feature)
```

Return true if the type object \( o \) sets the feature \( \text{feature} \). Type features are denoted by single bit flags.

```c
int PyType_IS_GC(PyTypeObject *o)
```

Return true if the type object includes support for the cycle detector; this tests the type flag \( \text{Py\_TPFLAGS\_HAVE\_GC} \).

```c
int PyType_IsSubtype(PyTypeObject *a, PyTypeObject *b)
```

Return true if \( a \) is a subtype of \( b \).

```c
PyObject* PyType_GenericAlloc(PyTypeObject *type, Py_ssize_t nitems)
```

*Return value: New reference.*

Generic handler for the \( \text{tp\_alloc} \) slot of a type object. Use Python's default memory allocation mechanism to allocate a new instance and initialize all its contents to \( \text{NULL} \).

```c
PyObject* PyType_GenericNew(PyTypeObject *type, PyObject *args, PyObject *kwds)
```

*Return value: New reference.*

Generic handler for the \( \text{tp\_new} \) slot of a type object. Create a new instance using the type’s \( \text{tp\_alloc} \) slot.

```c
int PyType_Ready(PyTypeObject *type)
```

Finalize a type object. This should be called on all type objects to finish their initialization. This function is responsible for adding inherited slots from a type’s base class. Return \( 0 \) on success, or return \( -1 \) and sets an exception on error.
PyObject* **PyType_FromSpec**(PyType_Spec *spec)

Creates and returns a heap type object from the spec passed to the function.

PyObject* **PyType_FromSpecWithBases**(PyType_Spec *spec, PyObject *bases)

Creates and returns a heap type object from the spec. In addition to that, the created heap type contains all types contained by the bases tuple as base types. This allows the caller to reference other heap types as base types.

*New in version 3.3.*

void* **PyType_GetSlot**(PyTypeObject *type, int slot)

Return the function pointer stored in the given slot. If the result is NULL, this indicates that either the slot is NULL, or that the function was called with invalid parameters. Callers will typically cast the result pointer into the appropriate function type.

*New in version 3.4.*
The None Object

Note that the PyTypeObject for None is not directly exposed in the Python/C API. Since None is a singleton, testing for object identity (using == in C) is sufficient. There is no PyNone_Check() function for the same reason.

PyObject* Py_None

The Python None object, denoting lack of value. This object has no methods. It needs to be treated just like any other object with respect to reference counts.

Py_RETURN_NONE

Properly handle returning Py_None from within a C function (that is, increment the reference count of None and return it.)
Integer Objects

All integers are implemented as “long” integer objects of arbitrary size.

PyLongObject
This subtype of PyObject represents a Python integer object.

PyTypeObject PyLong_Type
This instance of PyTypeObject represents the Python integer type. This is the same object as int in the Python layer.

int PyLong_Check(PyObject *p)
Return true if its argument is a PyLongObject or a subtype of PyLongObject.

int PyLong_CheckExact(PyObject *p)
Return true if its argument is a PyLongObject, but not a subtype of PyLongObject.

PyObject* PyLong_FromLong(long v)
Return a new PyLongObject object from v, or NULL on failure.

The current implementation keeps an array of integer objects for all integers between -5 and 256, when you create an int in that range you actually just get back a reference to the existing object. So it should be possible to change the value of 1. I suspect the behaviour of Python in this case is undefined. :-)

PyObject* PyLong_FromUnsignedLong(unsigned long v)
Return a new PyLongObject object from a C unsigned long, or NULL on failure.

PyObject* PyLong_FromSsize_t(Py_ssize_t v)
Return a new PyLongObject object from a C Py_ssize_t, or NULL on failure.

PyObject* PyLong_FromSize_t(size_t v)
Return a new PyLongObject object from a C size_t, or NULL on failure.

PyObject* PyLong_FromLongLong(PY_LONG_LONG v)
Return a new PyLongObject object from a C long long, or NULL on failure.

PyObject* PyLong_FromUnsignedLongLong(unsigned PY_LONG_LONG v)
Return a new PyLongObject object from a C unsigned long long, or NULL on failure.

PyObject* PyLong_FromDouble(double v)
Return a new PyLongObject object from the integer part of v, or NULL on failure.

PyObject* PyLong_FromString(const char *str, char **pend, int base)
Return a new PyLongObject based on the string value in str, which is interpreted according to the radix in base. If pend is non-
NULL, *pend will point to the first character in str which follows the representation of the number. If base is 0, the radix will be determined based on the leading characters of str: if str starts with '0x' or '0X', radix 16 will be used; if str starts with '0o' or '0O', radix 8 will be used; if str starts with '0b' or '0B', radix 2 will be used; otherwise radix 10 will be used. If base is not 0, it must be between 2 and 36, inclusive. Leading spaces are ignored. If there are no digits, ValueError will be raised.

**PyObject** PyLong_FromUnicode(Py_UNICODE *u, Py_ssize_t length, int base)

*Return value: New reference.*

Convert a sequence of Unicode digits to a Python integer value. The Unicode string is first encoded to a byte string using PyUnicode_EncodeDecimal() and then converted using PyLong_FromString().

*Deprecated since version 3.3, will be removed in version 4.0:* Part of the old-style Py_UNICODE API; please migrate to using PyLong_FromUnicodeObject().

**PyObject** PyLong_FromUnicodeObject(PyObject *u, int base)

Convert a sequence of Unicode digits in the string u to a Python integer value. The Unicode string is first encoded to a byte string using PyUnicode_EncodeDecimal() and then converted using PyLong_FromString().

*New in version 3.3.*

**PyObject** PyLong_FromVoidPtr(void *p)
Create a Python integer from the pointer p. The pointer value can be retrieved from the resulting value using PyLong_AsVoidPtr().

```c
long PyLong_AsLong(PyObject *obj)
```
Return a C long representation of obj. If obj is not an instance of PyLongObject, first call its __int__() method (if present) to convert it to a PyLongObject.

Raise OverflowError if the value of obj is out of range for a long.

```c
long PyLong_AsLongAndOverflow(PyObject *obj, int *overflow)
```
Return a C long representation of obj. If obj is not an instance of PyLongObject, first call its __int__() method (if present) to convert it to a PyLongObject.

If the value of obj is greater than LONG_MAX or less than LONG_MIN, set *overflow to 1 or -1, respectively, and return -1; otherwise, set *overflow to 0. If any other exception occurs set *overflow to 0 and return -1 as usual.

```c
PY_LONG_LONG PyLong_AsLongLong(PyObject *obj)
```
Return a C long long representation of obj. If obj is not an instance of PyLongObject, first call its __int__() method (if present) to convert it to a PyLongObject.

Raise OverflowError if the value of obj is out of range for a long.
PY_LONG_LONG

PyLong_AsLongLongAndOverflow(PyObject *obj, int *overflow)

Return a C long long representation of obj. If obj is not an instance of PyLongObject, first call its __int__() method (if present) to convert it to a PyLongObject.

If the value of obj is greater than PY_LLONG_MAX or less than PY_LLONG_MIN, set *overflow to 1 or -1, respectively, and return -1; otherwise, set *overflow to 0. If any other exception occurs set *overflow to 0 and return -1 as usual.

New in version 3.2.

Py_ssize_t PyLong_AsSsize_t(PyObject *pylong)

Return a C Py_ssize_t representation of pylong. pylong must be an instance of PyLongObject.

Raise OverflowError if the value of pylong is out of range for a Py_ssize_t.

unsigned long PyLong_AsUnsignedLong(PyObject *pylong)

Return a C unsigned long representation of pylong. pylong must be an instance of PyLongObject.

Raise OverflowError if the value of pylong is out of range for a unsigned long.

size_t PyLong_AsSize_t(PyObject *pylong)

Return a C size_t representation of pylong. pylong must be an instance of PyLongObject.
Raise `OverflowError` if the value of `pylong` is out of range for a size_t.

unsigned PY_LONG_LONG

`PyLong_AsUnsignedLongLong()` (PyObject *pylong)

Return a C unsigned PY_LONG_LONG representation of `pylong`. `pylong` must be an instance of PyLongObject.

Raise `OverflowError` if the value of `pylong` is out of range for an unsigned PY_LONG_LONG.

`Changed in version 3.1:` A negative `pylong` now raises `OverflowError`, not `TypeError`.

unsigned long `PyLong_AsUnsignedLongMask()` (PyObject *obj)

Return a C unsigned long representation of `obj`. If `obj` is not an instance of PyLongObject, first call its `__int__()` method (if present) to convert it to a PyLongObject.

If the value of `obj` is out of range for an unsigned long, return the reduction of that value modulo ULONG_MAX + 1.

unsigned PY_LONG_LONG

`PyLong_AsUnsignedLongLongMask()` (PyObject *obj)

Return a C unsigned long long representation of `obj`. If `obj` is not an instance of PyLongObject, first call its `__int__()` method (if present) to convert it to a PyLongObject.

If the value of `obj` is out of range for an unsigned long long, return the reduction of that value modulo PY_ULLONG_MAX + 1.

double `PyLong_AsDouble()` (PyObject *pylong)
Return a C double representation of `pylong`. `pylong` must be an instance of `PyLongObject`.

Raise `OverflowError` if the value of `pylong` is out of range for a double.

```c
void* PyLong_AsVoidPtr(PyObject *pylong)
```

Convert a Python integer `pylong` to a C void pointer. If `pylong` cannot be converted, an `OverflowError` will be raised. This is only assured to produce a usable void pointer for values created with `PyLong_FromVoidPtr()`.
Boolean Objects

Booleans in Python are implemented as a subclass of integers. There are only two booleans, Py_False and Py_True. As such, the normal creation and deletion functions don't apply to booleans. The following macros are available, however.

```c
int PyBool_Check(PyObject *o)
    Return true if o is of type PyBool_Type.
```

```c
PyObject* Py_False
    The Python False object. This object has no methods. It needs to be treated just like any other object with respect to reference counts.
```

```c
PyObject* Py_True
    The Python True object. This object has no methods. It needs to be treated just like any other object with respect to reference counts.
```

```c
Py_RETURN_FALSE
    Return Py_False from a function, properly incrementing its reference count.
```

```c
Py_RETURN_TRUE
    Return Py_True from a function, properly incrementing its reference count.
```

```c
PyObject* PyBool_FromLong(long v)
    Return a new reference to Py_TRUE or Py_FALSE depending on
```
the truth value of \( v \).
Floating Point Objects

**PyFloatObject**
This subtype of *PyObject* represents a Python floating point object.

**PyTypeObject PyFloat_Type**
This instance of *PyTypeObject* represents the Python floating point type. This is the same object as *float* in the Python layer.

`int PyFloat_Check(PyObject *p)`
Return true if its argument is a *PyFloatObject* or a subtype of *PyFloatObject*.

`int PyFloat_CheckExact(PyObject *p)`
Return true if its argument is a *PyFloatObject*, but not a subtype of *PyFloatObject*.

`PyObject* PyFloat_FromString(PyObject *str)`
*Return value: New reference.*
Create a *PyFloatObject* object based on the string value in *str*, or *NULL* on failure.

`PyObject* PyFloat_FromDouble(double v)`
*Return value: New reference.*
Create a *PyFloatObject* object from *v*, or *NULL* on failure.

`double PyFloat_AsDouble(PyObject *pyfloat)`
Return a C double representation of the contents of *pyfloat*. If *pyfloat* is not a Python floating point object but has a *__float__()* method, this method will first be called to convert
pyfloat into a float. This method returns \(-1.0\) upon failure, so one should call `PyErr_Occurred()` to check for errors.

double **PyFloat_AS_DOUBLE**(PyObject *pyfloat)

Return a C double representation of the contents of `pyfloat`, but without error checking.

PyObject* **PyFloat_GetInfo**(void)

Return a structseq instance which contains information about the precision, minimum and maximum values of a float. It's a thin wrapper around the header file `float.h`.

double **PyFloat_GetMax**(void)

Return the maximum representable finite float `DBL_MAX` as C double.

double **PyFloat_GetMin**(void)

Return the minimum normalized positive float `DBL_MIN` as C double.

int **PyFloat_ClearFreeList**(void)

Clear the float free list. Return the number of items that could not be freed.
Complex Number Objects

Python’s complex number objects are implemented as two distinct types when viewed from the C API: one is the Python object exposed to Python programs, and the other is a C structure which represents the actual complex number value. The API provides functions for working with both.
Complex Numbers as C Structures

Note that the functions which accept these structures as parameters and return them as results do so by value rather than dereferencing them through pointers. This is consistent throughout the API.

**Py_complex**

The C structure which corresponds to the value portion of a Python complex number object. Most of the functions for dealing with complex number objects use structures of this type as input or output values, as appropriate. It is defined as:

```c
typedef struct {
    double real;
    double imag;
} Py_complex;
```

**Py_complex Py_c_sum(Py_complex left, Py_complex right)**

Return the sum of two complex numbers, using the C Py_complex representation.

**Py_complex Py_c_diff(Py_complex left, Py_complex right)**

Return the difference between two complex numbers, using the C Py_complex representation.

**Py_complex Py_c_neg(Py_complex complex)**

Return the negation of the complex number complex, using the C Py_complex representation.

**Py_complex Py_c_prod(Py_complex left, Py_complex right)**

Return the product of two complex numbers, using the C Py_complex representation.
Py_complex _Py_c_quot(Py_complex dividend, Py_complex divisor)
    Return the quotient of two complex numbers, using the C Py_complex representation.
    
    If divisor is null, this method returns zero and sets errno to EDOM.

Py_complex _Py_c_pow(Py_complex num, Py_complex exp)
    Return the exponentiation of num by exp, using the C Py_complex representation.
    
    If num is null and exp is not a positive real number, this method returns zero and sets errno to EDOM.
Complex Numbers as Python Objects

**PyComplexObject**
This subtype of `PyObject` represents a Python complex number object.

**PyTypeObject PyComplex_Type**
This instance of `PyTypeObject` represents the Python complex number type. It is the same object as `complex` in the Python layer.

**int PyComplex_Check(PyObject *p)**
Return true if its argument is a `PyComplexObject` or a subtype of `PyComplexObject`.

**int PyComplex_CheckExact(PyObject *p)**
Return true if its argument is a `PyComplexObject`, but not a subtype of `PyComplexObject`.

**PyObject* PyComplex_FromCComplex(Py_complex v)**
*Return value: New reference.*
Create a new Python complex number object from a C `Py_complex` value.

**PyObject* PyComplex_FromDoubles(double real, double imag)**
*Return value: New reference.*
Return a new `PyComplexObject` object from `real` and `imag`.

**double PyComplex_RealAsDouble(PyObject *op)**
Return the real part of `op` as a C double.

**double PyComplex_ImagAsDouble(PyObject *op)**
Return the imaginary part of op as a C double.

Py_complex PyComplex_AsCComplex(PyObject *op)
Return the Py_complex value of the complex number op.

If op is not a Python complex number object but has a __complex__() method, this method will first be called to convert op to a Python complex number object. Upon failure, this method returns -1.0 as a real value.
Bytes Objects

These functions raise `TypeError` when expecting a bytes parameter and are called with a non-bytes parameter.

**PyBytesObject**

This subtype of `PyObject` represents a Python bytes object.

**PyTypeObject PyBytes_Type**

This instance of `PyTypeObject` represents the Python bytes type; it is the same object as `bytes` in the Python layer.

```c
int PyBytes_Check(PyObject *o)
```

Return true if the object o is a bytes object or an instance of a subtype of the bytes type.

```c
int PyBytes_CheckExact(PyObject *o)
```

Return true if the object o is a bytes object, but not an instance of a subtype of the bytes type.

```c
PyObject* PyBytes_FromString(const char *v)
```

Return a new bytes object with a copy of the string v as value on success, and `NULL` on failure. The parameter v must not be `NULL`; it will not be checked.

```c
PyObject* PyBytes_FromStringAndSize(const char *v, Py_ssize_t len)
```

Return a new bytes object with a copy of the string v as value and length len on success, and `NULL` on failure. If v is `NULL`, the contents of the bytes object are uninitialized.
PyObject* PyBytes_FromFormat(const char *format, ...)

Take a C printf()-style format string and a variable number of arguments, calculate the size of the resulting Python bytes object and return a bytes object with the values formatted into it. The variable arguments must be C types and must correspond exactly to the format characters in the format string. The following format characters are allowed:

<table>
<thead>
<tr>
<th>Format Characters</th>
<th>Type</th>
<th>Comment</th>
</tr>
</thead>
<tbody>
<tr>
<td>%</td>
<td>n/a</td>
<td>The literal % character.</td>
</tr>
<tr>
<td>%c</td>
<td>int</td>
<td>A single character, represented as an C int.</td>
</tr>
<tr>
<td>%d</td>
<td>int</td>
<td>Exactly equivalent to printf(&quot;%d&quot;).</td>
</tr>
<tr>
<td>%u</td>
<td>unsigned int</td>
<td>Exactly equivalent to printf(&quot;%u&quot;).</td>
</tr>
<tr>
<td>%ld</td>
<td>long</td>
<td>Exactly equivalent to printf(&quot;%ld&quot;).</td>
</tr>
<tr>
<td>%lu</td>
<td>unsigned long</td>
<td>Exactly equivalent to printf(&quot;%lu&quot;).</td>
</tr>
<tr>
<td>%zd</td>
<td>Py_ssize_t</td>
<td>Exactly equivalent to printf(&quot;%zd&quot;).</td>
</tr>
<tr>
<td>%zu</td>
<td>size_t</td>
<td>Exactly equivalent to printf(&quot;%zu&quot;).</td>
</tr>
<tr>
<td>%i</td>
<td>int</td>
<td>Exactly equivalent to printf(&quot;%i&quot;).</td>
</tr>
<tr>
<td>%x</td>
<td>int</td>
<td>Exactly equivalent to printf(&quot;%x&quot;).</td>
</tr>
<tr>
<td>%s</td>
<td>char*</td>
<td>A null-terminated C character</td>
</tr>
<tr>
<td>Format</td>
<td>Value Type</td>
<td>Description</td>
</tr>
<tr>
<td>--------</td>
<td>------------</td>
<td>-------------</td>
</tr>
<tr>
<td>%p</td>
<td>void*</td>
<td>The hex representation of a C pointer. Mostly equivalent to <code>printf(&quot;%p&quot;)</code> except that it is guaranteed to start with the literal 0x regardless of what the platform's <code>printf</code> yields.</td>
</tr>
</tbody>
</table>

An unrecognized format character causes all the rest of the format string to be copied as-is to the result string, and any extra arguments discarded.

**PyObject**\* **PyBytes_FromFormatV**(const char *format, va_list vargs)

Identical to **PyBytes_FromFormat()** except that it takes exactly two arguments.

**PyObject**\* **PyBytes_FromObject**(PyObject \*o)

Return the bytes representation of object o that implements the buffer protocol.

**Py_ssize_t** **PyBytes_Size**(PyObject \*o)

Return the length of the bytes in bytes object o.

**Py_ssize_t** **PyBytes_GET_SIZE**(PyObject \*o)

Macro form of **PyBytes_Size()** but without error checking.

**char**\* **PyBytes_AsString**(PyObject \*o)

Return a NUL-terminated representation of the contents of o. The pointer refers to the internal buffer of o, not a copy. The data must not be modified in any way, unless the string was just created using **PyBytes_FromStringAndSize**(NULL, size). It must not be
If \( o \) is not a string object at all, \texttt{PyBytes\_AsString()} returns \texttt{NULL} and raises \texttt{TypeError}.

\begin{verbatim}
char* \textbf{PyBytes\_AS\_STRING}(PyObject *string)
Macro form of \texttt{PyBytes\_AsString()} but without error checking.
\end{verbatim}

\begin{verbatim}
int \textbf{PyBytes\_AsStringAndSize}(PyObject *obj, char **buffer, Py_ssize_t *length)
Return a NUL-terminated representation of the contents of the object \( obj \) through the output variables \( buffer \) and \( length \).
If \( length \) is \texttt{NULL}, the resulting buffer may not contain NUL characters; if it does, the function returns \texttt{-1} and a \texttt{TypeError} is raised.

The buffer refers to an internal string buffer of \( obj \), not a copy. The data must not be modified in any way, unless the string was just created using \texttt{PyBytes\_FromStringAndSize(NULL, size)}. It must not be deallocated. If \( string \) is not a string object at all, \texttt{PyBytes\_AsStringAndSize()} returns \texttt{-1} and raises \texttt{TypeError}.
\end{verbatim}

\begin{verbatim}
void \textbf{PyBytes\_Concat}(PyObject **bytes, PyObject *newpart)
Create a new bytes object in \( *bytes \) containing the contents of \( newpart \) appended to \( bytes \); the caller will own the new reference. The reference to the old value of \( bytes \) will be stolen. If the new string cannot be created, the old reference to \( bytes \) will still be discarded and the value of \( *bytes \) will be set to \texttt{NULL}; the appropriate exception will be set.
\end{verbatim}

\begin{verbatim}
void \textbf{PyBytes\_ConcatAndDel}(PyObject **bytes, PyObject *newpart)
\end{verbatim}
Create a new string object in *bytes containing the contents of newpart appended to bytes. This version decrements the reference count of newpart.

```c
int _PyBytes_Resize(PyObject **bytes, Py_ssize_t newsize)
```

A way to resize a bytes object even though it is “immutable”. Only use this to build up a brand new bytes object; don’t use this if the bytes may already be known in other parts of the code. It is an error to call this function if the refcount on the input bytes object is not one. Pass the address of an existing bytes object as an lvalue (it may be written into), and the new size desired. On success, *bytes holds the resized bytes object and 0 is returned; the address in *bytes may differ from its input value. If the reallocation fails, the original bytes object at *bytes is deallocated, *bytes is set to NULL, a memory exception is set, and -1 is returned.
Byte Array Objects

**PyByteArrayObject**
This subtype of *PyObject* represents a Python bytearray object.

**PyTypeObject** **PyByteArray_Type**
This instance of *PyTypeObject* represents the Python bytearray type; it is the same object as *bytearray* in the Python layer.
Type check macros

int **PyByteArray_Check**(PyObject *o)
          
    Return true if the object o is a bytearray object or an instance of a
    subtype of the bytearray type.

int **PyByteArray_CheckExact**(PyObject *o)
          
    Return true if the object o is a bytearray object, but not an instance
    of a subtype of the bytearray type.
Direct API functions

PyObject* **PyByteArray_FromObject**(PyObject *o)

Return a new bytearray object from any object, \( o \), that implements the *buffer protocol*.

PyObject* **PyByteArray_FromStringAndSize**(const char *string, Py_ssize_t len)

Create a new bytearray object from \( \text{string} \) and its length, \( \text{len} \). On failure, \( \text{NULL} \) is returned.

PyObject* **PyByteArray_Concat**(PyObject *a, PyObject *b)

Concat bytearrays \( a \) and \( b \) and return a new bytearray with the result.

Py_ssize_t **PyByteArray_Size**(PyObject *bytearray)

Return the size of \( \text{bytearray} \) after checking for a NULL pointer.

char* **PyByteArray_AsString**(PyObject *bytearray)

Return the contents of \( \text{bytearray} \) as a char array after checking for a NULL pointer.

int **PyByteArray_Resize**(PyObject *bytearray, Py_ssize_t len)

Resize the internal buffer of \( \text{bytearray} \) to \( \text{len} \).
Macros

These macros trade safety for speed and they don’t check pointers.

```
char* PyByteArray_AS_STRING(PyObject *bytearray)
Macro version of PyByteArray_AsString().
```

```
Py_ssize_t PyByteArray_GET_SIZE(PyObject *bytearray)
Macro version of PyByteArray_Size().
```
Unicode Objects and Codecs
Unicode Objects

Since the implementation of PEP 393 in Python 3.3, Unicode objects internally use a variety of representations, in order to allow handling the complete range of Unicode characters while staying memory efficient. There are special cases for strings where all code points are below 128, 256, or 65536; otherwise, code points must be below 1114112 (which is the full Unicode range).

Py_UNICODE* and UTF-8 representations are created on demand and cached in the Unicode object. The Py_UNICODE* representation is deprecated and inefficient; it should be avoided in performance- or memory-sensitive situations.

Due to the transition between the old APIs and the new APIs, unicode objects can internally be in two states depending on how they were created:

- “canonical” unicode objects are all objects created by a non-deprecated unicode API. They use the most efficient representation allowed by the implementation.
- “legacy” unicode objects have been created through one of the deprecated APIs (typically PyUnicode_FromUnicode()) and only bear the Py_UNICODE* representation; you will have to call PyUnicode_READY() on them before calling any other API.

Unicode Type

These are the basic Unicode object types used for the Unicode implementation in Python:

Py_UCS4
**Py_UCS2**
**Py_UCS1**

These types are typedefs for unsigned integer types wide enough to contain characters of 32 bits, 16 bits and 8 bits, respectively. When dealing with single Unicode characters, use **Py_UCS4**.

*New in version 3.3.*

**Py_UNICODE**

This is a typedef of wchar_t, which is a 16-bit type or 32-bit type depending on the platform.

*Changed in version 3.3:* In previous versions, this was a 16-bit type or a 32-bit type depending on whether you selected a “narrow” or “wide” Unicode version of Python at build time.

**PyASCIIObject**
**PyCompactUnicodeObject**
**PyUnicodeObject**

These subtypes of **PyObject** represent a Python Unicode object. In almost all cases, they shouldn’t be used directly, since all API functions that deal with Unicode objects take and return **PyObject** pointers.

*New in version 3.3.*

**PyTypeObject** **PyUnicode_Type**

This instance of **PyTypeObject** represents the Python Unicode type. It is exposed to Python code as **str**.

The following APIs are really C macros and can be used to do fast checks and to access internal read-only data of Unicode objects:
int PyUnicode_Check(PyObject *o)
    Return true if the object \textit{o} is a Unicode object or an instance of a Unicode subtype.

int PyUnicode_CheckExact(PyObject *o)
    Return true if the object \textit{o} is a Unicode object, but not an instance of a subtype.

int PyUnicode_READY(PyObject *o)
    Ensure the string object \textit{o} is in the “canonical” representation. This is required before using any of the access macros described below.

    Returns 0 on success and -1 with an exception set on failure, which in particular happens if memory allocation fails.

    \textit{New in version 3.3}.

Py_ssize_t PyUnicode_GET_LENGTH(PyObject *o)
    Return the length of the Unicode string, in code points. \textit{o} has to be a Unicode object in the “canonical” representation (not checked).

    \textit{New in version 3.3}.

Py_UCS1* PyUnicode_1BYTE_DATA(PyObject *o)
Py_UCS2* PyUnicode_2BYTE_DATA(PyObject *o)
Py_UCS4* PyUnicode_4BYTE_DATA(PyObject *o)
    Return a pointer to the canonical representation cast to UCS1, UCS2 or UCS4 integer types for direct character access. No checks are performed if the canonical representation has the correct character size; use \textbf{PyUnicode_KIND()} to select the right macro. Make sure \textbf{PyUnicode_READY()} has been called before accessing this.
Return values of the \texttt{PyUnicode_KIND()} macro.

\texttt{PyUnicode_KIND} \texttt{(PyObject \ast o)}

Return one of the \texttt{PyUnicode} kind constants (see above) that indicate how many bytes per character this \texttt{Unicode} object uses to store its data. \texttt{o} has to be a \texttt{Unicode} object in the “canonical” representation (not checked).

\texttt{PyUnicode_DATA} \texttt{(PyObject \ast o)}

Return a void pointer to the raw unicode buffer. \texttt{o} has to be a \texttt{Unicode} object in the “canonical” representation (not checked).

\texttt{PyUnicode_WRITE(int kind, void \ast data, Py_ssize_t index, Py_UCS4 value)}

Write into a canonical representation \texttt{data} (as obtained with \texttt{PyUnicode_DATA()}). This macro does not do any sanity checks and is intended for usage in loops. The caller should cache the \texttt{kind} value and \texttt{data} pointer as obtained from other macro calls. \texttt{index} is the index in the string (starts at 0) and \texttt{value} is the new code point value which should be written to that location.
New in version 3.3.

**Py_UCS4 PyUnicode_READ**(int kind, void *data, Py_ssize_t index)

Read a code point from a canonical representation data (as obtained with `PyUnicode_DATA()`). No checks or ready calls are performed.

New in version 3.3.

**Py_UCS4 PyUnicode_READ_CHAR**(PyObject *o, Py_ssize_t index)

Read a character from a Unicode object o, which must be in the “canonical” representation. This is less efficient than `PyUnicode_READ()` if you do multiple consecutive reads.

New in version 3.3.

**PyUnicode_MAX_CHAR_VALUE**(PyObject *o)

Return the maximum code point that is suitable for creating another string based on o, which must be in the “canonical” representation. This is always an approximation but more efficient than iterating over the string.

New in version 3.3.

int **PyUnicode_ClearFreeList**()

Clear the free list. Return the total number of freed items.

Py_ssize_t **PyUnicode_GET_SIZE**(PyObject *o)

Return the size of the deprecated `Py_UNICODE` representation, in code units (this includes surrogate pairs as 2 units). o has to be a Unicode object (not checked).
Py_ssize_t **PyUnicode_GET_DATA_SIZE** *(PyObject *)o*

Return the size of the deprecated Py_UNICODE representation in bytes. *o* has to be a Unicode object (not checked).

**Deprecated since version 3.3, will be removed in version 4.0:**
Part of the old-style Unicode API, please migrate to using PyUnicode_GET_LENGTH().

**Py_UNICODE** *PyUnicode_AS_UNICODE* *(PyObject *)o*

**Py_UNICODE** *
const char* **PyUnicode_AS_DATA** *(PyObject *)o*

Return a pointer to a Py_UNICODE representation of the object. The AS_DATA form casts the pointer to const char *. *o* has to be a Unicode object (not checked).

*Changed in version 3.3:* This macro is now inefficient – because in many cases the Py_UNICODE representation does not exist and needs to be created – and can fail (return NULL with an exception set). Try to port the code to use the new PyUnicode_nBYTE_DATA() macros or use PyUnicode_WRITE() or PyUnicode_READ().

**Deprecated since version 3.3, will be removed in version 4.0:**
Part of the old-style Unicode API, please migrate to using the PyUnicode_nBYTE_DATA() family of macros.

**Unicode Character Properties**
Unicode provides many different character properties. The most often needed ones are available through these macros which are mapped to C functions depending on the Python configuration.

```
int Py_UNICODE_ISSPACE(Py_UNICODE ch)
    Return 1 or 0 depending on whether ch is a whitespace character.

int Py_UNICODE_ISLOWER(Py_UNICODE ch)
    Return 1 or 0 depending on whether ch is a lowercase character.

int Py_UNICODE_ISUPPER(Py_UNICODE ch)
    Return 1 or 0 depending on whether ch is an uppercase character.

int Py_UNICODE_ISTITLE(Py_UNICODE ch)
    Return 1 or 0 depending on whether ch is a titlecase character.

int Py_UNICODE_ISLINEBREAK(Py_UNICODE ch)
    Return 1 or 0 depending on whether ch is a linebreak character.

int Py_UNICODE_ISDECIMAL(Py_UNICODE ch)
    Return 1 or 0 depending on whether ch is a decimal character.

int Py_UNICODE_ISDIGIT(Py_UNICODE ch)
    Return 1 or 0 depending on whether ch is a digit character.

int Py_UNICODE_ISNUMERIC(Py_UNICODE ch)
    Return 1 or 0 depending on whether ch is a numeric character.

int Py_UNICODE_ISALPHA(Py_UNICODE ch)
    Return 1 or 0 depending on whether ch is an alphabetic character.

int Py_UNICODE_ISALNUM(Py_UNICODE ch)
    Return 1 or 0 depending on whether ch is an alphanumeric
```
int **Py_UNICODE** ISPRINTABLE**(Py_UNICODE** ch)

Return 1 or 0 depending on whether *ch* is a printable character. Nonprintable characters are those characters defined in the Unicode character database as “Other” or “Separator”, excepting the ASCII space (0x20) which is considered printable. (Note that printable characters in this context are those which should not be escaped when *repr()* is invoked on a string. It has no bearing on the handling of strings written to *sys.stdout* or *sys.stderr*.)

These APIs can be used for fast direct character conversions:

**Py_UNICODE** **Py_UNICODE** TOLOWER**(Py_UNICODE** ch)

Return the character *ch* converted to lower case.

*Deprecated since version 3.3*: This function uses simple case mappings.

**Py_UNICODE** **Py_UNICODE** TOUPPER**(Py_UNICODE** ch)

Return the character *ch* converted to upper case.

*Deprecated since version 3.3*: This function uses simple case mappings.

**Py_UNICODE** **Py_UNICODE** TOTITLE**(Py_UNICODE** ch)

Return the character *ch* converted to title case.

*Deprecated since version 3.3*: This function uses simple case mappings.

int **Py_UNICODE** TODECIMAL**(Py_UNICODE** ch)
Return the character \( ch \) converted to a decimal positive integer. Return \(-1\) if this is not possible. This macro does not raise exceptions.

\[
\text{int } \text{Py_UNICODE_TODIGIT}(\text{Py_UNICODE } ch)
\]

Return the character \( ch \) converted to a single digit integer. Return \(-1\) if this is not possible. This macro does not raise exceptions.

\[
\text{double } \text{Py_UNICODE_TONUMERIC}(\text{Py_UNICODE } ch)
\]

Return the character \( ch \) converted to a double. Return \(-1.0\) if this is not possible. This macro does not raise exceptions.

These APIs can be used to work with surrogates:

\[
\text{Py_UNICODE_IS_SURROGATE}(ch)
\]

Check if \( ch \) is a surrogate \((\text{0xD800} \leq ch \leq \text{0xDFFF})\).

\[
\text{Py_UNICODE_IS_HIGH_SURROGATE}(ch)
\]

Check if \( ch \) is an high surrogate \((\text{0xD800} \leq ch \leq \text{0xDBFF})\).

\[
\text{Py_UNICODE_IS_LOW_SURROGATE}(ch)
\]

Check if \( ch \) is a low surrogate \((\text{0xDC00} \leq ch \leq \text{0xDFFF})\).

\[
\text{Py_UNICODE_JOIN_SURROGATES}(high, low)
\]

Join two surrogate characters and return a single Py_UCS4 value. \( high \) and \( low \) are respectively the leading and trailing surrogates in a surrogate pair.

Creating and accessing Unicode strings

To create Unicode objects and access their basic sequence properties, use these APIs:
PyObject* **PyUnicode_New**(Py_ssize_t *size, Py_UCS4 *maxchar)

Create a new Unicode object. *maxchar* should be the true maximum code point to be placed in the string. As an approximation, it can be rounded up to the nearest value in the sequence 127, 255, 65535, 1114111.

This is the recommended way to allocate a new Unicode object. Objects created using this function are not resizable.

*New in version 3.3.*

PyObject* **PyUnicode_FromKindAndData**(int *kind*, const void *buffer, Py_ssize_t *size)

Create a new Unicode object with the given *kind* (possible values are *PyUnicode_1BYTE_KIND* etc., as returned by *PyUnicode_KIND()*)). The *buffer* must point to an array of *size* units of 1, 2 or 4 bytes per character, as given by the kind.

*New in version 3.3.*

PyObject* **PyUnicode_FromStringAndSize**(const char *u, Py_ssize_t *size)

Create a Unicode object from the char buffer *u*. The bytes will be interpreted as being UTF-8 encoded. The buffer is copied into the new object. If the buffer is not *NULL*, the return value might be a shared object, i.e. modification of the data is not allowed.

If *u* is *NULL*, this function behaves like *PyUnicode_FromUnicode()* with the buffer set to *NULL*. This usage is deprecated in favor of *PyUnicode_New()*.

PyObject **PyUnicode_FromString**(const char *u)

Create a Unicode object from an UTF-8 encoded null-terminated
char buffer u.

**PyObject** *PyUnicode_FromFormat**(const char *format, ...)

Take a C printf()-style *format* string and a variable number of arguments, calculate the size of the resulting Python unicode string and return a string with the values formatted into it. The variable arguments must be C types and must correspond exactly to the format characters in the *format* ASCII-encoded string. The following format characters are allowed:

<table>
<thead>
<tr>
<th>Format Characters</th>
<th>Type</th>
<th>Comment</th>
</tr>
</thead>
<tbody>
<tr>
<td>%%</td>
<td>n/a</td>
<td>The literal % character.</td>
</tr>
<tr>
<td>%c</td>
<td>int</td>
<td>A single character, represented as an C int.</td>
</tr>
<tr>
<td>%d</td>
<td>int</td>
<td>Exactly equivalent to printf(&quot;%d&quot;).</td>
</tr>
<tr>
<td>%u</td>
<td>unsigned int</td>
<td>Exactly equivalent to printf(&quot;%u&quot;).</td>
</tr>
<tr>
<td>%ld</td>
<td>long</td>
<td>Exactly equivalent to printf(&quot;%ld&quot;).</td>
</tr>
<tr>
<td>%li</td>
<td>long</td>
<td>Exactly equivalent to printf(&quot;%li&quot;).</td>
</tr>
<tr>
<td>%lu</td>
<td>unsigned long</td>
<td>Exactly equivalent to printf(&quot;%lu&quot;).</td>
</tr>
<tr>
<td>%lld</td>
<td>long long</td>
<td>Exactly equivalent to printf(&quot;%lld&quot;).</td>
</tr>
<tr>
<td>%lld</td>
<td>long long</td>
<td>Exactly equivalent to printf(&quot;%lld&quot;).</td>
</tr>
<tr>
<td>%lli</td>
<td>long long</td>
<td>Exactly equivalent to printf(&quot;%lli&quot;).</td>
</tr>
<tr>
<td>%llu</td>
<td>unsigned long long</td>
<td>Exactly equivalent to printf(&quot;%llu&quot;).</td>
</tr>
<tr>
<td>Format</td>
<td>Type</td>
<td>Description</td>
</tr>
<tr>
<td>--------</td>
<td>------</td>
<td>-------------</td>
</tr>
<tr>
<td>%zd</td>
<td>Py_ssize_t</td>
<td>Exactly equivalent to printf(&quot;%zd&quot;).</td>
</tr>
<tr>
<td>%zi</td>
<td>Py_ssize_t</td>
<td>Exactly equivalent to printf(&quot;%zi&quot;).</td>
</tr>
<tr>
<td>%zu</td>
<td>size_t</td>
<td>Exactly equivalent to printf(&quot;%zu&quot;).</td>
</tr>
<tr>
<td>%i</td>
<td>int</td>
<td>Exactly equivalent to printf(&quot;%i&quot;).</td>
</tr>
<tr>
<td>%x</td>
<td>int</td>
<td>Exactly equivalent to printf(&quot;%x&quot;).</td>
</tr>
<tr>
<td>%s</td>
<td>char*</td>
<td>A null-terminated C character array.</td>
</tr>
<tr>
<td>%p</td>
<td>void*</td>
<td>The hex representation of a C pointer. Mostly equivalent to printf(&quot;%p&quot;) except that it is guaranteed to start with the literal 0x regardless of what the platform’s printf yields.</td>
</tr>
<tr>
<td>%A</td>
<td>PyObject*</td>
<td>The result of calling ascii().</td>
</tr>
<tr>
<td>%U</td>
<td>PyObject*</td>
<td>A unicode object.</td>
</tr>
<tr>
<td>%V</td>
<td>PyObject*, char *</td>
<td>A unicode object (which may be NULL) and a null-terminated C character array as a second parameter (which will be used, if the first parameter is NULL).</td>
</tr>
<tr>
<td>%S</td>
<td>PyObject*</td>
<td>The result of calling PyObject_Str().</td>
</tr>
</tbody>
</table>
An unrecognized format character causes all the rest of the format string to be copied as-is to the result string, and any extra arguments discarded.

**Note:** The “%lld” and “%llu” format specifiers are only available when HAVE_LONG_LONG is defined.

**Note:** The width formatter unit is number of characters rather than bytes. The precision formatter unit is number of bytes for "%s" and "%V" (if the PyObject* argument is NULL), and a number of characters for "%A", "%U", "%S", "%R" and "%V" (if the PyObject* argument is not NULL).

*Changed in version 3.2:* Support for "%lld" and "%llu" added.

*Changed in version 3.3:* Support for "%li", "%lli" and "%zi" added.

*Changed in version 3.4:* Support width and precision formatter for "%s", "%A", "%U", "%V", "%S", "%R" added.

**PyObject**\* **PyUnicode_FromFormatV**(const char *format, va_list vargs)

Identical to **PyUnicode_FromFormat()** except that it takes exactly two arguments.

**PyObject**\* **PyUnicode_FromEncodedObject**(PyObject *obj, const char *encoding, const char *errors)

*Return value: New reference.*

Coerce an encoded object *obj* to an Unicode object and return a
reference with incremented refcount.

bytes, bytearray and other char buffer compatible objects are decoded according to the given encoding and using the error handling defined by errors. Both can be NULL to have the interface use the default values (see the next section for details).

All other objects, including Unicode objects, cause a TypeError to be set.

The API returns NULL if there was an error. The caller is responsible for decref’ing the returned objects.

Py_ssize_t PyUnicode_GetLength(PyObject *unicode)
Return the length of the Unicode object, in code points.

New in version 3.3.

int PyUnicode_CopyCharacters(PyObject *to, Py_ssize_t to_start, PyObject *from, Py_ssize_t from_start, Py_ssize_t how_many)
Copy characters from one Unicode object into another. This function performs character conversion when necessary and falls back to memcpy() if possible. Returns -1 and sets an exception on error, otherwise returns 0.

New in version 3.3.

Py_ssize_t PyUnicode_Fill(PyObject *unicode, Py_ssize_t start, Py_ssize_t length, Py_UCS4 fill_char)
Fill a string with a character: write fill_char into unicode[start:start+length].

Fail if fill_char is bigger than the string maximum character, or if the
string has more than 1 reference.

Return the number of written character, or return -1 and raise an exception on error.

New in version 3.3.

```c
int PyUnicode_WriteChar(PyObject *unicode,
Py_ssize_t index, Py_UCS4 character)
```

Write a character to a string. The string must have been created through `PyUnicode_New()`. Since Unicode strings are supposed to be immutable, the string must not be shared, or have been hashed yet.

This function checks that `unicode` is a Unicode object, that the index is not out of bounds, and that the object can be modified safely (i.e. that it its reference count is one), in contrast to the macro version `PyUnicode_WRITE_CHAR()`.

New in version 3.3.

```c
Py_UCS4 PyUnicode_ReadChar(PyObject *unicode,
Py_ssize_t index)
```

Read a character from a string. This function checks that `unicode` is a Unicode object and the index is not out of bounds, in contrast to the macro version `PyUnicode_READ_CHAR()`.

New in version 3.3.

```c
PyObject* PyUnicode_Substring(PyObject *str,
Py_ssize_t start, Py_ssize_t end)
```

Return a substring of `str`, from character index `start` (included) to character index `end` (excluded). Negative indices are not
supported.

*New in version 3.3.*

Py_UCS4* **PyUnicode_AsUCS4**(PyObject *u, Py_UNICODE *buffer, Py_ssize_t buflen, int copy_null)

Copy the string u into a UCS4 buffer, including a null character, if copy_null is set. Returns NULL and sets an exception on error (in particular, a ValueError if buflen is smaller than the length of u). buffer is returned on success.

*New in version 3.3.*

Py_UCS4* **PyUnicode_AsUCS4Copy**(PyObject *u)

Copy the string u into a new UCS4 buffer that is allocated using PyMem_Malloc(). If this fails, NULL is returned with a MemoryError set.

*New in version 3.3.*

---

**Deprecated Py_UNICODE APIs**

*Deprecated since version 3.3, will be removed in version 4.0.*

These API functions are deprecated with the implementation of PEP 393. Extension modules can continue using them, as they will not be removed in Python 3.x, but need to be aware that their use can now cause performance and memory hits.

PyObject* **PyUnicode_FromUnicode**(const Py_UNICODE *u, Py_ssize_t size)

*Return value: New reference.*
Create a Unicode object from the Py_UNICODE buffer \( u \) of the given size. \( u \) may be \texttt{NULL} which causes the contents to be undefined. It is the user’s responsibility to fill in the needed data. The buffer is copied into the new object.

If the buffer is not \texttt{NULL}, the return value might be a shared object. Therefore, modification of the resulting Unicode object is only allowed when \( u \) is \texttt{NULL}.

If the buffer is \texttt{NULL}, \texttt{PyUnicode_READY()} must be called once the string content has been filled before using any of the access macros such as \texttt{PyUnicode_KIND()}.

Please migrate to using \texttt{PyUnicode_FromKindAndData()} or \texttt{PyUnicode_New()}.

**\texttt{Py_UNICODE* PyUnicode_AsUnicode(PyObject *unicode)}**

Return a read-only pointer to the Unicode object’s internal \texttt{Py_UNICODE} buffer, or \texttt{NULL} on error. This will create the \texttt{Py_UNICODE*} representation of the object if it is not yet available. Note that the resulting \texttt{Py_UNICODE} string may contain embedded null characters, which would cause the string to be truncated when used in most C functions.

Please migrate to using \texttt{PyUnicode_AsUCS4()}, \texttt{PyUnicode_Substring()}, \texttt{PyUnicode_ReadChar()} or similar new APIs.

**\texttt{PyObject* PyUnicode_TransformDecimalToASCII(Py_UNICODE *s, Py_ssize_t size)}**

Create a Unicode object by replacing all decimal digits in \texttt{Py_UNICODE} buffer of the given size by ASCII digits 0–9 according
to their decimal value. Return NULL if an exception occurs.

**Py_UNICODE**

**PyUnicode_AsUnicodeAndSize** *(PyObject *unicode, Py_ssize_t *size)*  
Like **PyUnicode_AsUnicode()**, but also saves the **Py_UNICODE()** array length in *size*. Note that the resulting **Py_UNICODE** string may contain embedded null characters, which would cause the string to be truncated when used in most C functions.

*New in version 3.3.*

**Py_UNICODE**

**PyUnicode_AsUnicodeCopy** *(PyObject *unicode)*  
Create a copy of a Unicode string ending with a nul character. Return NULL and raise a MemoryError exception on memory allocation failure, otherwise return a new allocated buffer (use **PyMem_Free()** to free the buffer). Note that the resulting **Py_UNICODE** string may contain embedded null characters, which would cause the string to be truncated when used in most C functions.

*New in version 3.2.*

Please migrate to using **PyUnicode_AsUCS4Copy()** or similar new APIs.

**Py_ssize_t**

**PyUnicode_GetSize** *(PyObject *unicode)*  
Return the size of the deprecated **Py_UNICODE** representation, in code units (this includes surrogate pairs as 2 units).

Please migrate to using **PyUnicode_GetLength()**.
**PyObject** PyUnicode_FromObject***(PyObject *obj)**

*Return value: New reference.*

Shortcut for PyUnicode_FromEncodedObject(obj, NULL, "strict") which is used throughout the interpreter whenever coercion to Unicode is needed.

### Locale Encoding

The current locale encoding can be used to decode text from the operating system.

**PyObject** PyUnicode_DecodeLocaleAndSize**(const char *str, Py_ssize_t len, const char *errors)**

Decode a string from the current locale encoding. The supported error handlers are "strict" and "surrogateescape" (PEP 383). The decoder uses "strict" error handler if `errors` is NULL. `str` must end with a null character but cannot contain embedded null characters.

**See also:** Use PyUnicode_DecodeFSDefaultAndSize() to decode a string from Py_FileSystemDefaultEncoding (the locale encoding read at Python startup).

*New in version 3.3.*

**PyObject** PyUnicode_DecodeLocale**(const char *str, const char *errors)**

Similar to PyUnicode_DecodeLocaleAndSize(), but compute the string length using strlen().

*New in version 3.3.*
PyObject* PyUnicode_EncodeLocale(PyObject *unicode, const char *errors)

Encode a Unicode object to the current locale encoding. The supported error handlers are "strict" and "surrogateescape" (PEP 383). The encoder uses "strict" error handler if errors is NULL. Return a bytes object. str cannot contain embedded null characters.

See also: Use PyUnicode_EncodeFSDefault() to encode a string to Py_FileSystemDefaultEncoding (the locale encoding read at Python startup).

New in version 3.3.

File System Encoding

To encode and decode file names and other environment strings, Py_FileSystemEncoding should be used as the encoding, and "surrogateescape" should be used as the error handler (PEP 383). To encode file names during argument parsing, the "O&" converter should be used, passing PyUnicode_FSConverter() as the conversion function:

int PyUnicode_FSConverter(PyObject* obj, void* result)

ParseTuple converter: encode str objects to bytes using PyUnicode_EncodeFSDefault(); bytes objects are output as-is. result must be a PyBytesObject* which must be released when it is no longer used.

New in version 3.1.
To decode file names during argument parsing, the "O&" converter should be used, passing `PyUnicode_FSDecoder()` as the conversion function:

```c
int PyUnicode_FSDecoder(PyObject* obj, void* result)
```

ParseTuple converter: decode bytes objects to str using `PyUnicode_DecodeFSDefaultAndSize()`; str objects are output as-is. `result` must be a `PyUnicodeObject*` which must be released when it is no longer used.

*New in version 3.2.*

```c
PyObject* PyUnicode_DecodeFSDefaultAndSize(const char *s, Py_ssize_t size)
```

Decode a string using `Py_FileSystemDefaultEncoding` and the "surrogateescape" error handler, or "strict" on Windows.

If `Py_FileSystemDefaultEncoding` is not set, fall back to the locale encoding.

*See also:* `Py_FileSystemDefaultEncoding` is initialized at startup from the locale encoding and cannot be modified later. If you need to decode a string from the current locale encoding, use `PyUnicode_DecodeLocaleAndSize()`.

*Changed in version 3.2:* Use "strict" error handler on Windows.

```c
PyObject* PyUnicode_DecodeFSDefault(char *s)
```

Decode a null-terminated string using `Py_FileSystemDefaultEncoding` and the "surrogateescape" error handler, or "strict" on Windows.
If `Py_FileSystemDefaultEncoding` is not set, fall back to the locale encoding.

Use `PyUnicode_DecodeFSDefaultAndSize()` if you know the string length.

*Changed in version 3.2:* Use "strict" error handler on Windows.

```python
PyObject* PyUnicode_EncodeFSDefault(PyObject* unicode)
```

Encode a Unicode object to `Py_FileSystemDefaultEncoding` with the "surrogateescape" error handler, or "strict" on Windows, and return bytes. Note that the resulting bytes object may contain null bytes.

If `Py_FileSystemDefaultEncoding` is not set, fall back to the locale encoding.

See also: `Py_FileSystemDefaultEncoding` is initialized at startup from the locale encoding and cannot be modified later. If you need to encode a string to the current locale encoding, use `PyUnicode_EncodeLocale()`.

*New in version 3.2.*

**wchar_t Support**

 wchar_t support for platforms which support it:

```python
PyObject* PyUnicode_FromWideChar(const wchar_t *w,
Py_ssize_t size)
```

*Return value: New reference.*

Create a Unicode object from the wchar_t buffer `w` of the given
size. Passing -1 as the size indicates that the function must itself compute the length, using wcslen. Return NULL on failure.

Py_ssize_t
PyUnicode_AsWideChar(PyUnicodeObject *unicode,
wchar_t *w, Py_ssize_t size)
Copy the Unicode object contents into the wchar_t buffer w. At most size wchar_t characters are copied (excluding a possibly trailing 0-termination character). Return the number of wchar_t characters copied or -1 in case of an error. Note that the resulting wchar_t* string may or may not be 0-terminated. It is the responsibility of the caller to make sure that the wchar_t* string is 0-terminated in case this is required by the application. Also, note that the wchar_t* string might contain null characters, which would cause the string to be truncated when used with most C functions.

wchar_t* PyUnicode_AsWideCharString(PyObject *unicode,
Py_ssize_t *size)
Convert the Unicode object to a wide character string. The output string always ends with a nul character. If size is not NULL, write the number of wide characters (excluding the trailing 0-termination character) into *size.

Returns a buffer allocated by PyMem_Alloc() (use PyMem_Free() to free it) on success. On error, returns NULL, *size is undefined and raises a MemoryError. Note that the resulting wchar_t string might contain null characters, which would cause the string to be truncated when used with most C functions.

New in version 3.2.
UCS4 Support

New in version 3.3.

size_t Py_UCS4_strlen(const Py_UCS4 *u)
Py_UCS4* Py_UCS4_strcpy(Py_UCS4 *s1, const Py_UCS4 *s2)
Py_UCS4* Py_UCS4_strncpy(Py_UCS4 *s1, const Py_UCS4 *s2, size_t n)
Py_UCS4* Py_UCS4_strcat(Py_UCS4 *s1, const Py_UCS4 *s2)
int Py_UCS4_strcmp(const Py_UCS4 *s1, const Py_UCS4 *s2)
int Py_UCS4_strncmp(const Py_UCS4 *s1, const Py_UCS4 *s2, size_t n)
Py_UCS4* Py_UCS4_strchr(const Py_UCS4 *s, Py_UCS4 c)
Py_UCS4* Py_UCS4_strrchr(const Py_UCS4 *s, Py_UCS4 c)

These utility functions work on strings of Py_UCS4 characters and otherwise behave like the C standard library functions with the same name.
Built-in Codecs

Python provides a set of built-in codecs which are written in C for speed. All of these codecs are directly usable via the following functions.

Many of the following APIs take two arguments encoding and errors, and they have the same semantics as the ones of the built-in \texttt{str()} string object constructor.

Setting encoding to \texttt{NULL} causes the default encoding to be used which is ASCII. The file system calls should use \texttt{PyUnicode_FSConverter()} for encoding file names. This uses the variable \texttt{Py_FileSystemDefaultEncoding} internally. This variable should be treated as read-only: on some systems, it will be a pointer to a static string, on others, it will change at run-time (such as when the application invokes setlocale).

Error handling is set by errors which may also be set to \texttt{NULL} meaning to use the default handling defined for the codec. Default error handling for all built-in codecs is “strict” (\texttt{ValueError} is raised).

The codecs all use a similar interface. Only deviation from the following generic ones are documented for simplicity.

Generic Codecs

These are the generic codec APIs:

\begin{verbatim}
PyObject* PyUnicode_Decode(const char *s, Py_ssize_t size,
const char *encoding, const char *errors)
\end{verbatim}

\textit{Return value: New reference.}
Create a Unicode object by decoding size bytes of the encoded string s. `encoding` and `errors` have the same meaning as the parameters of the same name in the `str()` built-in function. The codec to be used is looked up using the Python codec registry. Return `NULL` if an exception was raised by the codec.

```c
PyObject* PyUnicode_AsEncodedString(PyObject *unicode, const char *encoding, const char *errors)
```

*Return value: New reference.*

Encode a Unicode object and return the result as Python bytes object. `encoding` and `errors` have the same meaning as the parameters of the same name in the Unicode `encode()` method. The codec to be used is looked up using the Python codec registry. Return `NULL` if an exception was raised by the codec.

```c
PyObject* PyUnicode_Encode(const Py_UNICODE *s, Py_ssize_t size, const char *encoding, const char *errors)
```

*Return value: New reference.*

Encode the Py_UNICODE buffer s of the given size and return a Python bytes object. `encoding` and `errors` have the same meaning as the parameters of the same name in the Unicode `encode()` method. The codec to be used is looked up using the Python codec registry. Return `NULL` if an exception was raised by the codec.

*Deprecated since version 3.3, will be removed in version 4.0:* Part of the old-style Py_UNICODE API; please migrate to using PyUnicode_AsEncodedString().

**UTF-8 Codecs**

These are the UTF-8 codec APIs:
PyObject* PyUnicode_DecodeUTF8(const char *s,
Py_ssize_t size, const char *errors)

Create a Unicode object by decoding size bytes of the UTF-8 encoded string s. Return NULL if an exception was raised by the codec.

PyObject* PyUnicode_DecodeUTF8Stateful(const char *s,
Py_ssize_t size, const char *errors, Py_ssize_t *consumed)

If consumed is NULL, behave like PyUnicode_DecodeUTF8(). If consumed is not NULL, trailing incomplete UTF-8 byte sequences will not be treated as an error. Those bytes will not be decoded and the number of bytes that have been decoded will be stored in consumed.

PyObject* PyUnicode_AsUTF8String(PyObject *unicode)

Encode a Unicode object using UTF-8 and return the result as Python bytes object. Error handling is “strict”. Return NULL if an exception was raised by the codec.

cchar* PyUnicode_AsUTF8AndSize(PyObject *unicode,
Py_ssize_t *size)

Return a pointer to the default encoding (UTF-8) of the Unicode object, and store the size of the encoded representation (in bytes) in size. size can be NULL, in this case no size will be stored.

In the case of an error, NULL is returned with an exception set and no size is stored.

This caches the UTF-8 representation of the string in the Unicode object, and subsequent calls will return a pointer to the same
buffer. The caller is not responsible for deallocating the buffer.

*New in version 3.3.*

```c
char* PyUnicode_AsUTF8(PyObject *unicode)
```

As `PyUnicode_AsUTF8AndSize()`, but does not store the size.

*New in version 3.3.*

```c
PyObject* PyUnicode_EncodeUTF8(const Py_UNICODE*s, Py_ssize_t size, const char *errors)
```

*Return value: New reference.*

Encode the `Py_UNICODE` buffer `s` of the given `size` using UTF-8 and return a Python bytes object. Return `NULL` if an exception was raised by the codec.

*Deprecated since version 3.3, will be removed in version 4.0:* Part of the old-style `Py_UNICODE` API; please migrate to using `PyUnicode_AsUTF8String()` or `PyUnicode_AsUTF8AndSize()`.

### UTF-32 Codecs

These are the UTF-32 codec APIs:

```c
PyObject* PyUnicode_DecodeUTF32(const char *s, Py_ssize_t size, const char *errors, int *byteorder)
```

Decode `size` bytes from a UTF-32 encoded buffer string and return the corresponding Unicode object. `errors` (if non-`NULL`) defines the error handling. It defaults to “strict”.

If `byteorder` is non-`NULL`, the decoder starts decoding using the
given byte order:

```
*byteorder == -1: little endian
*byteorder == 0: native order
*byteorder == 1: big endian
```

If `*byteorder` is zero, and the first four bytes of the input data are a byte order mark (BOM), the decoder switches to this byte order and the BOM is not copied into the resulting Unicode string. If `*byteorder` is -1 or 1, any byte order mark is copied to the output.

After completion, `*byteorder` is set to the current byte order at the end of input data.

If `byteorder` is `NULL`, the codec starts in native order mode.

Return `NULL` if an exception was raised by the codec.

```c
PyObject* PyUnicode_DecodeUTF32Stateful(const char *s,
Py_ssize_t size, const char *errors, int *byteorder,
Py_ssize_t *consumed)
```

If `consumed` is `NULL`, behave like `PyUnicode_DecodeUTF32()`.

If `consumed` is not `NULL`, `PyUnicode_DecodeUTF32Stateful()` will not treat trailing incomplete UTF-32 byte sequences (such as a number of bytes not divisible by four) as an error. Those bytes will not be decoded and the number of bytes that have been decoded will be stored in `consumed`.

```c
PyObject* PyUnicode_AsUTF32String(PyObject *unicode)
```

Return a Python byte string using the UTF-32 encoding in native byte order. The string always starts with a BOM mark. Error
handling is “strict”. Return NULL if an exception was raised by the codec.

PyObject* **PyUnicode_EncodeUTF32** (const Py_UNICODE *s, Py_ssize_t size, const char *errors, int byteorder)

Return a Python bytes object holding the UTF-32 encoded value of the Unicode data in s. Output is written according to the following byte order:

```
byteorder == -1: little endian
byteorder == 0: native byte order (writes a BOM if byteorder is 0)
byteorder == 1: big endian
```

If byteorder is 0, the output string will always start with the Unicode BOM mark (U+FEFF). In the other two modes, no BOM mark is prepended.

If Py_UNICODE_WIDE is not defined, surrogate pairs will be output as a single codepoint.

Return NULL if an exception was raised by the codec.

*Deprecated since version 3.3, will be removed in version 4.0:* Part of the old-style Py_UNICODE API; please migrate to using PyUnicode_AsUTF32String().

UTF-16 Codecs

These are the UTF-16 codec APIs:

PyObject* **PyUnicode_DecodeUTF16** (const char *s, Py_ssize_t size, const char *errors, int *byteorder)
Decode size bytes from a UTF-16 encoded buffer string and return the corresponding Unicode object. errors (if non-NULL) defines the error handling. It defaults to “strict”.

If byteorder is non-NULL, the decoder starts decoding using the given byte order:

*byteorder == -1: little endian
*byteorder == 0: native order
*byteorder == 1: big endian

If *byteorder is zero, and the first two bytes of the input data are a byte order mark (BOM), the decoder switches to this byte order and the BOM is not copied into the resulting Unicode string. If *byteorder is -1 or 1, any byte order mark is copied to the output (where it will result in either a \ufffe or a \ufffe character).

After completion, *byteorder is set to the current byte order at the end of input data.

If byteorder is NULL, the codec starts in native order mode.

Return NULL if an exception was raised by the codec.

PyObject* PyUnicode_DecodeUTF16Stateful(const char *s, Py_ssize_t size, const char *errors, int *byteorder, Py_ssize_t *consumed)

If consumed is NULL, behave like PyUnicode_DecodeUTF16().
If consumed is not NULL, PyUnicode_DecodeUTF16Stateful() will not treat trailing incomplete UTF-16 byte sequences (such as an odd number of
bytes or a split surrogate pair) as an error. Those bytes will not be decoded and the number of bytes that have been decoded will be stored in *consumed*.

**PyObject** `PyUnicode_AsUTF16String(PyObject *unicode)`

*Return value: New reference.*

Return a Python byte string using the UTF-16 encoding in native byte order. The string always starts with a BOM mark. Error handling is “strict”. Return `NULL` if an exception was raised by the codec.

**PyObject** `PyUnicode_EncodeUTF16(const Py_UNICODE *s, Py_ssize_t size, const char *errors, int byteorder)`

*Return value: New reference.*

Return a Python bytes object holding the UTF-16 encoded value of the Unicode data in `s`. Output is written according to the following byte order:

```
byteorder == -1: little endian
byteorder == 0: native byte order (writes a BOM mark)
byteorder == 1: big endian
```

If byteorder is 0, the output string will always start with the Unicode BOM mark (U+FEFF). In the other two modes, no BOM mark is prepended.

If `Py_UNICODE_WIDE` is defined, a single `Py_UNICODE` value may get represented as a surrogate pair. If it is not defined, each `Py_UNICODE` values is interpreted as an UCS-2 character.

Return `NULL` if an exception was raised by the codec.
Deprecated since version 3.3, will be removed in version 4.0: Part of the old-style Py_UNICODE API; please migrate to using PyUnicode_AsUTF16String().

UTF-7 Codecs

These are the UTF-7 codec APIs:

PyObject* **PyUnicode_DecodeUTF7**(const char *s, Py_ssize_t size, const char *errors)

Create a Unicode object by decoding size bytes of the UTF-7 encoded string s. Return NULL if an exception was raised by the codec.

PyObject* **PyUnicode_DecodeUTF7Stateful**(const char *s, Py_ssize_t size, const char *errors, Py_ssize_t *consumed)

If consumed is NULL, behave like PyUnicode_DecodeUTF7(). If consumed is not NULL, trailing incomplete UTF-7 base-64 sections will not be treated as an error. Those bytes will not be decoded and the number of bytes that have been decoded will be stored in consumed.

PyObject* **PyUnicode_EncodeUTF7**(const Py_UNICODE *s, Py_ssize_t size, int base64SetO, int base64WhiteSpace, const char *errors)

Encode the Py_UNICODE buffer of the given size using UTF-7 and return a Python bytes object. Return NULL if an exception was raised by the codec.

If base64SetO is nonzero, “Set O” (punctuation that has no otherwise special meaning) will be encoded in base-64. If base64WhiteSpace is nonzero, whitespace will be encoded in
base-64. Both are set to zero for the Python “utf-7” codec.

*Deprecated since version 3.3, will be removed in version 4.0:*
Part of the old-style Py_UNICODE API.

**Unicode-Escape Codecs**

These are the “Unicode Escape” codec APIs:

**PyObject**

*PyUnicode_DecodeUnicodeEscape*(const char *s, Py_ssize_t size, const char *errors)

*Return value: New reference.*
Create a Unicode object by decoding size bytes of the Unicode-Escape encoded string s. Return NULL if an exception was raised by the codec.

**PyObject**

*PyUnicode_AsUnicodeEscapeString*(PyObject *unicode)

*Return value: New reference.*
Encode a Unicode object using Unicode-Escape and return the result as Python string object. Error handling is “strict”. Return NULL if an exception was raised by the codec.

**PyObject**

*PyUnicode_EncodeUnicodeEscape*(const Py_UNICODE *s, Py_ssize_t size)

*Return value: New reference.*
Encode the Py_UNICODE buffer of the given size using Unicode-Escape and return a Python string object. Return NULL if an exception was raised by the codec.

*Deprecated since version 3.3, will be removed in version 4.0:*
Part of the old-style Py_UNICODE API; please migrate to using
PyUnicode_AsUnicodeEscapeString().

Raw-Unicode-Escape Codecs

These are the “Raw Unicode Escape” codec APIs:

*PyObject* **PyUnicode_DecodeRawUnicodeEscape**(const char *s, Py_ssize_t size, const char *errors)

*Return value: New reference.*

Create a Unicode object by decoding size bytes of the Raw-Unicode-Escape encoded string s. Return NULL if an exception was raised by the codec.

*PyObject*

**PyUnicode_AsRawUnicodeEscapeString**(PyObject *unicode)

*Return value: New reference.*

Encode a Unicode object using Raw-Unicode-Escape and return the result as Python string object. Error handling is “strict”. Return NULL if an exception was raised by the codec.

*PyObject*

**PyUnicode_EncodeRawUnicodeEscape**(const Py_UNICODE *s, Py_ssize_t size, const char *errors)

*Return value: New reference.*

Encode the Py_UNICODE buffer of the given size using Raw-Unicode-Escape and return a Python string object. Return NULL if an exception was raised by the codec.

*Deprecated since version 3.3, will be removed in version 4.0:* Part of the old-style Py_UNICODE API; please migrate to using PyUnicode_AsRawUnicodeEscapeString().

Latin-1 Codecs
These are the Latin-1 codec APIs: Latin-1 corresponds to the first 256 Unicode ordinals and only these are accepted by the codecs during encoding.

**PyObject** `PyUnicode_DecodeLatin1(const char *s, Py_ssize_t size, const char *errors)`

*Return value: New reference.*
Create a Unicode object by decoding size bytes of the Latin-1 encoded string s. Return `NULL` if an exception was raised by the codec.

**PyObject** `PyUnicode_AsLatin1String(PyObject *unicode)`

*Return value: New reference.*
Encode a Unicode object using Latin-1 and return the result as Python bytes object. Error handling is “strict”. Return `NULL` if an exception was raised by the codec.

**PyObject** `PyUnicode_EncodeLatin1(const Py_UNICODE *s, Py_ssize_t size, const char *errors)`

*Return value: New reference.*
Encode the `Py_UNICODE` buffer of the given size using Latin-1 and return a Python bytes object. Return `NULL` if an exception was raised by the codec.

*Deprecated since version 3.3, will be removed in version 4.0:*
Part of the old-style `Py_UNICODE` API; please migrate to using `PyUnicode_AsLatin1String()`.

**ASCII Codecs**

These are the ASCII codec APIs. Only 7-bit ASCII data is accepted.
All other codes generate errors.

PyObject* `PyUnicode_DecodeASCII`(const char *s,
Py_ssize_t size, const char *errors)

*Return value: New reference.*

Create a Unicode object by decoding `size` bytes of the ASCII encoded string `s`. Return `NULL` if an exception was raised by the codec.

PyObject* `PyUnicode_AsASCIIString`(PyObject *unicode)

*Return value: New reference.*

Encode a Unicode object using ASCII and return the result as Python bytes object. Error handling is “strict”. Return `NULL` if an exception was raised by the codec.

PyObject* `PyUnicode_EncodeASCII`(const Py_UNICODE *s,
Py_ssize_t size, const char *errors)

*Return value: New reference.*

Encode the Py_UNICODE buffer of the given `size` using ASCII and return a Python bytes object. Return `NULL` if an exception was raised by the codec.

*Deprecated since version 3.3, will be removed in version 4.0:* Part of the old-style Py_UNICODE API; please migrate to using `PyUnicode_AsASCIIString()`.

Character Map Codecs

This codec is special in that it can be used to implement many different codecs (and this is in fact what was done to obtain most of the standard codecs included in the encodings package). The codec uses mapping to encode and decode characters.
Decoding mappings must map single string characters to single Unicode characters, integers (which are then interpreted as Unicode ordinals) or None (meaning “undefined mapping” and causing an error).

Encoding mappings must map single Unicode characters to single string characters, integers (which are then interpreted as Latin-1 ordinals) or None (meaning “undefined mapping” and causing an error).

The mapping objects provided must only support the \texttt{\_\_getitem\_\_} mapping interface.

If a character lookup fails with a LookupError, the character is copied as-is meaning that its ordinal value will be interpreted as Unicode or Latin-1 ordinal resp. Because of this, mappings only need to contain those mappings which map characters to different code points.

These are the mapping codec APIs:

\texttt{PyObject* PyUnicode\_DecodeCharmap(const char* s, Py\_ssize\_t size, PyObject* mapping, const char* errors)}

\textit{Return value: New reference.}

Create a Unicode object by decoding size bytes of the encoded string s using the given mapping object. Return NULL if an exception was raised by the codec. If mapping is NULL latin-1 decoding will be done. Else it can be a dictionary mapping byte or a unicode string, which is treated as a lookup table. Byte values greater that the length of the string and U+FFFE “characters” are treated as “undefined mapping”.

\texttt{PyObject* PyUnicode\_AsCharmapString(PyObject* unicode, PyObject* mapping)}
Encode a Unicode object using the given mapping object and return the result as Python string object. Error handling is “strict”. Return NULL if an exception was raised by the codec.

The following codec API is special in that maps Unicode to Unicode.

PyObject* PyUnicode_TranslateCharmap(const Py_UNICODE*s, Py_ssize_t size, PyObject *table, const char *errors)
Translate a Py_UNICODE buffer of the given size by applying a character mapping table to it and return the resulting Unicode object. Return NULL when an exception was raised by the codec.

The mapping table must map Unicode ordinal integers to Unicode ordinal integers or None (causing deletion of the character).

Mapping tables need only provide the __getitem__() interface; dictionaries and sequences work well. Unmapped character ordinals (ones which cause a LookupError) are left untouched and are copied as-is.

Deprecated since version 3.3, will be removed in version 4.0: Part of the old-style Py_UNICODE API.

PyObject* PyUnicode_EncodeCharmap(const Py_UNICODE*s, Py_ssize_t size, PyObject *mapping, const char *errors)
Encode the Py_UNICODE buffer of the given size using the given mapping object and return a Python string object. Return NULL if an exception was raised by the codec.
Deprecated since version 3.3, will be removed in version 4.0:
Part of the old-style Py_UNICODE API; please migrate to using
PyUnicode_AsCharmapString().

MBCS codecs for Windows

These are the MBCS codec APIs. They are currently only available on
Windows and use the Win32 MBCS converters to implement the
conversions. Note that MBCS (or DBCS) is a class of encodings, not
just one. The target encoding is defined by the user settings on the
machine running the codec.

PyObject* PyUnicode_DecodeMBCS(const char *s,
Py_ssize_t size, const char *errors)

Create a Unicode object by decoding size bytes of the MBCS
encoded string s. Return NULL if an exception was raised by the
codec.

PyObject* PyUnicode_DecodeMBCSStateful(const char *s,
int size, const char *errors, int *consumed)

If consumed is NULL, behave like PyUnicode_DecodeMBCS(). If
consumed is not NULL, PyUnicode_DecodeMBCSStateful() will
not decode trailing lead byte and the number of bytes that have
been decoded will be stored in consumed.

PyObject* PyUnicode_AsMBCSString(PyObject *unicode)

Encode a Unicode object using MBCS and return the result as
Python bytes object. Error handling is “strict”. Return NULL if an
exception was raised by the codec.
PyObject* PyUnicode_EncodeCodePage(int code_page, PyObject *unicode, const char *errors)

  Encode the Unicode object using the specified code page and return a Python bytes object. Return NULL if an exception was raised by the codec. Use CP_ACP code page to get the MBCS encoder.

  New in version 3.3.

PyObject* PyUnicode_EncodeMBCS(const Py_UNICODE *s, Py_ssize_t size, const char *errors)

  Encode the Py_UNICODE buffer of the given size using MBCS and return a Python bytes object. Return NULL if an exception was raised by the codec.

  Deprecated since version 3.3, will be removed in version 4.0: Part of the old-style Py_UNICODE API; please migrate to using PyUnicode_AsMBCSString() or PyUnicode_EncodeCodePage().

Methods & Slots
Methods and Slot Functions

The following APIs are capable of handling Unicode objects and strings on input (we refer to them as strings in the descriptions) and return Unicode objects or integers as appropriate.

They all return `NULL` or `-1` if an exception occurs.

**PyObject* `PyUnicode_Concat(PyObject *left, PyObject *right)`**

*Return value: New reference.*
Concat two strings giving a new Unicode string.

**PyObject* `PyUnicode_Split(PyObject *s, PyObject *sep, Py_ssize_t maxsplit)`**

*Return value: New reference.*
Split a string giving a list of Unicode strings. If `sep` is `NULL`, splitting will be done at all whitespace substrings. Otherwise, splits occur at the given separator. At most `maxsplit` splits will be done. If negative, no limit is set. Separators are not included in the resulting list.

**PyObject* `PyUnicode_Splitlines(PyObject *s, int keepend)`**

*Return value: New reference.*
Split a Unicode string at line breaks, returning a list of Unicode strings. CRLF is considered to be one line break. If `keepend` is 0, the Line break characters are not included in the resulting strings.

**PyObject* `PyUnicode_Translate(PyObject *str, PyObject *table, const char *errors)`**

*Return value: New reference.*
Translate a string by applying a character mapping table to it and return the resulting Unicode object.
The mapping table must map Unicode ordinal integers to Unicode ordinal integers or None (causing deletion of the character).

Mapping tables need only provide the \_getitem\_(\_\_) interface; dictionaries and sequences work well. Unmapped character ordinals (ones which cause a LookupError) are left untouched and are copied as-is.

errors has the usual meaning for codecs. It may be NULL which indicates to use the default error handling.

PyObject\* PyUnicode\_Join(PyObject *separator, PyObject *seq)

Join a sequence of strings using the given separator and return the resulting Unicode string.

int PyUnicode\_Tailmatch(PyObject *str, PyObject *substr,
Py_ssize_t start, Py_ssize_t end, int direction)
Return 1 if substr matches str[start:end] at the given tail end (direction == -1 means to do a prefix match, direction == 1 a suffix match), 0 otherwise. Return -1 if an error occurred.

Py_ssize_t PyUnicode\_Find(PyObject *str, PyObject *substr,
Py_ssize_t start, Py_ssize_t end, int direction)
Return the first position of substr in str[start:end] using the given direction (direction == 1 means to do a forward search, direction == -1 a backward search). The return value is the index of the first match; a value of -1 indicates that no match was found, and -2 indicates that an error occurred and an exception has been set.

Py_ssize_t PyUnicode\_FindChar(PyObject *str, Py_UCS4 ch,
Py_ssize_t start, Py_ssize_t end, int direction)
Return the first position of the character \( ch \) in \( \text{str}[\text{start}:\text{end}] \) using the given \textit{direction} (\( \text{direction} == 1 \) means to do a forward search, \( \text{direction} == -1 \) a backward search). The return value is the index of the first match; a value of \( -1 \) indicates that no match was found, and \( -2 \) indicates that an error occurred and an exception has been set.

\textit{New in version 3.3.}

\texttt{Py_ssize_t \textbf{PyUnicode\_Count}(PyObject *str, PyObject *substr,}
\texttt{Py_ssize_t \texttt{start}, Py\_ssize\_t \texttt{end})}

Return the number of non-overlapping occurrences of \( \text{substr} \) in \( \text{str}[\text{start}:\text{end}] \). Return \(-1\) if an error occurred.

\texttt{PyObject* \textbf{PyUnicode\_Replace}(PyObject *str, PyObject *substr,}
\texttt{PyObject *replstr, Py\_ssize\_t \texttt{maxcount})}

\textit{Return value: New reference.}

Replace at most \( \text{maxcount} \) occurrences of \( \text{substr} \) in \( \text{str} \) with \( \text{replstr} \) and return the resulting Unicode object. \( \text{maxcount} == -1 \) means replace all occurrences.

\texttt{int \textbf{PyUnicode\_Compare}(PyObject *\texttt{left}, PyObject *\texttt{right})}

Compare two strings and return \(-1, 0, 1\) for less than, equal, and greater than, respectively.

\texttt{int \textbf{PyUnicode\_CompareWithASCIIString}(PyObject *\texttt{uni, char *string})}

Compare a unicode object, \( \text{uni} \), with \( \text{string} \) and return \(-1, 0, 1\) for less than, equal, and greater than, respectively. It is best to pass only ASCII-encoded strings, but the function interprets the input string as ISO-8859-1 if it contains non-ASCII characters”.

\texttt{PyObject* \textbf{PyUnicode\_RichCompare}(PyObject *\texttt{left,}
PyObject *right, int op)
Rich compare two unicode strings and return one of the following:

- NULL in case an exception was raised
- Py_True or Py_False for successful comparisons
- Py_NotImplemented in case the type combination is unknown

Note that Py_EQ and Py_NE comparisons can cause a UnicodeWarning in case the conversion of the arguments to Unicode fails with a UnicodeDecodeError.

Possible values for op are Py_GT, Py_GE, Py_EQ, Py_NE, Py_LT, and Py_LE.

PyObject* PyUnicode_Format(PyObject *format, PyObject *args)
Return a new string object from format and args; this is analogous to format % args. The args argument must be a tuple.

int PyUnicode_Contains(PyObject *container, PyObject *element)
Check whether element is contained in container and return true or false accordingly.

element has to coerce to a one element Unicode string. -1 is returned if there was an error.

void PyUnicode_InternInPlace(PyObject **string)
Intern the argument *string in place. The argument must be the address of a pointer variable pointing to a Python unicode string object. If there is an existing interned string that is the same as
*string, it sets *string to it (decrementing the reference count of the old string object and incrementing the reference count of the interned string object), otherwise it leaves *string alone and interns it (incrementing its reference count). (Clarification: even though there is a lot of talk about reference counts, think of this function as reference-count-neutral; you own the object after the call if and only if you owned it before the call.)

PyObject* **PyUnicode_InternFromString**(const char *v)

A combination of **PyUnicode_FromString()** and **PyUnicode_InternInPlace()**, returning either a new unicode string object that has been interned, or a new ("owned") reference to an earlier interned string object with the same value.
Tuple Objects

**PyTupleObject**
This subtype of *PyObject* represents a Python tuple object.

**PyTypeObject** *PyTuple_Type*
This instance of *PyTypeObject* represents the Python tuple type; it is the same object as *tuple* in the Python layer.

`int PyTuple_check(*PyObject p)`
Return true if `p` is a tuple object or an instance of a subtype of the tuple type.

`int PyTuple_checkExact(*PyObject p)`
Return true if `p` is a tuple object, but not an instance of a subtype of the tuple type.

`PyObject* PyTuple_New(Py_ssize_t len)`
*Return value: New reference.*
Return a new tuple object of size `len`, or NULL on failure.

`PyObject* PyTuple_pack(Py_ssize_t n, ...)`
*Return value: New reference.*
Return a new tuple object of size `n`, or NULL on failure. The tuple values are initialized to the subsequent `n` C arguments pointing to Python objects. `PyTuple_pack(2, a, b)` is equivalent to `Py_BuildValue("(OO)", a, b).

`Py_ssize_t PyTuple_size(*PyObject p)`
Take a pointer to a tuple object, and return the size of that tuple.
Py_ssize_t **PyTuple_GET_SIZE** *(PyObject *p)*

Return the size of the tuple *p*, which must be non-NULL and point to a tuple; no error checking is performed.

**PyObject** *PyTuple_GetItem** *(PyObject *p, Py_ssize_t pos)*

*Return value: Borrowed reference.*

Return the object at position *pos* in the tuple pointed to by *p*. If *pos* is out of bounds, return *NULL* and sets an *IndexError* exception.

**PyObject** *PyTuple_GET_ITEM** *(PyObject *p, Py_ssize_t pos)*

*Return value: Borrowed reference.*

Like **PyTuple_GetItem()**, but does no checking of its arguments.

**PyObject** *PyTuple_GetSlice** *(PyObject *p, Py_ssize_t low, Py_ssize_t high)*

*Return value: New reference.*

Take a slice of the tuple pointed to by *p* from *low* to *high* and return it as a new tuple.

**int** **PyTuple_SetItem** *(PyObject *p, Py_ssize_t pos, PyObject *o)*

Insert a reference to object *o* at position *pos* of the tuple pointed to by *p*. Return 0 on success.

**Note:** This function “steals” a reference to *o*.

**void** **PyTuple_SET_ITEM** *(PyObject *p, Py_ssize_t pos, PyObject *o)*

Like **PyTuple_SetItem()**, but does no error checking, and should only be used to fill in brand new tuples.

**Note:** This function “steals” a reference to *o*. 
int `_PyTuple_Resize`(PyObject **p, Py_ssize_t newsize)

Can be used to resize a tuple. `newsize` will be the new length of the tuple. Because tuples are *supposed* to be immutable, this should only be used if there is only one reference to the object. Do *not* use this if the tuple may already be known to some other part of the code. The tuple will always grow or shrink at the end. Think of this as destroying the old tuple and creating a new one, only more efficiently. Returns 0 on success. Client code should never assume that the resulting value of `*p` will be the same as before calling this function. If the object referenced by `*p` is replaced, the original `*p` is destroyed. On failure, returns -1 and sets `*p` to `NULL`, and raises `MemoryError` or `SystemError`.

int `PyTuple_ClearFreeList()`

Clear the free list. Return the total number of freed items.
Struct Sequence Objects

Struct sequence objects are the C equivalent of `namedtuple()` objects, i.e. a sequence whose items can also be accessed through attributes. To create a struct sequence, you first have to create a specific struct sequence type.

**PyTypeObject**  
`PyStructSequence_NewType(PyStructSequence_Desc *desc)`  
Create a new struct sequence type from the data in `desc`, described below. Instances of the resulting type can be created with `PyStructSequence_New()`.

```c
void PyStructSequence_InitType(PyTypeObject *type, PyStructSequence_Desc *desc)
```
Initializes a struct sequence type `type` from `desc` in place.

```c
int PyStructSequence_InitType2(PyTypeObject *type, PyStructSequence_Desc *desc)
```
The same as `PyStructSequence_InitType`, but returns 0 on success and -1 on failure.

*New in version 3.4.*

**PyStructSequence_Desc**  
Contains the meta information of a struct sequence type to create.

<table>
<thead>
<tr>
<th>Field</th>
<th>C Type</th>
<th>Meaning</th>
</tr>
</thead>
<tbody>
<tr>
<td>name</td>
<td>char *</td>
<td>name of the struct sequence type</td>
</tr>
<tr>
<td>Field</td>
<td>C Type</td>
<td>Meaning</td>
</tr>
<tr>
<td>--------------</td>
<td>------------</td>
<td>-------------------------------------------------------------------------</td>
</tr>
<tr>
<td>name</td>
<td>char *</td>
<td>name for the field or NULL to end the list of named fields, set to PyStructSequence_UnnamedField to leave unnamed</td>
</tr>
<tr>
<td>doc</td>
<td>char *</td>
<td>field docstring or NULL to omit</td>
</tr>
</tbody>
</table>

**PyStructSequence_Field**

Describes a field of a struct sequence. As a struct sequence is modeled as a tuple, all fields are typed as PyObject*. The index in the fields array of the PyStructSequence_Desc determines which field of the struct sequence is described.

<table>
<thead>
<tr>
<th>Field</th>
<th>C Type</th>
<th>Meaning</th>
</tr>
</thead>
<tbody>
<tr>
<td>name</td>
<td>char *</td>
<td>name for the field or NULL to end the list of named fields, set to PyStructSequence_UnnamedField to leave unnamed</td>
</tr>
<tr>
<td>doc</td>
<td>char *</td>
<td>field docstring or NULL to omit</td>
</tr>
</tbody>
</table>

char* **PyStructSequence_UnnamedField**

Special value for a field name to leave it unnamed.
PyObject* PyStructSequence_New(PyTypeObject *type)
Creates an instance of type, which must have been created with
PyStructSequence_NewType().

PyObject* PyStructSequence_GetItem(PyObject *p,
Py_ssize_t pos)
Return the object at position pos in the struct sequence pointed to
by p. No bounds checking is performed.

PyObject* PyStructSequence_GET_ITEM(PyObject *p,
Py_ssize_t pos)
Macro equivalent of PyStructSequence_GetItem().

void PyStructSequence_SetItem(PyObject *p,
Py_ssize_t pos, PyObject *o)
Sets the field at index pos of the struct sequence p to value o. Like
PyTuple_SET_ITEM(), this should only be used to fill in brand
new instances.

**Note:** This function “steals” a reference to o.

PyObject* PyStructSequence_SET_ITEM(PyObject *p,
Py_ssize_t *pos, PyObject *o)
Macro equivalent of PyStructSequence_SetItem().

**Note:** This function “steals” a reference to o.
List Objects

**PyListObject**
- This subtype of `PyObject` represents a Python list object.

**PyTypeObject PyList_Type**
- This instance of `PyTypeObject` represents the Python list type. This is the same object as `list` in the Python layer.

```c
int PyList_Check(PyObject *p)
```
- Return true if `p` is a list object or an instance of a subtype of the list type.

```c
int PyList_CheckExact(PyObject *p)
```
- Return true if `p` is a list object, but not an instance of a subtype of the list type.

```c
PyObject* PyList_New(Py_ssize_t len)
```
- **Return value: New reference.**
- Return a new list of length `len` on success, or `NULL` on failure.

**Note:** If `len` is greater than zero, the returned list object’s items are set to `NULL`. Thus you cannot use abstract API functions such as `PySequence_SetItem()` or expose the object to Python code before setting all items to a real object with `PyList_SetItem()`.

```c
Py_ssize_t PyList_Size(PyObject *list)
```
- Return the length of the list object in `list`; this is equivalent to `len(list)` on a list object.
Py_ssize_t **PyList_GET_SIZE**(PyObject *list)

Macro form of **PyList_Size()** without error checking.

**PyObject** * **PyList_GetItem**(PyObject *list, Py_ssize_t index)

*Return value: Borrowed reference.*

Return the object at position *index* in the list pointed to by *list*. The position must be positive, indexing from the end of the list is not supported. If *index* is out of bounds, return NULL and set an **IndexError** exception.

**PyObject** * **PyList_GET_ITEM**(PyObject *list, Py_ssize_t i)

*Return value: Borrowed reference.*

Macro form of **PyList_GetItem()** without error checking.

int **PyList_SetItem**(PyObject *list, Py_ssize_t index, PyObject *item)

Set the item at index *index* in list to *item*. Return 0 on success or -1 on failure.

**Note:** This function “steals” a reference to *item* and discards a reference to an item already in the list at the affected position.

void **PyList_SET_ITEM**(PyObject *list, Py_ssize_t i, PyObject *o)

Macro form of **PyList_SetItem()** without error checking. This is normally only used to fill in new lists where there is no previous content.

**Note:** This macro “steals” a reference to *item*, and, unlike **PyList_SetItem()**, does not discard a reference to any item that is being replaced; any reference in *list* at position *i* will be leaked.
int **PyList_Insert**(PyObject *list, Py_ssize_t index, PyObject *item)

Insert the item *item* into list *list* in front of index *index*. Return 0 if successful; return -1 and set an exception if unsuccessful. Analogous to *list.insert(index, item)*.

int **PyList_Append**(PyObject *list, PyObject *item)

Append the object *item* at the end of list *list*. Return 0 if successful; return -1 and set an exception if unsuccessful. Analogous to *list.append(item)*.

PyObject* **PyList_GetSlice**(PyObject *list, Py_ssize_t low, Py_ssize_t high)

*Return value: New reference.*

Return a list of the objects in *list* containing the objects between *low* and *high*. Return NULL and set an exception if unsuccessful. Analogous to *list[low:high]*. Negative indices, as when slicing from Python, are not supported.

int **PyList_SetSlice**(PyObject *list, Py_ssize_t low, Py_ssize_t high, PyObject *itemlist)

Set the slice of *list* between *low* and *high* to the contents of *itemlist*. Analogous to *list[low:high] = itemlist*. The *itemlist* may be NULL, indicating the assignment of an empty list (slice deletion). Return 0 on success, -1 on failure. Negative indices, as when slicing from Python, are not supported.

int **PyList_Sort**(PyObject *list)

Sort the items of *list* in place. Return 0 on success, -1 on failure. This is equivalent to *list.sort()*.

int **PyList_Reverse**(PyObject *list)
Reverse the items of list in place. Return 0 on success, -1 on failure. This is the equivalent of list.reverse().

PyObject* PyList_AsTuple(PyObject *list)

Return a new tuple object containing the contents of list; equivalent to tuple(list).

int PyList_ClearFreeList()
Clear the free list. Return the total number of freed items.

New in version 3.3.
Dictionary Objects

**PyDictObject**
This subtype of **PyObject** represents a Python dictionary object.

**PyTypeObject PyDict_Type**
This instance of **PyTypeObject** represents the Python dictionary type. This is the same object as `dict` in the Python layer.

```c
int PyDict_Check(PyObject *p)
```
Return true if `p` is a dict object or an instance of a subtype of the dict type.

```c
int PyDict_CheckExact(PyObject *p)
```
Return true if `p` is a dict object, but not an instance of a subtype of the dict type.

```c
PyObject* PyDict_New()
```
*Return value: New reference.*
Return a new empty dictionary, or `NULL` on failure.

```c
PyObject* PyDictProxy_New(PyObject *mapping)
```
*Return value: New reference.*
Return a `types.MappingProxyType` object for a mapping which enforces read-only behavior. This is normally used to create a view to prevent modification of the dictionary for non-dynamic class types.

```c
void PyDict_Clear(PyObject *p)
```
Empty an existing dictionary of all key-value pairs.
int **PyDict**-contains**(PyObject *p, PyObject *key)**

Determine if dictionary \( p \) contains \( key \). If an item in \( p \) is matches \( key \), return 1, otherwise return 0. On error, return -1. This is equivalent to the Python expression \( key \ in p \).

PyObject* **PyDict**-copy**(PyObject *p)**

\textit{Return value: New reference.}

Return a new dictionary that contains the same key-value pairs as \( p \).

int **PyDict**-set-item**(PyObject *p, PyObject *key, PyObject *val)**

Insert \( value \) into the dictionary \( p \) with a key of \( key \). \( key \) must be hashable; if it isn't, \texttt{TypeError} will be raised. Return 0 on success or -1 on failure.

int **PyDict**-set-item-string**(PyObject *p, const char *key, PyObject *val)**

Insert \( value \) into the dictionary \( p \) using \( key \) as a key. \( key \) should be a char*. The key object is created using \texttt{PyUnicode\_FromString(key)}. Return 0 on success or -1 on failure.

int **PyDict**-del-item**(PyObject *p, PyObject *key)**

Remove the entry in dictionary \( p \) with key \( key \). \( key \) must be hashable; if it isn't, \texttt{TypeError} is raised. Return 0 on success or -1 on failure.

int **PyDict**-del-item-string**(PyObject *p, const char *key)**

Remove the entry in dictionary \( p \) which has a key specified by the string \( key \). Return 0 on success or -1 on failure.

PyObject** PyDict**-get-item**(PyObject *p, PyObject *key)**
Return value: Borrowed reference.
Return the object from dictionary \( p \) which has a key \( key \). Return NULL if the key \( key \) is not present, but without setting an exception.

\textbf{PyObject* PyDict_GetItemWithError}(PyObject *\( p \), PyObject *\( key \))

Variant of \textbf{PyDict_GetItem()} that does not suppress exceptions. Return NULL with an exception set if an exception occurred. Return NULL without an exception set if the key wasn't present.

\textbf{PyObject* PyDict_GetItemString}(PyObject *\( p \), const char *\( key \))

Return value: Borrowed reference.
This is the same as \textbf{PyDict_GetItem()}, but \( key \) is specified as a char*, rather than a PyObject*.

\textbf{PyObject* PyDict_SetDefault}(PyObject *\( p \), PyObject *\( key \), PyObject *\( default \))

Return value: Borrowed reference.
This is the same as the Python-level \texttt{dict.setdefault()}. If present, it returns the value corresponding to \( key \) from the dictionary \( p \). If the key is not in the dict, it is inserted with value defaultobj and defaultobj is returned. This function evaluates the hash function of \( key \) only once, instead of evaluating it independently for the lookup and the insertion.

\textbf{PyObject* PyDict_Items}(PyObject *\( p \))

Return a \textbf{PyListObject} containing all the items from the dictionary.

\textbf{PyObject* PyDict.Keys}(PyObject *\( p \))
Return a PyListObject containing all the keys from the dictionary.

PyObject* PyDict_Values(PyObject *p)
Return a PyListObject containing all the values from the dictionary p.

Py_ssize_t PyDict_Size(PyObject *p)
Return the number of items in the dictionary. This is equivalent to len(p) on a dictionary.

int PyDict_Next(PyObject *p, Py_ssize_t *ppos, PyObject **pkey, PyObject **pvalue)
Iterate over all key-value pairs in the dictionary p. The Py_ssize_t referred to by ppos must be initialized to 0 prior to the first call to this function to start the iteration; the function returns true for each pair in the dictionary, and false once all pairs have been reported. The parameters pkey and pvalue should either point to PyObject* variables that will be filled in with each key and value, respectively, or may be NULL. Any references returned through them are borrowed. ppos should not be altered during iteration. Its value represents offsets within the internal dictionary structure, and since the structure is sparse, the offsets are not consecutive.

For example:

```c
PyObject *key, *value;
Py_ssize_t pos = 0;
while (PyDict_Next(self->dict, &pos, &key, &value
```
The dictionary \( p \) should not be mutated during iteration. It is safe to modify the values of the keys as you iterate over the dictionary, but only so long as the set of keys does not change. For example:

```c
PyObject *key, *value;
Py_ssize_t pos = 0;

while (PyDict_Next(self->dict, &pos, &key, &value
    long i = PyLong_AsLong(value);
    if (i == -1 && PyErr_Occurred()) {
        return -1;
    }
    PyObject *o = PyLong_FromLong(i + 1);
    if (o == NULL)
        return -1;
    if (PyDict_SetItem(self->dict, key, o) < 0) {
        Py_DECREF(o);
        return -1;
    }
    Py_DECREF(o);
}
```

int \texttt{PyDict\_Merge} (PyObject *a, PyObject *b, int \texttt{override})

Iterate over mapping object \( b \) adding key-value pairs to dictionary \( a \). \( b \) may be a dictionary, or any object supporting \texttt{PyMapping\_Keys()} and \texttt{PyObject\_GetItem()}. If \texttt{override} is true, existing pairs in \( a \) will be replaced if a matching key is found in \( b \), otherwise pairs will only be added if there is not a matching key in \( a \). Return 0 on success or -1 if an exception was raised.
int **PyDict_Update**(*PyObject* *a, *PyObject* *b*)

This is the same as `PyDict_Merge(a, b, 1)` in C, or `a.update(b)` in Python. Return 0 on success or -1 if an exception was raised.

int **PyDict_MergeFromSeq2**(*PyObject* *a, *PyObject* *seq2*, int *override*)

Update or merge into dictionary `a`, from the key-value pairs in `seq2`. `seq2` must be an iterable object producing iterable objects of length 2, viewed as key-value pairs. In case of duplicate keys, the last wins if `override` is true, else the first wins. Return 0 on success or -1 if an exception was raised. Equivalent Python (except for the return value):

```python
def PyDict_MergeFromSeq2(a, seq2, override):
    for key, value in seq2:
        if override or key not in a:
            a[key] = value
```

int **PyDict_ClearFreeList**()

Clear the free list. Return the total number of freed items.

*New in version 3.3.*
Set Objects

This section details the public API for set and frozenset objects. Any functionality not listed below is best accessed using the either the abstract object protocol (including PyObject_CallMethod(), PyObject_RichCompareBool(), PyObject_Hash(), PyObject_Repr(), PyObject_IsTrue(), PyObject_Print(), and PyObject_GetIter()) or the abstract number protocol (including PyNumber_And(), PyNumber_Subtract(), PyNumber_Or(), PyNumber_Xor(), PyNumber_InPlaceAnd(), PyNumber_InPlaceSubtract(), PyNumber_InPlaceOr(), and PyNumber_InPlaceXor()).

**PySetObject**

This subtype of PyObject is used to hold the internal data for both set and frozenset objects. It is like a PyDictObject in that it is a fixed size for small sets (much like tuple storage) and will point to a separate, variable sized block of memory for medium and large sized sets (much like list storage). None of the fields of this structure should be considered public and are subject to change. All access should be done through the documented API rather than by manipulating the values in the structure.

**PyTypeObject PySet_Type**

This is an instance of PyTypeObject representing the Python set type.

**PyTypeObject PyFrozenSet_Type**

This is an instance of PyTypeObject representing the Python frozenset type.
The following type check macros work on pointers to any Python object. Likewise, the constructor functions work with any iterable Python object.

```c
int PySet_Check(PyObject *p)
    Return true if p is a set object or an instance of a subtype.
```

```c
int PyFrozenSet_Check(PyObject *p)
    Return true if p is a frozenset object or an instance of a subtype.
```

```c
int PyAnySet_Check(PyObject *p)
    Return true if p is a set object, a frozenset object, or an instance of a subtype.
```

```c
int PyAnySet_CheckExact(PyObject *p)
    Return true if p is a set object or a frozenset object but not an instance of a subtype.
```

```c
int PyFrozenSet_CheckExact(PyObject *p)
    Return true if p is a frozenset object but not an instance of a subtype.
```

```c
PyObject* PySet_New(PyObject *iterable)
    Return a new set containing objects returned by the iterable. The iterable may be NULL to create a new empty set. Return the new set on success or NULL on failure. Raise TypeError if iterable is not actually iterable. The constructor is also useful for copying a set (c=set(s)).
```

```c
PyObject* PyFrozenSet_New(PyObject *iterable)
```
Return a new \texttt{frozenset} containing objects returned by the \textit{iterable}. The \textit{iterable} may be \texttt{NULL} to create a new empty \texttt{frozenset}. Return the new set on success or \texttt{NULL} on failure. Raise \texttt{TypeError} if \textit{iterable} is not actually iterable.

The following functions and macros are available for instances of \texttt{set} or \texttt{frozenset} or instances of their subtypes.

\textbf{Py\_ssize\_t} \texttt{PySet\_Size(PyObject \*anyset)}

Return the length of a \texttt{set} or \texttt{frozenset} object. Equivalent to \texttt{len(anyset)}. Raises a \texttt{PyExc\_SystemError} if \texttt{anyset} is not a \texttt{set}, \texttt{frozenset}, or an instance of a subtype.

\textbf{Py\_ssize\_t} \texttt{PySet\_GET\_SIZE(PyObject \*anyset)}

Macro form of \texttt{PySet\_Size()} without error checking.

\textbf{int} \texttt{PySet\_Contains(PyObject \*anyset, PyObject \*key)}

Return 1 if found, 0 if not found, and -1 if an error is encountered. Unlike the Python \texttt{\_contains\_()} method, this function does not automatically convert unhashable sets into temporary \texttt{frozensets}. Raise a \texttt{TypeError} if the \texttt{key} is unhashable. Raise \texttt{PyExc\_SystemError} if \texttt{anyset} is not a \texttt{set}, \texttt{frozenset}, or an instance of a subtype.

\textbf{int} \texttt{PySet\_Add(PyObject \*set, PyObject \*key)}

Add \texttt{key} to a \texttt{set} instance. Also works with \texttt{frozenset} instances (like \texttt{PyTuple\_SetItem()} it can be used to fill-in the values of brand new \texttt{frozensets} before they are exposed to other code). Return 0 on success or -1 on failure. Raise a \texttt{TypeError} if the \texttt{key} is unhashable. Raise a \texttt{MemoryError} if there is no room to grow.Raise a \texttt{SystemError} if \texttt{set} is an not an instance of \texttt{set} or
its subtype.

The following functions are available for instances of \texttt{set} or its subtypes but not for instances of \texttt{frozenset} or its subtypes.

\begin{verbatim}
int PySet_Discard(PyObject *set, PyObject *key)
    Return 1 if found and removed, 0 if not found (no action taken), and -1 if an error is encountered. Does not raise \texttt{KeyError} for missing keys. Raise a \texttt{TypeError} if the \texttt{key} is unhashable. Unlike the Python \texttt{discard()} method, this function does not automatically convert unhashable sets into temporary frozensets. Raise \texttt{PyExc\_SystemError} if \texttt{set} is an not an instance of \texttt{set} or its subtype.

PyObject* PySet_Pop(PyObject *set)
    \textit{Return value: New reference.}
    Return a new reference to an arbitrary object in the \texttt{set}, and removes the object from the \texttt{set}. Return \texttt{NULL} on failure. Raise \texttt{KeyError} if the set is empty. Raise a \texttt{SystemError} if \texttt{set} is an not an instance of \texttt{set} or its subtype.

int PySet_Clear(PyObject *set)
    Empty an existing set of all elements.

int PySet_ClearFreeList()
    Clear the free list. Return the total number of freed items.
\end{verbatim}

\textit{New in version 3.3.}

Last updated on Mar 16, 2014. Found a bug?

Created using Sphinx 1.2.
Function Objects

There are a few functions specific to Python functions.

**PyFunctionObject**

The C structure used for functions.

**PyTypeObject PyFunction_Type**

This is an instance of **PyTypeObject** and represents the Python function type. It is exposed to Python programmers as **types.FunctionType**.

```c
int PyFunction_Check(PyObject *o)
```

Return true if `o` is a function object (has type **PyFunction_Type**). The parameter must not be **NULL**.

```c
PyObject* PyFunction_New(PyObject *code, PyObject *globals)
```

*Return value: New reference.*

Return a new function object associated with the code object `code`. `globals` must be a dictionary with the global variables accessible to the function.

The function’s docstring, name and __module__ are retrieved from the code object, the argument defaults and closure are set to **NULL**.

```c
PyObject* PyFunction_NewWithQualName(PyObject *code, PyObject *globals, PyObject *qualname)
```

*Return value: New reference.*

As **PyFunction_New()**, but also allows to set the function object’s __qualname__ attribute. `qualname` should be a unicode
object or NULL; if NULL, the __qualname__ attribute is set to the same value as its __name__ attribute.

*New in version 3.3.*

**PyObject** PyFunction_GetCode(PyObject *op)

(Return value: Borrowed reference.)

Return the code object associated with the function object op.

**PyObject** PyFunction_GetGlobals(PyObject *op)

(Return value: Borrowed reference.)

Return the globals dictionary associated with the function object op.

**PyObject** PyFunction_GetModule(PyObject *op)

(Return value: Borrowed reference.)

Return the __module__ attribute of the function object op. This is normally a string containing the module name, but can be set to any other object by Python code.

**PyObject** PyFunction_GetDefaults(PyObject *op)

(Return value: Borrowed reference.)

Return the argument default values of the function object op. This can be a tuple of arguments or NULL.

**int** PyFunction_SetDefaults(PyObject *op, PyObject *defaults)

Set the argument default values for the function object op. defaults must be Py_None or a tuple.

Raises SystemError and returns -1 on failure.

**PyObject** PyFunction_GetClosure(PyObject *op)
Return value: Borrowed reference.
Return the closure associated with the function object \textit{op}. This can be \textit{NULL} or a tuple of cell objects.

\begin{verbatim}
int PyFunction_SetClosure(PyObject *op, PyObject *closure)
Set the closure associated with the function object \textit{op}. \textit{closure} must be \textit{Py_None} or a tuple of cell objects.

Raises \texttt{SystemError} and returns -1 on failure.
\end{verbatim}

\begin{verbatim}
PyObject *PyFunction_GetAnnotations(PyObject *op)
Return the annotations of the function object \textit{op}. This can be a mutable dictionary or \textit{NULL}.
\end{verbatim}

\begin{verbatim}
int PyFunction_SetAnnotations(PyObject *op, PyObject *annotations)
Set the annotations for the function object \textit{op}. \textit{annotations} must be a dictionary or \textit{Py_None}.

Raises \texttt{SystemError} and returns -1 on failure.
\end{verbatim}
Instance Method Objects

An instance method is a wrapper for a `PyCFunction` and the new way to bind a `PyCFunction` to a class object. It replaces the former call `PyMethod_New(func, NULL, class).

**PyTypeObject** `PyInstanceMethod_Type`

This instance of `PyTypeObject` represents the Python instance method type. It is not exposed to Python programs.

```c
int PyInstanceMethod_Check(PyObject *o)
```

Return true if `o` is an instance method object (has type `PyInstanceMethod_Type`). The parameter must not be `NULL`.

```c
PyObject* PyInstanceMethod_New(PyObject *func)
```

Return a new instance method object, with `func` being any callable object. `func` is the function that will be called when the instance method is called.

```c
PyObject* PyInstanceMethod_Function(PyObject *im)
```

Return the function object associated with the instance method `im`.

```c
PyObject*
PyInstanceMethod_GET_FUNCTION(PyObject *im)
```

Macro version of `PyInstanceMethod_Function()` which avoids error checking.
Method Objects

Methods are bound function objects. Methods are always bound to an instance of an user-defined class. Unbound methods (methods bound to a class object) are no longer available.

**PyTypeObject PyMethod_Type**

This instance of `PyTypeObject` represents the Python method type. This is exposed to Python programs as `types.MethodType`.

**int PyMethod_Check(PyObject *o)**

Return true if `o` is a method object (has type `PyMethod_Type`). The parameter must not be `NULL`.

**PyObject* PyMethod_New(PyObject *func, PyObject *self)**

*Return value: New reference.*

Return a new method object, with `func` being any callable object and `self` the instance the method should be bound. `func` is the function that will be called when the method is called. `self` must not be `NULL`.

**PyObject* PyMethod_Function(PyObject *meth)**

*Return value: Borrowed reference.*

Return the function object associated with the method `meth`.

**PyObject* PyMethod_GET_FUNCTION(PyObject *meth)**

*Return value: Borrowed reference.*

Macro version of `PyMethod_Function()` which avoids error checking.
PyObject* **PyMethod_Self**(PyObject *meth)

*Return value: Borrowed reference.*
Return the instance associated with the method `meth`.

PyObject* **PyMethod_GET_SELF**(PyObject *meth)

*Return value: Borrowed reference.*
Macro version of `PyMethod_Self()` which avoids error checking.

int **PyMethod_ClearFreeList**( )

Clear the free list. Return the total number of freed items.
Cell Objects

“Cell” objects are used to implement variables referenced by multiple scopes. For each such variable, a cell object is created to store the value; the local variables of each stack frame that references the value contains a reference to the cells from outer scopes which also use that variable. When the value is accessed, the value contained in the cell is used instead of the cell object itself. This de-referencing of the cell object requires support from the generated byte-code; these are not automatically de-referenced when accessed. Cell objects are not likely to be useful elsewhere.

**PyCellObject**
The C structure used for cell objects.

**PyTypeObject** **PyCell_Type**
The type object corresponding to cell objects.

int **PyCell_Check**(ob)
Return true if *ob* is a cell object; *ob* must not be NULL.

**PyObject**
* **PyCell_New**(PyObject **ob**)
  *Return value: New reference.*
  Create and return a new cell object containing the value *ob*. The parameter may be NULL.

**PyObject**
* **PyCell_Get**(PyObject **cell**)
  *Return value: New reference.*
  Return the contents of the cell *cell*.

**PyObject**
* **PyCell_GET**(PyObject **cell**)
  *Return value: Borrowed reference.*
Return the contents of the cell *cell*, but without checking that *cell* is non-`NULL` and a cell object.

```c
int PyCell_Set(PyObject *cell, PyObject *value)
```

Set the contents of the cell object *cell* to *value*. This releases the reference to any current content of the cell. *value* may be `NULL`. *cell* must be non-`NULL`; if it is not a cell object, `-1` will be returned. On success, `0` will be returned.

```c
void PyCell_SET(PyObject *cell, PyObject *value)
```

Sets the value of the cell object *cell* to *value*. No reference counts are adjusted, and no checks are made for safety; *cell* must be non-`NULL` and must be a cell object.
Code Objects

Code objects are a low-level detail of the CPython implementation. Each one represents a chunk of executable code that hasn’t yet been bound into a function.

PyCodeObject

The C structure of the objects used to describe code objects. The fields of this type are subject to change at any time.

PyTypeObject PyCode_Type

This is an instance of PyTypeObject representing the Python code type.

int PyCode_Check(PyObject *co)

Return true if co is a code object.

int PyCode_GetNumFree(PyCodeObject *co)

Return the number of free variables in co.

PyCodeObject* PyCode_New(int argcoun, int kwonlyargcount, int nlocals, int stacksize, int flags, PyObject *code, PyObject *consts, PyObject *names, PyObject *varnames, PyObject *freevars, PyObject *cellvars, PyObject *filename, PyObject *name, int firstlineno, PyObject *lnotab)

Return a new code object. If you need a dummy code object to create a frame, use PyCode_NewEmpty() instead. Calling PyCode_New() directly can bind you to a precise Python version since the definition of the bytecode changes often.

PyCodeObject* PyCode_NewEmpty(const char *filename, const char *funcname, int firstlineno)
Return a new empty code object with the specified filename, function name, and first line number. It is illegal to `exec()` or `eval()` the resulting code object.
File Objects

These APIs are a minimal emulation of the Python 2 C API for built-in file objects, which used to rely on the buffered I/O (FILE*) support from the C standard library. In Python 3, files and streams use the new `io` module, which defines several layers over the low-level unbuffered I/O of the operating system. The functions described below are convenience C wrappers over these new APIs, and meant mostly for internal error reporting in the interpreter; third-party code is advised to access the `io` APIs instead.

**PyFile_FromFd** (int *fd*, const char *name, const char *mode, int *buffering*, const char *encoding, const char *errors, const char *newline, int *closefd*)

Create a Python file object from the file descriptor of an already opened file *fd*. The arguments *name*, *encoding*, *errors* and *newline* can be NULL to use the defaults; *buffering* can be -1 to use the default. *name* is ignored and kept for backward compatibility. Return NULL on failure. For a more comprehensive description of the arguments, please refer to the `io.open()` function documentation.

**Warning:** Since Python streams have their own buffering layer, mixing them with OS-level file descriptors can produce various issues (such as unexpected ordering of data).

*Changed in version 3.2:* Ignore *name* attribute.

int **PyObject_AsFileDescriptor**(PyObject *p)

Return the file descriptor associated with *p* as an int. If the object is an integer, its value is returned. If not, the object's `fileno()`
method is called if it exists; the method must return an integer, which is returned as the file descriptor value. Sets an exception and returns \texttt{-1} on failure.

\texttt{PyObject* PyFile\_GetLine(PyObject *p, int n)}

\textit{Return value: New reference.}
Equivalent to \texttt{p.readline([n])}, this function reads one line from the object \texttt{p}. \texttt{p} may be a file object or any object with a \texttt{readline()} method. If \texttt{n} is \texttt{0}, exactly one line is read, regardless of the length of the line. If \texttt{n} is greater than \texttt{0}, no more than \texttt{n} bytes will be read from the file; a partial line can be returned. In both cases, an empty string is returned if the end of the file is reached immediately. If \texttt{n} is less than \texttt{0}, however, one line is read regardless of length, but \texttt{EOFError} is raised if the end of the file is reached immediately.

\texttt{int PyFile\_WriteObject(PyObject *obj, PyObject *p, int flags)}

Write object \texttt{obj} to file object \texttt{p}. The only supported flag for \texttt{flags} is \texttt{Py\_PRINT\_RAW}; if given, the \texttt{str()} of the object is written instead of the \texttt{repr()}. Return \texttt{0} on success or \texttt{-1} on failure; the appropriate exception will be set.

\texttt{int PyFile\_WriteString(const char *s, PyObject *p)}

Write string \texttt{s} to file object \texttt{p}. Return \texttt{0} on success or \texttt{-1} on failure; the appropriate exception will be set.
Module Objects

There are only a few functions special to module objects.

**PyTypeObject PyModule_Type**

This instance of `PyTypeObject` represents the Python module type. This is exposed to Python programs as `types.ModuleType`.

```c
int PyModule_Check(PyObject *p)
```

Return true if `p` is a module object, or a subtype of a module object.

```c
int PyModule_CheckExact(PyObject *p)
```

Return true if `p` is a module object, but not a subtype of `PyModule_Type`.

```c
PyObject* PyModule_NewObject(PyObject *name)
```

Return a new module object with the `__name__` attribute set to `name`. The module's `__name__`, `__doc__`, `__package__`, and `__loader__` attributes are filled in (all but `__name__` are set to `None`); the caller is responsible for providing a `__file__` attribute.

*New in version 3.3.*

*Changed in version 3.4: `__package__` and `__loader__` are set to `None`.*

```c
PyObject* PyModule_New(const char *name)
```

*Return value: New reference.*

Similar to `PyImport_NewObject()`, but the name is an UTF-8 encoded string instead of a Unicode object.
PyObject* PyModule_GetDict(PyObject *module)

*Return value: Borrowed reference.*
Return the dictionary object that implements module's namespace; this object is the same as the __dict__ attribute of the module object. This function never fails. It is recommended extensions use other PyModule_*() and PyObject_*() functions rather than directly manipulate a module's __dict__.

PyObject* PyModule_GetNameObject(PyObject *module)
Return module's __name__ value. If the module does not provide one, or if it is not a string, SystemError is raised and NULL is returned.

*New in version 3.3.*

char* PyModule_GetName(PyObject *module)
Similar to PyModule_GetNameObject() but return the name encoded to 'utf-8'.

PyObject* PyModule_GetFilenameObject(PyObject *module)
Return the name of the file from which module was loaded using module's __file__ attribute. If this is not defined, or if it is not a unicode string, raise SystemError and return NULL; otherwise return a reference to a Unicode object.

*New in version 3.2.*

char* PyModule_GetFilename(PyObject *module)
Similar to PyModule_GetFilenameObject() but return the filename encoded to 'utf-8'.

void* **PyModule_GetState**(PyObject *module)

Return the “state” of the module, that is, a pointer to the block of memory allocated at module creation time, or *NULL*. See `PyModuleDef.m_size`.

**PyModuleDef** * Py**PyModule_GetDef**(PyObject *module)

Return a pointer to the `PyModuleDef` struct from which the module was created, or *NULL* if the module wasn’t created with `PyModule_Create()`.

**PyObject** * Py**PyState_FindModule**(PyModuleDef *def)

Returns the module object that was created from `def` for the current interpreter. This method requires that the module object has been attached to the interpreter state with `PyState_AddModule()` beforehand. In case the corresponding module object is not found or has not been attached to the interpreter state yet, it returns *NULL*.

**int** **PyState_AddModule**(PyObject *module, PyModuleDef *def)

Attaches the module object passed to the function to the interpreter state. This allows the module object to be accessible via `PyState_FindModule()`.

*New in version 3.3.*

**int** **PyState_RemoveModule**(PyModuleDef *def)

Removes the module object created from `def` from the interpreter state.
New in version 3.3.
Initializing C modules

These functions are usually used in the module initialization function.

**PyObject** `PyModule_Create(PyModuleDef *module)`

Create a new module object, given the definition in `module`. This behaves like `PyModule_Create2()` with `module_api_version` set to PYTHON_API_VERSION.

**PyObject** `PyModule_Create2(PyModuleDef *module, int module_api_version)`

Create a new module object, given the definition in `module`, assuming the API version `module_api_version`. If that version does not match the version of the running interpreter, a `RuntimeWarning` is emitted.

**Note:** Most uses of this function should be using `PyModule_Create()` instead; only use this if you are sure you need it.

**PyModuleDef**

This struct holds all information that is needed to create a module object. There is usually only one static variable of that type for each module, which is statically initialized and then passed to `PyModule_Create()` in the module initialization function.

PyModuleDef_Base `m_base`

Always initialize this member to `PyModuleDef_HEAD_INIT`.

`char* m_name`

Name for the new module.
char* m_doc

Docstring for the module; usually a docstring variable created with PyDoc_STRVAR() is used.

Py_ssize_t m_size

Some modules allow re-initialization (calling their PyInit_* function more than once). These modules should keep their state in a per-module memory area that can be retrieved with PyModule_GetState().

This memory should be used, rather than static globals, to hold per-module state, since it is then safe for use in multiple sub-interpreters. It is freed when the module object is deallocated, after the m_free function has been called, if present.

Setting m_size to -1 means that the module can not be re-initialized because it has global state. Setting it to a non-negative value means that the module can be re-initialized and specifies the additional amount of memory it requires for its state.

See PEP 3121 for more details.

PyMethodDef* m_methods

A pointer to a table of module-level functions, described by PyMethodDef values. Can be NULL if no functions are present.

inquiry m_reload

Currently unused, should be NULL.

traverseproc m_traverse

A traversal function to call during GC traversal of the module
object, or NULL if not needed.

inquiry m_clear
A clear function to call during GC clearing of the module object, or NULL if not needed.

freefunc m_free
A function to call during deallocation of the module object, or NULL if not needed.

int PyModule_AddObject(PyObject *module, const char *name, PyObject *value)
Add an object to module as name. This is a convenience function which can be used from the module's initialization function. This steals a reference to value. Return -1 on error, 0 on success.

int PyModule_AddIntConstant(PyObject *module, const char *name, long value)
Add an integer constant to module as name. This convenience function can be used from the module's initialization function. Return -1 on error, 0 on success.

int PyModule_AddStringConstant(PyObject *module, const char *name, const char *value)
Add a string constant to module as name. This convenience function can be used from the module's initialization function. The string value must be null-terminated. Return -1 on error, 0 on success.

int PyModule_AddIntMacro(PyObject *module, macro)
Add an int constant to module. The name and the value are taken from macro. For example PyModule_AddIntMacro(module,
AF_INET) adds the int constant AF_INET with the value of AF_INET to module. Return -1 on error, 0 on success.

int PyModule_AddStringMacro(PyObject *module, macro)
Add a string constant to module.
Iterator Objects

Python provides two general-purpose iterator objects. The first, a sequence iterator, works with an arbitrary sequence supporting the \_\_getitem\_\_() method. The second works with a callable object and a sentinel value, calling the callable for each item in the sequence, and ending the iteration when the sentinel value is returned.

**PyTypeObject PySeqIter_Type**
Type object for iterator objects returned by PySeqIter_New() and the one-argument form of the \_\_iter\_\_() built-in function for built-in sequence types.

```
int PySeqIter_Check(op)
```
Return true if the type of `op` is PySeqIter_Type.

```
PyObject* PySeqIter_New(PyObject *seq)
```

*Return value: New reference.*
Return an iterator that works with a general sequence object, `seq`. The iteration ends when the sequence raises IndexError for the subscripting operation.

**PyTypeObject PyCallIter_Type**
Type object for iterator objects returned by PyCallIter_New() and the two-argument form of the \_\_iter\_\_() built-in function.

```
int PyCallIter_Check(op)
```
Return true if the type of `op` is PyCallIter_Type.

```
PyObject* PyCallIter_New(PyObject *callable,
PyObject *sentinel)
```

Return a new iterator. The first parameter, `callable`, can be any Python callable object that can be called with no parameters; each call to it should return the next item in the iteration. When `callable` returns a value equal to `sentinel`, the iteration will be terminated.
Descriptor Objects

“Descriptors” are objects that describe some attribute of an object. They are found in the dictionary of type objects.

PyTypeObject PyProperty_Type
The type object for the built-in descriptor types.

PyObject* PyDescr_NewGetSet(PyTypeObject *type, struct PyGetSetDef *getset)

PyObject* PyDescr_NewMember(PyTypeObject *type, struct PyMemberDef *meth)

PyObject* PyDescr_NewMethod(PyTypeObject *type, struct PyMethodDef *meth)

PyObject* PyDescr_NewWrapper(PyTypeObject *type, struct wrapperbase *wrapper, void *wrapped)

PyObject* PyDescr_NewClassMethod(PyTypeObject *type, PyMethodDef *method)

int PyDescr_IsData(PyObject *descr)
Return true if the descriptor objects descr describes a data attribute, or false if it describes a method. descr must be a descriptor object; there is no error checking.
PyObject* PyWrapper_New(PyObject *, PyObject *)

Slice Objects

PyTypeObject **PySlice_Type**

The type object for slice objects. This is the same as **slice** in the Python layer.

int **PySlice_Check**(PyObject *ob)

Return true if *ob* is a slice object; *ob* must not be **NULL**.

PyObject* **PySlice_New**(PyObject *start, PyObject *stop, PyObject *step)

*Return value: New reference.*

Return a new slice object with the given values. The *start*, *stop*, and *step* parameters are used as the values of the slice object attributes of the same names. Any of the values may be **NULL**, in which case the **None** will be used for the corresponding attribute. Return **NULL** if the new object could not be allocated.

int **PySlice_GetIndices**(PyObject *slice, Py_ssize_t length, Py_ssize_t *start, Py_ssize_t *stop, Py_ssize_t *step)

Retrieve the start, stop and step indices from the slice object *slice*, assuming a sequence of length *length*. Treats indices greater than *length* as errors.

Returns 0 on success and -1 on error with no exception set (unless one of the indices was not **None** and failed to be converted to an integer, in which case -1 is returned with an exception set).

You probably do not want to use this function.

*Changed in version 3.2:* The parameter type for the *slice* parameter
int **PySlice_GetIndicesEx**(
PyObject *slice, Py_ssize_t length,
Py_ssize_t *start, Py_ssize_t *stop, Py_ssize_t *step,
Py_ssize_t *slicelength)

Usable replacement for **PySlice_GetIndices()**. Retrieve the start, stop, and step indices from the slice object *slice* assuming a sequence of length *length*, and store the length of the slice in *slicelength*. Out of bounds indices are clipped in a manner consistent with the handling of normal slices.

Returns 0 on success and -1 on error with exception set.

*Changed in version 3.2:* The parameter type for the *slice* parameter was **PySliceObject** before.
MemoryView objects

A `memoryview` object exposes the C level `buffer interface` as a Python object which can then be passed around like any other object.

**PyObject *PyMemoryView_FromObject**(PyObject *obj)

Create a memoryview object from an object that provides the buffer interface. If `obj` supports writable buffer exports, the memoryview object will be read/write, otherwise it may be either read-only or read/write at the discretion of the exporter.

**PyObject *PyMemoryView_FromMemory**(char *mem, Py_ssize_t size, int flags)

Create a memoryview object using `mem` as the underlying buffer. `flags` can be one of PyBUF_READ or PyBUF_WRITE.

*New in version 3.3.*

**PyObject *PyMemoryView_FromBuffer**(Py_buffer *view)

Create a memoryview object wrapping the given buffer structure `view`. For simple byte buffers, `PyMemoryView_FromMemory()` is the preferred function.

**PyObject *PyMemoryView_GetContiguous**(PyObject *obj, int buffertype, char order)

Create a memoryview object to a contiguous chunk of memory (in either ‘C’ or ‘F’ortran order) from an object that defines the buffer interface. If memory is contiguous, the memoryview object points to the original memory. Otherwise, a copy is made and the memoryview points to a new bytes object.
int PyMemoryView_Check(PyObject *obj)

Return true if the object obj is a memoryview object. It is not currently allowed to create subclasses of memoryview.

Py_buffer *PyMemoryView_GET_BUFFER(PyObject *mview)

Return a pointer to the memoryview's private copy of the exporter's buffer. mview must be a memoryview instance; this macro doesn't check its type, you must do it yourself or you will risk crashes.

Py_buffer *PyMemoryView_GET_BASE(PyObject *mview)

Return either a pointer to the exporting object that the memoryview is based on or NULL if the memoryview has been created by one of the functions PyMemoryView_FromMemory() or PyMemoryView_FromBuffer(). mview must be a memoryview instance.
Weak Reference Objects

Python supports weak references as first-class objects. There are two specific object types which directly implement weak references. The first is a simple reference object, and the second acts as a proxy for the original object as much as it can.

```c
int PyWeakref_Check( ob )
    Return true if ob is either a reference or proxy object.
```

```c
int PyWeakref_CheckRef( ob )
    Return true if ob is a reference object.
```

```c
int PyWeakref_CheckProxy( ob )
    Return true if ob is a proxy object.
```

```c
PyObject* PyWeakref_NewRef(PyObject *ob, PyObject *callback)
    Return a weak reference object for the object ob. This will always
    return a new reference, but is not guaranteed to create a new
    object; an existing reference object may be returned. The second
    parameter, callback, can be a callable object that receives
    notification when ob is garbage collected; it should accept a single
    parameter, which will be the weak reference object itself. callback
    may also be None or NULL. If ob is not a weakly-referencable
    object, or if callback is not callable, None, or NULL, this will return
    NULL and raise TypeError.
```

```c
PyObject* PyWeakref_NewProxy(PyObject *ob, PyObject *callback)
```

Return a weak reference proxy object for the object \textit{ob}. This will always return a new reference, but is not guaranteed to create a new object; an existing proxy object may be returned. The second parameter, \textit{callback}, can be a callable object that receives notification when \textit{ob} is garbage collected; it should accept a single parameter, which will be the weak reference object itself. \textit{callback} may also be None or \texttt{NULL}. If \textit{ob} is not a weakly-referencable object, or if \textit{callback} is not callable, None, or \texttt{NULL}, this will return \texttt{NULL} and raise \texttt{TypeError}.

\textbf{PyObject* PyWeakref\_GetObject(PyObject *ref)}

Return value: Borrowed reference.

Return the referenced object from a weak reference, \textit{ref}. If the referent is no longer live, returns \texttt{Py\_None}.

\begin{quote}
\textbf{Note:} This function returns a \texttt{borrowed reference} to the referenced object. This means that you should always call \texttt{Py\_INCREF()} on the object except if you know that it cannot be destroyed while you are still using it.
\end{quote}

\textbf{PyObject* PyWeakref\_GET\_OBJECT(PyObject *ref)}

Return value: Borrowed reference.

Similar to \texttt{PyWeakref\_GetObject()}, but implemented as a macro that does no error checking.
Capsules

Refer to *Providing a C API for an Extension Module* for more information on using these objects.

**PyCapsule**
This subtype of *PyObject* represents an opaque value, useful for C extension modules who need to pass an opaque value (as a void* pointer) through Python code to other C code. It is often used to make a C function pointer defined in one module available to other modules, so the regular import mechanism can be used to access C APIs defined in dynamically loaded modules.

**PyCapsule_Destructor**
The type of a destructor callback for a capsule. Defined as:

```c
typedef void (*PyCapsule_Destructor)(PyObject *);
```

See *PyCapsule_New()* for the semantics of PyCapsule_Destructor callbacks.

```c
int PyCapsule_CheckExact(PyObject *p)
```

Return true if its argument is a PyCapsule.

```c
PyObject* PyCapsule_New(void *pointer, const char *name,
PyCapsule_Destructor destructor)
```

*Return value: New reference.*

Create a PyCapsule encapsulating the pointer. The pointer argument may not be NULL.

On failure, set an exception and return NULL.
The *name* string may either be *NULL* or a pointer to a valid C string. If non-*NULL*, this string must outlive the capsule. (Though it is permitted to free it inside the *destructor*.)

If the *destructor* argument is not *NULL*, it will be called with the capsule as its argument when it is destroyed.

If this capsule will be stored as an attribute of a module, the *name* should be specified as `modulename.attributename`. This will enable other modules to import the capsule using `PyCapsule_Import()`.

```c
void* PyCapsule_GetPointer(PyObject *capsule, const char *name)
```

Retrieve the *pointer* stored in the capsule. On failure, set an exception and return *NULL*.

The *name* parameter must compare exactly to the name stored in the capsule. If the name stored in the capsule is *NULL*, the *name* passed in must also be *NULL*. Python uses the C function `strcmp()` to compare capsule names.

```c
PyCapsule_Destructor
PyCapsule_GetDestructor(PyObject *capsule)
```

Return the current destructor stored in the capsule. On failure, set an exception and return *NULL*.

It is legal for a capsule to have a *NULL* destructor. This makes a *NULL* return code somewhat ambiguous; use `PyCapsule_IsValid()` or `PyErr_Occurred()` to disambiguate.

```c
void* PyCapsule_GetContext(PyObject *capsule)
```
Return the current context stored in the capsule. On failure, set an exception and return `NULL`.

It is legal for a capsule to have a `NULL` context. This makes a `NULL` return code somewhat ambiguous; use `PyCapsule_IsValid()` or `PyErr_Occurred()` to disambiguate.

```c
const char* PyCapsule_GetName(PyObject *capsule)
```
Return the current name stored in the capsule. On failure, set an exception and return `NULL`.

It is legal for a capsule to have a `NULL` name. This makes a `NULL` return code somewhat ambiguous; use `PyCapsule_IsValid()` or `PyErr_Occurred()` to disambiguate.

```c
void* PyCapsule_Import(const char *name, int no_block)
```
Import a pointer to a C object from a capsule attribute in a module. The `name` parameter should specify the full name to the attribute, as in `module.attribute`. The `name` stored in the capsule must match this string exactly. If `no_block` is true, import the module without blocking (using `PyImport_ImportModuleNoBlock()`). If `no_block` is false, import the module conventionally (using `PyImport_ImportModule()`).

Return the capsule's internal `pointer` on success. On failure, set an exception and return `NULL`. However, if `PyCapsule_Import()` failed to import the module, and `no_block` was true, no exception is set.

```c
int PyCapsule_IsValid(PyObject *capsule, const char *name)
```
Determines whether or not `capsule` is a valid capsule. A valid
capsule is non-NULL, passes `PyCapsule_CheckExact()`, has a non-NULL pointer stored in it, and its internal name matches the name parameter. (See `PyCapsule_GetPointer()` for information on how capsule names are compared.)

In other words, if `PyCapsule_IsValid()` returns a true value, calls to any of the accessors (any function starting with `PyCapsule_Get()`) are guaranteed to succeed.

Return a nonzero value if the object is valid and matches the name passed in. Return 0 otherwise. This function will not fail.

```c
int PyCapsule_SetContext(PyObject *capsule, void *context)
    Set the context pointer inside capsule to context.
    Return 0 on success. Return nonzero and set an exception on failure.
```

```c
int PyCapsule_SetDestructor(PyObject *capsule, PyCapsule_Destructor destructor)
    Set the destructor inside capsule to destructor.
    Return 0 on success. Return nonzero and set an exception on failure.
```

```c
int PyCapsule_SetName(PyObject *capsule, const char *name)
    Set the name inside capsule to name. If non-NULL, the name must outlive the capsule. If the previous name stored in the capsule was not NULL, no attempt is made to free it.
    Return 0 on success. Return nonzero and set an exception on failure.
```

```c
int PyCapsule_SetPointer(PyObject *capsule, void *pointer)
```
Set the void pointer inside capsule to pointer. The pointer may not be NULL.

Return 0 on success. Return nonzero and set an exception on failure.
Generator Objects

Generator objects are what Python uses to implement generator iterators. They are normally created by iterating over a function that yields values, rather than explicitly calling `PyGen_New()`.

**PyGenObject**

The C structure used for generator objects.

**PyTypeObject PyGen_Type**

The type object corresponding to generator objects

int **PyGen_Check**(ob)

Return true if `ob` is a generator object; `ob` must not be `NULL`.

int **PyGen_CheckExact**(ob)

Return true if `ob`'s type is `PyGen_Type` is a generator object; `ob` must not be `NULL`.

**PyObject* PyGen_New**(PyFrameObject *frame)

*Return value: New reference.*

Create and return a new generator object based on the `frame` object. A reference to `frame` is stolen by this function. The parameter must not be `NULL`. 
DateTime Objects

Various date and time objects are supplied by the `datetime` module. Before using any of these functions, the header file `datetime.h` must be included in your source (note that this is not included by `Python.h`), and the macro `PyDateTime_IMPORT` must be invoked, usually as part of the module initialisation function. The macro puts a pointer to a C structure into a static variable, `PyDateTimeAPI`, that is used by the following macros.

Type-check macros:

```c
int PyDate_Check(PyObject *ob)
    Return true if `ob` is of type `PyDateTime_DateType` or a subtype of `PyDateTime_DateType`. `ob` must not be `NULL`.

int PyDate_CheckExact(PyObject *ob)
    Return true if `ob` is of type `PyDateTime_DateType`. `ob` must not be `NULL`.

int PyDateTime_Check(PyObject *ob)
    Return true if `ob` is of type `PyDateTime_DateTimeType` or a subtype of `PyDateTime_DateTimeType`. `ob` must not be `NULL`.

int PyDateTime_CheckExact(PyObject *ob)
    Return true if `ob` is of type `PyDateTime_DateTimeType`. `ob` must not be `NULL`.

int PyTime_Check(PyObject *ob)
    Return true if `ob` is of type `PyDateTime_TimeType` or a subtype of `PyDateTime_TimeType`. `ob` must not be `NULL`.
```
int **PyTime_CheckExact**(*PyObject *ob*)
Return true if ob is of type PyDateTime_TimeType. ob must not be NULL.

int **PyDelta_Check**(*PyObject *ob*)
Return true if ob is of type PyDateTime_DeltaType or a subtype of PyDateTime_DeltaType. ob must not be NULL.

int **PyDelta_CheckExact**(*PyObject *ob*)
Return true if ob is of type PyDateTime_DeltaType. ob must not be NULL.

int **PyTZInfo_Check**(*PyObject *ob*)
Return true if ob is of type PyDateTime_TZInfoType or a subtype of PyDateTime_TZInfoType. ob must not be NULL.

int **PyTZInfo_CheckExact**(*PyObject *ob*)
Return true if ob is of type PyDateTime_TZInfoType. ob must not be NULL.

Macros to create objects:

PyObject* **PyDate_FromDate**(int year, int month, int day)
Return a datetime.date object with the specified year, month and day.

PyObject* **PyDateTime_FromDateAndTime**(int year, int month, int day, int hour, int minute, int second, int usecond)
Return a datetime.datetime object with the specified year,
month, day, hour, minute, second and microsecond.

PyObject* PyTime_FromTime(int hour, int minute, int second, int usecond)

    Return a datetime.time object with the specified hour, minute, second and microsecond.

PyObject* PyDelta_FromDSU(int days, int seconds, int useconds)

    Return a datetime.timedelta object representing the given number of days, seconds and microseconds. Normalization is performed so that the resulting number of microseconds and seconds lie in the ranges documented for datetime.timedelta objects.

Macros to extract fields from date objects. The argument must be an instance of PyDateTime_Date, including subclasses (such as PyDateTime_DateTime). The argument must not be NULL, and the type is not checked:

int PyDateTime_GET_YEAR(PyDateTime_Date *o)
    Return the year, as a positive int.

int PyDateTime_GET_MONTH(PyDateTime_Date *o)
    Return the month, as an int from 1 through 12.

int PyDateTime_GET_DAY(PyDateTime_Date *o)
    Return the day, as an int from 1 through 31.

Macros to extract fields from datetime objects. The argument must be an instance of PyDateTime_DateTime, including subclasses. The argument must not be NULL, and the type is not checked:
int PyDateTime_DATE_GET_HOUR(PyDateTime_DateTime *o)
    Return the hour, as an int from 0 through 23.

int PyDateTime_DATE_GET_MINUTE(PyDateTime_DateTime *o)
    Return the minute, as an int from 0 through 59.

int PyDateTime_DATE_GET_SECOND(PyDateTime_DateTime *o)
    Return the second, as an int from 0 through 59.

int PyDateTime_DATE_GET_MICROSECOND(PyDateTime_DateTime *o)
    Return the microsecond, as an int from 0 through 999999.

Macros to extract fields from time objects. The argument must be an
instance of PyDateTime_Time, including subclasses. The argument
must not be NULL, and the type is not checked:

int PyDateTime_TIME_GET.HOUR(PyDateTime_Time *o)
    Return the hour, as an int from 0 through 23.

int PyDateTime_TIME_GET_MINUTE(PyDateTime_Time *o)
    Return the minute, as an int from 0 through 59.

int PyDateTime_TIME_GET_SECOND(PyDateTime_Time *o)
    Return the second, as an int from 0 through 59.

int PyDateTime_TIME_GET_MICROSECOND(PyDateTime_Time *o)
    Return the microsecond, as an int from 0 through 999999.

Macros to extract fields from time delta objects. The argument must be
an instance of PyDateTime_Delta, including subclasses. The
argument must not be NULL, and the type is not checked:

```c
int PyDateTime_DELTA_GET_DAYS(PyDateTime_Delta *o)
    Return the number of days, as an int from -999999999 to 999999999.
    New in version 3.3.
```

```c
int PyDateTime_DELTA_GET_SECONDS(PyDateTime_Delta *o)
    Return the number of seconds, as an int from 0 through 86399.
    New in version 3.3.
```

```c
int PyDateTime_DELTA_GET_MICROSECOND(PyDateTime_Delta *o)
    Return the number of microseconds, as an int from 0 through 999999.
    New in version 3.3.
```

Macros for the convenience of modules implementing the DB API:

```c
PyObject* PyDateTime_FromTimestamp(PyObject *args)
    Create and return a new datetime.datetime object given an argument tuple suitable for passing to datetime.datetime.fromtimestamp().
```

```c
PyObject* PyDate_FromTimestamp(PyObject *args)
    Create and return a new datetime.date object given an argument tuple suitable for passing to datetime.date.fromtimestamp().
```
Initialization, Finalization, and Threads
Initializing and finalizing the interpreter

void **Py_Initialize()**

Initialize the Python interpreter. In an application embedding Python, this should be called before using any other Python/C API functions; with the exception of **Py_SetProgramName()**, **Py_SetPythonHome()** and **Py_SetPath()**. This initializes the table of loaded modules (sys.modules), and creates the fundamental modules **builtins, __main__** and **sys**. It also initializes the module search path (sys.path). It does not set **sys.argv**; use **PySys_SetArgvEx()** for that. This is a no-op when called for a second time (without calling **Py_Finalize()** first). There is no return value; it is a fatal error if the initialization fails.

void **Py_InitializeEx(int initsigs)**

This function works like **Py_Initialize()** if **initsigs** is 1. If **initsigs** is 0, it skips initialization registration of signal handlers, which might be useful when Python is embedded.

int **Py_IsInitialized()**

Return true (nonzero) when the Python interpreter has been initialized, false (zero) if not. After **Py_Finalize()** is called, this returns false until **Py_Initialize()** is called again.

void **Py_Finalize()**

Undo all initializations made by **Py_Initialize()** and subsequent use of Python/C API functions, and destroy all sub-interpreters (see **Py_NewInterpreter()** below) that were created and not yet destroyed since the last call to
`Py_Initialize()`. Ideally, this frees all memory allocated by the Python interpreter. This is a no-op when called for a second time (without calling `Py_Initialize()` again first). There is no return value; errors during finalization are ignored.

This function is provided for a number of reasons. An embedding application might want to restart Python without having to restart the application itself. An application that has loaded the Python interpreter from a dynamically loadable library (or DLL) might want to free all memory allocated by Python before unloading the DLL. During a hunt for memory leaks in an application a developer might want to free all memory allocated by Python before exiting from the application.

**Bugs and caveats:** The destruction of modules and objects in modules is done in random order; this may cause destructors (`__del__()` methods) to fail when they depend on other objects (even functions) or modules. Dynamically loaded extension modules loaded by Python are not unloaded. Small amounts of memory allocated by the Python interpreter may not be freed (if you find a leak, please report it). Memory tied up in circular references between objects is not freed. Some memory allocated by extension modules may not be freed. Some extensions may not work properly if their initialization routine is called more than once; this can happen if an application calls `Py_Initialize()` and `Py_Finalize()` more than once.
Process-wide parameters

int Py_SetStandardStreamEncoding(char *encoding, char *errors)

This function should be called before Py_Initialize(), if it is called at all. It specifies which encoding and error handling to use with standard IO, with the same meanings as in str.encode().

It overrides PYTHONIOENCODING values, and allows embedding code to control IO encoding when the environment variable does not work.

encoding and/or errors may be NULL to use PYTHONIOENCODING and/or default values (depending on other settings).

Note that sys.stderr always uses the “backslashreplace” error handler, regardless of this (or any other) setting.

If Py_Finalize() is called, this function will need to be called again in order to affect subsequent calls to Py_Initialize().

Returns 0 if successful, a nonzero value on error (e.g. calling after the interpreter has already been initialized).

New in version 3.4.

void Py_SetProgramName(wchar_t *name)

This function should be called before Py_Initialize() is called for the first time, if it is called at all. It tells the interpreter the value of the argv[0] argument to the main() function of the program (converted to wide characters). This is used by Py_GetPath()
and some other functions below to find the Python run-time libraries relative to the interpreter executable. The default value is 'python'. The argument should point to a zero-terminated wide character string in static storage whose contents will not change for the duration of the program’s execution. No code in the Python interpreter will change the contents of this storage.

```
wchar* Py_GetProgramName()
```

Return the program name set with Py_SetProgramName(), or the default. The returned string points into static storage; the caller should not modify its value.

```
wchar_t* Py_GetPrefix()
```

Return the prefix for installed platform-independent files. This is derived through a number of complicated rules from the program name set with Py_SetProgramName() and some environment variables; for example, if the program name is '/usr/local/bin/python', the prefix is '/usr/local'. The returned string points into static storage; the caller should not modify its value. This corresponds to the prefix variable in the top-level Makefile and the --prefix argument to the configure script at build time. The value is available to Python code as sys.prefix. It is only useful on Unix. See also the next function.

```
wchar_t* Py_GetExecPrefix()
```

Return the exec-prefix for installed platform-dependent files. This is derived through a number of complicated rules from the program name set with Py_SetProgramName() and some environment variables; for example, if the program name is '/usr/local/bin/python', the exec-prefix is '/usr/local'. The returned string points into static storage; the
caller should not modify its value. This corresponds to the exec_prefix variable in the top-level Makefile and the --exec-prefix argument to the configure script at build time. The value is available to Python code as sys.exec_prefix. It is only useful on Unix.

Background: The exec-prefix differs from the prefix when platform dependent files (such as executables and shared libraries) are installed in a different directory tree. In a typical installation, platform dependent files may be installed in the /usr/local/plat subtree while platform independent may be installed in /usr/local.

Generally speaking, a platform is a combination of hardware and software families, e.g. Sparc machines running the Solaris 2.x operating system are considered the same platform, but Intel machines running Solaris 2.x are another platform, and Intel machines running Linux are yet another platform. Different major revisions of the same operating system generally also form different platforms. Non-Unix operating systems are a different story; the installation strategies on those systems are so different that the prefix and exec-prefix are meaningless, and set to the empty string. Note that compiled Python bytecode files are platform independent (but not independent from the Python version by which they were compiled!).

System administrators will know how to configure the mount or automount programs to share /usr/local between platforms while having /usr/local/plat be a different filesystem for each platform.

wchar_t* Py_GetProgramFullPath()
Return the full program name of the Python executable; this is computed as a side-effect of deriving the default module search path from the program name (set by `Py_SetProgramName()` above). The returned string points into static storage; the caller should not modify its value. The value is available to Python code as `sys.executable`.

```c
wchar_t* Py_GetPath()
```

Return the default module search path; this is computed from the program name (set by `Py_SetProgramName()` above) and some environment variables. The returned string consists of a series of directory names separated by a platform dependent delimiter character. The delimiter character is `':'` on Unix and Mac OS X, `';'` on Windows. The returned string points into static storage; the caller should not modify its value. The list `sys.path` is initialized with this value on interpreter startup; it can be (and usually is) modified later to change the search path for loading modules.

```c
void Py_SetPath(const wchar_t *)
```

Set the default module search path. If this function is called before `Py_Initialize()`, then `Py_GetPath()` won’t attempt to compute a default search path but uses the one provided instead. This is useful if Python is embedded by an application that has full knowledge of the location of all modules. The path components should be separated by semicolons.

This also causes `sys.executable` to be set only to the raw program name (see `Py_SetProgramName()`) and for `sys.prefix` and `sys.exec_prefix` to be empty. It is up to the caller to modify these if required after calling `Py_Initialize()`.

```c
const char* Py_GetVersion()
```
Return the version of this Python interpreter. This is a string that looks something like

```
"3.0a5+ (py3k:63103M, May 12 2008, 00:53:55) \n[G
```

The first word (up to the first space character) is the current Python version; the first three characters are the major and minor version separated by a period. The returned string points into static storage; the caller should not modify its value. The value is available to Python code as `sys.version`.

```c
const char* Py_GetVersion()
```

Return the platform identifier for the current platform. On Unix, this is formed from the “official” name of the operating system, converted to lower case, followed by the major revision number; e.g., for Solaris 2.x, which is also known as SunOS 5.x, the value is `'sunos5'`. On Mac OS X, it is `'darwin'`. On Windows, it is `'win'`. The returned string points into static storage; the caller should not modify its value. The value is available to Python code as `sys.platform`.

```c
const char* Py_GetPlatform()
```

Return the official copyright string for the current Python version, for example

```
'Copyright 1991-1995 Stichting Mathematisch Centrum, Amsterdam'
```

The returned string points into static storage; the caller should not modify its value. The value is available to Python code as `sys.copyright`.

```c
const char* Py_GetCopyright()
```
const char* \texttt{Py\_GetCompiler}()  
Return an indication of the compiler used to build the current Python version, in square brackets, for example:

\begin{verbatim}
"[GCC 2.7.2.2]"
\end{verbatim}

The returned string points into static storage; the caller should not modify its value. The value is available to Python code as part of the variable \texttt{sys.version}.

const char* \texttt{Py\_GetBuildInfo}()  
Return information about the sequence number and build date and time of the current Python interpreter instance, for example

\begin{verbatim}
"#67, Aug 1 1997, 22:34:28"
\end{verbatim}

The returned string points into static storage; the caller should not modify its value. The value is available to Python code as part of the variable \texttt{sys.version}.

void \texttt{PySys\_SetArgvEx}(int argc, wchar_t **argv, int updatepath)  
Set \texttt{sys.argv} based on \texttt{argc} and \texttt{argv}. These parameters are similar to those passed to the program’s \texttt{main()} function with the difference that the first entry should refer to the script file to be executed rather than the executable hosting the Python interpreter. If there isn’t a script that will be run, the first entry in \texttt{argv} can be an empty string. If this function fails to initialize \texttt{sys.argv}, a fatal condition is signalled using \texttt{Py\_FatalError()}.  

If \texttt{updatepath} is zero, this is all the function does. If \texttt{updatepath} is non-zero, the function also modifies \texttt{sys.path} according to the following algorithm:
- If the name of an existing script is passed in \texttt{argv[0]} , the absolute path of the directory where the script is located is prepended to \texttt{sys.path}.
- Otherwise (that is, if \texttt{argc} is 0 or \texttt{argv[0]} doesn't point to an existing file name), an empty string is prepended to \texttt{sys.path} , which is the same as prepending the current working directory (".").

\begin{quote}
\textbf{Note:} It is recommended that applications embedding the Python interpreter for purposes other than executing a single script pass 0 as \textit{updatepath} , and update \texttt{sys.path} themselves if desired. See \texttt{CVE-2008-5983}.

On versions before 3.1.3, you can achieve the same effect by manually popping the first \texttt{sys.path} element after having called \texttt{PySys_SetArgv()} , for example using:

\begin{verbatim}
PyRun_SimpleString("import sys; sys.path.pop(0)\n
Note: It is recommended that applications embedding the Python interpreter for purposes other than executing a single script pass 0 as \textit{updatepath} , and update \texttt{sys.path} themselves if desired. See \texttt{CVE-2008-5983}.

On versions before 3.1.3, you can achieve the same effect by manually popping the first \texttt{sys.path} element after having called \texttt{PySys_SetArgv()} , for example using:

\begin{verbatim}
PyRun_SimpleString("import sys; sys.path.pop(0)\n
\end{verbatim}

\textit{New in version 3.1.3.}

\begin{verbatim}
void \textbf{PySys_SetArgv}(int argc, wchar_t **argv)
This function works like \texttt{PySys_SetArgvEx()} with \textit{updatepath} set to 1 unless the \texttt{python} interpreter was started with the \texttt{-l}.

\textit{Changed in version 3.4:} The \textit{updatepath} value depends on \texttt{-l}.

\begin{verbatim}
void \textbf{Py_SetPythonHome}(wchar_t *home)
Set the default “home” directory, that is, the location of the standard Python libraries. See \texttt{PYTHONHOME} for the meaning of the argument string.

The argument should point to a zero-terminated character string in
static storage whose contents will not change for the duration of the program’s execution. No code in the Python interpreter will change the contents of this storage.

\texttt{w\_char* Py\_GetPythonHome()}

Return the default “home”, that is, the value set by a previous call to \texttt{Py\_SetPythonHome()}, or the value of the \texttt{PYTHONHOME} environment variable if it is set.
Thread State and the Global Interpreter Lock

The Python interpreter is not fully thread-safe. In order to support multi-threaded Python programs, there's a global lock, called the global interpreter lock or GIL, that must be held by the current thread before it can safely access Python objects. Without the lock, even the simplest operations could cause problems in a multi-threaded program: for example, when two threads simultaneously increment the reference count of the same object, the reference count could end up being incremented only once instead of twice.

Therefore, the rule exists that only the thread that has acquired the GIL may operate on Python objects or call Python/C API functions. In order to emulate concurrency of execution, the interpreter regularly tries to switch threads (see sys.setswitchinterval()). The lock is also released around potentially blocking I/O operations like reading or writing a file, so that other Python threads can run in the meantime.

The Python interpreter keeps some thread-specific bookkeeping information inside a data structure called PyThreadState. There's also one global variable pointing to the current PyThreadState: it can be retrieved using PyThreadState_Get().

Releasing the GIL from extension code

Most extension code manipulating the GIL has the following simple structure:

Save the thread state in a local variable.
Release the global interpreter lock.
... Do some blocking I/O operation ...
Reacquire the global interpreter lock.
Restore the thread state from the local variable.

This is so common that a pair of macros exists to simplify it:

```
Py_BEGIN_ALLOW_THREADS
... Do some blocking I/O operation ...
Py_END_ALLOW_THREADS
```

The `Py_BEGIN_ALLOW_THREADS` macro opens a new block and declares a hidden local variable; the `Py_END_ALLOW_THREADS` macro closes the block. These two macros are still available when Python is compiled without thread support (they simply have an empty expansion).

When thread support is enabled, the block above expands to the following code:

```
PyThreadState *_save;
(save = PyEval_SaveThread();
...Do some blocking I/O operation...
PyEval_RestoreThread(_save);
```

Here is how these functions work: the global interpreter lock is used to protect the pointer to the current thread state. When releasing the lock and saving the thread state, the current thread state pointer must be retrieved before the lock is released (since another thread could immediately acquire the lock and store its own thread state in the global variable). Conversely, when acquiring the lock and restoring the thread state, the lock must be acquired before storing the thread state pointer.
Note: Calling system I/O functions is the most common use case for releasing the GIL, but it can also be useful before calling long-running computations which don’t need access to Python objects, such as compression or cryptographic functions operating over memory buffers. For example, the standard zlib and hashlib modules release the GIL when compressing or hashing data.

Non-Python created threads

When threads are created using the dedicated Python APIs (such as the threading module), a thread state is automatically associated to them and the code showed above is therefore correct. However, when threads are created from C (for example by a third-party library with its own thread management), they don’t hold the GIL, nor is there a thread state structure for them.

If you need to call Python code from these threads (often this will be part of a callback API provided by the aforementioned third-party library), you must first register these threads with the interpreter by creating a thread state data structure, then acquiring the GIL, and finally storing their thread state pointer, before you can start using the Python/C API. When you are done, you should reset the thread state pointer, release the GIL, and finally free the thread state data structure.

The PyGILState_Ensure() and PyGILState_Release() functions do all of the above automatically. The typical idiom for calling into Python from a C thread is:

```c
PyGILState_STATE gstate;
gstate = PyGILState_Ensure();
```
Note that the PyGILState_*() functions assume there is only one global interpreter (created automatically by Py_Initialize()). Python supports the creation of additional interpreters (using Py_NewInterpreter()), but mixing multiple interpreters and the PyGILState_*() API is unsupported.

Another important thing to note about threads is their behaviour in the face of the C fork() call. On most systems with fork(), after a process forks only the thread that issued the fork will exist. That also means any locks held by other threads will never be released. Python solves this for os.fork() by acquiring the locks it uses internally before the fork, and releasing them afterwards. In addition, it resets any Lock Objects in the child. When extending or embedding Python, there is no way to inform Python of additional (non-Python) locks that need to be acquired before or reset after a fork. OS facilities such as pthread_atfork() would need to be used to accomplish the same thing. Additionally, when extending or embedding Python, calling fork() directly rather than through os.fork() (and returning to or calling into Python) may result in a deadlock by one of Python's internal locks being held by a thread that is defunct after the fork. PyOS_AfterFork() tries to reset the necessary locks, but is not always able to.

High-level API
These are the most commonly used types and functions when writing C extension code, or when embedding the Python interpreter:

**PyInterpreterState**

This data structure represents the state shared by a number of cooperating threads. Threads belonging to the same interpreter share their module administration and a few other internal items. There are no public members in this structure.

Threads belonging to different interpreters initially share nothing, except process state like available memory, open file descriptors and such. The global interpreter lock is also shared by all threads, regardless of to which interpreter they belong.

**PyThreadState**

This data structure represents the state of a single thread. The only public data member is `PyInterpreterState *interp`, which points to this thread’s interpreter state.

```c
void PyEval_InitThreads()
```

Initialize and acquire the global interpreter lock. It should be called in the main thread before creating a second thread or engaging in any other thread operations such as `PyEval_ReleaseThread(tstate)`. It is not needed before calling `PyEval_SaveThread()` or `PyEval_RestoreThread()`.

This is a no-op when called for a second time.

*Changed in version 3.2:* This function cannot be called before `Py_Initialize()` anymore.

---

**Note:** When only the main thread exists, no GIL operations are needed. This is a common situation (most Python programs do
not use threads), and the lock operations slow the interpreter down a bit. Therefore, the lock is not created initially. This situation is equivalent to having acquired the lock: when there is only a single thread, all object accesses are safe. Therefore, when this function initializes the global interpreter lock, it also acquires it. Before the Python _thread module creates a new thread, knowing that either it has the lock or the lock hasn’t been created yet, it calls PyEval_InitThreads(). When this call returns, it is guaranteed that the lock has been created and that the calling thread has acquired it.

It is not safe to call this function when it is unknown which thread (if any) currently has the global interpreter lock.

This function is not available when thread support is disabled at compile time.

int PyEval_ThreadsInitialized()

Returns a non-zero value if PyEval_InitThreads() has been called. This function can be called without holding the GIL, and therefore can be used to avoid calls to the locking API when running single-threaded. This function is not available when thread support is disabled at compile time.

PyThreadState* PyEval_SaveThread()

Release the global interpreter lock (if it has been created and thread support is enabled) and reset the thread state to NULL, returning the previous thread state (which is not NULL). If the lock has been created, the current thread must have acquired it. (This function is available even when thread support is disabled at compile time.)

void PyEval_RestoreThread(PyThreadState *tstate)
Acquire the global interpreter lock (if it has been created and thread support is enabled) and set the thread state to \textit{tstate}, which must not be \textit{NULL}. If the lock has been created, the current thread must not have acquired it, otherwise deadlock ensues. (This function is available even when thread support is disabled at compile time.)

**PyThreadState**\* \textbf{PyThreadState\_Get()}  
Return the current thread state. The global interpreter lock must be held. When the current thread state is \textit{NULL}, this issues a fatal error (so that the caller needn't check for \textit{NULL}).

**PyThreadState**\* \textbf{PyThreadState\_Swap(} \textbf{PyThreadState} *\textit{tstate})  
Swap the current thread state with the thread state given by the argument \textit{tstate}, which may be \textit{NULL}. The global interpreter lock must be held and is not released.

\textbf{void PyEval\_ReInitThreads()}  
This function is called from \textbf{PyOS\_AfterFork()} to ensure that newly created child processes don't hold locks referring to threads which are not running in the child process.

The following functions use thread-local storage, and are not compatible with sub-interpreters:

**PyGILState\_STATE PyGILState\_Ensure()**  
Ensure that the current thread is ready to call the Python C API regardless of the current state of Python, or of the global interpreter lock. This may be called as many times as desired by a thread as long as each call is matched with a call to \textbf{PyGILState\_Release()}. In general, other thread-related APIs may be used between \textbf{PyGILState\_Ensure()} and
PyGILState_Release() calls as long as the thread state is restored to its previous state before the Release(). For example, normal usage of the Py_BEGIN_ALLOW_THREADS and Py_END_ALLOW_THREADS macros is acceptable.

The return value is an opaque “handle” to the thread state when PyGILState_Ensure() was called, and must be passed to PyGILState_Release() to ensure Python is left in the same state. Even though recursive calls are allowed, these handles cannot be shared - each unique call to PyGILState_Ensure() must save the handle for its call to PyGILState_Release().

When the function returns, the current thread will hold the GIL and be able to call arbitrary Python code. Failure is a fatal error.

void PyGILState_Release(PyGILState_STATE)
Release any resources previously acquired. After this call, Python's state will be the same as it was prior to the corresponding PyGILState_Ensure() call (but generally this state will be unknown to the caller, hence the use of the GILState API).

Every call to PyGILState_Ensure() must be matched by a call to PyGILState_Release() on the same thread.

PyThreadState* PyGILState_GetThisThreadState()
Get the current thread state for this thread. May return NULL if no GILState API has been used on the current thread. Note that the main thread always has such a thread-state, even if no auto-thread-state call has been made on the main thread. This is mainly a helper/diagnostic function.

int PyGILState_Check()
Return 1 if the current thread is holding the GIL and 0 otherwise. This function can be called from any thread at any time. Only if it has had its Python thread state initialized and currently is holding the GIL will it return 1. This is mainly a helper/diagnostic function. It can be useful for example in callback contexts or memory allocation functions when knowing that the GIL is locked can allow the caller to perform sensitive actions or otherwise behave differently.

New in version 3.4.

The following macros are normally used without a trailing semicolon; look for example usage in the Python source distribution.

**Py_BEGIN_ALLOW_THREADS**

This macro expands to `{ PyThreadState * _save; _save = PyEval_SaveThread(); }`. Note that it contains an opening brace; it must be matched with a following **Py_END_ALLOW_THREADS** macro. See above for further discussion of this macro. It is a no-op when thread support is disabled at compile time.

**Py_END_ALLOW_THREADS**

This macro expands to `PyEval_RestoreThread(_save); }`. Note that it contains a closing brace; it must be matched with an earlier **Py_BEGIN_ALLOW_THREADS** macro. See above for further discussion of this macro. It is a no-op when thread support is disabled at compile time.

**Py_BLOCK_THREADS**

This macro expands to `PyEval_RestoreThread(_save);`; it is equivalent to **Py_END_ALLOW_THREADS** without the closing brace. It is a no-op when thread support is disabled at compile time.
**Py_UNBLOCK_THREADS**

This macro expands to `save = PyEval_SaveThread();`: it is equivalent to `Py_BEGIN_ALLOW_THREADS` without the opening brace and variable declaration. It is a no-op when thread support is disabled at compile time.

**Low-level API**

All of the following functions are only available when thread support is enabled at compile time, and must be called only when the global interpreter lock has been created.

**PyInterpreterState**

* **PyInterpreterState_New()**
  
  Create a new interpreter state object. The global interpreter lock need not be held, but may be held if it is necessary to serialize calls to this function.

**void**  

PyInterpreterState_Clear(PyInterpreterState *interp)

  Reset all information in an interpreter state object. The global interpreter lock must be held.

**void**  

PyInterpreterState_Delete(PyInterpreterState *interp)

  Destroy an interpreter state object. The global interpreter lock need not be held. The interpreter state must have been reset with a previous call to PyInterpreterState_Clear().

**PyThreadState**

* **PyThreadState_New(PyInterpreterState *interp)**

  Create a new thread state object belonging to the given interpreter object. The global interpreter lock need not be held, but may be held if it is necessary to serialize calls to this function.
void **PyThreadState_Clear** (*tstate*)

Reset all information in a thread state object. The global interpreter lock must be held.

void **PyThreadState_Delete** (*tstate*)

Destroy a thread state object. The global interpreter lock need not be held. The thread state must have been reset with a previous call to **PyThreadState_Clear**().

**PyObject** *PyThreadState_GetDict*()

*Return value: Borrowed reference.*

Return a dictionary in which extensions can store thread-specific state information. Each extension should use a unique key to use to store state in the dictionary. It is okay to call this function when no current thread state is available. If this function returns *NULL*, no exception has been raised and the caller should assume no current thread state is available.

int **PyThreadState_SetAsyncExc** (*id*, *exc*)

Asynchronously raise an exception in a thread. The *id* argument is the thread id of the target thread; *exc* is the exception object to be raised. This function does not steal any references to *exc*. To prevent naive misuse, you must write your own C extension to call this. Must be called with the GIL held. Returns the number of thread states modified; this is normally one, but will be zero if the thread id isn’t found. If *exc* is *NULL*, the pending exception (if any) for the thread is cleared. This raises no exceptions.

void **PyEval_AcquireThread** (*tstate*)

Acquire the global interpreter lock and set the current thread state to *tstate*, which should not be *NULL*. The lock must have been created earlier. If this thread already has the lock, deadlock
ensues.

PyEval_RestoreThread() is a higher-level function which is always available (even when thread support isn’t enabled or when threads have not been initialized).

```c
void PyEval_ReleaseThread(PyThreadState *tstate)
```

Reset the current thread state to NULL and release the global interpreter lock. The lock must have been created earlier and must be held by the current thread. The tstate argument, which must not be NULL, is only used to check that it represents the current thread state — if it isn’t, a fatal error is reported.

PyEval_SaveThread() is a higher-level function which is always available (even when thread support isn’t enabled or when threads have not been initialized).

void PyEval_AcquireLock()

Acquire the global interpreter lock. The lock must have been created earlier. If this thread already has the lock, a deadlock ensues.

```
Deprecated since version 3.2: This function does not update the current thread state. Please use PyEval_RestoreThread() or PyEval_AcquireThread() instead.
```

void PyEval_ReleaseLock()

Release the global interpreter lock. The lock must have been created earlier.

```
Deprecated since version 3.2: This function does not update the current thread state. Please use PyEval_SaveThread() or
```
PyEval_ReleaseThread() instead.
Sub-interpreter support

While in most uses, you will only embed a single Python interpreter, there are cases where you need to create several independent interpreters in the same process and perhaps even in the same thread. Sub-interpreters allow you to do that. You can switch between sub-interpreters using the `PyThreadState_Swap()` function. You can create and destroy them using the following functions:

**PyThreadState* Py_NewInterpreter()**

Create a new sub-interpreter. This is an (almost) totally separate environment for the execution of Python code. In particular, the new interpreter has separate, independent versions of all imported modules, including the fundamental modules `builtins`, `__main__` and `sys`. The table of loaded modules (`sys.modules`) and the module search path (`sys.path`) are also separate. The new environment has no `sys.argv` variable. It has new standard I/O stream file objects `sys.stdin`, `sys.stdout` and `sys.stderr` (however these refer to the same underlying file descriptors).

The return value points to the first thread state created in the new sub-interpreter. This thread state is made in the current thread state. Note that no actual thread is created; see the discussion of thread states below. If creation of the new interpreter is unsuccessful, `NULL` is returned; no exception is set since the exception state is stored in the current thread state and there may not be a current thread state. (Like all other Python/C API functions, the global interpreter lock must be held before calling this function and is still held when it returns; however, unlike most other Python/C API functions, there needn’t be a current thread
Extension modules are shared between (sub-)interpreters as follows: the first time a particular extension is imported, it is initialized normally, and a (shallow) copy of its module's dictionary is squirreled away. When the same extension is imported by another (sub-)interpreter, a new module is initialized and filled with the contents of this copy; the extension's `init` function is not called. Note that this is different from what happens when an extension is imported after the interpreter has been completely re-initialized by calling `Py_Finalize()` and `Py_Initialize()`; in that case, the extension's `init` function is called again.

```c
void Py_EndInterpreter(PyThreadState *tstate)

Destroy the (sub-)interpreter represented by the given thread state. The given thread state must be the current thread state. See the discussion of thread states below. When the call returns, the current thread state is `NULL`. All thread states associated with this interpreter are destroyed. (The global interpreter lock must be held before calling this function and is still held when it returns.) `Py_Finalize()` will destroy all sub-interpreters that haven't been explicitly destroyed at that point.
```

Bugs and caveats

Because sub-interpreters (and the main interpreter) are part of the same process, the insulation between them isn't perfect — for example, using low-level file operations like `os.close()` they can (accidentally or maliciously) affect each other's open files. Because of the way extensions are shared between (sub-)interpreters, some extensions may not work properly; this is especially likely when the extension makes use of (static) global variables, or when the
extension manipulates its module's dictionary after its initialization. It is possible to insert objects created in one sub-interpreter into a namespace of another sub-interpreter; this should be done with great care to avoid sharing user-defined functions, methods, instances or classes between sub-interpreters, since import operations executed by such objects may affect the wrong (sub-)interpreter’s dictionary of loaded modules.

Also note that combining this functionality with PyGILState_*( ) APIs is delicate, because these APIs assume a bijection between Python thread states and OS-level threads, an assumption broken by the presence of sub-interpreters. It is highly recommended that you don’t switch sub-interpreters between a pair of matching PyGILState_Ensure() and PyGILState_Release() calls. Furthermore, extensions (such as ctypes) using these APIs to allow calling of Python code from non-Python created threads will probably be broken when using sub-interpreters.
Asynchronous Notifications

A mechanism is provided to make asynchronous notifications to the main interpreter thread. These notifications take the form of a function pointer and a void pointer argument.

```c
int Py_AddPendingCall(int (*func)(void *), void *arg)
```

Schedule a function to be called from the main interpreter thread. On success, 0 is returned and `func` is queued for being called in the main thread. On failure, -1 is returned without setting any exception.

When successfully queued, `func` will be eventually called from the main interpreter thread with the argument `arg`. It will be called asynchronously with respect to normally running Python code, but with both these conditions met:

- on a `bytecode` boundary;
- with the main thread holding the `global interpreter lock` (`func` can therefore use the full C API).

`func` must return 0 on success, or -1 on failure with an exception set. `func` won’t be interrupted to perform another asynchronous notification recursively, but it can still be interrupted to switch threads if the global interpreter lock is released.

This function doesn’t need a current thread state to run, and it doesn’t need the global interpreter lock.

**Warning:** This is a low-level function, only useful for very special cases. There is no guarantee that `func` will be called as quick as possible. If the main thread is busy executing a system call, `func` won’t be called before the system call returns. This
function is generally **not** suitable for calling Python code from arbitrary C threads. Instead, use the *PyGILState API*.

*New in version 3.1.*
Profiling and Tracing

The Python interpreter provides some low-level support for attaching profiling and execution tracing facilities. These are used for profiling, debugging, and coverage analysis tools.

This C interface allows the profiling or tracing code to avoid the overhead of calling through Python-level callable objects, making a direct C function call instead. The essential attributes of the facility have not changed; the interface allows trace functions to be installed per-thread, and the basic events reported to the trace function are the same as had been reported to the Python-level trace functions in previous versions.

```c
int (*Py_tracefunc)(PyObject *obj, PyFrameObject *frame, int what, PyObject *arg)
```

The type of the trace function registered using `PyEval_SetProfile()` and `PyEval_SetTrace()`. The first parameter is the object passed to the registration function as `obj`, `frame` is the frame object to which the event pertains, `what` is one of the constants `PyTrace_CALL`, `PyTrace_EXCEPTION`, `PyTrace_LINE`, `PyTrace_RETURN`, `PyTrace_C_CALL`, `PyTrace_C_EXCEPTION`, or `PyTrace_C_RETURN`, and `arg` depends on the value of `what`:

<table>
<thead>
<tr>
<th>Value of <code>what</code></th>
<th>Meaning of <code>arg</code></th>
</tr>
</thead>
<tbody>
<tr>
<td><code>PyTrace_CALL</code></td>
<td>Always <code>NULL</code>.</td>
</tr>
<tr>
<td><code>PyTrace_EXCEPTION</code></td>
<td>Exception information as returned by <code>sys.exc_info()</code></td>
</tr>
<tr>
<td><code>PyTrace_LINE</code></td>
<td>Always <code>NULL</code>.</td>
</tr>
</tbody>
</table>

<table>
<thead>
<tr>
<th>PyTrace_RETURN</th>
<th>Value being returned to the caller, or NULL if caused by an exception.</th>
</tr>
</thead>
<tbody>
<tr>
<td>PyTrace_C_CALL</td>
<td>Function object being called.</td>
</tr>
<tr>
<td>PyTrace_C_EXCEPTION</td>
<td>Function object being called.</td>
</tr>
<tr>
<td>PyTrace_C_RETURN</td>
<td>Function object being called.</td>
</tr>
</tbody>
</table>

**int PyTrace_CALL**

The value of the *what* parameter to a `Py_tracefunc` function when a new call to a function or method is being reported, or a new entry into a generator. Note that the creation of the iterator for a generator function is not reported as there is no control transfer to the Python bytecode in the corresponding frame.

**int PyTrace_EXCEPTION**

The value of the *what* parameter to a `Py_tracefunc` function when an exception has been raised. The callback function is called with this value for *what* when after any bytecode is processed after which the exception becomes set within the frame being executed. The effect of this is that as exception propagation causes the Python stack to unwind, the callback is called upon return to each frame as the exception propagates. Only trace functions receives these events; they are not needed by the profiler.

**int PyTrace_LINE**

The value passed as the *what* parameter to a trace function (but not a profiling function) when a line-number event is being reported.

**int PyTrace_RETURN**

The value for the *what* parameter to `Py_tracefunc` functions when a call is returning without propagating an exception.
int `PyTrace_C_CALL`

The value for the `what` parameter to `Py_tracefunc` functions when a C function is about to be called.

int `PyTrace_C_EXCEPTION`

The value for the `what` parameter to `Py_tracefunc` functions when a C function has raised an exception.

int `PyTrace_C_RETURN`

The value for the `what` parameter to `Py_tracefunc` functions when a C function has returned.

void `PyEval_SetProfile`(`Py_tracefunc` `func`, `PyObject` *`obj`)

Set the profiler function to `func`. The `obj` parameter is passed to the function as its first parameter, and may be any Python object, or `NULL`. If the profile function needs to maintain state, using a different value for `obj` for each thread provides a convenient and thread-safe place to store it. The profile function is called for all monitored events except the line-number events.

void `PyEval_SetTrace`(`Py_tracefunc` `func`, `PyObject` *`obj`)

Set the tracing function to `func`. This is similar to `PyEval_SetProfile()`, except the tracing function does receive line-number events.

`PyObject`* `PyEval_GetCallStats`(`PyObject` *`self`)

Return a tuple of function call counts. There are constants defined for the positions within the tuple:

<table>
<thead>
<tr>
<th>Name</th>
<th>Value</th>
</tr>
</thead>
<tbody>
<tr>
<td>PCALL_ALL</td>
<td>0</td>
</tr>
<tr>
<td>PCALL_FUNCTION</td>
<td>1</td>
</tr>
</tbody>
</table>
PCALL_FAST_FUNCTION 2
PCALL_FASTER_FUNCTION 3
PCALL_METHOD 4
PCALL_BOUND_METHOD 5
PCALL_CFUNCTION 6
PCALL_TYPE 7
PCALL_GENERATOR 8
PCALL_OTHER 9
PCALL_POP 10

PCALL_FAST_FUNCTION means no argument tuple needs to be created. PCALL_FASTER_FUNCTION means that the fast-path frame setup code is used.

If there is a method call where the call can be optimized by changing the argument tuple and calling the function directly, it gets recorded twice.

This function is only present if Python is compiled with CALL_PROFILE defined.
Advanced Debugger Support

These functions are only intended to be used by advanced debugging tools.

**PyInterpreterState**\* **PyInterpreterState\_Head()**

Return the interpreter state object at the head of the list of all such objects.

**PyInterpreterState\***

**PyInterpreterState\_Next**(PyInterpreterState \*interp)

Return the next interpreter state object after interp from the list of all such objects.

**PyThreadState** \*

**PyInterpreterState\_ThreadHead**(PyInterpreterState \*interp)

Return the a pointer to the first PyThreadState object in the list of threads associated with the interpreter interp.

**PyThreadState**\* **PyThreadState\_Next**(PyThreadState \*tstate)

Return the next thread state object after tstate from the list of all such objects belonging to the same PyInterpreterState object.
Memory Management
Overview

Memory management in Python involves a private heap containing all Python objects and data structures. The management of this private heap is ensured internally by the Python memory manager. The Python memory manager has different components which deal with various dynamic storage management aspects, like sharing, segmentation, preallocation or caching.

At the lowest level, a raw memory allocator ensures that there is enough room in the private heap for storing all Python-related data by interacting with the memory manager of the operating system. On top of the raw memory allocator, several object-specific allocators operate on the same heap and implement distinct memory management policies adapted to the peculiarities of every object type. For example, integer objects are managed differently within the heap than strings, tuples or dictionaries because integers imply different storage requirements and speed/space tradeoffs. The Python memory manager thus delegates some of the work to the object-specific allocators, but ensures that the latter operate within the bounds of the private heap.

It is important to understand that the management of the Python heap is performed by the interpreter itself and that the user has no control over it, even if she regularly manipulates object pointers to memory blocks inside that heap. The allocation of heap space for Python objects and other internal buffers is performed on demand by the Python memory manager through the Python/C API functions listed in this document.

To avoid memory corruption, extension writers should never try to operate on Python objects with the functions exported by the C library:
malloc(), calloc(), realloc() and free(). This will result in mixed calls between the C allocator and the Python memory manager with fatal consequences, because they implement different algorithms and operate on different heaps. However, one may safely allocate and release memory blocks with the C library allocator for individual purposes, as shown in the following example:

```c
PyObject *res;
char *buf = (char *) malloc(BUFSIZE); /* for I/O */

if (buf == NULL)
    return PyErr_NoMemory();
...Do some I/O operation involving buf...
res = PyBytes_FromString(buf);
free(buf); /* malloc'ed */
return res;
```

In this example, the memory request for the I/O buffer is handled by the C library allocator. The Python memory manager is involved only in the allocation of the string object returned as a result.

In most situations, however, it is recommended to allocate memory from the Python heap specifically because the latter is under control of the Python memory manager. For example, this is required when the interpreter is extended with new object types written in C. Another reason for using the Python heap is the desire to inform the Python memory manager about the memory needs of the extension module. Even when the requested memory is used exclusively for internal, highly-specific purposes, delegating all memory requests to the Python memory manager causes the interpreter to have a more accurate image of its memory footprint as a whole. Consequently, under certain circumstances, the Python memory manager may or may not trigger appropriate actions, like garbage collection, memory compaction or
other preventive procedures. Note that by using the C library allocator as shown in the previous example, the allocated memory for the I/O buffer escapes completely the Python memory manager.
Raw Memory Interface

The following function sets are wrappers to the system allocator. These functions are thread-safe, the GIL does not need to be held.

The default raw memory block allocator uses the following functions: malloc(), realloc() and free(); call malloc(1) when requesting zero bytes.

*New in version 3.4.*

void* **PyMem_RawMalloc**(size_t *n)

Allocates *n* bytes and returns a pointer of type void* to the allocated memory, or *NULL* if the request fails. Requesting zero bytes returns a distinct non-*NULL* pointer if possible, as if **PyMem_RawMalloc(1)** had been called instead. The memory will not have been initialized in any way.

void* **PyMem_RawRealloc**(void* *p, size_t *n)

Resizes the memory block pointed to by *p* to *n* bytes. The contents will be unchanged to the minimum of the old and the new sizes. If *p* is *NULL*, the call is equivalent to **PyMem_RawMalloc(n)**; else if *n* is equal to zero, the memory block is resized but is not freed, and the returned pointer is non-*NULL*. Unless *p* is *NULL*, it must have been returned by a previous call to **PyMem_RawMalloc()** or **PyMem_RawRealloc()**. If the request fails, **PyMem_RawRealloc()** returns *NULL* and *p* remains a valid pointer to the previous memory area.

void **PyMem_RawFree**(void* *p)

Frees the memory block pointed to by *p*, which must have been
returned by a previous call to \texttt{PyMem\_RawMalloc()} or \texttt{PyMem\_RawRealloc()}. Otherwise, or if \texttt{PyMem\_Free(p)} has been called before, undefined behavior occurs. If \( p \) is \textit{NULL}, no operation is performed.
Memory Interface

The following function sets, modeled after the ANSI C standard, but specifying behavior when requesting zero bytes, are available for allocating and releasing memory from the Python heap.

The default memory block allocator uses the following functions: malloc(), realloc() and free(); call malloc(1) when requesting zero bytes.

**Warning:** The GIL must be held when using these functions.

```c
void* PyMem_Malloc(size_t n)

Allocates n bytes and returns a pointer of type void* to the allocated memory, or NULL if the request fails. Requesting zero bytes returns a distinct non-NULL pointer if possible, as if PyMem_Malloc(1) had been called instead. The memory will not have been initialized in any way.

void* PyMem_Realloc(void *p, size_t n)

Resizes the memory block pointed to by p to n bytes. The contents will be unchanged to the minimum of the old and the new sizes. If p is NULL, the call is equivalent to PyMem_Malloc(n); else if n is equal to zero, the memory block is resized but is not freed, and the returned pointer is non-NULL. Unless p is NULL, it must have been returned by a previous call to PyMem_Malloc() or PyMem_Realloc(). If the request fails, PyMem_Realloc() returns NULL and p remains a valid pointer to the previous memory area.

void PyMem_Free(void *p)```
Frees the memory block pointed to by \( p \), which must have been returned by a previous call to \texttt{PyMem_Malloc()} or \texttt{PyMem_Realloc()}. Otherwise, or if \texttt{PyMem_Free(p)} has been called before, undefined behavior occurs. If \( p \) is \texttt{NULL}, no operation is performed.

The following type-oriented macros are provided for convenience. Note that \textit{TYPE} refers to any C type.

\begin{verbatim}
TYPE* PyMem_New(TYPE, size_t n)
Same as \texttt{PyMem_Malloc()}, but allocates \((n \ast \text{sizeof(TYPE)})\) bytes of memory. Returns a pointer cast to \textit{TYPE*}. The memory will not have been initialized in any way.

TYPE* PyMem_Resize(void *p, TYPE, size_t n)
Same as \texttt{PyMem_Realloc()}, but the memory block is resized to \((n \ast \text{sizeof(TYPE)})\) bytes. Returns a pointer cast to \textit{TYPE*}. On return, \( p \) will be a pointer to the new memory area, or \texttt{NULL} in the event of failure. This is a C preprocessor macro; \( p \) is always reassigned. Save the original value of \( p \) to avoid losing memory when handling errors.

void PyMem_Del(void *p)
Same as \texttt{PyMem_Free()}.\end{verbatim}

In addition, the following macro sets are provided for calling the Python memory allocator directly, without involving the C API functions listed above. However, note that their use does not preserve binary compatibility across Python versions and is therefore deprecated in extension modules.

\texttt{PyMem_MALLOC()}, \texttt{PyMem_REALLOC()}, \texttt{PyMem_FREE()}. 
PyMem_NEW(), PyMem_RESIZE(), PyMem_DEL().
Customize Memory Allocators

*New in version 3.4.*

**PyMemAllocator**
Structure used to describe a memory block allocator. The structure has four fields:

<table>
<thead>
<tr>
<th>Field</th>
<th>Meaning</th>
</tr>
</thead>
<tbody>
<tr>
<td>void *ctx</td>
<td>user context passed as first argument</td>
</tr>
<tr>
<td>void* malloc(void *ctx, size_t size)</td>
<td>allocate a memory block</td>
</tr>
<tr>
<td>void* realloc(void *ctx, void *ptr, size_t new_size)</td>
<td>allocate or resize a memory block</td>
</tr>
<tr>
<td>void free(void *ctx, void *ptr)</td>
<td>free a memory block</td>
</tr>
</tbody>
</table>

**PyMemAllocatorDomain**
Enum used to identify an allocator domain. Domains:

- PYMEM_DOMAIN_RAW: functions PyMem_RawMalloc(), PyMem_RawRealloc() and PyMem_RawFree()
- PYMEM_DOMAIN_MEM: functions PyMem_MALLOC(), PyMem_Realloc() and PyMem_Free()
- PYMEM_DOMAIN_OBJ: functions PyObject_Malloc(), PyObject_Realloc() and PyObject_Free()

void **PyMem_GetAllocator**(PyMemAllocatorDomain domain, PyMemAllocator *allocator)
Get the memory block allocator of the specified domain.
void **PyMem_SetAllocator** (PyMemAllocatorDomain *domain, PyMemAllocator *allocator)

Set the memory block allocator of the specified domain.

The new allocator must return a distinct non-NULL pointer when requesting zero bytes.

For the PYMEM_DOMAIN_RAW domain, the allocator must be thread-safe: the **GIL** is not held when the allocator is called.

If the new allocator is not a hook (does not call the previous allocator), the **PyMem_SetupDebugHooks()** function must be called to reinstall the debug hooks on top on the new allocator.

void **PyMem_SetupDebugHooks**(void)

Setup hooks to detect bugs in the following Python memory allocator functions:

- **PyMem_RawMalloc()**, **PyMem_RawRealloc()**, **PyMem_RawFree()**
- **PyMemMalloc()**, **PyMem_Realloc()**, **PyMem_Free()**
- **PyObject_Malloc()**, **PyObject_Realloc()**, **PyObject_Free()**

Newly allocated memory is filled with the byte 0xCB, freed memory is filled with the byte 0xDB. Additional checks:

- detect API violations, ex: **PyObject_Free()** called on a buffer allocated by **PyMem_Malloc()**
- detect write before the start of the buffer (buffer underflow)
- detect write after the end of the buffer (buffer overflow)

The function does nothing if Python is not compiled in debug mode.
Customize PyObject Arena Allocator

Python has a `pymalloc` allocator for allocations smaller than 512 bytes. This allocator is optimized for small objects with a short lifetime. It uses memory mappings called “arenas” with a fixed size of 256 KB. It falls back to `PyMem_RawMalloc()` and `PyMem_RawRealloc()` for allocations larger than 512 bytes. `pymalloc` is the default allocator used by `PyObject_Malloc()`.

The default arena allocator uses the following functions:

- `VirtualAlloc()` and `VirtualFree()` on Windows,
- `mmap()` and `munmap()` if available,
- `malloc()` and `free()` otherwise.

*New in version 3.4.*

**PyObjectArenaAllocator**

Structure used to describe an arena allocator. The structure has three fields:

<table>
<thead>
<tr>
<th>Field</th>
<th>Meaning</th>
</tr>
</thead>
<tbody>
<tr>
<td><code>void  *ctx</code></td>
<td>user context passed as first argument</td>
</tr>
<tr>
<td><code>void* alloc(void *ctx, size_t size)</code></td>
<td>allocate an arena of size bytes</td>
</tr>
<tr>
<td><code>void free(void *ctx, size_t size, void *ptr)</code></td>
<td>free an arena</td>
</tr>
</tbody>
</table>

**PyObject_GetArenaAllocator**

Get the arena allocator.
PyObject_SetArenaAllocator(PyObjectArenaAllocator *allocator)
Set the arena allocator.
Examples

Here is the example from section *Overview*, rewritten so that the I/O buffer is allocated from the Python heap by using the first function set:

```python
PyObject *res;
char *buf = (char *)PyMem_Malloc(BUFSIZ); /* for I/O */

if (buf == NULL)
    return PyErr_NoMemory();
/* ...Do some I/O operation involving buf... */
res = PyBytes_FromString(buf);
PyMem_Free(buf); /* allocated with PyMem_Malloc */
return res;
```

The same code using the type-oriented function set:

```python
PyObject *res;
char *buf = PyMem_New(char, BUFSIZ); /* for I/O */

if (buf == NULL)
    return PyErr_NoMemory();
/* ...Do some I/O operation involving buf... */
res = PyBytes_FromString(buf);
PyMem_Del(buf); /* allocated with PyMem_New */
return res;
```

Note that in the two examples above, the buffer is always manipulated via functions belonging to the same set. Indeed, it is required to use the same memory API family for a given memory block, so that the risk of mixing different allocators is reduced to a minimum. The following code sequence contains two errors, one of which is labeled as *fatal* because it mixes two different allocators operating on different heaps.
char *buf1 = PyMem_New(char, BUFSIZ);
char *buf2 = (char *) malloc(BUFSIZ);
char *buf3 = (char *) PyMem_Malloc(BUFSIZ);
...
PyMem_Del(buf3);  /* Wrong -- should be PyMem_Free() */
free(buf2);      /* Right -- allocated via malloc() */
free(buf1);      /* Fatal -- should be PyMem_Del() */

In addition to the functions aimed at handling raw memory blocks from the Python heap, objects in Python are allocated and released with PyObject_New(), PyObject_NewVar() and PyObject_Del().

These will be explained in the next chapter on defining and implementing new object types in C.
Object Implementation Support

This chapter describes the functions, types, and macros used when defining new object types.

- Allocating Objects on the Heap
- Common Object Structures
- Type Objects
- Number Object Structures
- Mapping Object Structures
- Sequence Object Structures
- Buffer Object Structures
- Supporting Cyclic Garbage Collection
Allocating Objects on the Heap

PyObject* _PyObject_New(PyTypeObject *type)

PyVarObject* _PyObject_NewVar(PyTypeObject *type, Py_ssize_t size)

PyObject* PyObject_Init(PyObject *op, PyTypeObject *type)

Return value: Borrowed reference.
Initialize a newly-allocated object op with its type and initial reference. Returns the initialized object. If type indicates that the object participates in the cyclic garbage detector, it is added to the detector’s set of observed objects. Other fields of the object are not affected.

PyVarObject* PyObject_InitVar(PyVarObject *op, PyTypeObject *type, Py_ssize_t size)

Return value: Borrowed reference.
This does everything PyObject_Init() does, and also initializes the length information for a variable-size object.

TYPE* PyObject_New(TYPE, PyTypeObject *type)

Allocate a new Python object using the C structure type TYPE and the Python type object type. Fields not defined by the Python object header are not initialized; the object’s reference count will be one. The size of the memory allocation is determined from the tp_basicsize field of the type object.
TYPE* PyObject_NewVar(TYPE, PyTypeObject *type, Py_ssize_t size)

Allocate a new Python object using the C structure type TYPE and the Python type object type. Fields not defined by the Python object header are not initialized. The allocated memory allows for the TYPE structure plus size fields of the size given by the tp_itemsize field of type. This is useful for implementing objects like tuples, which are able to determine their size at construction time. Embedding the array of fields into the same allocation decreases the number of allocations, improving the memory management efficiency.

void PyObject_Del(PyObject *op)
Releases memory allocated to an object using PyObject_New() or PyObject_NewVar(). This is normally called from the tp_dealloc handler specified in the object’s type. The fields of the object should not be accessed after this call as the memory is no longer a valid Python object.

PyObject _Py_NoneStruct
Object which is visible in Python as None. This should only be accessed using the Py_None macro, which evaluates to a pointer to this object.

See also:
PyModule_Create()
To allocate and create extension modules.
Common Object Structures

There are a large number of structures which are used in the definition of object types for Python. This section describes these structures and how they are used.

All Python objects ultimately share a small number of fields at the beginning of the object’s representation in memory. These are represented by the `PyObject` and `PyVarObject` types, which are defined, in turn, by the expansions of some macros also used, whether directly or indirectly, in the definition of all other Python objects.

**PyObject**

All object types are extensions of this type. This is a type which contains the information Python needs to treat a pointer to an object as an object. In a normal “release” build, it contains only the object’s reference count and a pointer to the corresponding type object. It corresponds to the fields defined by the expansion of the `PyObject_HEAD` macro.

**PyVarObject**

This is an extension of `PyObject` that adds the `ob_size` field. This is only used for objects that have some notion of `length`. This type does not often appear in the Python/C API. It corresponds to the fields defined by the expansion of the `PyObject_VAR_HEAD` macro.

These macros are used in the definition of `PyObject` and `PyVarObject`:

**PyObject_HEAD**
This is a macro which expands to the declarations of the fields of the `PyObject` type; it is used when declaring new types which represent objects without a varying length. The specific fields it expands to depend on the definition of `Py_TRACE_REFS`. By default, that macro is not defined, and `PyObject_HEAD` expands to:

```c
Py_ssize_t ob_refcnt;
PyTypeObject *ob_type;
```

When `Py_TRACE_REFS` is defined, it expands to:

```c
PyObject *__ob_next, *__ob_prev;
Py_ssize_t ob_refcnt;
PyTypeObject *ob_type;
```

### `PyObject_VAR_HEAD`

This is a macro which expands to the declarations of the fields of the `PyVarObject` type; it is used when declaring new types which represent objects with a length that varies from instance to instance. This macro always expands to:

```c
PyObject_HEAD
Py_ssize_t ob_size;
```

Note that `PyObject_HEAD` is part of the expansion, and that its own expansion varies depending on the definition of `Py_TRACE_REFS`.

### `PyObject_HEAD_INIT`(type)

This is a macro which expands to initialization values for a new `PyObject` type. This macro expands to:
_PyObject_EXTRA_INIT
1, type,

PyVarObject_HEAD_INIT(type, size)

This is a macro which expands to initialization values for a new PyVarObject type, including the ob_size field. This macro expands to:

_PyObject_EXTRA_INIT
1, type, size,

PyCFunction

Type of the functions used to implement most Python callables in C. Functions of this type take two PyObject* parameters and return one such value. If the return value is NULL, an exception shall have been set. If not NULL, the return value is interpreted as the return value of the function as exposed in Python. The function must return a new reference.

PyCFunctionWithKeywords

Type of the functions used to implement Python callables in C that take keyword arguments: they take three PyObject* parameters and return one such value. See PyCFunction above for the meaning of the return value.

PyMethodDef

Structure used to describe a method of an extension type. This structure has four fields:

<table>
<thead>
<tr>
<th>Field</th>
<th>C Type</th>
<th>Meaning</th>
</tr>
</thead>
<tbody>
<tr>
<td>ml_name</td>
<td>char *</td>
<td>name of the method</td>
</tr>
<tr>
<td>ml_meth</td>
<td>PyCFunction</td>
<td>pointer to the C</td>
</tr>
</tbody>
</table>
The `ml_meth` is a C function pointer. The functions may be of different types, but they always return `PyObject*`. If the function is not of the `PyCFunction`, the compiler will require a cast in the method table. Even though `PyCFunction` defines the first parameter as `PyObject*`, it is common that the method implementation uses a the specific C type of the `self` object.

The `ml_flags` field is a bitfield which can include the following flags. The individual flags indicate either a calling convention or a binding convention. Of the calling convention flags, only `METH_VARARGS` and `METH_KEYWORDS` can be combined (but note that `METH_KEYWORDS` alone is equivalent to `METH_VARARGS | METH_KEYWORDS`). Any of the calling convention flags can be combined with a binding flag.

**METH_VARARGS**

This is the typical calling convention, where the methods have the type `PyCFunction`. The function expects two `PyObject*` values. The first one is the `self` object for methods; for module functions, it is the module object. The second parameter (often called `args`) is a tuple object representing all arguments. This parameter is typically processed using `PyArg_ParseTuple()` or `PyArg_UnpackTuple()`.

**METH_KEYWORDS**

Methods with these flags must be of type

<table>
<thead>
<tr>
<th>ml_flags</th>
<th>int</th>
<th>flag bits indicating how the call should be constructed</th>
</tr>
</thead>
<tbody>
<tr>
<td>ml_doc</td>
<td>char *</td>
<td>points to the contents of the docstring</td>
</tr>
</tbody>
</table>
**PyCFunctionWithKeywords**. The function expects three parameters: `self`, `args`, and a dictionary of all the keyword arguments. The flag is typically combined with `METH_VARARGS`, and the parameters are typically processed using `PyArg_ParseTupleAndKeywords()`.

**METH_NOARGS**
Methods without parameters don’t need to check whether arguments are given if they are listed with the `METH_NOARGS` flag. They need to be of type `PyCFunction`. The first parameter is typically named `self` and will hold a reference to the module or object instance. In all cases the second parameter will be `NULL`.

**METH_O**
Methods with a single object argument can be listed with the `METH_O` flag, instead of invoking `PyArg_ParseTuple()` with a "0" argument. They have the type `PyCFunction`, with the `self` parameter, and a `PyObject*` parameter representing the single argument.

These two constants are not used to indicate the calling convention but the binding when use with methods of classes. These may not be used for functions defined for modules. At most one of these flags may be set for any given method.

**METH_CLASS**
The method will be passed the type object as the first parameter rather than an instance of the type. This is used to create class methods, similar to what is created when using the `classmethod()` built-in function.

**METH_STATIC**
The method will be passed *NULL* as the first parameter rather than an instance of the type. This is used to create *static methods*, similar to what is created when using the *staticmethod()* built-in function.

One other constant controls whether a method is loaded in place of another definition with the same method name.

**METH_COEXIST**

The method will be loaded in place of existing definitions. Without *METH_COEXIST*, the default is to skip repeated definitions. Since slot wrappers are loaded before the method table, the existence of a *sq_contains* slot, for example, would generate a wrapped method named *__contains__()* and preclude the loading of a corresponding *PyCFunction* with the same name. With the flag defined, the *PyCFunction* will be loaded in place of the wrapper object and will co-exist with the slot. This is helpful because calls to *PyCFunctions* are optimized more than wrapper object calls.

**PyMemberDef**

Structure which describes an attribute of a type which corresponds to a C struct member. Its fields are:

<table>
<thead>
<tr>
<th>Field</th>
<th>C Type</th>
<th>Meaning</th>
</tr>
</thead>
<tbody>
<tr>
<td>name</td>
<td>char *</td>
<td>name of the member</td>
</tr>
<tr>
<td>type</td>
<td>int</td>
<td>the type of the member in the C struct</td>
</tr>
<tr>
<td>offset</td>
<td>Py_ssize_t</td>
<td>the offset in bytes that the member is located on the type's object struct</td>
</tr>
<tr>
<td>flags</td>
<td>int</td>
<td>flag bits indicating if the field should be read-only or writable</td>
</tr>
<tr>
<td>Macro name</td>
<td>C type</td>
<td></td>
</tr>
<tr>
<td>------------------</td>
<td>----------------</td>
<td></td>
</tr>
<tr>
<td>T_SHORT</td>
<td>short</td>
<td></td>
</tr>
<tr>
<td>T_INT</td>
<td>int</td>
<td></td>
</tr>
<tr>
<td>T_LONG</td>
<td>long</td>
<td></td>
</tr>
<tr>
<td>T_FLOAT</td>
<td>float</td>
<td></td>
</tr>
<tr>
<td>T_DOUBLE</td>
<td>double</td>
<td></td>
</tr>
<tr>
<td>T_STRING</td>
<td>char *</td>
<td></td>
</tr>
<tr>
<td>T_OBJECT</td>
<td>PyObject *</td>
<td></td>
</tr>
<tr>
<td>T_OBJECT_EX</td>
<td>PyObject *</td>
<td></td>
</tr>
<tr>
<td>T_CHAR</td>
<td>char</td>
<td></td>
</tr>
<tr>
<td>T_BYTE</td>
<td>char</td>
<td></td>
</tr>
<tr>
<td>T_UBYTE</td>
<td>unsigned char</td>
<td></td>
</tr>
<tr>
<td>T_UINT</td>
<td>unsigned int</td>
<td></td>
</tr>
<tr>
<td>T_USHORT</td>
<td>unsigned short</td>
<td></td>
</tr>
<tr>
<td>T_UULONG</td>
<td>unsigned long</td>
<td></td>
</tr>
<tr>
<td>T_BOOL</td>
<td>char</td>
<td></td>
</tr>
<tr>
<td>T_LONGLONG</td>
<td>long long</td>
<td></td>
</tr>
<tr>
<td>T_ULONGLONG</td>
<td>unsigned long long</td>
<td></td>
</tr>
<tr>
<td>T_PYSSIZET</td>
<td>Py_ssize_t</td>
<td></td>
</tr>
</tbody>
</table>

_type_ can be one of many _T_ macros corresponding to various C types. When the member is accessed in Python, it will be converted to the equivalent Python type.

_T_OBJECT_ and _T_OBJECT_EX_ differ in that _T_OBJECT_ returns
None if the member is NULL and T_OBJECT_EX raises an `AttributeError`. Try to use T_OBJECT_EX over T_OBJECT because T_OBJECT_EX handles use of the `del` statement on that attribute more correctly than T_OBJECT.

Flags can be 0 for write and read access or READONLY for read-only access. Using T_STRING for `type` implies READONLY. Only T_OBJECT and T_OBJECT_EX members can be deleted. (They are set to NULL).
Type Objects

Perhaps one of the most important structures of the Python object system is the structure that defines a new type: the `PyTypeObject` structure. Type objects can be handled using any of the `PyObject_*` or `PyType_*` functions, but do not offer much that's interesting to most Python applications. These objects are fundamental to how objects behave, so they are very important to the interpreter itself and to any extension module that implements new types.

Type objects are fairly large compared to most of the standard types. The reason for the size is that each type object stores a large number of values, mostly C function pointers, each of which implements a small part of the type's functionality. The fields of the type object are examined in detail in this section. The fields will be described in the order in which they occur in the structure.

Typedefs: unaryfunc, binaryfunc, ternaryfunc, inquiry, intargfunc, intintargfunc, intobjargproc, intintobjargproc, objobjargproc, destructor, freefunc, printfunc, getattrfunc, getattrofunc, setattrfunc, setattrofunc, reprfunc, hashfunc

The structure definition for `PyTypeObject` can be found in `Include/object.h`. For convenience of reference, this repeats the definition found there:

```c
typedef struct _typeobject {
    PyObject_VAR_HEAD
    char *tp_name; /* For printing, in format "<module>.<name>" */
    int tp_basicsize, tp_itemsize; /* For allocation */
    /* Methods to implement standard operations */
```
destructor tp_dealloc;
printfunc tp_print;
getattrfunc tp_getattr;
setattrfunc tp_setattr;
void *tp_reserved;
reprfunc tp_repr;

/* Method suites for standard classes */

PyNumberMethods *tp_as_number;
PySequenceMethods *tp_as_sequence;
PyMappingMethods *tp_as_mapping;

/* More standard operations (here for binary compatibility) */

hashfunc tp_hash;
ternaryfunc tp_call;
reprfunc tp_str;
getattrofunc tp_getattro;
setattrofunc tp_setattro;

/* Functions to access object as input/output buffer */

PyBufferProcs *tp_as_buffer;

/* Flags to define presence of optional/expanded features */

long tp_flags;

char *tp_doc; /* Documentation string */

/* call function for all accessible objects */

traverseproc tp_traverse;

/* delete references to contained objects */

inquiry tp_clear;

/* rich comparisons */
richcmpfunc tp_richcompare;

/* weak reference enabler */
long tp_weaklistoffset;

/* Iterators */
getiterfunc tp_iter;
iternextfunc tp_iternext;

/* Attribute descriptor and subclassing stuff */
struct PyMethodDef *tp_methods;
struct PyMemberDef *tp_members;
struct PyGetSetDef *tp_getset;
struct _typeobject *tp_base;
PyObject *tp_dict;
descrgetfunc tp_descr_get;
descrsetfunc tp_descr_set;
long tp_dictoffset;
initproc tp_init;
allocfunc tp_alloc;
newfunc tp_new;
freefunc tp_free; /* Low-level free-memory routine */
inquiry tp_is_gc; /* For PyObject_IS_GC */
PyObject *tp_bases;
PyObject *tp_mro; /* method resolution order */
PyObject *tp_cache;
PyObject *tp_subclasses;
PyObject *tp_weaklist;

destructor tp_del;

/* Type attribute cache version tag. Added in version 2.6 */
unsigned int tp_version_tag;

destructor tp_finalize;

} PyTypeObject;
The type object structure extends the `PyVarObject` structure. The `ob_size` field is used for dynamic types (created by `type_new()`, usually called from a class statement). Note that `PyType_Type` (the metatype) initializes `tp_itemsize`, which means that its instances (i.e. type objects) must have the `ob_size` field.

`PyObject* PyObject._ob_next`  
`PyObject* PyObject._ob_prev`  
These fields are only present when the macro `Py_TRACE_REFS` is defined. Their initialization to `NULL` is taken care of by the `PyObject_HEAD_INIT` macro. For statically allocated objects, these fields always remain `NULL`. For dynamically allocated objects, these two fields are used to link the object into a doubly-linked list of *all* live objects on the heap. This could be used for various debugging purposes; currently the only use is to print the objects that are still alive at the end of a run when the environment variable `PYTHONDUMPREFS` is set.

These fields are not inherited by subtypes.

`Py_ssize_t PyObject.ob_refcnt`  
This is the type object's reference count, initialized to `1` by the `PyObject_HEAD_INIT` macro. Note that for statically allocated type objects, the type's instances (objects whose `ob_type` points back to the type) do *not* count as references. But for dynamically allocated type objects, the instances *do* count as references.

This field is not inherited by subtypes.

`PyTypeObject* PyObject.ob_type`  
This is the type's type, in other words its metatype. It is initialized
by the argument to the `PyObject_HEAD_INIT` macro, and its value should normally be `&PyType_Type`. However, for dynamically loadable extension modules that must be usable on Windows (at least), the compiler complains that this is not a valid initializer. Therefore, the convention is to pass `NULL` to the `PyObject_HEAD_INIT` macro and to initialize this field explicitly at the start of the module’s initialization function, before doing anything else. This is typically done like this:

```c
Foo_Type.ob_type = &PyType_Type;
```

This should be done before any instances of the type are created. `PyType_Ready()` checks if `ob_type` is `NULL`, and if so, initializes it to the `ob_type` field of the base class. `PyType_Ready()` will not change this field if it is non-zero.

This field is inherited by subtypes.

**Py_ssize_t `PyVarObject.ob_size`**

For statically allocated type objects, this should be initialized to zero. For dynamically allocated type objects, this field has a special internal meaning.

This field is not inherited by subtypes.

**char* `PyTypeObject.tp_name`**

Pointer to a NULL-terminated string containing the name of the type. For types that are accessible as module globals, the string should be the full module name, followed by a dot, followed by the type name; for built-in types, it should be just the type name. If the module is a submodule of a package, the full package name is part of the full module name. For example, a type named `T` defined in
module M in subpackage Q in package P should have the \texttt{tp\_name} initializer \texttt{"P.Q.M.T"}.

For dynamically allocated type objects, this should just be the type name, and the module name explicitly stored in the type dict as the value for key \texttt{"\_\_module\_\_"}.

For statically allocated type objects, the \texttt{tp\_name} field should contain a dot. Everything before the last dot is made accessible as the \texttt{\_\_module\_\_} attribute, and everything after the last dot is made accessible as the \texttt{\_\_name\_\_} attribute.

If no dot is present, the entire \texttt{tp\_name} field is made accessible as the \texttt{\_\_name\_\_} attribute, and the \texttt{\_\_module\_\_} attribute is undefined (unless explicitly set in the dictionary, as explained above). This means your type will be impossible to pickle.

This field is not inherited by subtypes.

\begin{itemize}
\item \texttt{Py\_ssize\_t \texttt{PyTypeObject\_tp\_basicsize}}
\item \texttt{Py\_ssize\_t \texttt{PyTypeObject\_tp\_itemsize}}
\end{itemize}

These fields allow calculating the size in bytes of instances of the type.

There are two kinds of types: types with fixed-length instances have a zero \texttt{tp\_itemsize} field, types with variable-length instances have a non-zero \texttt{tp\_itemsize} field. For a type with fixed-length instances, all instances have the same size, given in \texttt{tp\_basicsize}.

For a type with variable-length instances, the instances must have an \texttt{ob\_size} field, and the instance size is \texttt{tp\_basicsize} plus N times \texttt{tp\_itemsize}, where N is the “length” of the object. The
value of N is typically stored in the instance's ob_size field. There are exceptions: for example, ints use a negative ob_size to indicate a negative number, and N is abs(ob_size) there. Also, the presence of an ob_size field in the instance layout doesn't mean that the instance structure is variable-length (for example, the structure for the list type has fixed-length instances, yet those instances have a meaningful ob_size field).

The basic size includes the fields in the instance declared by the macro PyObject_HEAD or PyObject_VAR_HEAD (whichever is used to declare the instance struct) and this in turn includes the _ob_prev and _ob_next fields if they are present. This means that the only correct way to get an initializer for the tp_basicsize is to use the sizeof operator on the struct used to declare the instance layout. The basic size does not include the GC header size.

These fields are inherited separately by subtypes. If the base type has a non-zero tp_itemsize, it is generally not safe to set tp_itemsize to a different non-zero value in a subtype (though this depends on the implementation of the base type).

A note about alignment: if the variable items require a particular alignment, this should be taken care of by the value of tp_basicsize. Example: suppose a type implements an array of double. tp_itemsize is sizeof(double). It is the programmer's responsibility that tp_basicsize is a multiple of sizeof(double) (assuming this is the alignment requirement for double).

destructor PyTypeObject.tp_dealloc

A pointer to the instance destructor function. This function must be
defined unless the type guarantees that its instances will never be deallocated (as is the case for the singletons `None` and `Ellipsis`).

The destructor function is called by the `Py_DECREF()` and `Py_XDECREF()` macros when the new reference count is zero. At this point, the instance is still in existence, but there are no references to it. The destructor function should free all references which the instance owns, free all memory buffers owned by the instance (using the freeing function corresponding to the allocation function used to allocate the buffer), and finally (as its last action) call the type’s `tp_free` function. If the type is not subtypable (doesn’t have the `Py_TPFLAGS_BASETYPE` flag bit set), it is permissible to call the object deallocator directly instead of via `tp_free`. The object deallocator should be the one used to allocate the instance; this is normally `PyObject_Del()` if the instance was allocated using `PyObject_New()` or `PyObject_VarNew()`, or `PyObject_GC_Del()` if the instance was allocated using `PyObject_GC_New()` or `PyObject_GC_NewVar()`.

This field is inherited by subtypes.

`printfunc` **PyTypeObject.tp_print**

An optional pointer to the instance print function.

The print function is only called when the instance is printed to a real file; when it is printed to a pseudo-file (like a `io.StringIO` instance), the instance’s `tp_repr` or `tp_str` function is called to convert it to a string. These are also called when the type’s `tp_print` field is `NULL`. A type should never implement `tp_print` in a way that produces different output than `tp_repr`
or \texttt{tp\_str} would.

The print function is called with the same signature as
\texttt{PyObject\_Print()}:
\begin{verbatim}
int tp_print(PyObject *self, FILE *file, int flags).
\end{verbatim}
The \textit{self} argument is the instance to be printed. The \textit{file} argument is the stdio file to which it is to be printed. The \textit{flags} argument is composed of flag bits. The only flag bit currently defined is \texttt{Py\_PRINT\_RAW}. When the \texttt{Py\_PRINT\_RAW} flag bit is set, the instance should be printed the same way as \texttt{tp\_str} would format it; when the \texttt{Py\_PRINT\_RAW} flag bit is clear, the instance should be printed the same way as \texttt{tp\_repr} would format it. It should return \texttt{-1} and set an exception condition when an error occurs.

It is possible that the \texttt{tp\_print} field will be deprecated. In any case, it is recommended not to define \texttt{tp\_print}, but instead to rely on \texttt{tp\_repr} and \texttt{tp\_str} for printing.

This field is inherited by subtypes.

\textbf{getattrfunc} \texttt{PyTypeObject\_tp\_getattr}

An optional pointer to the get-attribute-string function.

This field is deprecated. When it is defined, it should point to a function that acts the same as the \texttt{tp\_getattr} function, but taking a C string instead of a Python string object to give the attribute name. The signature is the same as for \texttt{PyObject\_GetAttrString()}.

This field is inherited by subtypes together with \texttt{tp\_getattr}: a subtype inherits both \texttt{tp\_getattr} and \texttt{tp\_getattr} from its base type when the subtype's \texttt{tp\_getattr} and \texttt{tp\_getattr}
are both *NULL*.

**setattrfunc PyTypeObject.tp_setattr**

An optional pointer to the set-attribute-string function.

This field is deprecated. When it is defined, it should point to a function that acts the same as the *tp_setattr*ro function, but taking a C string instead of a Python string object to give the attribute name. The signature is the same as for `PyObject_SetAttrString()`.

This field is inherited by subtypes together with *tp_setattr*ro: a subtype inherits both *tp_setattr* and *tp_setattr*ro from its base type when the subtype's *tp_setattr* and *tp_setattr*ro are both *NULL*.

**void* PyTypeObject.tp_reserved**

Reserved slot, formerly known as *tp_compare*.

**reprfunc PyTypeObject.tp_repr**

An optional pointer to a function that implements the built-in function *repr()*.

The signature is the same as for `PyObject_Repr()`; it must return a string or a Unicode object. Ideally, this function should return a string that, when passed to *eval()*, given a suitable environment, returns an object with the same value. If this is not feasible, it should return a string starting with '<' and ending with '>' from which both the type and the value of the object can be deduced.

When this field is not set, a string of the form `<%s object at %p>` is returned, where %s is replaced by the type name, and %p
by the object’s memory address.

This field is inherited by subtypes.

**PyNumberMethods**\* \textit{tp\_as\_number}

Pointer to an additional structure that contains fields relevant only to objects which implement the number protocol. These fields are documented in \textit{Number Object Structures}.

The \textit{tp\_as\_number} field is not inherited, but the contained fields are inherited individually.

**PySequenceMethods**\* \textit{tp\_as\_sequence}

Pointer to an additional structure that contains fields relevant only to objects which implement the sequence protocol. These fields are documented in \textit{Sequence Object Structures}.

The \textit{tp\_as\_sequence} field is not inherited, but the contained fields are inherited individually.

**PyMappingMethods**\* \textit{tp\_as\_mapping}

Pointer to an additional structure that contains fields relevant only to objects which implement the mapping protocol. These fields are documented in \textit{Mapping Object Structures}.

The \textit{tp\_as\_mapping} field is not inherited, but the contained fields are inherited individually.

\texttt{hashfunc} \texttt{PyTypeObject.tp\_hash}

An optional pointer to a function that implements the built-in function \texttt{hash()}. The signature is the same as for \texttt{PyObject\_Hash()}; it must return a value of the type \texttt{Py\_hash\_t}. The value \texttt{-1} should not be
returned as a normal return value; when an error occurs during the computation of the hash value, the function should set an exception and return -1.

This field can be set explicitly to `PyObject_HashNotImplemented()` to block inheritance of the hash method from a parent type. This is interpreted as the equivalent of `__hash__ = None` at the Python level, causing `isinstance(o, collections.Hashable)` to correctly return False. Note that the converse is also true - setting `__hash__ = None` on a class at the Python level will result in the `tp_hash` slot being set to `PyObject_HashNotImplemented()`.

When this field is not set, an attempt to take the hash of the object raises `TypeError`.

This field is inherited by subtypes together with `tp_richcompare`: a subtype inherits both of `tp_richcompare` and `tp_hash`, when the subtype’s `tp_richcompare` and `tp_hash` are both `NULL`.

ternaryfunc `PyObject.tp_call`
An optional pointer to a function that implements calling the object. This should be `NULL` if the object is not callable. The signature is the same as for `PyObject_Call()`.

This field is inherited by subtypes.

reprfunc `PyObject.tp_str`
An optional pointer to a function that implements the built-in operation `str()`. (Note that `str` is a type now, and `str()` calls the constructor for that type. This constructor calls `PyObject_Str()` to do the actual work, and `PyObject_Str()`
will call this handler.)

The signature is the same as for `PyObject_Str()`. It must return a string or a Unicode object. This function should return a “friendly” string representation of the object, as this is the representation that will be used, among other things, by the `print()` function.

When this field is not set, `PyObject_Repr()` is called to return a string representation.

This field is inherited by subtypes.

**getattrofunc** `PyTypeObject.tp_getattro`

An optional pointer to the get-attribute function.

The signature is the same as for `PyObject_GetAttr()`. It is usually convenient to set this field to `PyObject_GenericGetAttr()`, which implements the normal way of looking for object attributes.

This field is inherited by subtypes together with `tp_getattr`: a subtype inherits both `tp_getattr` and `tp_getattro` from its base type when the subtype's `tp_getattr` and `tp_getattro` are both `NULL`.

**setattrofunc** `PyTypeObject.tp_setattro`

An optional pointer to the set-attribute function.

The signature is the same as for `PyObject_SetAttr()`. It is usually convenient to set this field to `PyObject_GenericSetAttr()`, which implements the normal way of setting object attributes.
This field is inherited by subtypes together with `tp_setattr`: a subtype inherits both `tp_setattr` and `tp_setattro` from its base type when the subtype's `tp_setattr` and `tp_setattro` are both `NULL`.

**PyBufferProcs** * `PyTypeObject.tp_as_buffer`

Pointer to an additional structure that contains fields relevant only to objects which implement the buffer interface. These fields are documented in *Buffer Object Structures*.

The `tp_as_buffer` field is not inherited, but the contained fields are inherited individually.

**long** `PyTypeObject.tp_flags`

This field is a bit mask of various flags. Some flags indicate variant semantics for certain situations; others are used to indicate that certain fields in the type object (or in the extension structures referenced via `tp_as_number`, `tp_as_sequence`, `tp_as_mapping`, and `tp_as_buffer`) that were historically not always present are valid; if such a flag bit is clear, the type fields it guards must not be accessed and must be considered to have a zero or `NULL` value instead.

Inheritance of this field is complicated. Most flag bits are inherited individually, i.e. if the base type has a flag bit set, the subtype inherits this flag bit. The flag bits that pertain to extension structures are strictly inherited if the extension structure is inherited, i.e. the base type's value of the flag bit is copied into the subtype together with a pointer to the extension structure. The `Py_TPFLAGS_HAVE_GC` flag bit is inherited together with the `tp_traverse` and `tp_clear` fields, i.e. if the `Py_TPFLAGS_HAVE_GC` flag bit is clear in the subtype and the
tp_traverse and tp_clear fields in the subtype exist and have NULL values.

The following bit masks are currently defined; these can be ORed together using the | operator to form the value of the tp_flags field. The macro PyType_HasFeature() takes a type and a flags value, tp and f, and checks whether tp->tp_flags & f is non-zero.

**Py_TPFLAGS_HEAPTYPE**
This bit is set when the type object itself is allocated on the heap. In this case, the ob_type field of its instances is considered a reference to the type, and the type object is INCREF'ed when a new instance is created, and DECREF'ed when an instance is destroyed (this does not apply to instances of subtypes; only the type referenced by the instance's ob_type gets INCREF'ed or DECREF'ed).

**Py_TPFLAGS_BASETYPE**
This bit is set when the type can be used as the base type of another type. If this bit is clear, the type cannot be subtyped (similar to a “final” class in Java).

**Py_TPFLAGS_READY**
This bit is set when the type object has been fully initialized by PyType_Ready().

**Py_TPFLAGS_READYING**
This bit is set while PyType_Ready() is in the process of initializing the type object.

**Py_TPFLAGS_HAVE_GC**
This bit is set when the object supports garbage collection. If
this bit is set, instances must be created using `PyObject_GC_New()` and destroyed using `PyObject_GC_Del()`. More information in section *Supporting Cyclic Garbage Collection*. This bit also implies that the GC-related fields `tp_traverse` and `tp_clear` are present in the type object.

**Py_TPFLAGS_DEFAULT**

This is a bitmask of all the bits that pertain to the existence of certain fields in the type object and its extension structures. Currently, it includes the following bits:

- `Py_TPFLAGS_HAVE_STACKLESS_EXTENSION`
- `Py_TPFLAGS_HAVE_VERSION_TAG`
- `Py_TPFLAGS_HAVE_FINALIZE`

This bit is set when the `tp_finalize` slot is present in the type structure.

*New in version 3.4.*

**char* PyTypeObject.tp_doc**

An optional pointer to a NUL-terminated C string giving the docstring for this type object. This is exposed as the `__doc__` attribute on the type and instances of the type.

This field is *not* inherited by subtypes.

**traverseproc PyTypeObject.tp_traverse**

An optional pointer to a traversal function for the garbage collector. This is only used if the `Py_TPFLAGS_HAVE_GC` flag bit is set. More information about Python’s garbage collection scheme can be found in section *Supporting Cyclic Garbage Collection*. 
The `tp_traverse` pointer is used by the garbage collector to detect reference cycles. A typical implementation of a `tp_traverse` function simply calls `Py_VISIT()` on each of the instance's members that are Python objects. For example, this is function `local_traverse()` from the `_thread` extension module:

```c
static int
local_traverse(localobject *self, visitproc visit
{
    Py_VISIT(self->args);
    Py_VISIT(self->kw);
    Py_VISIT(self->dict);
    return 0;
}
```

Note that `Py_VISIT()` is called only on those members that can participate in reference cycles. Although there is also a `self->key` member, it can only be `NULL` or a Python string and therefore cannot be part of a reference cycle.

On the other hand, even if you know a member can never be part of a cycle, as a debugging aid you may want to visit it anyway just so the `gc` module's `get_referents()` function will include it.

Note that `Py_VISIT()` requires the `visit` and `arg` parameters to `local_traverse()` to have these specific names; don’t name them just anything.

This field is inherited by subtypes together with `tp_clear` and the `Py_TPFLAGS_HAVE_GC` flag bit: the flag bit, `tp_traverse`, and `tp_clear` are all inherited from the base type if they are all zero in
the subtype.

**inquiry** `PyTypeObject.tp_clear`

An optional pointer to a clear function for the garbage collector. This is only used if the `Py_TPFLAGS_HAVE_GC` flag bit is set.

The `tp_clear` member function is used to break reference cycles in cyclic garbage detected by the garbage collector. Taken together, all `tp_clear` functions in the system must combine to break all reference cycles. This is subtle, and if in any doubt supply a `tp_clear` function. For example, the tuple type does not implement a `tp_clear` function, because it's possible to prove that no reference cycle can be composed entirely of tuples. Therefore the `tp_clear` functions of other types must be sufficient to break any cycle containing a tuple. This isn't immediately obvious, and there's rarely a good reason to avoid implementing `tp_clear`.

Implementations of `tp_clear` should drop the instance's references to those of its members that may be Python objects, and set its pointers to those members to `NULL`, as in the following example:

```c
static int
local_clear(localobject *self)
{
    Py_CLEAR(self->key);
    Py_CLEAR(self->args);
    Py_CLEAR(self->kw);
    Py_CLEAR(self->dict);
    return 0;
}
```
The `Py_CLEAR()` macro should be used, because clearing references is delicate: the reference to the contained object must not be decremented until after the pointer to the contained object is set to `NULL`. This is because decrementing the reference count may cause the contained object to become trash, triggering a chain of reclamation activity that may include invoking arbitrary Python code (due to finalizers, or weakref callbacks, associated with the contained object). If it’s possible for such code to reference `self` again, it’s important that the pointer to the contained object be `NULL` at that time, so that `self` knows the contained object can no longer be used. The `Py_CLEAR()` macro performs the operations in a safe order.

Because the goal of `tp_clear` functions is to break reference cycles, it’s not necessary to clear contained objects like Python strings or Python integers, which can’t participate in reference cycles. On the other hand, it may be convenient to clear all contained Python objects, and write the type’s `tp_dealloc` function to invoke `tp_clear`.

More information about Python’s garbage collection scheme can be found in section *Supporting Cyclic Garbage Collection*.

This field is inherited by subtypes together with `tp_traverse` and the `Py_TPFLAGS_HAVE_GC` flag bit: the flag bit, `tp_traverse`, and `tp_clear` are all inherited from the base type if they are all zero in the subtype.

`richcmpfunc PyTypeObject.tp_richcompare`

An optional pointer to the rich comparison function, whose signature is `PyObject *tp_richcompare(PyObject *a, PyObject *b, int op)`.
The function should return the result of the comparison (usually `Py_True` or `Py_False`). If the comparison is undefined, it must return `Py_NotImplemented`, if another error occurred it must return `NULL` and set an exception condition.

**Note:** If you want to implement a type for which only a limited set of comparisons makes sense (e.g. `==` and `!=`, but not `<` and friends), directly raise `TypeError` in the rich comparison function.

This field is inherited by subtypes together with `tp_hash`: a subtype inherits `tp_richcompare` and `tp_hash` when the subtype's `tp_richcompare` and `tp_hash` are both `NULL`.

The following constants are defined to be used as the third argument for `tp_richcompare` and for `PyObject_RichCompare()`:

<table>
<thead>
<tr>
<th>Constant</th>
<th>Comparison</th>
</tr>
</thead>
<tbody>
<tr>
<td><code>Py_LT</code></td>
<td><code>&lt;</code></td>
</tr>
<tr>
<td><code>Py_LE</code></td>
<td><code>&lt;=</code></td>
</tr>
<tr>
<td><code>Py_EQ</code></td>
<td><code>==</code></td>
</tr>
<tr>
<td><code>Py_NE</code></td>
<td><code>!=</code></td>
</tr>
<tr>
<td><code>Py_GT</code></td>
<td><code>&gt;</code></td>
</tr>
<tr>
<td><code>Py_GE</code></td>
<td><code>&gt;=</code></td>
</tr>
</tbody>
</table>

`long PyTypeObject.tp_weaklistoffset`

If the instances of this type are weakly referenceable, this field is greater than zero and contains the offset in the instance structure of the weak reference list head (ignoring the GC header, if
present); this offset is used by PyObject_ClearWeakRefs() and the PyWeakref_*() functions. The instance structure needs to include a field of type PyObject* which is initialized to NULL.

Do not confuse this field with tp_weaklist; that is the list head for weak references to the type object itself.

This field is inherited by subtypes, but see the rules listed below. A subtype may override this offset; this means that the subtype uses a different weak reference list head than the base type. Since the list head is always found via tp_weaklistoffset, this should not be a problem.

When a type defined by a class statement has no __slots__ declaration, and none of its base types are weakly referenceable, the type is made weakly referenceable by adding a weak reference list head slot to the instance layout and setting the tp_weaklistoffset of that slot's offset.

When a type's __slots__ declaration contains a slot named __weakref__, that slot becomes the weak reference list head for instances of the type, and the slot's offset is stored in the type's tp_weaklistoffset.

When a type's __slots__ declaration does not contain a slot named __weakref__, the type inherits its tp_weaklistoffset from its base type.

getiterfunc PyTypeObject.tp_iter
An optional pointer to a function that returns an iterator for the object. Its presence normally signals that the instances of this type are iterable (although sequences may be iterable without this
This function has the same signature as `PyObject_GetIter()`.

This field is inherited by subtypes.

`iternextfunc PyTypeObject.tp_iternext`

An optional pointer to a function that returns the next item in an iterator. When the iterator is exhausted, it must return `NULL`; a `StopIteration` exception may or may not be set. When another error occurs, it must return `NULL` too. Its presence signals that the instances of this type are iterators.

Iterator types should also define the `tp_iter` function, and that function should return the iterator instance itself (not a new iterator instance).

This function has the same signature as `PyIter_Next()`.

This field is inherited by subtypes.

`struct PyMethodDef* PyTypeObject.tp_methods`

An optional pointer to a static `NULL`-terminated array of `PyMethodDef` structures, declaring regular methods of this type.

For each entry in the array, an entry is added to the type's dictionary (see `tp_dict` below) containing a method descriptor.

This field is not inherited by subtypes (methods are inherited through a different mechanism).

`struct PyMemberDef* PyTypeObject.tp_members`

An optional pointer to a static `NULL`-terminated array of `PyMemberDef` structures, declaring regular data members (fields...
or slots) of instances of this type.

For each entry in the array, an entry is added to the type's dictionary (see `tp_dict` below) containing a member descriptor.

This field is not inherited by subtypes (members are inherited through a different mechanism).

**struct PyGetSetDef**

*PyTypeObject* `.tp_getset`

An optional pointer to a static `NULL`-terminated array of `PyGetSetDef` structures, declaring computed attributes of instances of this type.

For each entry in the array, an entry is added to the type's dictionary (see `tp_dict` below) containing a getset descriptor.

This field is not inherited by subtypes (computed attributes are inherited through a different mechanism).

Docs for `PyGetSetDef`:

```c
typedef PyObject *(*getter)(PyObject *, void *);
typedef int (*setter)(PyObject *, PyObject *, void *);
typedef struct PyGetSetDef {
    char *name;    /* attribute name */
    getter get;    /* C function to get the attribute */
    setter set;    /* C function to set the attribute */
    char *doc;    /* optional doc string */
    void *closure;    /* optional additional data for */
} PyGetSetDef;
```

*PyTypeObject* `*PyTypeObject.tp_base`

An optional pointer to a base type from which type properties are
inherited. At this level, only single inheritance is supported; multiple inheritance require dynamically creating a type object by calling the metatype.

This field is not inherited by subtypes (obviously), but it defaults to &PyBaseObject_Type (which to Python programmers is known as the type object).

PyObject* PyTypeObject.tp_dict

The type’s dictionary is stored here by PyType_Ready().

This field should normally be initialized to NULL before PyType_Ready is called; it may also be initialized to a dictionary containing initial attributes for the type. Once PyType_Ready() has initialized the type, extra attributes for the type may be added to this dictionary only if they don’t correspond to overloaded operations (like __add__()).

This field is not inherited by subtypes (though the attributes defined in here are inherited through a different mechanism).

**Warning:** It is not safe to use PyDict_SetItem() on or otherwise modify tp_dict with the dictionary C-API.

descrgetfunc PyTypeObject.tp_descr_get

An optional pointer to a “descriptor get” function.

The function signature is

```c
PyObject * tp_descr_get(PyObject *self, PyObject *, PyObject *)
```

This field is inherited by subtypes.
**descrsetfunc** PyTypeObject.tp_descr_set

An optional pointer to a “descriptor set” function.

The function signature is

```c
int tp_descr_set(PyObject *self, PyObject *obj, P
```

This field is inherited by subtypes.

**long** PyTypeObject.tp_dictoffset

If the instances of this type have a dictionary containing instance variables, this field is non-zero and contains the offset in the instances of the type of the instance variable dictionary; this offset is used by PyObject_GenericGetAttr().

Do not confuse this field with tp_dict; that is the dictionary for attributes of the type object itself.

If the value of this field is greater than zero, it specifies the offset from the start of the instance structure. If the value is less than zero, it specifies the offset from the end of the instance structure. A negative offset is more expensive to use, and should only be used when the instance structure contains a variable-length part. This is used for example to add an instance variable dictionary to subtypes of str or tuple. Note that the tp_basicsize field should account for the dictionary added to the end in that case, even though the dictionary is not included in the basic object layout. On a system with a pointer size of 4 bytes, tp_dictoffset should be set to -4 to indicate that the dictionary is at the very end of the structure.

The real dictionary offset in an instance can be computed from a
negative `tp_dictoffset` as follows:

```
dictoffset = tp_basicsize + abs(ob_size)*tp_itemsize
if dictoffset is not aligned on sizeof(void*):
    round up to sizeof(void*)
```

where `tp_basicsize`, `tp_itemsize` and `tp_dictoffset` are taken from the type object, and `ob_size` is taken from the instance. The absolute value is taken because ints use the sign of `ob_size` to store the sign of the number. (There’s never a need to do this calculation yourself; it is done for you by `_PyObject_GetDictPtr()`.)

This field is inherited by subtypes, but see the rules listed below. A subtype may override this offset; this means that the subtype instances store the dictionary at a difference offset than the base type. Since the dictionary is always found via `tp_dictoffset`, this should not be a problem.

When a type defined by a class statement has no `__slots__` declaration, and none of its base types has an instance variable dictionary, a dictionary slot is added to the instance layout and the `tp_dictoffset` is set to that slot’s offset.

When a type defined by a class statement has a `__slots__` declaration, the type inherits its `tp_dictoffset` from its base type.

(Adding a slot named `__dict__` to the `__slots__` declaration does not have the expected effect, it just causes confusion. Maybe this should be added as a feature just like `__weakref__` though.)
initproc **PyTypeObject.tp_init**

An optional pointer to an instance initialization function.

This function corresponds to the `__init__() method of classes. Like `__init__()`, it is possible to create an instance without calling `__init__()`, and it is possible to reinitialize an instance by calling its `__init__() method again.

The function signature is

```c
int tp_init(PyObject *self, PyObject *args, PyObject *kwds)
```

The self argument is the instance to be initialized; the `args` and `kwds` arguments represent positional and keyword arguments of the call to `__init__()`.  

The `tp_init` function, if not `NULL`, is called when an instance is created normally by calling its type, after the type's `tp_new` function has returned an instance of the type. If the `tp_new` function returns an instance of some other type that is not a subtype of the original type, no `tp_init` function is called; if `tp_new` returns an instance of a subtype of the original type, the subtype's `tp_init` is called.

This field is inherited by subtypes.

allocfunc **PyTypeObject.tp_alloc**

An optional pointer to an instance allocation function.

The function signature is

```c
PyObject *tp_alloc(PyTypeObject *self, Py_ssize_t t)
```
The purpose of this function is to separate memory allocation from memory initialization. It should return a pointer to a block of memory of adequate length for the instance, suitably aligned, and initialized to zeros, but with ob_refcnt set to 1 and ob_type set to the type argument. If the type's tp_itemsize is non-zero, the object's ob_size field should be initialized to nitems and the length of the allocated memory block should be tp_basicsize + nitems*tp_itemsize, rounded up to a multiple of sizeof(void*); otherwise, nitems is not used and the length of the block should be tp_basicsize.

Do not use this function to do any other instance initialization, not even to allocate additional memory; that should be done by tp_new.

This field is inherited by static subtypes, but not by dynamic subtypes (subtypes created by a class statement); in the latter, this field is always set to PyType_GenericAlloc(), to force a standard heap allocation strategy. That is also the recommended value for statically defined types.

newfunc PyObject.tp_new

An optional pointer to an instance creation function.

If this function is NULL for a particular type, that type cannot be called to create new instances; presumably there is some other way to create instances, like a factory function.

The function signature is

```c
PyObject *tp_new(PyTypeObject *subtype, PyObject... args)
```
The subtype argument is the type of the object being created; the args and kwds arguments represent positional and keyword arguments of the call to the type. Note that subtype doesn’t have to equal the type whose tp_new function is called; it may be a subtype of that type (but not an unrelated type).

The tp_new function should call subtype->tp_alloc(subtype, nitems) to allocate space for the object, and then do only as much further initialization as is absolutely necessary. Initialization that can safely be ignored or repeated should be placed in the tp_init handler. A good rule of thumb is that for immutable types, all initialization should take place in tp_new, while for mutable types, most initialization should be deferred to tp_init.

This field is inherited by subtypes, except it is not inherited by static types whose tp_base is NULL or &PyBaseObject_Type.

defstructor PyTypeObject.tp_free

An optional pointer to an instance deallocation function. Its signature is freefunc:

```c
void tp_free(void *)
```

An initializer that is compatible with this signature is PyObject_Free().

This field is inherited by static subtypes, but not by dynamic subtypes (subtypes created by a class statement); in the latter, this field is set to a deallocator suitable to match PyType_GenericAlloc() and the value of the Py_TPFLAGS_HAVE_GC flag bit.
**inquiry** `PyTypeObject.tp_is_gc`

An optional pointer to a function called by the garbage collector.

The garbage collector needs to know whether a particular object is collectible or not. Normally, it is sufficient to look at the object's type's `tp_flags` field, and check the `Py_TPFLAGS_HAVE_GC` flag bit. But some types have a mixture of statically and dynamically allocated instances, and the statically allocated instances are not collectible. Such types should define this function; it should return 1 for a collectible instance, and 0 for a non-collectible instance. The signature is

```c
int tp_is_gc(PyObject *self)
```

(The only example of this are types themselves. The metatype, `PyType_Type`, defines this function to distinguish between statically and dynamically allocated types.)

This field is inherited by subtypes.

`PyObject*` `PyTypeObject.tp_bases`

Tuple of base types.

This is set for types created by a class statement. It should be `NULL` for statically defined types.

This field is not inherited.

`PyObject*` `PyTypeObject.tp_mro`

Tuple containing the expanded set of base types, starting with the type itself and ending with `object`, in Method Resolution Order.

This field is not inherited; it is calculated fresh by
PyType_Ready().

destructor PyTypeObject.tp_finalize

An optional pointer to an instance finalization function. Its signature is destructor:

```c
void tp_finalize(PyObject *)
```

If tp_finalize is set, the interpreter calls it once when finalizing an instance. It is called either from the garbage collector (if the instance is part of an isolated reference cycle) or just before the object is deallocated. Either way, it is guaranteed to be called before attempting to break reference cycles, ensuring that it finds the object in a sane state.

tp_finalize should not mutate the current exception status; therefore, a recommended way to write a non-trivial finalizer is:

```c
static void local_finalize(PyObject *self)
{
    PyObject *error_type, *error_value, *error_traceback

    /* Save the current exception, if any. */
    PyErr_Fetch(&error_type, &error_value, &error_traceback

    /* ... */

    /* Restore the saved exception. */
    PyErr_Restore(error_type, error_value, error_traceback
}
```

For this field to be taken into account (even through inheritance), you must also set the Py_TPFLAGS_HAVE_FINALIZE flags bit.
This field is inherited by subtypes.

*New in version 3.4.*

**See also:** “Safe object finalization” *(PEP 442)*

*PyObject* **PyTypeObject.tp_cache**

Unused. Not inherited. Internal use only.

*PyObject* **PyTypeObject.tp_subclasses**

List of weak references to subclasses. Not inherited. Internal use only.

*PyObject* **PyTypeObject.tp_weaklist**

Weak reference list head, for weak references to this type object. Not inherited. Internal use only.

The remaining fields are only defined if the feature test macro COUNT_ALLOCS is defined, and are for internal use only. They are documented here for completeness. None of these fields are inherited by subtypes.

*Py_ssize_t* **PyTypeObject.tp Allocs**

Number of allocations.

*Py_ssize_t* **PyTypeObject.tp_frees**

Number of frees.

*Py_ssize_t* **PyTypeObject.tp_maxalloc**

Maximum simultaneously allocated objects.

**PyTypeObject** **PyTypeObject.tp_next**

Pointer to the next type object with a non-zero *tp Allocs* field.
Also, note that, in a garbage collected Python, tp_dealloc may be called from any Python thread, not just the thread which created the object (if the object becomes part of a refcount cycle, that cycle might be collected by a garbage collection on any thread). This is not a problem for Python API calls, since the thread on which tp_dealloc is called will own the Global Interpreter Lock (GIL). However, if the object being destroyed in turn destroys objects from some other C or C++ library, care should be taken to ensure that destroying those objects on the thread which called tp_dealloc will not violate any assumptions of the library.
Number Object Structures

**PyNumberMethods**

This structure holds pointers to the functions which an object uses to implement the number protocol. Each function is used by the function of similar name documented in the *Number Protocol* section.

Here is the structure definition:

```c
typedef struct {
    binaryfunc nb_add;
    binaryfunc nb_subtract;
    binaryfunc nb_multiply;
    binaryfunc nb_remainder;
    binaryfunc nb_divmod;
    ternaryfunc nb_power;
    unaryfunc nb_negative;
    unaryfunc nb_positive;
    unaryfunc nb_absolute;
    inquiry nb_bool;
    unaryfunc nb_invert;
    binaryfunc nb_lshift;
    binaryfunc nb_rshift;
    binaryfunc nb_and;
    binaryfunc nb_xor;
    binaryfunc nb_or;
    unaryfunc nb_int;
    **void** *nb_reserved;
    unaryfunc nb_float;

    binaryfunc nb_inplace_add;
    binaryfunc nb_inplace_subtract;
    binaryfunc nb_inplace_multiply;
} PyNumberMethods;
```
Note: Binary and ternary functions must check the type of all their operands, and implement the necessary conversions (at least one of the operands is an instance of the defined type). If the operation is not defined for the given operands, binary and ternary functions must return Py_NotImplemented, if another error occurred they must return NULL and set an exception.

Note: The nb_reserved field should always be NULL. It was previously called nb_long, and was renamed in Python 3.0.1.
Mapping Object Structures

**PyMappingMethods**

This structure holds pointers to the functions which an object uses to implement the mapping protocol. It has three members:

**lenfunc **`PyMappingMethods.mp_length`

This function is used by `PyMapping_Length()` and `PyObject_Size()`, and has the same signature. This slot may be set to `NULL` if the object has no defined length.

**binaryfunc **`PyMappingMethods.mp_subscript`

This function is used by `PyObject_GetItem()` and has the same signature. This slot must be filled for the `PyMapping_Check()` function to return 1, it can be `NULL` otherwise.

**objobjargproc **`PyMappingMethods.mp_ass_subscript`

This function is used by `PyObject_SetItem()` and has the same signature. If this slot is `NULL`, the object does not support item assignment.
Sequence Object Structures

**PySequenceMethods**

This structure holds pointers to the functions which an object uses to implement the sequence protocol.

**lenfunc** `PySequenceMethods.sq_length`

This function is used by `PySequence_Size()` and `PyObject_Size()`, and has the same signature.

**binaryfunc** `PySequenceMethods.sq_concat`

This function is used by `PySequence_Concat()` and has the same signature. It is also used by the `+` operator, after trying the numeric addition via the `nb_add` slot.

**ssizeargfunc** `PySequenceMethods.sq_repeat`

This function is used by `PySequence_Repeat()` and has the same signature. It is also used by the `*` operator, after trying numeric multiplication via the `nb_mul` slot.

**ssizeargfunc** `PySequenceMethods.sq_item`

This function is used by `PySequence_GetItem()` and has the same signature. This slot must be filled for the `PySequence_Check()` function to return 1, it can be `NULL` otherwise.

Negative indexes are handled as follows: if the `sq_length` slot is filled, it is called and the sequence length is used to compute a positive index which is passed to `sq_item`. If `sq_length` is `NULL`, the index is passed as is to the function.
ssizeobjargproc **PySequenceMethods.sq_ass_item**

This function is used by `PySequence_SetItem()` and has the same signature. This slot may be left to `NULL` if the object does not support item assignment.

objobjproc **PySequenceMethods.sq_contains**

This function may be used by `PySequence_Contains()` and has the same signature. This slot may be left to `NULL`, in this case `PySequence_Contains()` simply traverses the sequence until it finds a match.

binaryfunc **PySequenceMethods.sq_inplace_concat**

This function is used by `PySequence_InPlaceConcat()` and has the same signature. It should modify its first operand, and return it.

ssizeargfunc **PySequenceMethods.sq_inplace_repeat**

This function is used by `PySequence_InPlaceRepeat()` and has the same signature. It should modify its first operand, and return it.
Buffer Object Structures

**PyBufferProcs**

This structure holds pointers to the functions required by the *Buffer protocol*. The protocol defines how an exporter object can expose its internal data to consumer objects.

**getbufferproc** *PyBufferProcs.bf_getbuffer*

The signature of this function is:

```c
int (PyObject *exporter, Py_buffer *view, int flags)
```

Handle a request to `exporter` to fill in `view` as specified by `flags`. Except for point (3), an implementation of this function MUST take these steps:

1. Check if the request can be met. If not, raise `PyExc_BufferError`, set `view->obj` to `NULL` and return -1.
2. Fill in the requested fields.
3. Increment an internal counter for the number of exports.
4. Set `view->obj` to `exporter` and increment `view->obj`.
5. Return 0.

If `exporter` is part of a chain or tree of buffer providers, two main schemes can be used:

- **Re-export**: Each member of the tree acts as the exporting object and sets `view->obj` to a new reference to itself.
- **Redirect**: The buffer request is redirected to the root object of the tree. Here, `view->obj` will be a new reference to the root object.
The individual fields of view are described in section Buffer structure, the rules how an exporter must react to specific requests are in section Buffer request types.

All memory pointed to in the Py_buffer structure belongs to the exporter and must remain valid until there are no consumers left. format, shape, strides, suboffsets and internal are read-only for the consumer.

PyBuffer_FillInfo() provides an easy way of exposing a simple bytes buffer while dealing correctly with all request types.

PyObject_GetBuffer() is the interface for the consumer that wraps this function.

releasebufferproc PyBufferProcs.bf_releasebuffer

The signature of this function is:

```
void (PyObject *exporter, Py_buffer *view);
```

Handle a request to release the resources of the buffer. If no resources need to be released, PyBufferProcs.bf_releasebuffer may be NULL. Otherwise, a standard implementation of this function will take these optional steps:

1. Decrement an internal counter for the number of exports.
2. If the counter is 0, free all memory associated with view.

The exporter MUST use the internal field to keep track of buffer-specific resources. This field is guaranteed to remain constant, while a consumer MAY pass a copy of the original buffer as the view argument.
This function MUST NOT decrement view->obj, since that is done automatically in `PyBuffer_Release()` (this scheme is useful for breaking reference cycles).

`PyBuffer_Release()` is the interface for the consumer that wraps this function.
Supporting Cyclic Garbage Collection

Python's support for detecting and collecting garbage which involves circular references requires support from object types which are "containers" for other objects which may also be containers. Types which do not store references to other objects, or which only store references to atomic types (such as numbers or strings), do not need to provide any explicit support for garbage collection.

To create a container type, the `tp_flags` field of the type object must include the `Py_TPFLAGS_HAVE_GC` and provide an implementation of the `tp_traverse` handler. If instances of the type are mutable, a `tp_clear` implementation must also be provided.

**Py_TPFLAGS_HAVE_GC**

Objects with a type with this flag set must conform with the rules documented here. For convenience these objects will be referred to as container objects.

Constructors for container types must conform to two rules:

1. The memory for the object must be allocated using `PyObject_GC_New()` or `PyObject_GC_NewVar()`.
2. Once all the fields which may contain references to other containers are initialized, it must call `PyObject_GC_Track()`.

`TYPE* PyObject_GC_New(TYPE, PyTypeObject *type)`

Analogous to `PyObject_New()` but for container objects with the `Py_TPFLAGS_HAVE_GC` flag set.
TYPE* `PyObject_GC_NewVar` (TYPE, PyTypeObject *type, Py_ssize_t size)

Analogous to `PyObject_NewVar()` but for container objects with the `Py_TPFLAGS_HAVE_GC` flag set.

TYPE* `PyObject_GC_Resize` (TYPE, PyVarObject *op, Py_ssize_t newsize)

Resize an object allocated by `PyObject_NewVar()`. Returns the resized object or `NULL` on failure.

void `PyObject_GC_Track` (PyObject *op)

 Adds the object `op` to the set of container objects tracked by the collector. The collector can run at unexpected times so objects must be valid while being tracked. This should be called once all the fields followed by the `tp_traverse` handler become valid, usually near the end of the constructor.

void `_PyObject_GC_TRACK` (PyObject *op)

A macro version of `PyObject_GC_Track()`. It should not be used for extension modules.

Similarly, the deallocator for the object must conform to a similar pair of rules:

1. Before fields which refer to other containers are invalidated, `PyObject_GC_UnTrack()` must be called.
2. The object’s memory must be deallocated using `PyObject_GC_Del()`.

void `PyObject_GC_Del` (void *op)

Releases memory allocated to an object using `PyObject_GC_New()` or `PyObject_GC_NewVar()`.
void **PyObject** **GC** **_** **UnTrack**(void *op)

Remove the object op from the set of container objects tracked by the collector. Note that **PyObject** **GC** **_** **Track**() can be called again on this object to add it back to the set of tracked objects. The deallocator (**tp** **dealloc** handler) should call this for the object before any of the fields used by the **tp** **traverse** handler become invalid.

void **_PyObject** **GC** **_** **UNTRACK**(PyObject *op)

A macro version of **PyObject** **GC** **_** **UnTrack**(). It should not be used for extension modules.

The **tp** **traverse** handler accepts a function parameter of this type:

int (**visitproc**)(PyObject *object, void *arg)

Type of the visitor function passed to the **tp** **traverse** handler. The function should be called with an object to traverse as **object** and the third parameter to the **tp** **traverse** handler as **arg**. The Python core uses several visitor functions to implement cyclic garbage detection; it’s not expected that users will need to write their own visitor functions.

The **tp** **traverse** handler must have the following type:

int (**traverseproc**)(PyObject *self, **visitproc** **visit**, void *arg)

Traversal function for a container object. Implementations must call the **visit** function for each object directly contained by **self**, with the parameters to **visit** being the contained object and the **arg** value passed to the handler. The **visit** function must not be called with a **NULL** object argument. If **visit** returns a non-zero value that value should be returned immediately.
To simplify writing `tp_traverse` handlers, a `Py_VISIT()` macro is provided. In order to use this macro, the `tp_traverse` implementation must name its arguments exactly `visit` and `arg`:

```c
void Py_VISIT(PyObject *o)
{
    Call the visit callback, with arguments `o` and `arg`. If `visit` returns a non-zero value, then return it. Using this macro, `tp_traverse` handlers look like:

```c
static int my_traverse(Noddy *self, visitproc visit, void *arg)
{
    Py_VISIT(self->foo);
    Py_VISIT(self->bar);
    return 0;
}
```

The `tp_clear` handler must be of the `inquiry` type, or `NULL` if the object is immutable.

```c
int (*inquiry)(PyObject *self)
```

Drop references that may have created reference cycles. Immutable objects do not have to define this method since they can never directly create reference cycles. Note that the object must still be valid after calling this method (don’t just call `Py_DECREF()` on a reference). The collector will call this method if it detects that this object is involved in a reference cycle.
API and ABI Versioning

PY_VERSION_HEX is the Python version number encoded in a single integer.

For example if the PY_VERSION_HEX is set to 0x030401a2, the underlying version information can be found by treating it as a 32 bit number in the following manner:

<table>
<thead>
<tr>
<th>Bytes</th>
<th>Bits (big endian order)</th>
<th>Meaning</th>
</tr>
</thead>
<tbody>
<tr>
<td>1</td>
<td>1-8</td>
<td>PY_MAJOR_VERSION (the 3 in 3.4.1a2)</td>
</tr>
<tr>
<td>2</td>
<td>9-16</td>
<td>PY_MINOR_VERSION (the 4 in 3.4.1a2)</td>
</tr>
<tr>
<td>3</td>
<td>17-24</td>
<td>PY_MICRO_VERSION (the 1 in 3.4.1a2)</td>
</tr>
<tr>
<td>4</td>
<td>25-28</td>
<td>PY_RELEASE_LEVEL (0xA for alpha, 0xB for beta, 0xC for release candidate and 0xF for final), in this case it is alpha.</td>
</tr>
<tr>
<td></td>
<td>29-32</td>
<td>PY_RELEASE_SERIAL (the 2 in 3.4.1a2, zero for final releases)</td>
</tr>
</tbody>
</table>

Thus 3.4.1a2 is hexversion 0x030401a2.

All the given macros are defined in Include/patchlevel.h.
Porting Python 2 Code to Python 3

**author:** Brett Cannon

**Abstract**

With Python 3 being the future of Python while Python 2 is still in active use, it is good to have your project available for both major releases of Python. This guide is meant to help you figure out how best to support both Python 2 & 3 simultaneously.

If you are looking to port an extension module instead of pure Python code, please see *Porting Extension Modules to Python 3*.

If you would like to read one core Python developer’s take on why Python 3 came into existence, you can read Nick Coghlan’s *Python 3 Q & A*.

If you prefer to read a (free) book on porting a project to Python 3, consider reading *Porting to Python 3* by Lennart Regebro which should cover much of what is discussed in this HOWTO.

For help with porting, you can email the python-porting mailing list with questions.
The Short Version

- Decide what’s the oldest version of Python 2 you want to support (if at all)
- Make sure you have a thorough test suite and use continuous integration testing to make sure you stay compatible with the versions of Python you care about
- If you have dependencies, check their Python 3 status using caniusepython3 (command-line tool, web app)

With that done, your options are:

- If you are dropping Python 2 support, use 2to3 to port to Python 3
- If you are keeping Python 2 support, then start writing Python 2/3-compatible code starting TODAY
  - If you have dependencies that have not been ported, reach out to them to port their project while working to make your code compatible with Python 3 so you’re ready when your dependencies are all ported
  - If all your dependencies have been ported (or you have none), go ahead and port to Python 3
- If you are creating a new project that wants to have 2/3 compatibility, code in Python 3 and then backport to Python 2
Before You Begin

If your project is on the Cheeseshop/PyPI, make sure it has the proper *trove classifiers* to signify what versions of Python it *currently* supports. At minimum you should specify the major version(s), e.g. 

```
Programming Language :: Python :: 2
```

if your project currently only supports Python 2. It is preferrable that you be as specific as possible by listing every major/minor version of Python that you support, e.g. if your project supports Python 2.6 and 2.7, then you want the classifiers of:

```
Programming Language :: Python :: 2
Programming Language :: Python :: 2.6
Programming Language :: Python :: 2.7
```

Once your project supports Python 3 you will want to go back and add the appropriate classifiers for Python 3 as well. This is important as setting the *Programming Language :: Python :: 3* classifier will lead to your project being listed under the *Python 3 Packages* section of PyPI.

Make sure you have a robust test suite. You need to make sure everything continues to work, just like when you support a new minor/feature release of Python. This means making sure your test suite is thorough and is ported properly between Python 2 & 3 (consider using *coverage* to measure that you have effective test coverage). You will also most likely want to use something like *tox* to automate testing between all of your supported versions of Python. You will also want to *port your tests first* so that you can make sure that you detect breakage during the transition. Tests also tend to be simpler than the code they are testing so it gives you an idea of how easy it can be to port code.
Drop support for older Python versions if possible. **Python 2.5** introduced a lot of useful syntax and libraries which have become idiomatic in Python 3. **Python 2.6** introduced future statements which makes compatibility much easier if you are going from Python 2 to 3. **Python 2.7** continues the trend in the stdlib. Choose the newest version of Python which you believe can be your minimum support version and work from there.

Target the newest version of Python 3 that you can. Beyond just the usual bugfixes, compatibility has continued to improve between Python 2 and 3 as time has passed. E.g. Python 3.3 added back the `u` prefix for strings, making source-compatible Python code easier to write.
Writing Source-Compatible Python 2/3 Code

Over the years the Python community has discovered that the easiest way to support both Python 2 and 3 in parallel is to write Python code that works in either version. While this might sound counter-intuitive at first, it actually is not difficult and typically only requires following some select (non-idiomatic) practices and using some key projects to help make bridging between Python 2 and 3 easier.

Projects to Consider

The lowest level library for supporting Python 2 & 3 simultaneously is six. Reading through its documentation will give you an idea of where exactly the Python language changed between versions 2 & 3 and thus what you will want the library to help you continue to support.

To help automate porting your code over to using six, you can use modernize. This project will attempt to rewrite your code to be as modern as possible while using six to smooth out any differences between Python 2 & 3.

If you want to write your compatible code to feel more like Python 3 there is the future project. It tries to provide backports of objects from Python 3 so that you can use them from Python 2-compatible code, e.g. replacing the bytes type from Python 2 with the one from Python 3. It also provides a translation script like modernize (its translation code is actually partially based on it) to help start working with a pre-existing code base. It is also unique in that its translation script will also port Python 3 code backwards as well as Python 2 code forwards.
Tips & Tricks

To help with writing source-compatible code using one of the projects mentioned in Projects to Consider, consider following the below suggestions. Some of them are handled by the suggested projects, so if you do use one of them then read their documentation first to see which suggestions below will taken care of for you.

Support Python 2.7

As a first step, make sure that your project is compatible with Python 2.7. This is just good to do as Python 2.7 is the last release of Python 2 and thus will be used for a rather long time. It also allows for use of the -3 flag to Python to help discover places in your code where compatibility might be an issue (the -3 flag is in Python 2.6 but Python 2.7 adds more warnings).

Try to Support Python 2.6 and Newer Only

While not possible for all projects, if you can support Python 2.6 and newer only, your life will be much easier. Various future statements, stdlib additions, etc. exist only in Python 2.6 and later which greatly assist in supporting Python 3. But if your project must keep support for Python 2.5 then it is still possible to simultaneously support Python 3.

Below are the benefits you gain if you only have to support Python 2.6 and newer. Some of these options are personal choice while others are strongly recommended (the ones that are more for personal choice are labeled as such). If you continue to support older versions of Python then you at least need to watch out for situations that these solutions fix and handle them appropriately (which is where library help from e.g. six comes in handy).
from __future__ import print_function

It will not only get you used to typing `print()` as a function instead of a statement, but it will also give you the various benefits the function has over the Python 2 statement (`six` provides a function if you support Python 2.5 or older).

from __future__ import unicode_literals

If you choose to use this future statement then all string literals in Python 2 will be assumed to be Unicode (as is already the case in Python 3). If you choose not to use this future statement then you should mark all of your text strings with a `u` prefix and only support Python 3.3 or newer. But you are strongly advised to do one or the other (`six` provides a function in case you don't want to use the future statement and you want to support Python 3.2 or older).

Bytes/string literals

This is a very important one. Prefix Python 2 strings that are meant to contain bytes with a `b` prefix to very clearly delineate what is and is not a Python 3 text string (`six` provides a function to use for Python 2.5 compatibility).

This point cannot be stressed enough: make sure you know what all of your string literals in Python 2 are meant to be in Python 3. Any string literal that should be treated as bytes should have the `b` prefix. Any string literal that should be Unicode/text in Python 2 should either have the `u` literal (supported, but ignored, in Python 3.3 and later) or you should have `from __future__ import unicode_literals` at the top of the file. But the key point is you should know how Python 3 will treat every one one of your string literals and you should mark
them as appropriate.

There are some differences between byte literals in Python 2 and those in Python 3 thanks to the bytes type just being an alias to `str` in Python 2. See the Handle Common “Gotchas” section for what to watch out for.

```python
from __future__ import absolute_import
```

Discussed in more detail below, but you should use this future statement to prevent yourself from accidentally using implicit relative imports.

**Supporting Python 2.5 and Newer Only**

If you are supporting Python 2.5 and newer there are still some features of Python that you can utilize.

```python
from __future__ import absolute_import
```

Implicit relative imports (e.g., importing `spam.bacon` from within `spam.eggs` with the statement `import bacon`) do not work in Python 3. This future statement moves away from that and allows the use of explicit relative imports (e.g., `from . import bacon`).

In Python 2.5 you must use the `__future__` statement to get to use explicit relative imports and prevent implicit ones. In Python 2.6 explicit relative imports are available without the statement, but you still want the `__future__` statement to prevent implicit relative imports. In Python 2.7 the `__future__` statement is not needed. In other words, unless you are only supporting Python 2.7 or a version earlier than Python 2.5, use this `__future__` statement.
Mark all Unicode strings with a `u` prefix

While Python 2.6 has a `__future__` statement to automatically cause Python 2 to treat all string literals as Unicode, Python 2.5 does not have that shortcut. This means you should go through and mark all string literals with a `u` prefix to turn them explicitly into text strings where appropriate and only support Python 3.3 or newer. Otherwise use a project like `six` which provides a function to pass all text string literals through.

Capturing the Currently Raised Exception

In Python 2.5 and earlier the syntax to access the current exception is:

```python
try:
    raise Exception()
except Exception, exc:
    # Current exception is 'exc'.
    pass
```

This syntax changed in Python 3 (and backported to Python 2.6 and later) to:

```python
try:
    raise Exception()
except Exception as exc:
    # Current exception is 'exc'.
    # In Python 3, 'exc' is restricted to the block; in Python 2.6/2.7 it will "leak".
    pass
```

Because of this syntax change you must change how you capture the current exception in Python 2.5 and earlier to:
try:
    raise Exception()
except Exception:
    import sys
    exc = sys.exc_info()[1]
    # Current exception is 'exc'.
    pass

You can get more information about the raised exception from `sys.exc_info()` than simply the current exception instance, but you most likely don’t need it.

**Note:** In Python 3, the traceback is attached to the exception instance through the `__traceback__` attribute. If the instance is saved in a local variable that persists outside of the except block, the traceback will create a reference cycle with the current frame and its dictionary of local variables. This will delay reclaiming dead resources until the next cyclic *garbage collection* pass.

In Python 2, this problem only occurs if you save the traceback itself (e.g. the third element of the tuple returned by `sys.exc_info()`) in a variable.

**Handle Common “Gotchas”**

These are things to watch out for no matter what version of Python 2 you are supporting which are not syntactic considerations.

```python
from __future__ import division
```

While the exact same outcome can be had by using the `-Qnew` argument to Python, using this future statement lifts the requirement that your users use the flag to get the expected behavior of division in
Python 3 (e.g., \(1/2 == 0.5\); \(1//2 == 0\)).

Specify when opening a file as binary

Unless you have been working on Windows, there is a chance you have not always bothered to add the `b` mode when opening a binary file (e.g., `rb` for binary reading). Under Python 3, binary files and text files are clearly distinct and mutually incompatible; see the `io` module for details. Therefore, you **must** make a decision of whether a file will be used for binary access (allowing to read and/or write bytes data) or text access (allowing to read and/or write unicode data).

Text files

Text files created using `open()` under Python 2 return byte strings, while under Python 3 they return unicode strings. Depending on your porting strategy, this can be an issue.

If you want text files to return unicode strings in Python 2, you have two possibilities:

- Under Python 2.6 and higher, use `io.open()`. Since `io.open()` is essentially the same function in both Python 2 and Python 3, it will help iron out any issues that might arise.
- If pre-2.6 compatibility is needed, then you should use `codecs.open()` instead. This will make sure that you get back unicode strings in Python 2.

Subclass object

New-style classes have been around since Python 2.2. You need to make sure you are subclassing from `object` to avoid odd edge cases
involving method resolution order, etc. This continues to be totally valid in Python 3 (although unneeded as all classes implicitly inherit from `object`).

**Deal With the Bytes/String Dichotomy**

One of the biggest issues people have when porting code to Python 3 is handling the bytes/string dichotomy. Because Python 2 allowed the `str` type to hold textual data, people have over the years been rather loose in their delineation of what `str` instances held text compared to bytes. In Python 3 you cannot be so care-free anymore and need to properly handle the difference. The key to handling this issue is to make sure that **every** string literal in your Python 2 code is either syntactically or functionally marked as either bytes or text data. After this is done you then need to make sure your APIs are designed to either handle a specific type or made to be properly polymorphic.

**Mark Up Python 2 String Literals**

First thing you must do is designate every single string literal in Python 2 as either textual or bytes data. If you are only supporting Python 2.6 or newer, this can be accomplished by marking bytes literals with a `b` prefix and then designating textual data with a `u` prefix or using the `unicode_literals` future statement.

If your project supports versions of Python predating 2.6, then you should use the `six` project and its `b()` function to denote bytes literals. For text literals you can either use six’s `u()` function or use a `u` prefix.

**Decide what APIs Will Accept**

In Python 2 it was very easy to accidentally create an API that
accepted both bytes and textual data. But in Python 3, thanks to the more strict handling of disparate types, this loose usage of bytes and text together tends to fail.

Take the dict `{b'a': 'bytes', u'a': 'text'}` in Python 2.6. It creates the dict `{u'a': 'text'}` since `b'a' == u'a'`. But in Python 3 the equivalent dict creates `{b'a': 'bytes', 'a': 'text'}`, i.e., no lost data. Similar issues can crop up when transitioning Python 2 code to Python 3.

This means you need to choose what an API is going to accept and create and consistently stick to that API in both Python 2 and 3.

Bytes / Unicode Comparison

In Python 3, mixing bytes and unicode is forbidden in most situations; it will raise a `TypeError` where Python 2 would have attempted an implicit coercion between types. However, there is one case where it doesn’t and it can be very misleading:

```python
>>> b'' == ''
False
```

This is because an equality comparison is required by the language to always succeed (and return `False` for incompatible types). However, this also means that code incorrectly ported to Python 3 can display buggy behaviour if such comparisons are silently executed. To detect such situations, Python 3 has a `-b` flag that will display a warning:

```bash
$ python3 -b
>>> b'' == ''
__main__:1: BytesWarning: Comparison between bytes and string False
```

```python
>>> b'' == ''
False
```
To turn the warning into an exception, use the `-bb` flag instead:

```bash
$ python3 -bb
>>> b'' == ''
```

```
Traceback (most recent call last):
  File "<stdin>", line 1, in <module>
BytesWarning: Comparison between bytes and string
```

**Indexing bytes objects**

Another potentially surprising change is the indexing behaviour of bytes objects in Python 3:

```python
>>> b"xyz"[0]
120
```

Indeed, Python 3 bytes objects (as well as `bytearray` objects) are sequences of integers. But code converted from Python 2 will often assume that indexing a bytestring produces another bytestring, not an integer. To reconcile both behaviours, use slicing:

```python
>>> b"xyz"[0:1]
b'x'
>>> n = 1
>>> b"xyz"[n:n+1]
b'y'
```

The only remaining gotcha is that an out-of-bounds slice returns an empty bytes object instead of raising `IndexError`:

```python
>>> b"xyz"[3]
Traceback (most recent call last):
  File "<stdin>", line 1, in <module>
```

```
IndexError: index out of range

```python
>>> b"xyz"[3:4]
b''
```

**__str__()/__unicode__()**

In Python 2, objects can specify both a string and unicode representation of themselves. In Python 3, though, there is only a string representation. This becomes an issue as people can inadvertently do things in their `__str__()` methods which have unpredictable results (e.g., infinite recursion if you happen to use the `unicode(self).encode('utf8')` idiom as the body of your `__str__()` method).

You can use a mixin class to work around this. This allows you to only define a `__unicode__()` method for your class and let the mixin derive `__str__()` for you (code from http://lucumr.pocoo.org/2011/1/22/forwards-compatible-python/):

```python
import sys

class UnicodeMixin(object):

    """Mixin class to handle defining the proper __str__ methods in Python 2 or 3."""

    if sys.version_info[0] >= 3: # Python 3
        def __str__(self):
            return self.__unicode__()
    else: # Python 2
        def __str__(self):
            return self.__unicode__().encode('utf8')
```
class Spam(UnicodeMixin):
    
def __unicode__(self):
        return u'spam-spam-bacon-spam'  # 2to3 will remove the 'u'

Don't Index on Exceptions

In Python 2, the following worked:

>>> exc = Exception(1, 2, 3)
>>> exc.args[1]
2
>>> exc[1]  # Python 2 only!
2

But in Python 3, indexing directly on an exception is an error. You need to make sure to only index on the `BaseException.args` attribute which is a sequence containing all arguments passed to the `__init__()` method.

Even better is to use the documented attributes the exception provides.

Don't use __getslice__ & Friends

Been deprecated for a while, but Python 3 finally drops support for `__getslice__()` etc. Move completely over to `__getitem__()` and friends.

Updating doctests

Don't forget to make them Python 2/3 compatible as well. If you wrote a monolithic set of doctests (e.g., a single docstring containing all of
your doctests), you should at least consider breaking the doctests up into smaller pieces to make it more manageable to fix. Otherwise it might very well be worth your time and effort to port your tests to unittest.

Update map for imbalanced input sequences

With Python 2, when map was given more than one input sequence it would pad the shorter sequences with None values, returning a sequence as long as the longest input sequence.

With Python 3, if the input sequences to map are of unequal length, map will stop at the termination of the shortest of the sequences. For full compatibility with map from Python 2.x, wrap the sequence arguments in itertools.zip_longest(), e.g. map(func, *sequences) becomes list(map(func, itertools.zip_longest(*sequences))).

Eliminate -3 Warnings

When you run your application’s test suite, run it using the -3 flag passed to Python. This will cause various warnings to be raised during execution about things that are semantic changes between Python 2 and 3. Try to eliminate those warnings to make your code even more portable to Python 3.
Alternative Approaches

While supporting Python 2 & 3 simultaneously is typically the preferred choice by people so that they can continue to improve code and have it work for the most number of users, your life may be easier if you only have to support one major version of Python going forward.

Supporting Only Python 3 Going Forward From Python 2 Code

If you have Python 2 code but going forward only want to improve it as Python 3 code, then you can use 2to3 to translate your Python 2 code to Python 3 code. This is only recommended, though, if your current version of your project is going into maintenance mode and you want all new features to be exclusive to Python 3.

Backporting Python 3 code to Python 2

If you have Python 3 code and have little interest in supporting Python 2 you can use 3to2 to translate from Python 3 code to Python 2 code. This is only recommended if you don’t plan to heavily support Python 2 users. Otherwise write your code for Python 3 and then backport as far back as you want. This is typically easier than going from Python 2 to 3 as you will have worked out any difficulties with e.g. bytes/strings, etc.
Other Resources

The authors of the following blog posts, wiki pages, and books deserve special thanks for making public their tips for porting Python 2 code to Python 3 (and thus helping provide information for this document and its various revisions over the years):

Porting Extension Modules to Python 3

**author:** Benjamin Peterson

**Abstract**

Although changing the C-API was not one of Python 3's objectives, the many Python-level changes made leaving Python 2's API intact impossible. In fact, some changes such as `int()` and `long()` unification are more obvious on the C level. This document endeavors to document incompatibilities and how they can be worked around.
Conditional compilation

The easiest way to compile only some code for Python 3 is to check if `PY_MAJOR_VERSION` is greater than or equal to 3.

```python
#if PY_MAJOR_VERSION >= 3
#define IS_PY3K
#endif
```

API functions that are not present can be aliased to their equivalents within conditional blocks.
Changes to Object APIs

Python 3 merged together some types with similar functions while cleanly separating others.

str/unicode Unification

Python 3’s `str()` (PyString_* functions in C) type is equivalent to Python 2’s `unicode()` (PyUnicode_*). The old 8-bit string type has become `bytes()`. Python 2.6 and later provide a compatibility header, `bytesobject.h`, mapping `PyBytes` names to `PyString` ones. For best compatibility with Python 3, `PyUnicode` should be used for textual data and `PyBytes` for binary data. It’s also important to remember that `PyBytes` and `PyUnicode` in Python 3 are not interchangeable like `PyString` and `PyUnicode` are in Python 2. The following example shows best practices with regards to `PyUnicode`, `PyString`, and `PyBytes`.

```c
#include "stdlib.h"
#include "Python.h"
#include "bytesobject.h"

/* text example */
static PyObject *
say_hello(PyObject *self, PyObject *args) {
    PyObject *name, *result;

    if (!PyArg_ParseTuple(args, "U:say_hello", &name
                         return NULL;

    result = PyUnicode_FromFormat("Hello, %S!", name
    return result;
```
long/int Unification

Python 3 has only one integer type, int(). But it actually corresponds to Python 2's long() type—the int() type used in Python 2 was removed. In the C-API, PyInt_* functions are replaced by their PyLong_* equivalents.
Module initialization and state

Python 3 has a revamped extension module initialization system. (See PEP 3121.) Instead of storing module state in globals, they should be stored in an interpreter specific structure. Creating modules that act correctly in both Python 2 and Python 3 is tricky. The following simple example demonstrates how.

```c
#include "Python.h"

struct module_state {
    PyObject *error;
};

#if PY_MAJOR_VERSION >= 3
#define GETSTATE(m) ((struct module_state*)PyModule_GetState(m))
#else
#define GETSTATE(m) (&_state)
#endif

static struct module_state _state;

static PyObject *
error_out(PyObject *m) {
    struct module_state *st = GETSTATE(m);
    PyErr_SetString(st->error, "something bad happened");
    return NULL;
}

static PyMethodDef myextension_methods[] = {
    {"error_out", (PyCFunction)error_out, METH_NOARGS, NULL, NULL}
};

#if PY_MAJOR_VERSION >= 3
"something bad happened"
```
static int myextension_traverse(PyObject *m, visitproc visitp, void *_visit_data)
    Py_VISIT(GETSTATE(m)->error);
    return 0;
}

static int myextension_clear(PyObject *m) {
    Py_CLEAR(GETSTATE(m)->error);
    return 0;
}

static struct PyModuleDef moduledef = {
    PyModuleDef_HEAD_INIT,
    "myextension",
    NULL,
    sizeof(struct module_state),
    myextension_methods,
    NULL,
    myextension_traverse,
    myextension_clear,
    NULL
};

#define INITERROR return NULL

PyObject *
PyInit_myextension(void)

#else
#define INITERROR return

void
initmyextension(void)
#endif
{
#if PY_MAJOR_VERSION >= 3
    PyObject *module = PyModule_Create(&moduledef);

#else
    PyObject *module = Py_InitModule("myextension",
#endif

    if (module == NULL)
        INITERROR;
    struct module_state *st = GETSTATE(module);

    st->error = PyErr_NewException("myextension.Error",
    if (st->error == NULL) {
        Py_DECREF(module);
        INITERROR;
    }

#if PY_MAJOR_VERSION >= 3
    return module;
#endif
}
CObject replaced with Capsule

The Capsule object was introduced in Python 3.1 and 2.7 to replace CObject. CObjects were useful, but the CObject API was problematic: it didn’t permit distinguishing between valid CObjects, which allowed mismatched CObjects to crash the interpreter, and some of its APIs relied on undefined behavior in C. (For further reading on the rationale behind Capsules, please see issue 5630.)

If you’re currently using CObjects, and you want to migrate to 3.1 or newer, you’ll need to switch to Capsules. CObject was deprecated in 3.1 and 2.7 and completely removed in Python 3.2. If you only support 2.7, or 3.1 and above, you can simply switch to Capsule. If you need to support Python 3.0, or versions of Python earlier than 2.7, you’ll have to support both CObjects and Capsules. (Note that Python 3.0 is no longer supported, and it is not recommended for production use.)

The following example header file capsulethunk.h may solve the problem for you. Simply write your code against the Capsule API and include this header file after Python.h. Your code will automatically use Capsules in versions of Python with Capsules, and switch to CObjects when Capsules are unavailable.

capsulethunk.h simulates Capsules using CObjects. However, CObject provides no place to store the capsule’s “name”. As a result the simulated Capsule objects created by capsulethunk.h behave slightly differently from real Capsules. Specifically:

- The name parameter passed in to PyCapsule_New() is ignored.
- The name parameter passed in to PyCapsule_IsValid()
and `PyCapsule_GetPointer()` is ignored, and no error checking of the name is performed.

- `PyCapsuleGetName()` always returns NULL.
- `PyCapsuleSetName()` always raises an exception and returns failure. (Since there’s no way to store a name in a CObject, noisy failure of `PyCapsuleSetName()` was deemed preferable to silent failure here. If this is inconvenient, feel free to modify your local copy as you see fit.)

You can find `capsulethunk.h` in the Python source distribution as `Doc/includes/capsulethunk.h`. We also include it here for your convenience:

```c
#ifndef __CAPSULETHUNK_H
#define __CAPSULETHUNK_H

#if ((PY_VERSION_HEX < 0x02070000) || ((PY_VERSION_HEX >= 0x03000000) && (PY_VERSION_HEX < 0x03010000)))
#define __PyCapsule_GetField(capsule, field, default_value)  
  (PyCapsule_CheckExact(capsule)  
   ? (((PyCObject *)capsule)->field)  
     : (default_value)  
   )
#endif

#define __PyCapsule_SetField(capsule, field, value)  
  (PyCapsule_CheckExact(capsule)  
   ? (((PyCObject *)capsule)->field = value), 1  
     : 0  
   )

#define PyCapsule_Type PyCObject_Type
```
#define PyCapsule_CheckExact(capsule)  (PyQObject_Check(capsule))
#define PyCapsule_IsValid(capsule, name)  (PyQObject_Check(capsule))
#define PyCapsule_New(pointer, name, destructor)  
  (PyQObject_FromVoidPtr(pointer, destructor))

**Abstract**

This document describes how to use the `curses` extension module to control text-mode displays.
What is curses?

The curses library supplies a terminal-independent screen-painting and keyboard-handling facility for text-based terminals; such terminals include VT100s, the Linux console, and the simulated terminal provided by various programs. Display terminals support various control codes to perform common operations such as moving the cursor, scrolling the screen, and erasing areas. Different terminals use widely differing codes, and often have their own minor quirks.

In a world of graphical displays, one might ask “why bother”? It’s true that character-cell display terminals are an obsolete technology, but there are niches in which being able to do fancy things with them are still valuable. One niche is on small-footprint or embedded Unixes that don’t run an X server. Another is tools such as OS installers and kernel configurators that may have to run before any graphical support is available.

The curses library provides fairly basic functionality, providing the programmer with an abstraction of a display containing multiple non-overlapping windows of text. The contents of a window can be changed in various ways—adding text, erasing it, changing its appearance—and the curses library will figure out what control codes need to be sent to the terminal to produce the right output. curses doesn’t provide many user-interface concepts such as buttons, checkboxes, or dialogs; if you need such features, consider a user interface library such as Urwid.

The curses library was originally written for BSD Unix; the later System V versions of Unix from AT&T added many enhancements and new functions. BSD curses is no longer maintained, having been replaced by ncurses, which is an open-source implementation of the AT&T
interface. If you’re using an open-source Unix such as Linux or FreeBSD, your system almost certainly uses ncurses. Since most current commercial Unix versions are based on System V code, all the functions described here will probably be available. The older versions of curses carried by some proprietary Unixes may not support everything, though.

The Windows version of Python doesn’t include the curses module. A ported version called UniCurses is available. You could also try the Console module written by Fredrik Lundh, which doesn’t use the same API as curses but provides cursor-addressable text output and full support for mouse and keyboard input.

The Python curses module

The Python module is a fairly simple wrapper over the C functions provided by curses; if you’re already familiar with curses programming in C, it’s really easy to transfer that knowledge to Python. The biggest difference is that the Python interface makes things simpler by merging different C functions such as addstr(), mvaddstr(), and mvwaddstr() into a single addstr() method. You’ll see this covered in more detail later.

This HOWTO is an introduction to writing text-mode programs with curses and Python. It doesn’t attempt to be a complete guide to the curses API; for that, see the Python library guide’s section on ncurses, and the C manual pages for ncurses. It will, however, give you the basic ideas.
Starting and ending a curses application

Before doing anything, curses must be initialized. This is done by calling the `initscr()` function, which will determine the terminal type, send any required setup codes to the terminal, and create various internal data structures. If successful, `initscr()` returns a window object representing the entire screen; this is usually called `stdscr` after the name of the corresponding C variable.

```python
import curses
stdscr = curses.initscr()
```

Usually curses applications turn off automatic echoing of keys to the screen, in order to be able to read keys and only display them under certain circumstances. This requires calling the `noecho()` function.

```python
curses.noecho()
```

Applications will also commonly need to react to keys instantly, without requiring the Enter key to be pressed; this is called cbreak mode, as opposed to the usual buffered input mode.

```python
curses.cbreak()
```

Terminals usually return special keys, such as the cursor keys or navigation keys such as Page Up and Home, as a multibyte escape sequence. While you could write your application to expect such sequences and process them accordingly, curses can do it for you, returning a special value such as `curses.KEY_LEFT`. To get curses to do the job, you’ll have to enable keypad mode.

```python
stdscr.keypad(True)
```
Terminating a curses application is much easier than starting one. You'll need to call:

```python
curses.nocbreak()
stdscr.keypad(False)
curses.echo()
```

to reverse the curses-friendly terminal settings. Then call the `endwin()` function to restore the terminal to its original operating mode.

```python
curses.endwin()
```

A common problem when debugging a curses application is to get your terminal messed up when the application dies without restoring the terminal to its previous state. In Python this commonly happens when your code is buggy and raises an uncaught exception. Keys are no longer echoed to the screen when you type them, for example, which makes using the shell difficult.

In Python you can avoid these complications and make debugging much easier by importing the `curses.wrapper()` function and using it like this:

```python
from curses import wrapper

def main(stdscr):
    # Clear screen
    stdscr.clear()

    # This raises ZeroDivisionError when i == 10.
    for i in range(0, 11):
        v = i-10
```
The `wrapper()` function takes a callable object and does the initializations described above, also initializing colors if color support is present. `wrapper()` then runs your provided callable. Once the callable returns, `wrapper()` will restore the original state of the terminal. The callable is called inside a `try...except` that catches exceptions, restores the state of the terminal, and then re-raises the exception. Therefore your terminal won’t be left in a funny state on exception and you'll be able to read the exception's message and traceback.
Windows and Pads

Windows are the basic abstraction in curses. A window object represents a rectangular area of the screen, and supports methods to display text, erase it, allow the user to input strings, and so forth.

The `stdscr` object returned by the `initscr()` function is a window object that covers the entire screen. Many programs may need only this single window, but you might wish to divide the screen into smaller windows, in order to redraw or clear them separately. The `newwin()` function creates a new window of a given size, returning the new window object.

```c
begin_x = 20; begin_y = 7
height = 5; width = 40
win = curses.newwin(height, width, begin_y, begin_x)
```

Note that the coordinate system used in curses is unusual. Coordinates are always passed in the order y,x, and the top-left corner of a window is coordinate (0,0). This breaks the normal convention for handling coordinates where the x coordinate comes first. This is an unfortunate difference from most other computer applications, but it's been part of curses since it was first written, and it's too late to change things now.

Your application can determine the size of the screen by using the `curses.LINES` and `curses.COLS` variables to obtain the y and x sizes. Legal coordinates will then extend from (0,0) to (`curses.LINES - 1`, `curses.COLS - 1`).

When you call a method to display or erase text, the effect doesn't
immediately show up on the display. Instead you must call the refresh() method of window objects to update the screen.

This is because curses was originally written with slow 300-baud terminal connections in mind; with these terminals, minimizing the time required to redraw the screen was very important. Instead curses accumulates changes to the screen and displays them in the most efficient manner when you call refresh(). For example, if your program displays some text in a window and then clears the window, there's no need to send the original text because they're never visible.

In practice, explicitly telling curses to redraw a window doesn't really complicate programming with curses much. Most programs go into a flurry of activity, and then pause waiting for a keypress or some other action on the part of the user. All you have to do is to be sure that the screen has been redrawn before pausing to wait for user input, by first calling stdscr.refresh() or the refresh() method of some other relevant window.

A pad is a special case of a window; it can be larger than the actual display screen, and only a portion of the pad displayed at a time. Creating a pad requires the pad's height and width, while refreshing a pad requires giving the coordinates of the on-screen area where a subsection of the pad will be displayed.

```python
pad = curses.newpad(100, 100)
# These loops fill the pad with letters; addch() is explained in the next section
for y in range(0, 99):
    for x in range(0, 99):
        pad.addch(y, x, ord('a') + (x*x+y*y) % 26)

# Displays a section of the pad in the middle of the screen
# (0,0) : coordinate of upper-left corner of pad area
```
The `refresh()` call displays a section of the pad in the rectangle extending from coordinate (5,5) to coordinate (20,75) on the screen; the upper left corner of the displayed section is coordinate (0,0) on the pad. Beyond that difference, pads are exactly like ordinary windows and support the same methods.

If you have multiple windows and pads on screen there is a more efficient way to update the screen and prevent annoying screen flicker as each part of the screen gets updated. `refresh()` actually does two things:

1. Calls the `noutrefresh()` method of each window to update an underlying data structure representing the desired state of the screen.
2. Calls the function `doupdate()` function to change the physical screen to match the desired state recorded in the data structure.

Instead you can call `noutrefresh()` on a number of windows to update the data structure, and then call `doupdate()` to update the screen.
Displaying Text

From a C programmer’s point of view, curses may sometimes look like a twisty maze of functions, all subtly different. For example, `addstr()` displays a string at the current cursor location in the `stdscr` window, while `mvaddstr()` moves to a given y,x coordinate first before displaying the string. `waddstr()` is just like `addstr()`, but allows specifying a window to use instead of using `stdscr` by default. `mvwaddstr()` allows specifying both a window and a coordinate.

Fortunately the Python interface hides all these details. `stdscr` is a window object like any other, and methods such as `addstr()` accept multiple argument forms. Usually there are four different forms.

<table>
<thead>
<tr>
<th>Form</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td><code>str</code> or <code>ch</code></td>
<td>Display the string <code>str</code> or character <code>ch</code> at the current position</td>
</tr>
<tr>
<td><code>str</code> or <code>ch</code>, <code>attr</code></td>
<td>Display the string <code>str</code> or character <code>ch</code>, using attribute <code>attr</code> at the current position</td>
</tr>
<tr>
<td><code>y</code>, <code>x</code>, <code>str</code> or <code>ch</code></td>
<td>Move to position <code>y</code>,<code>x</code> within the window, and display <code>str</code> or <code>ch</code></td>
</tr>
<tr>
<td><code>y</code>, <code>x</code>, <code>str</code> or <code>ch</code>, <code>attr</code></td>
<td>Move to position <code>y</code>,<code>x</code> within the window, and display <code>str</code> or <code>ch</code>, using attribute <code>attr</code></td>
</tr>
</tbody>
</table>

Attributes allow displaying text in highlighted forms such as boldface, underline, reverse code, or in color. They’ll be explained in more detail in the next subsection.
The `addstr()` method takes a Python string or bytestring as the value to be displayed. The contents of bytestrings are sent to the terminal as-is. Strings are encoded to bytes using the value of the window's encoding attribute; this defaults to the default system encoding as returned by `locale.getpreferredencoding()`.

The `addch()` methods take a character, which can be either a string of length 1, a bytestring of length 1, or an integer.

Constants are provided for extension characters; these constants are integers greater than 255. For example, ACS_PLMINUS is a +/- symbol, and ACS_ULCORNER is the upper left corner of a box (handy for drawing borders). You can also use the appropriate Unicode character.

Windows remember where the cursor was left after the last operation, so if you leave out the `y,x` coordinates, the string or character will be displayed wherever the last operation left off. You can also move the cursor with the `move(y,x)` method. Because some terminals always display a flashing cursor, you may want to ensure that the cursor is positioned in some location where it won’t be distracting; it can be confusing to have the cursor blinking at some apparently random location.

If your application doesn’t need a blinking cursor at all, you can call `curs_set(False)` to make it invisible. For compatibility with older curses versions, there’s a `leaveok(bool)` function that’s a synonym for `curs_set()`. When `bool` is true, the curses library will attempt to suppress the flashing cursor, and you won’t need to worry about leaving it in odd locations.

**Attributes and Color**
Characters can be displayed in different ways. Status lines in a text-based application are commonly shown in reverse video, or a text viewer may need to highlight certain words. curses supports this by allowing you to specify an attribute for each cell on the screen.

An attribute is an integer, each bit representing a different attribute. You can try to display text with multiple attribute bits set, but curses doesn’t guarantee that all the possible combinations are available, or that they’re all visually distinct. That depends on the ability of the terminal being used, so it’s safest to stick to the most commonly available attributes, listed here.

<table>
<thead>
<tr>
<th>Attribute</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>A_BLINK</td>
<td>Blinking text</td>
</tr>
<tr>
<td>A_BOLD</td>
<td>Extra bright or bold text</td>
</tr>
<tr>
<td>A_DIM</td>
<td>Half bright text</td>
</tr>
<tr>
<td>A_REVERSE</td>
<td>Reverse-video text</td>
</tr>
<tr>
<td>A_STANDOUT</td>
<td>The best highlighting mode available</td>
</tr>
<tr>
<td>A_UNDERLINE</td>
<td>Underlined text</td>
</tr>
</tbody>
</table>

So, to display a reverse-video status line on the top line of the screen, you could code:

```python
stdscr.addstr(0, 0, "Current mode: Typing mode", curses.A_REVERSE)
stdscr.refresh()
```

The curses library also supports color on those terminals that provide it. The most common such terminal is probably the Linux console, followed by color xterms.
To use color, you must call the `start_color()` function soon after calling `initscr()`, to initialize the default color set (the `curses.wrapper()` function does this automatically). Once that’s done, the `has_colors()` function returns TRUE if the terminal in use can actually display color. (Note: `curses` uses the American spelling ‘color’, instead of the Canadian/British spelling ‘colour’. If you’re used to the British spelling, you’ll have to resign yourself to misspelling it for the sake of these functions.)

The `curses` library maintains a finite number of color pairs, containing a foreground (or text) color and a background color. You can get the attribute value corresponding to a color pair with the `color_pair()` function; this can be bitwise-OR’ed with other attributes such as `A_REVERSE`, but again, such combinations are not guaranteed to work on all terminals.

An example, which displays a line of text using color pair 1:

```python
stdscr.addstr("Pretty text", curses.color_pair(1))
stdscr.refresh()
```

As I said before, a color pair consists of a foreground and background color. The `init_pair(n, f, b)` function changes the definition of color pair `n`, to foreground color `f` and background color `b`. Color pair 0 is hard-wired to white on black, and cannot be changed.

Colors are numbered, and `start_color()` initializes 8 basic colors when it activates color mode. They are: 0:black, 1:red, 2:green, 3:yellow, 4:blue, 5:magenta, 6:cyan, and 7:white. The `curses` module defines named constants for each of these colors: `curses.COLOR_BLACK`, `curses.COLOR_RED`, and so forth.

Let’s put all this together. To change color 1 to red text on a white
background, you would call:

```python
curses.init_pair(1, curses.COLOR_RED, curses.COLOR_WHITE)
```

When you change a color pair, any text already displayed using that color pair will change to the new colors. You can also display new text in this color with:

```python
stdscr.addstr(0, 0, "RED ALERT!", curses.color_pair(1))
```

Very fancy terminals can change the definitions of the actual colors to a given RGB value. This lets you change color 1, which is usually red, to purple or blue or any other color you like. Unfortunately, the Linux console doesn’t support this, so I’m unable to try it out, and can’t provide any examples. You can check if your terminal can do this by calling `can_change_color()`, which returns `True` if the capability is there. If you’re lucky enough to have such a talented terminal, consult your system’s man pages for more information.
User Input

The C curses library offers only very simple input mechanisms. Python’s `curses` module adds a basic text-input widget. (Other libraries such as `Urwid` have more extensive collections of widgets.)

There are two methods for getting input from a window:

- `getch()` refreshes the screen and then waits for the user to hit a key, displaying the key if `echo()` has been called earlier. You can optionally specify a coordinate to which the cursor should be moved before pausing.
- `getkey()` does the same thing but converts the integer to a string. Individual characters are returned as 1-character strings, and special keys such as function keys return longer strings containing a key name such as `KEY_UP` or `^G`.

It’s possible to not wait for the user using the `nodelay()` window method. After `nodelay(True)`, `getch()` and `getkey()` for the window become non-blocking. To signal that no input is ready, `getch()` returns `curses.ERR` (a value of -1) and `getkey()` raises an exception. There’s also a `halfdelay()` function, which can be used to (in effect) set a timer on each `getch()`; if no input becomes available within a specified delay (measured in tenths of a second), `curses` raises an exception.

The `getch()` method returns an integer; if it’s between 0 and 255, it represents the ASCII code of the key pressed. Values greater than 255 are special keys such as Page Up, Home, or the cursor keys. You can compare the value returned to constants such as `curses.KEY_PPAGE`, `curses.KEY_HOME`, or `curses.KEY_LEFT`. The main loop of your program may look something like this:
while True:
    c = stdscr.getch()
    if c == ord('p'):
        PrintDocument()
    elif c == ord('q'):
        break  # Exit the while loop
    elif c == curses.KEY_HOME:
        x = y = 0

The `curses.ascii` module supplies ASCII class membership functions that take either integer or 1-character string arguments; these may be useful in writing more readable tests for such loops. It also supplies conversion functions that take either integer or 1-character-string arguments and return the same type. For example, `curses.ascii.ctrl()` returns the control character corresponding to its argument.

There's also a method to retrieve an entire string, `getstr()`. It isn't used very often, because its functionality is quite limited; the only editing keys available are the backspace key and the Enter key, which terminates the string. It can optionally be limited to a fixed number of characters.

curses.echo()  # Enable echoing of characters

# Get a 15-character string, with the cursor on the
s = stdscr.getstr(0, 0, 15)

The `curses.textpad` module supplies a text box that supports an Emacs-like set of keybindings. Various methods of the `Textbox` class support editing with input validation and gathering the edit results either with or without trailing spaces. Here’s an example:
import curses
from curses.textpad import Textbox, rectangle

def main(stdscr):
    stdscr.addstr(0, 0, "Enter IM message: (hit Ctrl-G to send)"

    editwin = curses.newwin(5, 30, 2, 1)
    rectangle(stdscr, 1, 0, 1+5+1, 1+30+1)
    stdscr.refresh()

    box = Textbox(editwin)

    # Let the user edit until Ctrl-G is struck.
    box.edit()

    # Get resulting contents
    message = box.gather()

See the library documentation on `curses.textpad` for more details.
For More Information

This HOWTO doesn’t cover some advanced topics, such as reading the contents of the screen or capturing mouse events from an xterm instance, but the Python library page for the `curses` module is now reasonably complete. You should browse it next.

If you’re in doubt about the detailed behavior of the curses functions, consult the manual pages for your curses implementation, whether it’s ncurses or a proprietary Unix vendor’s. The manual pages will document any quirks, and provide complete lists of all the functions, attributes, and ACS_* characters available to you.

Because the curses API is so large, some functions aren’t supported in the Python interface. Often this isn’t because they’re difficult to implement, but because no one has needed them yet. Also, Python doesn’t yet support the menu library associated with ncurses. Patches adding support for these would be welcome; see the Python Developer’s Guide to learn more about submitting patches to Python.

Abstract

Defines descriptors, summarizes the protocol, and shows how descriptors are called. Examines a custom descriptor and several built-in python descriptors including functions, properties, static methods, and class methods. Shows how each works by giving a pure Python equivalent and a sample application.

Learning about descriptors not only provides access to a larger toolset, it creates a deeper understanding of how Python works and an appreciation for the elegance of its design.
Definition and Introduction

In general, a descriptor is an object attribute with “binding behavior”, one whose attribute access has been overridden by methods in the descriptor protocol. Those methods are `__get__()`, `__set__()`, and `__delete__()`. If any of those methods are defined for an object, it is said to be a descriptor.

The default behavior for attribute access is to get, set, or delete the attribute from an object’s dictionary. For instance, `a.x` has a lookup chain starting with `a.__dict__['x']`, then `type(a).__dict__['x']`, and continuing through the base classes of `type(a)` excluding metaclasses. If the looked-up value is an object defining one of the descriptor methods, then Python may override the default behavior and invoke the descriptor method instead. Where this occurs in the precedence chain depends on which descriptor methods were defined.

Descriptors are a powerful, general purpose protocol. They are the mechanism behind properties, methods, static methods, class methods, and `super()`. They are used throughout Python itself to implement the new style classes introduced in version 2.2. Descriptors simplify the underlying C-code and offer a flexible set of new tools for everyday Python programs.
## Descriptor Protocol

```python
descr.__get__(self, obj, type=None) --> value

descr.__set__(self, obj, value) --> None

descr.__delete__(self, obj) --> None
```

That is all there is to it. Define any of these methods and an object is considered a descriptor and can override default behavior upon being looked up as an attribute.

If an object defines both `__get__()` and `__set__()`, it is considered a data descriptor. Descriptors that only define `__get__()` are called non-data descriptors (they are typically used for methods but other uses are possible).

Data and non-data descriptors differ in how overrides are calculated with respect to entries in an instance's dictionary. If an instance's dictionary has an entry with the same name as a data descriptor, the data descriptor takes precedence. If an instance's dictionary has an entry with the same name as a non-data descriptor, the dictionary entry takes precedence.

To make a read-only data descriptor, define both `__get__()` and `__set__()` with the `__set__()` raising an `AttributeError` when called. Defining the `__set__()` method with an exception raising placeholder is enough to make it a data descriptor.
Invoking Descriptors

A descriptor can be called directly by its method name. For example, d.__get__(obj).

Alternatively, it is more common for a descriptor to be invoked automatically upon attribute access. For example, obj.d looks up d in the dictionary of obj. If d defines the method __get__(), then d.__get__(obj) is invoked according to the precedence rules listed below.

The details of invocation depend on whether obj is an object or a class.

For objects, the machinery is in object.__getattribute__() which transforms b.x into type(b).__dict__['x'].__get__(b, type(b)). The implementation works through a precedence chain that gives data descriptors priority over instance variables, instance variables priority over non-data descriptors, and assigns lowest priority to __getattr__() if provided. The full C implementation can be found in PyObject_GenericGetAttr() in Objects/object.c.

For classes, the machinery is in type.__getattribute__() which transforms B.x into B.__dict__['x'].__get__(None, B). In pure Python, it looks like:

```python
def __getattribute__(self, key):
    "Emulate type_getattro() in Objects/typeobject.c"
    v = object.__getattribute__(self, key)
    if hasattr(v, '__get__'):
        return v.__get__(None, self)
    return v
```
The important points to remember are:

- descriptors are invoked by the `__getattribute__()` method
- overriding `__getattribute__()` prevents automatic descriptor calls
- `object.__getattribute__()` and `type.__getattribute__()` make different calls to `__get__()`.
- data descriptors always override instance dictionaries.
- non-data descriptors may be overridden by instance dictionaries.

The object returned by `super()` also has a custom `__getattribute__()` method for invoking descriptors. The call `super(B, obj).m()` searches `obj.__class__.__mro__` for the base class `A` immediately following `B` and then returns `A.__dict__['m'].__get__(obj, B)`. If not a descriptor, `m` is returned unchanged. If not in the dictionary, `m` reverts to a search using `object.__getattribute__()`.

The implementation details are in `super_getattro()` in `Objects/typeobject.c` and a pure Python equivalent can be found in Guido's Tutorial.

The details above show that the mechanism for descriptors is embedded in the `__getattribute__()` methods for `object`, `type`, and `super()`. Classes inherit this machinery when they derive from `object` or if they have a meta-class providing similar functionality. Likewise, classes can turn-off descriptor invocation by overriding `__getattribute__()`. 
Descriptor Example

The following code creates a class whose objects are data descriptors which print a message for each get or set. Overriding \_\_getattribute\_\_() is alternate approach that could do this for every attribute. However, this descriptor is useful for monitoring just a few chosen attributes:

```python
class RevealAccess(object):
    '''A data descriptor that sets and returns values normally and prints a message logging their access.'''
    def __init__(self, initval=None, name='var'):
        self.val = initval
        self.name = name

    def __get__(self, obj, objtype):
        print('Retrieving', self.name)
        return self.val

    def __set__(self, obj, val):
        print('Updating', self.name)
        self.val = val

>>> class MyClass(object):
    x = RevealAccess(10, 'var "x"')
y = 5

>>> m = MyClass()
>>> m.x
Retrieving var "x"
10
>>> m.x = 20
Updating var "x"
```
The protocol is simple and offers exciting possibilities. Several use cases are so common that they have been packaged into individual function calls. Properties, bound and unbound methods, static methods, and class methods are all based on the descriptor protocol.
Properties

Calling `property()` is a succinct way of building a data descriptor that triggers function calls upon access to an attribute. Its signature is:

```
property(fget=None, fset=None, fdel=None, doc=None)
```

The documentation shows a typical use to define a managed attribute `x`:

```python
class C(object):
    def getx(self): return self.__x
    def setx(self, value): self.__x = value
    def delx(self): del self.__x
    x = property(getx, setx, delx, "I'm the 'x' property.
```

To see how `property()` is implemented in terms of the descriptor protocol, here is a pure Python equivalent:

```python
class Property(object):
    "Emulate PyProperty_Type() in Objects/descrobject.c"

    def __init__(self, fget=None, fset=None, fdel=None, doc=None):
        self.fget = fget
        self.fset = fset
        self.fdel = fdel
        if doc is None and fget is not None:
            doc = fget.__doc__
            self.__doc__ = doc

    def __get__(self, obj, objtype=None):
        if obj is None:
            return self
```
if self.fget is None:
    raise AttributeError("unreadable attribute")
return self.fget(obj)

def __set__(self, obj, value):
    if self.fset is None:
        raise AttributeError("can't set attribute")
    self.fset(obj, value)

def __delete__(self, obj):
    if self.fdel is None:
        raise AttributeError("can't delete attribute")
    self.fdel(obj)

def getter(self, fget):
    return type(self)(fget, self.fset, self.fdel)

def setter(self, fset):
    return type(self)(self.fget, fset, self.fdel)

def deleter(self, fdel):
    return type(self)(self.fget, self.fset, fdel)

The `property()` builtin helps whenever a user interface has granted attribute access and then subsequent changes require the intervention of a method.

For instance, a spreadsheet class may grant access to a cell value through `Cell('b10').value`. Subsequent improvements to the program require the cell to be recalculated on every access; however, the programmer does not want to affect existing client code accessing the attribute directly. The solution is to wrap access to the value attribute in a property data descriptor:

class Cell(object):

def getvalue(self, obj):
    "Recalculate cell before returning value"
    self.recalc()
    return obj._value
value = property(getvalue)
Functions and Methods

Python's object oriented features are built upon a function based environment. Using non-data descriptors, the two are merged seamlessly.

Class dictionaries store methods as functions. In a class definition, methods are written using `def` and `lambda`, the usual tools for creating functions. The only difference from regular functions is that the first argument is reserved for the object instance. By Python convention, the instance reference is called `self` but may be called `this` or any other variable name.

To support method calls, functions include the `__get__()` method for binding methods during attribute access. This means that all functions are non-data descriptors which return bound or unbound methods depending whether they are invoked from an object or a class. In pure python, it works like this:

```python
class Function(object):
    ...
    def __get__(self, obj, objtype=None):
        "Simulate func_descr_get() in Objects/funcobject.c"
        return types.MethodType(self, obj, objtype)
```

Running the interpreter shows how the function descriptor works in practice:

```python
>>> class D(object):
    def f(self, x):
        return x
```
The output suggests that bound and unbound methods are two different types. While they could have been implemented that way, the actual C implementation of PyMethod_Type in Objects/classobject.c is a single object with two different representations depending on whether the im_self field is set or is NULL (the C equivalent of None).

Likewise, the effects of calling a method object depend on the im_self field. If set (meaning bound), the original function (stored in the im_func field) is called as expected with the first argument set to the instance. If unbound, all of the arguments are passed unchanged to the original function. The actual C implementation of instancemethod_call() is only slightly more complex in that it includes some type checking.
Static Methods and Class Methods

Non-data descriptors provide a simple mechanism for variations on the usual patterns of binding functions into methods.

To recap, functions have a `__get__()` method so that they can be converted to a method when accessed as attributes. The non-data descriptor transforms a `obj.f(*args)` call into `f(obj, *args)`. Calling `klass.f(*args)` becomes `f(*args)`.

This chart summarizes the binding and its two most useful variants:

<table>
<thead>
<tr>
<th>Transformation</th>
<th>Called from an Object</th>
<th>Called from a Class</th>
</tr>
</thead>
<tbody>
<tr>
<td>function</td>
<td><code>f(obj, *args)</code></td>
<td><code>f(*args)</code></td>
</tr>
<tr>
<td>staticmethod</td>
<td><code>f(*args)</code></td>
<td><code>f(*args)</code></td>
</tr>
<tr>
<td>classmethod</td>
<td><code>f(type(obj), *args)</code></td>
<td><code>f(klass, *args)</code></td>
</tr>
</tbody>
</table>

Static methods return the underlying function without changes. Calling either `c.f` or `C.f` is the equivalent of a direct lookup into `object.__getattribute__(c, "f")` or `object.__getattribute__(C, "f")`. As a result, the function becomes identically accessible from either an object or a class.

Good candidates for static methods are methods that do not reference the `self` variable.

For instance, a statistics package may include a container class for experimental data. The class provides normal methods for computing the average, mean, median, and other descriptive statistics that depend on the data. However, there may be useful functions which are
conceptually related but do not depend on the data. For instance, erf(x) is handy conversion routine that comes up in statistical work but does not directly depend on a particular dataset. It can be called either from an object or the class: \[ \text{s.erf}(1.5) \rightarrow .9332 \] or \[ \text{Sample.erf}(1.5) \rightarrow .9332. \]

Since staticmethods return the underlying function with no changes, the example calls are unexciting:

```python
>>> class E(object):
    def f(x):
        print(x)
    f = staticmethod(f)

>>> print(E.f(3))
3
>>> print(E().f(3))
3
```

Using the non-data descriptor protocol, a pure Python version of `staticmethod()` would look like this:

```python
class StaticMethod(object):
    "Emulate PyStaticMethod_Type() in Objects/funcobject.c"
    def __init__(self, f):
        self.f = f

    def __get__(self, obj, objtype=None):
        return self.f
```

Unlike static methods, class methods prepend the class reference to the argument list before calling the function. This format is the same for whether the caller is an object or a class:
This behavior is useful whenever the function only needs to have a class reference and does not care about any underlying data. One use for classmethods is to create alternate class constructors. In Python 2.3, the classmethod `dict.fromkeys()` creates a new dictionary from a list of keys. The pure Python equivalent is:

```python
class Dict(object):
    ...
    def fromkeys(klass, iterable, value=None):
        """Emulate dict_fromkeys() in Objects/dictobject.c"
        d = klass()
        for key in iterable:
            d[key] = value
        return d
    fromkeys = classmethod(fromkeys)
```

Now a new dictionary of unique keys can be constructed like this:

```python
>>> Dict.fromkeys('abracadabra')
{'a': None, 'r': None, 'b': None, 'c': None, 'd': None}
```

Using the non-data descriptor protocol, a pure Python version of `classmethod()` would look like this:
class ClassMethod(object):
    "Emulate PyClassMethod_Type() in Objects/funcobject.c"

    def __init__(self, f):
        self.f = f

    def __get__(self, obj, klass=None):
        if klass is None:
            klass = type(obj)
        def newfunc(*args):
            return self.f(klass, *args)
        return newfunc
In this document, we'll take a tour of Python’s features suitable for implementing programs in a functional style. After an introduction to the concepts of functional programming, we'll look at language features such as *iterators* and *generators* and relevant library modules such as *itertools* and *functools*.
Introduction

This section explains the basic concept of functional programming; if you're just interested in learning about Python language features, skip to the next section on *Iterators*.

Programming languages support decomposing problems in several different ways:

- Most programming languages are **procedural**: programs are lists of instructions that tell the computer what to do with the program's input. C, Pascal, and even Unix shells are procedural languages.
- In **declarative** languages, you write a specification that describes the problem to be solved, and the language implementation figures out how to perform the computation efficiently. SQL is the declarative language you’re most likely to be familiar with; a SQL query describes the data set you want to retrieve, and the SQL engine decides whether to scan tables or use indexes, which subclauses should be performed first, etc.
- **Object-oriented** programs manipulate collections of objects. Objects have internal state and support methods that query or modify this internal state in some way. Smalltalk and Java are object-oriented languages. C++ and Python are languages that support object-oriented programming, but don’t force the use of object-oriented features.
- **Functional** programming decomposes a problem into a set of functions. Ideally, functions only take inputs and produce outputs, and don’t have any internal state that affects the output produced for a given input. Well-known functional languages include the ML family (Standard ML, OCaml, and other variants) and Haskell.

The designers of some computer languages choose to emphasize one particular approach to programming. This often makes it difficult to
write programs that use a different approach. Other languages are multi-paradigm languages that support several different approaches. Lisp, C++, and Python are multi-paradigm; you can write programs or libraries that are largely procedural, object-oriented, or functional in all of these languages. In a large program, different sections might be written using different approaches; the GUI might be object-oriented while the processing logic is procedural or functional, for example.

In a functional program, input flows through a set of functions. Each function operates on its input and produces some output. Functional style discourages functions with side effects that modify internal state or make other changes that aren’t visible in the function’s return value. Functions that have no side effects at all are called purely functional. Avoiding side effects means not using data structures that get updated as a program runs; every function’s output must only depend on its input.

Some languages are very strict about purity and don’t even have assignment statements such as \( a = 3 \) or \( c = a + b \), but it’s difficult to avoid all side effects. Printing to the screen or writing to a disk file are side effects, for example. For example, in Python a call to the `print()` or `time.sleep()` function both return no useful value; they’re only called for their side effects of sending some text to the screen or pausing execution for a second.

Python programs written in functional style usually won’t go to the extreme of avoiding all I/O or all assignments; instead, they’ll provide a functional-appearing interface but will use non-functional features internally. For example, the implementation of a function will still use assignments to local variables, but won’t modify global variables or have other side effects.

Functional programming can be considered the opposite of object-
oriented programming. Objects are little capsules containing some internal state along with a collection of method calls that let you modify this state, and programs consist of making the right set of state changes. Functional programming wants to avoid state changes as much as possible and works with data flowing between functions. In Python you might combine the two approaches by writing functions that take and return instances representing objects in your application (e-mail messages, transactions, etc.).

Functional design may seem like an odd constraint to work under. Why should you avoid objects and side effects? There are theoretical and practical advantages to the functional style:

- Formal provability.
- Modularity.
- Composability.
- Ease of debugging and testing.

**Formal provability**

A theoretical benefit is that it's easier to construct a mathematical proof that a functional program is correct.

For a long time researchers have been interested in finding ways to mathematically prove programs correct. This is different from testing a program on numerous inputs and concluding that its output is usually correct, or reading a program's source code and concluding that the code looks right; the goal is instead a rigorous proof that a program produces the right result for all possible inputs.

The technique used to prove programs correct is to write down invariants, properties of the input data and of the program's variables that are always true. For each line of code, you then show that if
invariants X and Y are true **before** the line is executed, the slightly different invariants X' and Y' are true **after** the line is executed. This continues until you reach the end of the program, at which point the invariants should match the desired conditions on the program’s output.

Functional programming’s avoidance of assignments arose because assignments are difficult to handle with this technique; assignments can break invariants that were true before the assignment without producing any new invariants that can be propagated onward.

Unfortunately, proving programs correct is largely impractical and not relevant to Python software. Even trivial programs require proofs that are several pages long; the proof of correctness for a moderately complicated program would be enormous, and few or none of the programs you use daily (the Python interpreter, your XML parser, your web browser) could be proven correct. Even if you wrote down or generated a proof, there would then be the question of verifying the proof; maybe there’s an error in it, and you wrongly believe you’ve proved the program correct.

**Modularity**

A more practical benefit of functional programming is that it forces you to break apart your problem into small pieces. Programs are more modular as a result. It’s easier to specify and write a small function that does one thing than a large function that performs a complicated transformation. Small functions are also easier to read and to check for errors.

**Ease of debugging and testing**
Testing and debugging a functional-style program is easier.

Debugging is simplified because functions are generally small and clearly specified. When a program doesn’t work, each function is an interface point where you can check that the data are correct. You can look at the intermediate inputs and outputs to quickly isolate the function that’s responsible for a bug.

Testing is easier because each function is a potential subject for a unit test. Functions don’t depend on system state that needs to be replicated before running a test; instead you only have to synthesize the right input and then check that the output matches expectations.

**Composability**

As you work on a functional-style program, you’ll write a number of functions with varying inputs and outputs. Some of these functions will be unavoidably specialized to a particular application, but others will be useful in a wide variety of programs. For example, a function that takes a directory path and returns all the XML files in the directory, or a function that takes a filename and returns its contents, can be applied to many different situations.

Over time you’ll form a personal library of utilities. Often you’ll assemble new programs by arranging existing functions in a new configuration and writing a few functions specialized for the current task.
Iterators

I'll start by looking at a Python language feature that's an important foundation for writing functional-style programs: iterators.

An iterator is an object representing a stream of data; this object returns the data one element at a time. A Python iterator must support a method called __next__() that takes no arguments and always returns the next element of the stream. If there are no more elements in the stream, __next__() must raise the StopIteration exception. Iterators don't have to be finite, though; it's perfectly reasonable to write an iterator that produces an infinite stream of data.

The built-in iter() function takes an arbitrary object and tries to return an iterator that will return the object's contents or elements, raising TypeError if the object doesn't support iteration. Several of Python's built-in data types support iteration, the most common being lists and dictionaries. An object is called iterable if you can get an iterator for it.

You can experiment with the iteration interface manually:

```python
>>> L = [1,2,3]
>>> it = iter(L)
>>> it
<...iterator object at ...>
>>> it.__next__()  # same as next(it)
1
>>> next(it)
2
>>> next(it)
3
>>> next(it)
```
Python expects iterable objects in several different contexts, the most important being the `for` statement. In the statement `for X in Y`, `Y` must be an iterator or some object for which `iter()` can create an iterator. These two statements are equivalent:

```python
for i in iter(obj):
    print(i)
for i in obj:
    print(i)
```

Iterators can be materialized as lists or tuples by using the `list()` or `tuple()` constructor functions:

```python
>>> L = [1,2,3]
>>> iterator = iter(L)
>>> t = tuple(iterator)
>>> t
(1, 2, 3)
```

Sequence unpacking also supports iterators: if you know an iterator will return `N` elements, you can unpack them into an `N`-tuple:

```python
>>> L = [1,2,3]
>>> iterator = iter(L)
>>> a,b,c = iterator
>>> a,b,c
(1, 2, 3)
```

Built-in functions such as `max()` and `min()` can take a single iterator
argument and will return the largest or smallest element. The "in" and "not in" operators also support iterators: \( X \text{ in } \text{iterator} \) is true if \( X \) is found in the stream returned by the iterator. You'll run into obvious problems if the iterator is infinite; \( \text{max}(), \text{min}() \) will never return, and if the element \( X \) never appears in the stream, the "in" and "not in" operators won't return either.

Note that you can only go forward in an iterator; there's no way to get the previous element, reset the iterator, or make a copy of it. Iterator objects can optionally provide these additional capabilities, but the iterator protocol only specifies the \texttt{__next__()} method. Functions may therefore consume all of the iterator's output, and if you need to do something different with the same stream, you'll have to create a new iterator.

**Data Types That Support Iterators**

We've already seen how lists and tuples support iterators. In fact, any Python sequence type, such as strings, will automatically support creation of an iterator.

Calling \texttt{iter()} on a dictionary returns an iterator that will loop over the dictionary's keys:

```python
>>> m = {'Jan': 1, 'Feb': 2, 'Mar': 3, 'Apr': 4, 'May': ...
    'Jul': 7, 'Aug': 8, 'Sep': 9, 'Oct': 10, 'Nov': ...
>>> for key in m:
...    print(key, m[key])
Mar 3
Feb 2
Aug 8
Sep 9
Apr 4
```
Note that the order is essentially random, because it’s based on the hash ordering of the objects in the dictionary.

Applying `iter()` to a dictionary always loops over the keys, but dictionaries have methods that return other iterators. If you want to iterate over values or key/value pairs, you can explicitly call the `values()` or `items()` methods to get an appropriate iterator.

The `dict()` constructor can accept an iterator that returns a finite stream of `(key, value)` tuples:

```python
>>> L = [('Italy', 'Rome'), ('France', 'Paris'), ('US', 'Washington DC')]
>>> dict(iter(L))
{'Italy': 'Rome', 'US': 'Washington DC', 'France': 'Paris'}
```

Files also support iteration by calling the `readline()` method until there are no more lines in the file. This means you can read each line of a file like this:

```python
for line in file:
    # do something for each line
...
```

Sets can take their contents from an iterable and let you iterate over the set's elements:
S = \{2, 3, 5, 7, 11, 13\}
for i in S:
    print(i)
Generator expressions and list comprehensions

Two common operations on an iterator’s output are 1) performing some operation for every element, 2) selecting a subset of elements that meet some condition. For example, given a list of strings, you might want to strip off trailing whitespace from each line or extract all the strings containing a given substring.

List comprehensions and generator expressions (short form: “listcomps” and “genexps”) are a concise notation for such operations, borrowed from the functional programming language Haskell (http://www.haskell.org/). You can strip all the whitespace from a stream of strings with the following code:

```
line_list = [' line 1
', 'line 2 
', ...]

# Generator expression -- returns iterator
stripped_iter = (line.strip() for line in line_list)

# List comprehension -- returns list
stripped_list = [line.strip() for line in line_list]
```

You can select only certain elements by adding an "if" condition:

```
stripped_list = [line.strip() for line in line_list if line != '']
```

With a list comprehension, you get back a Python list; stripped_list is a list containing the resulting lines, not an iterator. Generator expressions return an iterator that computes the values as necessary, not needing to materialize all the values at once. This
means that list comprehensions aren’t useful if you’re working with iterators that return an infinite stream or a very large amount of data. Generator expressions are preferable in these situations.

Generator expressions are surrounded by parentheses ("()") and list comprehensions are surrounded by square brackets ("[]"). Generator expressions have the form:

```
( expression for expr in sequence1
    if condition1
    for expr2 in sequence2
    if condition2
    for expr3 in sequence3 ...
    if condition3
    for exprN in sequenceN
    if conditionN )
```

Again, for a list comprehension only the outside brackets are different (square brackets instead of parentheses).

The elements of the generated output will be the successive values of expression. The if clauses are all optional; if present, expression is only evaluated and added to the result when condition is true.

Generator expressions always have to be written inside parentheses, but the parentheses signalling a function call also count. If you want to create an iterator that will be immediately passed to a function you can write:

```
obj_total = sum(obj.count for obj in list_all_objects)
```

The for...in clauses contain the sequences to be iterated over.
The sequences do not have to be the same length, because they are iterated over from left to right, **not** in parallel. For each element in `sequence1`, `sequence2` is looped over from the beginning. `sequence3` is then looped over for each resulting pair of elements from `sequence1` and `sequence2`.

To put it another way, a list comprehension or generator expression is equivalent to the following Python code:

```python
for expr1 in sequence1:
    if not (condition1):
        continue  # Skip this element
for expr2 in sequence2:
    if not (condition2):
        continue  # Skip this element
...
for exprN in sequenceN:
    if not (conditionN):
        continue  # Skip this element

# Output the value of # the expression.
```

This means that when there are multiple `for...in` clauses but no `if` clauses, the length of the resulting output will be equal to the product of the lengths of all the sequences. If you have two lists of length 3, the output list is 9 elements long:

```python
>>> seq1 = 'abc'
>>> seq2 = (1, 2, 3)
>>> [(x, y) for x in seq1 for y in seq2]
[('a', 1), ('a', 2), ('a', 3),
 ('b', 1), ('b', 2), ('b', 3),
 ('c', 1), ('c', 2), ('c', 3)]
```
To avoid introducing an ambiguity into Python’s grammar, if expression is creating a tuple, it must be surrounded with parentheses. The first list comprehension below is a syntax error, while the second one is correct:

```python
# Syntax error
[x, y for x in seq1 for y in seq2]
# Correct
[(x, y) for x in seq1 for y in seq2]
```
Generators

Generators are a special class of functions that simplify the task of writing iterators. Regular functions compute a value and return it, but generators return an iterator that returns a stream of values.

You’re doubtless familiar with how regular function calls work in Python or C. When you call a function, it gets a private namespace where its local variables are created. When the function reaches a `return` statement, the local variables are destroyed and the value is returned to the caller. A later call to the same function creates a new private namespace and a fresh set of local variables. But, what if the local variables weren’t thrown away on exiting a function? What if you could later resume the function where it left off? This is what generators provide; they can be thought of as resumable functions.

Here’s the simplest example of a generator function:

```python
>>> def generate_ints(N):
...   for i in range(N):
...     yield i
```

Any function containing a `yield` keyword is a generator function; this is detected by Python’s `bytecode` compiler which compiles the function specially as a result.

When you call a generator function, it doesn’t return a single value; instead it returns a generator object that supports the iterator protocol. On executing the `yield` expression, the generator outputs the value of `i`, similar to a `return` statement. The big difference between `yield` and a `return` statement is that on reaching a `yield` the generator’s state of execution is suspended and local variables are
preserved. On the next call to the generator’s \_
next\_
() method, the function will resume executing.

Here’s a sample usage of the generate_ints() generator:

```python
>>> gen = generate_ints(3)
>>> gen
<generator object generate_ints at ...>
>>> next(gen)
0
>>> next(gen)
1
>>> next(gen)
2
>>> next(gen)
Traceback (most recent call last):
  File "stdin", line 1, in ?
  File "stdin", line 2, in generate_ints
StopIteration
```

You could equally write for i in generate_ints(5), or a,b,c = generate_ints(3).

Inside a generator function, return value is semantically equivalent to raise StopIteration(value). If no value is returned or the bottom of the function is reached, the procession of values ends and the generator cannot return any further values.

You could achieve the effect of generators manually by writing your own class and storing all the local variables of the generator as instance variables. For example, returning a list of integers could be done by setting self.count to 0, and having the \_
next\_
() method increment self.count and return it. However, for a moderately complicated generator, writing a corresponding class can
be much messier.

The test suite included with Python's library, `Lib/test/test_generators.py`, contains a number of more interesting examples. Here's one generator that implements an in-order traversal of a tree using generators recursively.

```python
# A recursive generator that generates Tree leaves in order.
def inorder(t):
    if t:
        for x in inorder(t.left):
            yield x

        yield t.label

        for x in inorder(t.right):
            yield x
```

Two other examples in `test_generators.py` produce solutions for the N-Queens problem (placing N queens on an NxN chess board so that no queen threatens another) and the Knight's Tour (finding a route that takes a knight to every square of an NxN chessboard without visiting any square twice).

**Passing values into a generator**

In Python 2.4 and earlier, generators only produced output. Once a generator's code was invoked to create an iterator, there was no way to pass any new information into the function when its execution is resumed. You could hack together this ability by making the generator look at a global variable or by passing in some mutable object that callers then modify, but these approaches are messy.
In Python 2.5 there's a simple way to pass values into a generator. `yield` became an expression, returning a value that can be assigned to a variable or otherwise operated on:

```python
val = (yield i)
```

I recommend that you **always** put parentheses around a `yield` expression when you're doing something with the returned value, as in the above example. The parentheses aren't always necessary, but it's easier to always add them instead of having to remember when they're needed.

(PEP 342 explains the exact rules, which are that a `yield`-expression must always be parenthesized except when it occurs at the top-level expression on the right-hand side of an assignment. This means you can write `val = yield i` but have to use parentheses when there's an operation, as in `val = (yield i) + 12`.)

Values are sent into a generator by calling its `send(value)` method. This method resumes the generator's code and the `yield` expression returns the specified value. If the regular `__next__()` method is called, the `yield` returns `None`.

Here’s a simple counter that increments by 1 and allows changing the value of the internal counter.

```python
def counter(maximum):
    i = 0
    while i < maximum:
        val = (yield i)
        # If value provided, change counter
        if val is not None:
            i = val
```
else:
    i += 1

And here's an example of changing the counter:

```
>>> it = counter(10)
>>> next(it)
0
>>> next(it)
1
>>> it.send(8)
8
>>> next(it)
9
>>> next(it)
Traceback (most recent call last):
  File "t.py", line 15, in ?
    it.next()
StopIteration
```

Because `yield` will often be returning `None`, you should always check for this case. Don’t just use its value in expressions unless you’re sure that the `send()` method will be the only method used resume your generator function.

In addition to `send()`, there are two other methods on generators:

- `throw(type, value=None, traceback=None)` is used to raise an exception inside the generator; the exception is raised by the `yield` expression where the generator’s execution is paused.

- `close()` raises a `GeneratorExit` exception inside the generator to terminate the iteration. On receiving this exception, the generator’s code must either raise `GeneratorExit` or
StopIteration; catching the exception and doing anything else is illegal and will trigger a RuntimeError. close() will also be called by Python's garbage collector when the generator is garbage-collected.

If you need to run cleanup code when a GeneratorExit occurs, I suggest using a try: ... finally: suite instead of catching GeneratorExit.

The cumulative effect of these changes is to turn generators from one-way producers of information into both producers and consumers.

Generators also become coroutines, a more generalized form of subroutines. Subroutines are entered at one point and exited at another point (the top of the function, and a return statement), but coroutines can be entered, exited, and resumed at many different points (the yield statements).
Built-in functions

Let's look in more detail at built-in functions often used with iterators.

Two of Python's built-in functions, `map()` and `filter()` duplicate the features of generator expressions:

map(f, iterA, iterB, ...) returns an iterator over the sequence

\[ f(\text{iterA}[0], \text{iterB}[0]), f(\text{iterA}[1], \text{iterB}[1]), f(\text{iterA}[2], \text{iterB}[2]), \ldots \]

```python
>>> def upper(s):
...     return s.upper()

>>> list(map(upper, ['sentence', 'fragment']))
['SENTENCE', 'FRAGMENT']
>>> list([upper(s) for s in ['sentence', 'fragment']])
['SENTENCE', 'FRAGMENT']
```

You can of course achieve the same effect with a list comprehension.

filter(predicate, iter) returns an iterator over all the sequence elements that meet a certain condition, and is similarly duplicated by list comprehensions. A predicate is a function that returns the truth value of some condition; for use with `filter()`, the predicate must take a single value.

```python
>>> def is_even(x):
...     return (x % 2) == 0

>>> list(filter(is_even, range(10)))
[0, 2, 4, 6, 8]
```
This can also be written as a list comprehension:

```python
>>> list(x for x in range(10) if is_even(x))
[0, 2, 4, 6, 8]
```

`enumerate(iter)` counts off the elements in the iterable, returning 2-tuples containing the count and each element.

```python
>>> for item in enumerate(['subject', 'verb', 'object', ...
    print(item)
(0, 'subject')
(1, 'verb')
(2, 'object')
```

`enumerate()` is often used when looping through a list and recording the indexes at which certain conditions are met:

```python
f = open('data.txt', 'r')
for i, line in enumerate(f):
    if line.strip() == '':
        print('Blank line at line #%i' % i)
```

`sorted(iterable, key=None, reverse=False)` collects all the elements of the iterable into a list, sorts the list, and returns the sorted result. The `key` and `reverse` arguments are passed through to the constructed list's `sort()` method.

```python
>>> import random
>>> # Generate 8 random numbers between [0, 10000)
>>> rand_list = random.sample(range(10000), 8)
>>> rand_list
[769, 7953, 9828, 6431, 8442, 9878, 6213, 2207]
>>> sorted(rand_list)
[769, 2207, 6213, 6431, 7953, 8442, 9828, 9878]
```
sorted(rand_list, reverse=True)
[9878, 9828, 8442, 7953, 6431, 6213, 2207, 769]

(For a more detailed discussion of sorting, see the Sorting HOW TO.)

The any(iter) and all(iter) built-ins look at the truth values of an iterable's contents. any() returns True if any element in the iterable is a true value, and all() returns True if all of the elements are true values:

>>> any([0,1,0])
True
>>> any([0,0,0])
False
>>> any([1,1,1])
True
>>> all([0,1,0])
False
>>> all([0,0,0])
False
>>> all([1,1,1])
True

zip(iterA, iterB, ...) takes one element from each iterable and returns them in a tuple:

zip(['a', 'b', 'c'], (1, 2, 3)) => ('a', 1), ('b', 2), ('c', 3)

It doesn't construct an in-memory list and exhaust all the input iterators before returning; instead tuples are constructed and returned only if they're requested. (The technical term for this behaviour is lazy evaluation.)

This iterator is intended to be used with iterables that are all of the
same length. If the iterables are of different lengths, the resulting stream will be the same length as the shortest iterable.

```
zip(["a", "b"], (1, 2, 3)) =>
    ("a", 1), ("b", 2)
```

You should avoid doing this, though, because an element may be taken from the longer iterators and discarded. This means you can’t go on to use the iterators further because you risk skipping a discarded element.
The itertools module

The `itertools` module contains a number of commonly-used iterators as well as functions for combining several iterators. This section will introduce the module's contents by showing small examples.

The module's functions fall into a few broad classes:

- Functions that create a new iterator based on an existing iterator.
- Functions for treating an iterator’s elements as function arguments.
- Functions for selecting portions of an iterator’s output.
- A function for grouping an iterator’s output.

Creating new iterators

`itertools.count(n)` returns an infinite stream of integers, increasing by 1 each time. You can optionally supply the starting number, which defaults to 0:

```
> itertools.count() => 0, 1, 2, 3, 4, 5, 6, 7, 8, 9, ...
> itertools.count(10) => 10, 11, 12, 13, 14, 15, 16, 17, 18, 19, ...
```

`itertools.cycle(iter)` saves a copy of the contents of a provided iterable and returns a new iterator that returns its elements from first to last. The new iterator will repeat these elements infinitely:

```
> itertools.cycle([1,2,3,4,5]) => 1, 2, 3, 4, 5, 1, 2, 3, 4, 5, ...
```
`itertools.repeat(elem, [n])` returns the provided element $n$ times, or returns the element endlessly if $n$ is not provided.

```python
itertools.repeat('abc') =>
  abc, abc, abc, abc, abc, abc, abc, abc, abc, abc
itertools.repeat('abc', 5) =>
  abc, abc, abc, abc, abc
```

`itertools.chain(iterA, iterB, ...)` takes an arbitrary number of iterables as input, and returns all the elements of the first iterator, then all the elements of the second, and so on, until all of the iterables have been exhausted.

```python
itertools.chain(['a', 'b', 'c'], (1, 2, 3)) =>
  a, b, c, 1, 2, 3
```

`itertools.islice(iter, [start], stop, [step])` returns a stream that's a slice of the iterator. With a single `stop` argument, it will return the first `stop` elements. If you supply a starting index, you'll get `stop-start` elements, and if you supply a value for `step`, elements will be skipped accordingly. Unlike Python's string and list slicing, you can't use negative values for `start`, `stop`, or `step`.

```python
itertools.islice(range(10), 8) =>
  0, 1, 2, 3, 4, 5, 6, 7
itertools.islice(range(10), 2, 8) =>
  2, 3, 4, 5, 6, 7
itertools.islice(range(10), 2, 8, 2) =>
  2, 4, 6
```

`itertools.tee(iter, [n])` replicates an iterator; it returns $n$ independent iterators that will all return the contents of the source iterator. If you don't supply a value for $n$, the default is 2. Replicating
Iterators requires saving some of the contents of the source iterator, so this can consume significant memory if the iterator is large and one of the new iterators is consumed more than the others.

```python
import itertools

itertools.tee( itertools.count() ) =>
    iterA, iterB

where iterA =>
    0, 1, 2, 3, 4, 5, 6, 7, 8, 9, ...

and iterB =>
    0, 1, 2, 3, 4, 5, 6, 7, 8, 9, ...
```

**Calling functions on elements**

The `operator` module contains a set of functions corresponding to Python's operators. Some examples are `operator.add(a, b)` (adds two values), `operator.ne(a, b)` (same as `a != b`), and `operator.attrgetter('id')` (returns a callable that fetches the `.id` attribute).

`itertools.starmap(func, iter)` assumes that the iterable will return a stream of tuples, and calls `func` using these tuples as the arguments:

```python
import os

itertools.starmap(os.path.join,
    [('bin', 'python'), ('usr', 'bin', 'java'), ('usr', 'bin', 'perl'), ('usr', 'bin', 'perl'),
     =>
        '/bin/python', '/usr/bin/java', '/usr/bin/perl', '/usr/bin/perl')
```

**Selecting elements**
Another group of functions chooses a subset of an iterator’s elements based on a predicate.

`itertools.filterfalse(predicate, iter)` is the opposite of `filter()`, returning all elements for which the predicate returns false:

```
>>> itertools.filterfalse(is_even, itertools.count()) =>
1, 3, 5, 7, 9, 11, 13, 15, ...
```

`itertools.takewhile(predicate, iter)` returns elements for as long as the predicate returns true. Once the predicate returns false, the iterator will signal the end of its results.

```
def less_than_10(x):
    return x < 10

>>> itertools.takewhile(less_than_10, itertools.count())
0, 1, 2, 3, 4, 5, 6, 7, 8, 9

>>> itertools.takewhile(is_even, itertools.count()) =>
0
```

`itertools.dropwhile(predicate, iter)` discards elements while the predicate returns true, and then returns the rest of the iterable's results.

```
>>> itertools.dropwhile(less_than_10, itertools.count())
10, 11, 12, 13, 14, 15, 16, 17, 18, 19, ...

>>> itertools.dropwhile(is_even, itertools.count()) =>
1, 2, 3, 4, 5, 6, 7, 8, 9, 10, ...
```
`itertools.compress(data, selectors)` takes two iterators and returns only those elements of `data` for which the corresponding element of `selectors` is true, stopping whenever either one is exhausted:

```python
itertools.compress([1,2,3,4,5], [True, True, False, 1, 2, 5])
```

**Combinatoric functions**

The `itertools.combinations(iterable, r)` returns an iterator giving all possible \(r\)-tuple combinations of the elements contained in `iterable`.

```python
itertools.combinations([1, 2, 3, 4, 5], 2) =>
(1, 2), (1, 3), (1, 4), (1, 5),
(2, 3), (2, 4), (2, 5),
(3, 4), (3, 5),
(4, 5)
```

```python
itertools.combinations([1, 2, 3, 4, 5], 3) =>
(1, 2, 3), (1, 2, 4), (1, 2, 5), (1, 3, 4), (1, 3, 5),
(2, 3, 4), (2, 3, 5), (2, 4, 5),
(3, 4, 5)
```

The elements within each tuple remain in the same order as `iterable` returned them. For example, the number 1 is always before 2, 3, 4, or 5 in the examples above. A similar function, `itertools.permutations(iterable, r=None)`, removes this constraint on the order, returning all possible arrangements of length \(r\):

```python
itertools.permutations([1, 2, 3, 4, 5], 2) =>
```
(1, 2), (1, 3), (1, 4), (1, 5),
(2, 1), (2, 3), (2, 4), (2, 5),
(3, 1), (3, 2), (3, 4), (3, 5),
(4, 1), (4, 2), (4, 3), (4, 5),
(5, 1), (5, 2), (5, 3), (5, 4)

```
import itertools
permutations = itertools.permutations([1, 2, 3, 4, 5])

(1, 2, 3, 4, 5), (1, 2, 3, 5, 4), (1, 2, 4, 3, 5),
...
(5, 4, 3, 2, 1)
```

If you don’t supply a value for \( r \) the length of the iterable is used, meaning that all the elements are permuted.

Note that these functions produce all of the possible combinations by position and don’t require that the contents of *iterable* are unique:

```
import itertools
permutations = itertools.permutations('aba', 3)

('a', 'b', 'a'), ('a', 'a', 'b'), ('b', 'a', 'a'),
('b', 'a', 'a'), ('a', 'a', 'b'), ('a', 'b', 'a')
```

The identical tuple ('a', 'a', 'b') occurs twice, but the two ‘a’ strings came from different positions.

The
```
import itertools
combinations_with_replacement = itertools.combinations_with_replacement
```

function relaxes a different constraint: elements can be repeated within a single tuple. Conceptually an element is selected for the first position of each tuple and then is replaced before the second element is selected.

```
import itertools
combinations_with_replacement = itertools.combinations_with_replacement([1, 2, 3, 4, 5], 2)

(1, 1), (1, 2), (1, 3), (1, 4), (1, 5),
(2, 2), (2, 3), (2, 4), (2, 5),
```
Grouping elements

The last function I'll discuss, `itertools.groupby(iter, key_func=None)`, is the most complicated. `key_func(elem)` is a function that can compute a key value for each element returned by the iterable. If you don't supply a key function, the key is simply each element itself.

`groupby()` collects all the consecutive elements from the underlying iterable that have the same key value, and returns a stream of 2-tuples containing a key value and an iterator for the elements with that key.

city_list = [('Decatur', 'AL'), ('Huntsville', 'AL'),
             ('Anchorage', 'AK'), ('Nome', 'AK'),
             ('Flagstaff', 'AZ'), ('Phoenix', 'AZ'),
             ...]

```python
def get_state(city_state):
    return city_state[1]
```

```python
itertools.groupby(city_list, get_state) =>
    ('AL', iterator-1),
    ('AK', iterator-2),
    ('AZ', iterator-3), ...
```

where
```
iterator-1 =>
    ('Decatur', 'AL'), ('Huntsville', 'AL'), ('Selma',
```
```
iterator-2 =>
```
groupby() assumes that the underlying iterable's contents will already be sorted based on the key. Note that the returned iterators also use the underlying iterable, so you have to consume the results of iterator-1 before requesting iterator-2 and its corresponding key.
The **functools** module

The **functools** module in Python 2.5 contains some higher-order functions. A **higher-order function** takes one or more functions as input and returns a new function. The most useful tool in this module is the **functools.partial()** function.

For programs written in a functional style, you'll sometimes want to construct variants of existing functions that have some of the parameters filled in. Consider a Python function `f(a, b, c)`; you may wish to create a new function `g(b, c)` that's equivalent to `f(1, b, c)`; you're filling in a value for one of `f()`'s parameters. This is called “partial function application”.

The constructor for **partial()** takes the arguments `(function, arg1, arg2, ..., kwarg1=value1, kwarg2=value2)`. The resulting object is callable, so you can just call it to invoke `function` with the filled-in arguments.

Here's a small but realistic example:

```python
import functools

def log(message, subsystem):
    """Write the contents of 'message' to the specified subsystem."
    print('%s: %s' % (subsystem, message))
...

server_log = functools.partial(log, subsystem='server')
server_log('Unable to open socket')

functools.reduce(func, iter, [initial_value])
```
cumulatively performs an operation on all the iterable's elements and, therefore, can't be applied to infinite iterables. `func` must be a function that takes two elements and returns a single value. `functools.reduce()` takes the first two elements A and B returned by the iterator and calculates `func(A, B)`. It then requests the third element, C, calculates `func(func(A, B), C)`. combines this result with the fourth element returned, and continues until the iterable is exhausted. If the iterable returns no values at all, a `TypeError` exception is raised. If the initial value is supplied, it's used as a starting point and `func(initial_value, A)` is the first calculation.

```python
>>> import operator, functools
>>> functools.reduce(operator.concat, ["A", "BB", "C", "ABBC"])
Traceback (most recent call last):
  ...TypeError: reduce() of empty sequence with no initial value
>>> functools.reduce(operator.concat, [])
```

If you use `operator.add()` with `functools.reduce()`, you'll add up all the elements of the iterable. This case is so common that there's a special built-in called `sum()` to compute it:

```python
>>> import functools
>>> functools.reduce(operator.add, [1,2,3,4], 0)
10
>>> sum([1,2,3,4])
10
>>> sum([])
```
For many uses of `functools.reduce()`, though, it can be clearer to just write the obvious `for` loop:

```python
import functools
# Instead of:
product = functools.reduce(operator.mul, [1, 2, 3], 1)

# You can write:
product = 1
for i in [1, 2, 3]:
    product *= i
```

A related function is `itertools.accumulate(iterable, func=operator.add)`. It performs the same calculation, but instead of returning only the final result, `accumulate()` returns an iterator that also yields each partial result:

```python
itertools.accumulate([1, 2, 3, 4, 5]) => 1, 3, 6, 10, 15

itertools.accumulate([1, 2, 3, 4, 5], operator.mul) => 1, 2, 6, 24, 120
```

The **operator** module

The `operator` module was mentioned earlier. It contains a set of functions corresponding to Python’s operators. These functions are often useful in functional-style code because they save you from writing trivial functions that perform a single operation.

Some of the functions in this module are:
• Math operations: `add()`, `sub()`, `mul()`, `floordiv()`, `abs()`, ...
• Logical operations: `not_()`, `truth()`.
• Bitwise operations: `and_()`, `or_()`, `invert()`.
• Comparisons: `eq()`, `ne()`, `lt()`, `le()`, `gt()`, and `ge()`.
• Object identity: `is_()`, `is_not()`.

Consult the operator module's documentation for a complete list.
Small functions and the lambda expression

When writing functional-style programs, you'll often need little functions that act as predicates or that combine elements in some way.

If there's a Python built-in or a module function that's suitable, you don't need to define a new function at all:

```python
stripped_lines = [line.strip() for line in lines]
existing_files = filter(os.path.exists, file_list)
```

If the function you need doesn't exist, you need to write it. One way to write small functions is to use the `lambda` statement. `lambda` takes a number of parameters and an expression combining these parameters, and creates an anonymous function that returns the value of the expression:

```python
adder = lambda x, y: x+y
print_assign = lambda name, value: name + ' ' + str(value)
```

An alternative is to just use the `def` statement and define a function in the usual way:

```python
def adder(x, y):
    return x + y

def print_assign(name, value):
    return name + ' ' + str(value)
```

Which alternative is preferable? That's a style question; my usual
course is to avoid using `lambda`.

One reason for my preference is that `lambda` is quite limited in the functions it can define. The result has to be computable as a single expression, which means you can't have multiway `if... elif... else` comparisons or `try... except` statements. If you try to do too much in a `lambda` statement, you'll end up with an overly complicated expression that's hard to read. Quick, what's the following code doing?

```python
import functools
total = functools.reduce(lambda a, b: (0, a[1] + b[1]),
```

You can figure it out, but it takes time to disentangle the expression to figure out what's going on. Using a short nested `def` statements makes things a little bit better:

```python
import functools
def combine(a, b):
    return 0, a[1] + b[1]
total = functools.reduce(combine, items)[1]
```

But it would be best of all if I had simply used a `for` loop:

```python
total = 0
for a, b in items:
    total += b
```

Or the `sum()` built-in and a generator expression:

```python
total = sum(b for a, b in items)
```
Many uses of `functools.reduce()` are clearer when written as for loops.

Fredrik Lundh once suggested the following set of rules for refactoring uses of `lambda`:

1. Write a lambda function.
2. Write a comment explaining what the heck that lambda does.
3. Study the comment for a while, and think of a name that captures the essence of the comment.
4. Convert the lambda to a def statement, using that name.
5. Remove the comment.

I really like these rules, but you’re free to disagree about whether this lambda-free style is better.
Revision History and Acknowledgements

The author would like to thank the following people for offering suggestions, corrections and assistance with various drafts of this article: Ian Bicking, Nick Coghlan, Nick Efford, Raymond Hettinger, Jim Jewett, Mike Krell, Leandro Lameiro, Jussi Salmela, Collin Winter, Blake Winton.

Version 0.1: posted June 30 2006.

Version 0.11: posted July 1 2006. Typo fixes.

Version 0.2: posted July 10 2006. Merged genexp and listcomp sections into one. Typo fixes.

Version 0.21: Added more references suggested on the tutor mailing list.

Version 0.30: Adds a section on the functional module written by Collin Winter; adds short section on the operator module; a few other edits.

Logging HOWTO

Author: Vinay Sajip <vinay_sajip at red-dove dot com>
Basic Logging Tutorial

Logging is a means of tracking events that happen when some software runs. The software’s developer adds logging calls to their code to indicate that certain events have occurred. An event is described by a descriptive message which can optionally contain variable data (i.e. data that is potentially different for each occurrence of the event). Events also have an importance which the developer ascribes to the event; the importance can also be called the level or severity.

When to use logging

Logging provides a set of convenience functions for simple logging usage. These are debug(), info(), warning(), error() and critical(). To determine when to use logging, see the table below, which states, for each of a set of common tasks, the best tool to use for it.

<table>
<thead>
<tr>
<th>Task you want to perform</th>
<th>The best tool for the task</th>
</tr>
</thead>
<tbody>
<tr>
<td>Display console output for ordinary usage of a command line script or program</td>
<td>print()</td>
</tr>
<tr>
<td>Report events that occur during normal operation of a program (e.g. for status monitoring or fault investigation)</td>
<td>logging.info() (or logging.debug() for very detailed output for diagnostic purposes)</td>
</tr>
<tr>
<td></td>
<td>warnings.warn() in library code if the issue is avoidable and the client application should be</td>
</tr>
</tbody>
</table>
Issue a warning regarding a particular runtime event

modified to eliminate the warning

```
logging.warning()
```

if there is nothing the client application can do about the situation, but the event should still be noted

Report an error regarding a particular runtime event

Raise an exception

Report suppression of an error without raising an exception (e.g. error handler in a long-running server process)

```
logging.error(),
logging.exception() or
logging.critical()
```
as appropriate for the specific error and application domain

The logging functions are named after the level or severity of the events they are used to track. The standard levels and their applicability are described below (in increasing order of severity):

<table>
<thead>
<tr>
<th>Level</th>
<th>When it's used</th>
</tr>
</thead>
<tbody>
<tr>
<td>DEBUG</td>
<td>Detailed information, typically of interest only when diagnosing problems.</td>
</tr>
<tr>
<td>INFO</td>
<td>Confirmation that things are working as expected.</td>
</tr>
<tr>
<td>WARNING</td>
<td>An indication that something unexpected happened, or indicative of some problem in the near future (e.g. ‘disk space low’). The software is still working as expected.</td>
</tr>
<tr>
<td>ERROR</td>
<td>Due to a more serious problem, the software has not been able to perform some function.</td>
</tr>
<tr>
<td>CRITICAL</td>
<td>A serious error, indicating that the program itself may be unable to continue running.</td>
</tr>
</tbody>
</table>

The default level is **WARNING**, which means that only events of this
level and above will be tracked, unless the logging package is configured to do otherwise.

Events that are tracked can be handled in different ways. The simplest way of handling tracked events is to print them to the console. Another common way is to write them to a disk file.

A simple example

A very simple example is:

```python
import logging
logging.warning('Watch out!')  # will print a message
logging.info('I told you so')  # will not print anything
```

If you type these lines into a script and run it, you'll see:

```
WARNING:root:Watch out!
```

printed out on the console. The INFO message doesn’t appear because the default level is WARNING. The printed message includes the indication of the level and the description of the event provided in the logging call, i.e. ‘Watch out!’. Don’t worry about the ‘root’ part for now: it will be explained later. The actual output can be formatted quite flexibly if you need that; formatting options will also be explained later.

Logging to a file

A very common situation is that of recording logging events in a file, so let’s look at that next. Be sure to try the following in a newly-started Python interpreter, and don’t just continue from the session described above:
```python
import logging
logging.basicConfig(filename='example.log', level=logging.DEBUG)
logging.debug('This message should go to the log file
logging.info('So should this')
logging.warning('And this, too')
```

And now if we open the file and look at what we have, we should find the log messages:

```
DEBUG:root:This message should go to the log file
INFO:root:So should this
WARNING:root:And this, too
```

This example also shows how you can set the logging level which acts as the threshold for tracking. In this case, because we set the threshold to DEBUG, all of the messages were printed.

If you want to set the logging level from a command-line option such as:

```
--log=INFO
```

and you have the value of the parameter passed for --log in some variable `loglevel`, you can use:

```python
getattr(logging, loglevel.upper())
```

to get the value which you'll pass to `basicConfig()` via the `level` argument. You may want to error check any user input value, perhaps as in the following example:

```
# assuming loglevel is bound to the string value obt
# command line argument. Convert to upper case to all
```
The call to `basicConfig()` should come before any calls to `debug()`, `info()` etc. As it's intended as a one-off simple configuration facility, only the first call will actually do anything: subsequent calls are effectively no-ops.

If you run the above script several times, the messages from successive runs are appended to the file `example.log`. If you want each run to start afresh, not remembering the messages from earlier runs, you can specify the `filemode` argument, by changing the call in the above example to:

```python
logging.basicConfig(filename='example.log', filemode='w')
```

The output will be the same as before, but the log file is no longer appended to, so the messages from earlier runs are lost.

**Logging from multiple modules**

If your program consists of multiple modules, here's an example of how you could organize logging in it:

```python
# myapp.py
import logging
import mylib

def main():
```
```python
logging.basicConfig(filename='myapp.log', level=logging.info('Started'))
mylib.do_something()
logging.info('Finished')

if __name__ == '__main__':
    main()
```

```python
# mylib.py
import logging

def do_something():
    logging.info('Doing something')
```

If you run `myapp.py`, you should see this in `myapp.log`:

```
INFO:root:Started
INFO:root:Doing something
INFO:root:Finished
```

which is hopefully what you were expecting to see. You can generalize this to multiple modules, using the pattern in `mylib.py`. Note that for this simple usage pattern, you won't know, by looking in the log file, where in your application your messages came from, apart from looking at the event description. If you want to track the location of your messages, you'll need to refer to the documentation beyond the tutorial level – see Advanced Logging Tutorial.

### Logging variable data

To log variable data, use a format string for the event description message and append the variable data as arguments. For example:
As you can see, merging of variable data into the event description message uses the old, %-style of string formatting. This is for backwards compatibility: the logging package pre-dates newer formatting options such as \texttt{str.format()} and \texttt{string.Template}. These newer formatting options \textit{are} supported, but exploring them is outside the scope of this tutorial: see \textit{Using particular formatting styles throughout your application} for more information.

### Changing the format of displayed messages

To change the format which is used to display messages, you need to specify the format you want to use:

```python
import logging
logging.basicConfig(format='%(levelname)s:%(message)s')
logging.debug('This message should appear on the console')
logging.info('So should this')
logging.warning('And this, too')
```

which would print:

```
DEBUG:This message should appear on the console
INFO:So should this
WARNING:And this, too
```
Notice that the ‘root’ which appeared in earlier examples has disappeared. For a full set of things that can appear in format strings, you can refer to the documentation for `LogRecord attributes`, but for simple usage, you just need the `levelname` (severity), `message` (event description, including variable data) and perhaps to display when the event occurred. This is described in the next section.

**Displaying the date/time in messages**

To display the date and time of an event, you would place ‘% (asctime)s’ in your format string:

```python
import logging
logging.basicConfig(format='%(asctime)s %(message)s'
logging.warning('is when this event was logged. ')
```

which should print something like this:

```
2010-12-12 11:41:42,612 is when this event was logged.
```

The default format for date/time display (shown above) is ISO8601. If you need more control over the formatting of the date/time, provide a `datefmt` argument to `basicConfig`, as in this example:

```python
import logging
logging.basicConfig(format='%(asctime)s %(message)s'
logging.warning('is when this event was logged. ')
```

which would display something like this:

```
12/12/2010 11:46:36 AM is when this event was logged.
```
The format of the *datefmt* argument is the same as supported by `time.strftime()`.

Next Steps

That concludes the basic tutorial. It should be enough to get you up and running with logging. There’s a lot more that the logging package offers, but to get the best out of it, you’ll need to invest a little more of your time in reading the following sections. If you’re ready for that, grab some of your favourite beverage and carry on.

If your logging needs are simple, then use the above examples to incorporate logging into your own scripts, and if you run into problems or don’t understand something, please post a question on the comp.lang.python Usenet group (available at http://groups.google.com/group/comp.lang.python) and you should receive help before too long.

Still here? You can carry on reading the next few sections, which provide a slightly more advanced/in-depth tutorial than the basic one above. After that, you can take a look at the *Logging Cookbook*. 
Advanced Logging Tutorial

The logging library takes a modular approach and offers several categories of components: loggers, handlers, filters, and formatters.

- Loggers expose the interface that application code directly uses.
- Handlers send the log records (created by loggers) to the appropriate destination.
- Filters provide a finer grained facility for determining which log records to output.
- Formatters specify the layout of log records in the final output.

Log event information is passed between loggers, handlers, filters and formatters in a LogRecord instance.

Logging is performed by calling methods on instances of the Logger class (hereafter called loggers). Each instance has a name, and they are conceptually arranged in a namespace hierarchy using dots (periods) as separators. For example, a logger named ‘scan’ is the parent of loggers ‘scan.text’, ‘scan.html’ and ‘scan.pdf’. Logger names can be anything you want, and indicate the area of an application in which a logged message originates.

A good convention to use when naming loggers is to use a module-level logger, in each module which uses logging, named as follows:

```python
logger = logging.getLogger(__name__)
```

This means that logger names track the package/module hierarchy, and it’s intuitively obvious where events are logged just from the logger name.

The root of the hierarchy of loggers is called the root logger. That’s the
logger used by the functions debug(), info(), warning(), error() and critical(), which just call the same-named method of the root logger. The functions and the methods have the same signatures. The root logger’s name is printed as ‘root’ in the logged output.

It is, of course, possible to log messages to different destinations. Support is included in the package for writing log messages to files, HTTP GET/POST locations, email via SMTP, generic sockets, queues, or OS-specific logging mechanisms such as syslog or the Windows NT event log. Destinations are served by handler classes. You can create your own log destination class if you have special requirements not met by any of the built-in handler classes.

By default, no destination is set for any logging messages. You can specify a destination (such as console or file) by using basicConfig() as in the tutorial examples. If you call the functions debug(), info(), warning(), error() and critical(), they will check to see if no destination is set; and if one is not set, they will set a destination of the console (sys.stderr) and a default format for the displayed message before delegating to the root logger to do the actual message output.

The default format set by basicConfig() for messages is:

```
severity:logger name:message
```

You can change this by passing a format string to basicConfig() with the format keyword argument. For all options regarding how a format string is constructed, see Formatter Objects.

Logging Flow
The flow of log event information in loggers and handlers is illustrated in the following diagram.

**Loggers**

**Logger** objects have a threefold job. First, they expose several methods to application code so that applications can log messages at runtime. Second, logger objects determine which log messages to act upon based upon severity (the default filtering facility) or filter objects. Third, logger objects pass along relevant log messages to all interested log handlers.

The most widely used methods on logger objects fall into two categories: configuration and message sending.
These are the most common configuration methods:

- `Logger.setLevel()` specifies the lowest-severity log message a logger will handle, where debug is the lowest built-in severity level and critical is the highest built-in severity. For example, if the severity level is INFO, the logger will handle only INFO, WARNING, ERROR, and CRITICAL messages and will ignore DEBUG messages.
- `Logger.addHandler()` and `Logger.removeHandler()` add and remove handler objects from the logger object. Handlers are covered in more detail in *Handlers*.
- `Logger.addFilter()` and `Logger.removeFilter()` add and remove filter objects from the logger object. Filters are covered in more detail in *Filter Objects*.

You don’t need to always call these methods on every logger you create. See the last two paragraphs in this section.

With the logger object configured, the following methods create log messages:

- `Logger.debug()`, `Logger.info()`, `Logger.warning()`, `Logger.error()`, and `Logger.critical()` all create log records with a message and a level that corresponds to their respective method names. The message is actually a format string, which may contain the standard string substitution syntax of %s, %d, %f, and so on. The rest of their arguments is a list of objects that correspond with the substitution fields in the message. With regard to **kwargs, the logging methods care only about a keyword of exc_info and use it to determine whether to log exception information.
- `Logger.exception()` creates a log message similar to `Logger.error()`. The difference is that `Logger.exception()` dumps a stack trace along with it. Call
this method only from an exception handler.

- **Logger.log()** takes a log level as an explicit argument. This is a little more verbose for logging messages than using the log level convenience methods listed above, but this is how to log at custom log levels.

getLogger() returns a reference to a logger instance with the specified name if it is provided, or root if not. The names are period-separated hierarchical structures. Multiple calls to getLogger() with the same name will return a reference to the same logger object. Loggers that are further down in the hierarchical list are children of loggers higher up in the list. For example, given a logger with a name of foo, loggers with names of foo.bar, foo.bar.baz, and foo.bam are all descendants of foo.

Loggers have a concept of **effective level**. If a level is not explicitly set on a logger, the level of its parent is used instead as its effective level. If the parent has no explicit level set, its parent is examined, and so on - all ancestors are searched until an explicitly set level is found. The root logger always has an explicit level set (WARNING by default).

When deciding whether to process an event, the effective level of the logger is used to determine whether the event is passed to the logger's handlers.

Child loggers propagate messages up to the handlers associated with their ancestor loggers. Because of this, it is unnecessary to define and configure handlers for all the loggers an application uses. It is sufficient to configure handlers for a top-level logger and create child loggers as needed. (You can, however, turn off propagation by setting the **propagate** attribute of a logger to False.)

**Handlers**
Handler objects are responsible for dispatching the appropriate log messages (based on the log messages' severity) to the handler's specified destination. Logger objects can add zero or more handler objects to themselves with an addHandler() method. As an example scenario, an application may want to send all log messages to a log file, all log messages of error or higher to stdout, and all messages of critical to an email address. This scenario requires three individual handlers where each handler is responsible for sending messages of a specific severity to a specific location.

The standard library includes quite a few handler types (see Useful Handlers); the tutorials use mainly StreamHandler and FileHandler in its examples.

There are very few methods in a handler for application developers to concern themselves with. The only handler methods that seem relevant for application developers who are using the built-in handler objects (that is, not creating custom handlers) are the following configuration methods:

- The setLevel() method, just as in logger objects, specifies the lowest severity that will be dispatched to the appropriate destination. Why are there two setLevel() methods? The level set in the logger determines which severity of messages it will pass to its handlers. The level set in each handler determines which messages that handler will send on.
- setFormatter() selects a Formatter object for this handler to use.
- addFilter() and removeFilter() respectively configure and deconfigure filter objects on handlers.

Application code should not directly instantiate and use instances of Handler. Instead, the Handler class is a base class that defines the
interface that all handlers should have and establishes some default behavior that child classes can use (or override).

Formatters

Formatter objects configure the final order, structure, and contents of the log message. Unlike the base logging.Handler class, application code may instantiate formatter classes, although you could likely subclass the formatter if your application needs special behavior. The constructor takes three optional arguments – a message format string, a date format string and a style indicator.

logging.Formatter.__init__(fmt=None, datefmt=None, style='%')

If there is no message format string, the default is to use the raw message. If there is no date format string, the default date format is:

```
%Y-%m-%d %H:%M:%S
```

with the milliseconds tacked on at the end. The style is one of %, {' or '$'. If one of these is not specified, then '%' will be used.

If the style is '%', the message format string uses %(<dictionary key>)s styled string substitution; the possible keys are documented in LogRecord attributes. If the style is '{', the message format string is assumed to be compatible with str.format() (using keyword arguments), while if the style is '$' then the message format string should conform to what is expected by string.Template.substitute().

Changed in version 3.2: Added the style parameter.
The following message format string will log the time in a human-readable format, the severity of the message, and the contents of the message, in that order:

'%(asctime)s - %(levelname)s - %(message)s'

Formatters use a user-configurable function to convert the creation time of a record to a tuple. By default, `time.localtime()` is used; to change this for a particular formatter instance, set the `converter` attribute of the instance to a function with the same signature as `time.localtime()` or `time.gmtime()`. To change it for all formatters, for example if you want all logging times to be shown in GMT, set the `converter` attribute in the Formatter class (to `time.gmtime` for GMT display).

Configuring Logging

Programmers can configure logging in three ways:

1. Creating loggers, handlers, and formatters explicitly using Python code that calls the configuration methods listed above.
2. Creating a logging config file and reading it using the `fileConfig()` function.
3. Creating a dictionary of configuration information and passing it to the `dictConfig()` function.

For the reference documentation on the last two options, see *Configuration functions*. The following example configures a very simple logger, a console handler, and a simple formatter using Python code:

```python
import logging
```
# create logger
logger = logging.getLogger('simple_example')
logger.setLevel(logging.DEBUG)

# create console handler and set level to debug
ch = logging.StreamHandler()
ch.setLevel(logging.DEBUG)

# create formatter
formatter = logging.Formatter('%(asctime)s - %(name)s - %(levelname)s - %(message)s')

# add formatter to ch
ch.setFormatter(formatter)

# add ch to logger
logger.addHandler(ch)

# 'application' code
logger.debug('debug message')
logger.info('info message')
logger.warn('warn message')
logger.error('error message')
logger.critical('critical message')

Running this module from the command line produces the following output:

$ python simple_logging_module.py
2005-03-19 15:10:26,618 - simple_example - DEBUG - debug message
2005-03-19 15:10:26,620 - simple_example - INFO - info message
2005-03-19 15:10:26,695 - simple_example - WARNING - warn message
2005-03-19 15:10:26,697 - simple_example - ERROR - error message
2005-03-19 15:10:26,773 - simple_example - CRITICAL - critical message

The following Python module creates a logger, handler, and formatter
nearly identical to those in the example listed above, with the only difference being the names of the objects:

```python
import logging
import logging.config

logging.config.fileConfig('logging.conf')

# create logger
logger = logging.getLogger('simpleExample')

# 'application' code
logger.debug('debug message')
logger.info('info message')
logger.warn('warn message')
logger.error('error message')
logger.critical('critical message')
```

Here is the logging.conf file:

```
[loggers]
keys=root,simpleExample

[handlers]
keys=consoleHandler

[formatters]
keys=simpleFormatter

[logger_root]
level=DEBUG
handlers=consoleHandler

[logger_simpleExample]
level=DEBUG
handlers=consoleHandler
```
qualname=simpleExample
propagate=0

[handler_consoleHandler]
class=StreamHandler
level=DEBUG
formatter=simpleFormatter
args=(sys.stdout,)

[formatter_simpleFormatter]
format=%(asctime)s - %(name)s - %(levelname)s - %(message)s
datefmt=

The output is nearly identical to that of the non-config-file-based example:

$ python simple_logging_config.py
2005-03-19 15:38:55,977 - simpleExample - DEBUG - debug message
2005-03-19 15:38:55,979 - simpleExample - INFO - info message
2005-03-19 15:38:56,054 - simpleExample - WARNING - warn message
2005-03-19 15:38:56,055 - simpleExample - ERROR - error message
2005-03-19 15:38:56,130 - simpleExample - CRITICAL - critical message

You can see that the config file approach has a few advantages over the Python code approach, mainly separation of configuration and code and the ability of noncoders to easily modify the logging properties.

**Warning:** The fileConfig() function takes a default parameter, disable_existing_loggers, which defaults to True for reasons of backward compatibility. This may or may not be what you want, since it will cause any loggers existing before the fileConfig() call to be disabled unless they (or an ancestor) are
explicitly named in the configuration. Please refer to the reference documentation for more information, and specify False for this parameter if you wish.

The dictionary passed to `dictConfig()` can also specify a Boolean value with key `disable_existing_loggers`, which if not specified explicitly in the dictionary also defaults to being interpreted as True. This leads to the logger-disabling behaviour described above, which may not be what you want - in which case, provide the key explicitly with a value of False.

Note that the class names referenced in config files need to be either relative to the logging module, or absolute values which can be resolved using normal import mechanisms. Thus, you could use either `WatchedFileHandler` (relative to the logging module) or `mypackage.mymodule.MyHandler` (for a class defined in package `mypackage` and module `mymodule`, where `mypackage` is available on the Python import path).

In Python 3.2, a new means of configuring logging has been introduced, using dictionaries to hold configuration information. This provides a superset of the functionality of the config-file-based approach outlined above, and is the recommended configuration method for new applications and deployments. Because a Python dictionary is used to hold configuration information, and since you can populate that dictionary using different means, you have more options for configuration. For example, you can use a configuration file in JSON format, or, if you have access to YAML processing functionality, a file in YAML format, to populate the configuration dictionary. Or, of course, you can construct the dictionary in Python code, receive it in pickled form over a socket, or use whatever approach makes sense
for your application.

Here's an example of the same configuration as above, in YAML format for the new dictionary-based approach:

```yaml
version: 1
formatters:
    simple:
        format: '%(asctime)s - %(name)s - %(levelname)s

handlers:
    console:
        class: logging.StreamHandler
        level: DEBUG
        formatter: simple
        stream: ext://sys.stdout

loggers:
    simpleExample:
        level: DEBUG
        handlers: [console]
        propagate: no

root:
    level: DEBUG
    handlers: [console]
```

For more information about logging using a dictionary, see [Configuration functions](#).

What happens if no configuration is provided

If no logging configuration is provided, it is possible to have a situation where a logging event needs to be output, but no handlers can be found to output the event. The behaviour of the logging package in these circumstances is dependent on the Python version.
For versions of Python prior to 3.2, the behaviour is as follows:

- If `logging.raiseExceptions` is `False` (production mode), the event is silently dropped.
- If `logging.raiseExceptions` is `True` (development mode), a message ‘No handlers could be found for logger X.Y.Z’ is printed once.

In Python 3.2 and later, the behaviour is as follows:

- The event is output using a ‘handler of last resort’, stored in `logging.lastResort`. This internal handler is not associated with any logger, and acts like a `StreamHandler` which writes the event description message to the current value of `sys.stderr` (therefore respecting any redirections which may be in effect). No formatting is done on the message - just the bare event description message is printed. The handler’s level is set to `WARNING`, so all events at this and greater severities will be output.

To obtain the pre-3.2 behaviour, `logging.lastResort` can be set to `None`.

**Configuring Logging for a Library**

When developing a library which uses logging, you should take care to document how the library uses logging - for example, the names of loggers used. Some consideration also needs to be given to its logging configuration. If the using application does not use logging, and library code makes logging calls, then (as described in the previous section) events of severity `WARNING` and greater will be printed to `sys.stderr`. This is regarded as the best default behaviour.
If for some reason you don’t want these messages printed in the absence of any logging configuration, you can attach a do-nothing handler to the top-level logger for your library. This avoids the message being printed, since a handler will be always be found for the library’s events: it just doesn’t produce any output. If the library user configures logging for application use, presumably that configuration will add some handlers, and if levels are suitably configured then logging calls made in library code will send output to those handlers, as normal.

A do-nothing handler is included in the logging package: `NullHandler` (since Python 3.1). An instance of this handler could be added to the top-level logger of the logging namespace used by the library (if you want to prevent your library’s logged events being output to `sys.stdout` in the absence of logging configuration). If all logging by a library `foo` is done using loggers with names matching ‘foo.x’, ‘foo.x.y’, etc. then the code:

```python
import logging
logging.getLogger('foo').addHandler(logging.NullHandler())
```

should have the desired effect. If an organisation produces a number of libraries, then the logger name specified can be ‘orgname.foo’ rather than just ‘foo’.

**Note:** It is strongly advised that you do not add any handlers other than `NullHandler` to your library’s loggers. This is because the configuration of handlers is the prerogative of the application developer who uses your library. The application developer knows their target audience and what handlers are most appropriate for their application: if you add handlers ‘under the hood’, you might well interfere with their ability to carry out unit tests and deliver logs which
suit their requirements.
Logging Levels

The numeric values of logging levels are given in the following table. These are primarily of interest if you want to define your own levels, and need them to have specific values relative to the predefined levels. If you define a level with the same numeric value, it overwrites the predefined value; the predefined name is lost.

<table>
<thead>
<tr>
<th>Level</th>
<th>Numeric value</th>
</tr>
</thead>
<tbody>
<tr>
<td>CRITICAL</td>
<td>50</td>
</tr>
<tr>
<td>ERROR</td>
<td>40</td>
</tr>
<tr>
<td>WARNING</td>
<td>30</td>
</tr>
<tr>
<td>INFO</td>
<td>20</td>
</tr>
<tr>
<td>DEBUG</td>
<td>10</td>
</tr>
<tr>
<td>NOTSET</td>
<td>0</td>
</tr>
</tbody>
</table>

Levels can also be associated with loggers, being set either by the developer or through loading a saved logging configuration. When a logging method is called on a logger, the logger compares its own level with the level associated with the method call. If the logger’s level is higher than the method call’s, no logging message is actually generated. This is the basic mechanism controlling the verbosity of logging output.

Logging messages are encoded as instances of the LogRecord class. When a logger decides to actually log an event, a LogRecord instance is created from the logging message.

Logging messages are subjected to a dispatch mechanism through
the use of *handlers*, which are instances of subclasses of the Handler class. Handlers are responsible for ensuring that a logged message (in the form of a LogRecord) ends up in a particular location (or set of locations) which is useful for the target audience for that message (such as end users, support desk staff, system administrators, developers). Handlers are passed LogRecord instances intended for particular destinations. Each logger can have zero, one or more handlers associated with it (via the addHandler() method of Logger). In addition to any handlers directly associated with a logger, *all handlers associated with all ancestors of the logger* are called to dispatch the message (unless the propagate flag for a logger is set to a false value, at which point the passing to ancestor handlers stops).

Just as for loggers, handlers can have levels associated with them. A handler’s level acts as a filter in the same way as a logger’s level does. If a handler decides to actually dispatch an event, the emit() method is used to send the message to its destination. Most user-defined subclasses of Handler will need to override this emit().

### Custom Levels

Defining your own levels is possible, but should not be necessary, as the existing levels have been chosen on the basis of practical experience. However, if you are convinced that you need custom levels, great care should be exercised when doing this, and it is possibly a very bad idea to define custom levels if you are developing a library. That’s because if multiple library authors all define their own custom levels, there is a chance that the logging output from such multiple libraries used together will be difficult for the using developer to control and/or interpret, because a given numeric value might mean
different things for different libraries.
Useful Handlers

In addition to the base Handler class, many useful subclasses are provided:

1. **StreamHandler** instances send messages to streams (file-like objects).
2. **FileHandler** instances send messages to disk files.
3. **BaseRotatingHandler** is the base class for handlers that rotate log files at a certain point. It is not meant to be instantiated directly. Instead, use `RotatingFileHandler` or `TimedRotatingFileHandler`.
4. **RotatingFileHandler** instances send messages to disk files, with support for maximum log file sizes and log file rotation.
5. **TimedRotatingFileHandler** instances send messages to disk files, rotating the log file at certain timed intervals.
6. **SocketHandler** instances send messages to TCP/IP sockets. Since 3.4, Unix domain sockets are also supported.
7. **DatagramHandler** instances send messages to UDP sockets. Since 3.4, Unix domain sockets are also supported.
8. **SMTPHandler** instances send messages to a designated email address.
9. **SysLogHandler** instances send messages to a Unix syslog daemon, possibly on a remote machine.
10. **NTEventLogHandler** instances send messages to a Windows NT/2000/XP event log.
11. **MemoryHandler** instances send messages to a buffer in memory, which is flushed whenever specific criteria are met.
12. **HTTPHandler** instances send messages to an HTTP server using either GET or POST semantics.
13. **WatchedFileHandler** instances watch the file they are logging to. If the file changes, it is closed and reopened using the file
name. This handler is only useful on Unix-like systems; Windows does not support the underlying mechanism used.

14. **QueueHandler** instances send messages to a queue, such as those implemented in the `queue` or `multiprocessing` modules.

15. **NullHandler** instances do nothing with error messages. They are used by library developers who want to use logging, but want to avoid the ‘No handlers could be found for logger XXX’ message which can be displayed if the library user has not configured logging. See *Configuring Logging for a Library* for more information.

*New in version 3.1:* The **NullHandler** class.

*New in version 3.2:* The **QueueHandler** class.

The **NullHandler**, **StreamHandler** and **FileHandler** classes are defined in the core logging package. The other handlers are defined in a sub-module, `logging.handlers`. (There is also another sub-module, `logging.config`, for configuration functionality.)

Logged messages are formatted for presentation through instances of the **Formatter** class. They are initialized with a format string suitable for use with the % operator and a dictionary.

For formatting multiple messages in a batch, instances of **BufferingFormatter** can be used. In addition to the format string (which is applied to each message in the batch), there is provision for header and trailer format strings.

When filtering based on logger level and/or handler level is not enough, instances of **Filter** can be added to both **Logger** and
Handler instances (through their \texttt{addFilter()} method). Before deciding to process a message further, both loggers and handlers consult all their filters for permission. If any filter returns a false value, the message is not processed further.

The basic \texttt{Filter} functionality allows filtering by specific logger name. If this feature is used, messages sent to the named logger and its children are allowed through the filter, and all others dropped.
Exceptions raised during logging

The logging package is designed to swallow exceptions which occur while logging in production. This is so that errors which occur while handling logging events - such as logging misconfiguration, network or other similar errors - do not cause the application using logging to terminate prematurely.

**SystemExit** and **KeyboardInterrupt** exceptions are never swallowed. Other exceptions which occur during the `emit()` method of a Handler subclass are passed to its `handleError()` method.

The default implementation of `handleError()` in Handler checks to see if a module-level variable, `raiseExceptions`, is set. If set, a traceback is printed to `sys.stderr`. If not set, the exception is swallowed.

**Note:** The default value of `raiseExceptions` is True. This is because during development, you typically want to be notified of any exceptions that occur. It’s advised that you set `raiseExceptions` to False for production usage.
Using arbitrary objects as messages

In the preceding sections and examples, it has been assumed that the message passed when logging the event is a string. However, this is not the only possibility. You can pass an arbitrary object as a message, and its \_str\_() method will be called when the logging system needs to convert it to a string representation. In fact, if you want to, you can avoid computing a string representation altogether - for example, the \texttt{SocketHandler} emits an event by pickling it and sending it over the wire.
Optimization

Formatting of message arguments is deferred until it cannot be avoided. However, computing the arguments passed to the logging method can also be expensive, and you may want to avoid doing it if the logger will just throw away your event. To decide what to do, you can call the `isEnabledFor()` method which takes a level argument and returns true if the event would be created by the Logger for that level of call. You can write code like this:

```python
if logger.isEnabledFor(logging.DEBUG):
    logger.debug('Message with %s, %s', expensive_func1, expensive_func2)
```

so that if the logger's threshold is set above `DEBUG`, the calls to `expensive_func1()` and `expensive_func2()` are never made.

There are other optimizations which can be made for specific applications which need more precise control over what logging information is collected. Here's a list of things you can do to avoid processing during logging which you don't need:

<table>
<thead>
<tr>
<th>What you don’t want to collect</th>
<th>How to avoid collecting it</th>
</tr>
</thead>
<tbody>
<tr>
<td>Information about where calls were made from.</td>
<td>Set <code>logging._srcfile</code> to <code>None</code>.</td>
</tr>
<tr>
<td>Threading information.</td>
<td>Set <code>logging.logThreads</code> to <code>0</code>.</td>
</tr>
<tr>
<td>Process information.</td>
<td>Set <code>logging.logProcesses</code> to <code>0</code>.</td>
</tr>
</tbody>
</table>
Also note that the core logging module only includes the basic handlers. If you don't import `logging.handlers` and `logging.config`, they won’t take up any memory.

*A logging cookbook*
Logging Cookbook

Author: Vinay Sajip <vinay_sajip at red-dove dot com>

This page contains a number of recipes related to logging, which have been found useful in the past.
Using logging in multiple modules

Multiple calls to `logging.getLogger('someLogger')` return a reference to the same logger object. This is true not only within the same module, but also across modules as long as it is in the same Python interpreter process. It is true for references to the same object; additionally, application code can define and configure a parent logger in one module and create (but not configure) a child logger in a separate module, and all logger calls to the child will pass up to the parent. Here is a main module:

```python
import logging
import auxiliary_module

# create logger with 'spam_application'
logger = logging.getLogger('spam_application')
logger.setLevel(logging.DEBUG)
# create file handler which logs even debug messages
fh = logging.FileHandler('spam.log')
fh.setLevel(logging.DEBUG)
# create console handler with a higher log level
ch = logging.StreamHandler()
ch.setLevel(logging.ERROR)
# create formatter and add it to the handlers
formatter = logging.Formatter('%(asctime)s - %(name)s - %(levelname)s - %(message)s')
fh.setFormatter(formatter)
ch.setFormatter(formatter)
# add the handlers to the logger
logger.addHandler(fh)
logger.addHandler(ch)

logger.info('creating an instance of auxiliary_module')
a = auxiliary_module.Auxiliary()
logger.info('created an instance of auxiliary_module')
```
logger.info('calling auxiliary_module.Auxiliary.do_something()')
logger.info('finished auxiliary_module.Auxiliary.do_something()')
logger.info('calling auxiliary_module.some_function()')
auxiliary_module.some_function()
logger.info('done with auxiliary_module.some_function()')

Here is the auxiliary module:

```python
import logging

# create logger
module_logger = logging.getLogger('spam_application.auxiliary')

class Auxiliary:
    def __init__(self):
        self.logger = logging.getLogger('spam_application.auxiliary.Auxiliary')
        self.logger.info('creating an instance of Auxiliary')
    def do_something(self):
        self.logger.info('doing something')
        a = 1 + 1
        self.logger.info('done doing something')

def some_function():
    module_logger.info('received a call to "some_function()"')
```

The output looks like this:

```
2005-03-23 23:47:11,663 - spam_application - INFO -
    creating an instance of auxiliary_module.Auxiliary
2005-03-23 23:47:11,665 - spam_application.auxiliary - INFO -
    creating an instance of Auxiliary
2005-03-23 23:47:11,665 - spam_application - INFO -
    created an instance of auxiliary_module.Auxiliary
2005-03-23 23:47:11,668 - spam_application - INFO -
```
calling auxiliary_module.Auxiliary.do_something
2005-03-23 23:47:11,668 - spam_application.auxiliary
  doing something
2005-03-23 23:47:11,669 - spam_application.auxiliary
  done doing something
2005-03-23 23:47:11,670 - spam_application - INFO -
  finished auxiliary_module.Auxiliary.do_something
2005-03-23 23:47:11,671 - spam_application - INFO -
  calling auxiliary_module.some_function()
2005-03-23 23:47:11,672 - spam_application.auxiliary
  received a call to 'some_function'
2005-03-23 23:47:11,673 - spam_application - INFO -
  done with auxiliary_module.some_function()
Multiple handlers and formatters

Loggers are plain Python objects. The `addHandler()` method has no minimum or maximum quota for the number of handlers you may add. Sometimes it will be beneficial for an application to log all messages of all severities to a text file while simultaneously logging errors or above to the console. To set this up, simply configure the appropriate handlers. The logging calls in the application code will remain unchanged. Here is a slight modification to the previous simple module-based configuration example:

```python
import logging

logger = logging.getLogger('simple_example')
logger.setLevel(logging.DEBUG)

# create file handler which logs even debug messages
fh = logging.FileHandler('spam.log')
fh.setLevel(logging.DEBUG)

# create console handler with a higher log level
ch = logging.StreamHandler()
ch.setLevel(logging.ERROR)

# create formatter and add it to the handlers
formatter = logging.Formatter('%(asctime)s - %(levelname)s - %(message)s')
ch.setFormatter(formatter)
fh.setFormatter(formatter)

# add the handlers to logger
logger.addHandler(ch)
logger.addHandler(fh)

# 'application' code
logger.debug('debug message')
logger.info('info message')
logger.warn('warn message')
logger.error('error message')
```
Notice that the ‘application’ code does not care about multiple handlers. All that changed was the addition and configuration of a new handler named `fh`.

The ability to create new handlers with higher- or lower-severity filters can be very helpful when writing and testing an application. Instead of using many `print` statements for debugging, use `logger.debug`:

Unlike the print statements, which you will have to delete or comment out later, the `logger.debug` statements can remain intact in the source code and remain dormant until you need them again. At that time, the only change that needs to happen is to modify the severity level of the logger and/or handler to debug.
Logging to multiple destinations

Let's say you want to log to console and file with different message formats and in differing circumstances. Say you want to log messages with levels of DEBUG and higher to file, and those messages at level INFO and higher to the console. Let's also assume that the file should contain timestamps, but the console messages should not. Here's how you can achieve this:

```python
import logging

# set up logging to file - see previous section for logging.basicConfig(level=logging.DEBUG,
    format='%(asctime)s %(name)-12s %(levelname)-8s %(message)s',
    datefmt='%m-%d %H:%M',
    filename='/temp/myapp.log',
    filemode='w')

# define a Handler which writes INFO messages or higher
console = logging.StreamHandler()
console.setLevel(logging.INFO)
# set a format which is simpler for console use
formatter = logging.Formatter('%(name)-12s: %(levelname)-8s %(message)s')
# tell the handler to use this format
console.setFormatter(formatter)
# add the handler to the root logger
logging.getLogger('').addHandler(console)

# Now, we can log to the root logger, or any other logger
logging.info('Jackdaws love my big sphinx of quartz.

# Now, define a couple of other loggers which might # application:

logger1 = logging.getLogger('myapp.area1')
logger2 = logging.getLogger('myapp.area2')
```
logger1.debug('Quick zephyrs blow, vexing daft Jim.')
logger1.info('How quickly daft jumping zebras vex.')
logger2.warning('Jail zesty vixen who grabbed pay from quack.')
logger2.error('The five boxing wizards jump quickly.

When you run this, on the console you will see

```
root    : INFO   Jackdaws love my big sphinx of a beard.
myapp.area1 : INFO   How quickly daft jumping zebras vex.
myapp.area2 : WARNING  Jail zesty vixen who grabbed pay from quack.
myapp.area2 : ERROR   The five boxing wizards jump quickly.
```

and in the file you will see something like

```
10-22 22:19 myapp.area1 DEBUG  Quick zephyrs blow,...
10-22 22:19 myapp.area1 INFO   How quickly daft jumping zebras vex.
10-22 22:19 myapp.area2 WARNING  Jail zesty vixen who grabbed pay from quack.
10-22 22:19 myapp.area2 ERROR   The five boxing wizards jump quickly.
```

As you can see, the DEBUG message only shows up in the file. The other messages are sent to both destinations.

This example uses console and file handlers, but you can use any number and combination of handlers you choose.
Configuration server example

Here is an example of a module using the logging configuration server:

```python
import logging
import logging.config
import time
import os

# read initial config file
logging.config.fileConfig('logging.conf')

# create and start listener on port 9999
r = logging.config.listen(9999)
r.start()

logger = logging.getLogger('simpleExample')

try:
    # loop through logging calls to see the difference
    # new configurations make, until Ctrl+C is pressed
    while True:
        logger.debug('debug message')
        logger.info('info message')
        logger.warn('warn message')
        logger.error('error message')
        logger.critical('critical message')
        time.sleep(5)
except KeyboardInterrupt:
    # cleanup
    logging.config.stopListening()
    t.join()
```

And here is a script that takes a filename and sends that file to the
server, properly preceded with the binary-encoded length, as the new logging configuration:

```python
#!/usr/bin/env python
import socket, sys, struct

with open(sys.argv[1], 'rb') as f:
    data_to_send = f.read()

HOST = 'localhost'
PORT = 9999
s = socket.socket(socket.AF_INET, socket.SOCK_STREAM)
print('connecting...')
s.connect((HOST, PORT))
print('sending config...')
s.send(struct.pack('>L', len(data_to_send)))
s.send(data_to_send)
s.close()
print('complete')
```
Dealing with handlers that block

Sometimes you have to get your logging handlers to do their work without blocking the thread you're logging from. This is common in Web applications, though of course it also occurs in other scenarios.

A common culprit which demonstrates sluggish behaviour is the SMTPHandler: sending emails can take a long time, for a number of reasons outside the developer's control (for example, a poorly performing mail or network infrastructure). But almost any network-based handler can block: Even a SocketHandler operation may do a DNS query under the hood which is too slow (and this query can be deep in the socket library code, below the Python layer, and outside your control).

One solution is to use a two-part approach. For the first part, attach only a QueueHandler to those loggers which are accessed from performance-critical threads. They simply write to their queue, which can be sized to a large enough capacity or initialized with no upper bound to their size. The write to the queue will typically be accepted quickly, though you will probably need to catch the queue.Full exception as a precaution in your code. If you are a library developer who has performance-critical threads in their code, be sure to document this (together with a suggestion to attach only QueueHandlers to your loggers) for the benefit of other developers who will use your code.

The second part of the solution is QueueListener, which has been designed as the counterpart to QueueHandler. A QueueListener is very simple: it's passed a queue and some handlers, and it fires up an internal thread which listens to its queue for LogRecords sent from...
QueueHandlers (or any other source of LogRecords, for that matter). The LogRecords are removed from the queue and passed to the handlers for processing.

The advantage of having a separate QueueListener class is that you can use the same instance to service multiple QueueHandlers. This is more resource-friendly than, say, having threaded versions of the existing handler classes, which would eat up one thread per handler for no particular benefit.

An example of using these two classes follows (imports omitted):

```python
que = queue.Queue(-1) # no limit on size
queue_handler = QueueHandler(que)
handler = logging.StreamHandler()
listener = QueueListener(que, handler)
root = logging.getLogger()
root.addHandler(queue_handler)
formatter = logging.Formatter('%(threadName)s: %(message)s')
handler.setFormatter(formatter)
listener.start()
root.warning('Look out!')
listener.stop()
```

which, when run, will produce:

```
MainThread: Look out!
```
Sending and receiving logging events across a network

Let's say you want to send logging events across a network, and handle them at the receiving end. A simple way of doing this is attaching a `SocketHandler` instance to the root logger at the sending end:

```python
import logging, logging.handlers

rootLogger = logging.getLogger('')
rootLogger.setLevel(logging.DEBUG)
socketHandler = logging.handlers.SocketHandler('localhost',
                                               logging.handlers.DEFAULT_TCP_LOGGING_PORT)

# don't bother with a formatter, since a socket handler sends the event as
# an unformatted pickle
rootLogger.addHandler(socketHandler)

# Now, we can log to the root logger, or any other logger:
logging.info('Jackdaws love my big sphinx of quartz.

# Now, define a couple of other loggers which might represent areas in your application:
logger1 = logging.getLogger('myapp.area1')
logger2 = logging.getLogger('myapp.area2')

logger1.debug('Quick zephyrs blow, vexing daft Jim.
logger1.info('How quickly daft jumping zebras vex.')
logger2.warning('Jail zesty vixen who grabbed pay from')
logger2.error('The five boxing wizards jump quickly.
```

At the receiving end, you can set up a receiver using the
socketserver module. Here is a basic working example:

```python
import pickle
import logging
import logging.handlers
import socketserver
import struct

class LogRecordStreamHandler(socketserver.StreamRequestHandler):
    """Handler for a streaming logging request.
    This basically logs the record using whatever logging policy is configured locally.
    """
    def handle(self):
        """Handle multiple requests - each expected to be 4-byte length, followed by the LogRecord in pickle format. Logs the record according to whatever policy is configured locally."
        while True:
            chunk = self.connection.recv(4)
            if len(chunk) < 4:
                break
            slen = struct.unpack('>L', chunk)[0]
            chunk = self.connection.recv(slen)
            while len(chunk) < slen:
                chunk = chunk + self.connection.recv(slen - len(chunk))
            obj = self.unPickle(chunk)
            record = logging.makeLogRecord(obj)
            self.handleLogRecord(record)

    def unPickle(self, data):
        return pickle.loads(data)
```
def handleLogRecord(self, record):
    # if a name is specified, we use the named logger
    # implied by the record.
    if self.server.logname is not None:
        name = self.server.logname
    else:
        name = record.name
    logger = logging.getLogger(name)
    # N.B. EVERY record gets logged. This is because
    # is normally called AFTER logger-level filtering.
    # to do filtering, do it at the client end to
    # cycles and network bandwidth!
    logger.handle(record)

class LogRecordSocketReceiver(socketserver.ThreadingTCPServer):
    """Simple TCP socket-based logging receiver suitable for testing."
    ""
    allow_reuse_address = 1

def __init__(self, host='localhost',
             port=logging.handlers.DEFAULT_TCP_LOGGING_PORT,
             handler=LogRecordStreamHandler):
    socketserver.ThreadingTCPServer.__init__(self,
                                              self.abort = 0
                                              self.timeout = 1

                                   self.timeout)
        if rd:

First run the server, and then the client. On the client side, nothing is printed on the console; on the server side, you should see something like:

Note that there are some security issues with pickle in some scenarios. If these affect you, you can use an alternative serialization scheme by overriding the makePickle() method and implementing your alternative there, as well as adapting the above script to use your alternative serialization.
Adding contextual information to your logging output

Sometimes you want logging output to contain contextual information in addition to the parameters passed to the logging call. For example, in a networked application, it may be desirable to log client-specific information in the log (e.g. remote client’s username, or IP address). Although you could use the `extra` parameter to achieve this, it's not always convenient to pass the information in this way. While it might be tempting to create Logger instances on a per-connection basis, this is not a good idea because these instances are not garbage collected. While this is not a problem in practice, when the number of Logger instances is dependent on the level of granularity you want to use in logging an application, it could be hard to manage if the number of Logger instances becomes effectively unbounded.

Using LoggerAdapters to impart contextual information

An easy way in which you can pass contextual information to be output along with logging event information is to use the LoggerAdapter class. This class is designed to look like a Logger, so that you can call `debug()`, `info()`, `warning()`, `error()`, `exception()`, `critical()` and `log()`. These methods have the same signatures as their counterparts in Logger, so you can use the two types of instances interchangeably.

When you create an instance of LoggerAdapter, you pass it a Logger instance and a dict-like object which contains your contextual information. When you call one of the logging methods on an instance
of LoggerAdapter, it delegates the call to the underlying instance of Logger passed to its constructor, and arranges to pass the contextual information in the delegated call. Here's a snippet from the code of LoggerAdapter:

```python
def debug(self, msg, *args, **kwargs):
    """
    Delegate a debug call to the underlying logger, contextual information from this adapter instance
    """
    msg, kwargs = self.process(msg, kwargs)
    self.logger.debug(msg, *args, **kwargs)
```

The `process()` method of LoggerAdapter is where the contextual information is added to the logging output. It's passed the message and keyword arguments of the logging call, and it passes back (potentially) modified versions of these to use in the call to the underlying logger. The default implementation of this method leaves the message alone, but inserts an ‘extra’ key in the keyword argument whose value is the dict-like object passed to the constructor. Of course, if you had passed an ‘extra’ keyword argument in the call to the adapter, it will be silently overwritten.

The advantage of using ‘extra’ is that the values in the dict-like object are merged into the LogRecord instance’s `__dict__`, allowing you to use customized strings with your Formatter instances which know about the keys of the dict-like object. If you need a different method, e.g. if you want to prepend or append the contextual information to the message string, you just need to subclass LoggerAdapter and override `process()` to do what you need. Here is a simple example:

```python
class CustomAdapter(logging.LoggerAdapter):
```
This example adapter expects the passed in dict-like object to have a 'connid' key, whose value in brackets is prepended to the log message.

```python
def process(self, msg, kwargs):
    return ' [%s] %s' % (self.extra['connid'], msg)
```

which you can use like this:

```python
logger = logging.getLogger(__name__)
adaper = CustomAdapter(logger, {'connid': some_conn_id})
```

Then any events that you log to the adapter will have the value of some_conn_id prepended to the log messages.

**Using objects other than dicts to pass contextual information**

You don’t need to pass an actual dict to a LoggerAdapter - you could pass an instance of a class which implements `__getitem__` and `__iter__` so that it looks like a dict to logging. This would be useful if you want to generate values dynamically (whereas the values in a dict would be constant).

**Using Filters to impart contextual information**

You can also add contextual information to log output using a user-defined Filter. Filter instances are allowed to modify the LogRecords passed to them, including adding additional attributes which can then be output using a suitable format string, or if needed a custom Formatter.

For example in a web application, the request being processed (or at
least, the interesting parts of it) can be stored in a threadlocal (`threading.local`) variable, and then accessed from a `Filter` to add, say, information from the request - say, the remote IP address and remote user's username - to the `LogRecord`, using the attribute names ‘ip’ and ‘user’ as in the `LoggerAdapter` example above. In that case, the same format string can be used to get similar output to that shown above. Here's an example script:

```python
import logging
from random import choice

class ContextFilter(logging.Filter):
    """
    This is a filter which injects contextual information.

    Rather than use actual contextual information, we just use random data in this demo.
    """

    USERS = ['jim', 'fred', 'sheila']
    IPS = ['123.231.231.123', '127.0.0.1', '192.168.0.1']

def filter(self, record):
    record.ip = choice(ContextFilter.IPS)
    record.user = choice(ContextFilter.USERS)
    return True

if __name__ == '__main__':
    levels = (logging.DEBUG, logging.INFO, logging.WARNING)
    logging.basicConfig(level=logging.DEBUG, format='%(asctime)-15s	%(name)-5s	%(levelname)-8s	IP:	%(ip)-15s	User:	%(user)-8s	%(message)s')
    a1 = logging.getLogger('a.b.c')
    a2 = logging.getLogger('d.e.f')
    f = ContextFilter()
```
a1.addFilter(f)
a2.addFilter(f)
a1.debug('A debug message')
a1.info('An info message with %s', 'some parameter')
for x in range(10):
    lvl = choice(levels)
    lvlname = logging.getLevelName(lvl)
    a2.log(lvl, 'A message at %s level with %d %s')

which, when run, produces something like:

```
2010-09-06 22:38:15,292 a.b.c DEBUG   IP: 123.231.231.123

Logging to a single file from multiple processes

Although logging is thread-safe, and logging to a single file from multiple threads in a single process is supported, logging to a single file from multiple processes is not supported, because there is no standard way to serialize access to a single file across multiple processes in Python. If you need to log to a single file from multiple processes, one way of doing this is to have all the processes log to a SocketHandler, and have a separate process which implements a socket server which reads from the socket and logs to file. (If you prefer, you can dedicate one thread in one of the existing processes to perform this function.) This section documents this approach in more detail and includes a working socket receiver which can be used as a starting point for you to adapt in your own applications.

If you are using a recent version of Python which includes the multiprocessing module, you could write your own handler which uses the Lock class from this module to serialize access to the file from your processes. The existing FileHandler and subclasses do not make use of multiprocessing at present, though they may do so in the future. Note that at present, the multiprocessing module does not provide working lock functionality on all platforms (see http://bugs.python.org/issue3770).

Alternatively, you can use a Queue and a QueueHandler to send all logging events to one of the processes in your multi-process application. The following example script demonstrates how you can do this; in the example a separate listener process listens for events sent by other processes and logs them according to its own logging configuration. Although the example only demonstrates one way of
doing it (for example, you may want to use a listener thread rather than a separate listener process – the implementation would be analogous) it does allow for completely different logging configurations for the listener and the other processes in your application, and can be used as the basis for code meeting your own specific requirements:

```python
# You'll need these imports in your own code
import logging
import logging.handlers
import multiprocessing

# Next two import lines for this demo only
from random import choice, random
import time

# Because you'll want to define the logging configurations for listener and worker process functions take a configurer parameter which they use for communication.
#
# In practice, you can configure the listener however you want, but in this simple example, the listener does not apply level or filter logic to received records.
# In practice, you would probably want to do this logic in the worker processes, to avoid sending events which would be filtered out between processes.
#
# The size of the rotated files is made small so you can see the results easily.

def listener_configurer():
    root = logging.getLogger()
    h = logging.handlers.RotatingFileHandler('mptest.log')
    f = logging.Formatter('%(asctime)s %(processName)-10s %(name)s %(levelname)-8s %(message)s')
    h.setFormatter(f)
    root.addHandler(h)

# This is the listener process top-level loop: wait for (LogRecords) on the queue and handle them, quit when you get a None
# LogRecord.

def listener_process(queue, configurer):
    configurer()
    while True:
        try:
            record = queue.get()
            if record is None:  # We send this as a sentinel to tell the listener to quit.
                break
            logger = logging.getLogger(record.name)
            logger.handle(record)  # No level or filter logic applied - just do it!
        except Exception:
            import sys, traceback
            print('Whoops! Problem:', file=sys.stderr)
            traceback.print_exc(file=sys.stderr)

    # Arrays used for random selections in this demo

    LEVELS = [logging.DEBUG, logging.INFO, logging.WARN, logging.ERROR, logging.CRITICAL]
    LOGGERS = ['a.b.c', 'd.e.f']
    MESSAGES = ['Random message #1',
                 'Random message #2',
                 'Random message #3',
                 ]

    # The worker configuration is done at the start of the worker process run.
    # Note that on Windows you can't rely on fork semantics, so each process
    # will run the logging configuration code when it starts.

def worker_configurer(queue):
    h = logging.handlers.QueueHandler(queue)  # Just
    root = logging.getLogger()
    root.addHandler(h)
    root.setLevel(logging.DEBUG)  # send all messages
# This is the worker process top-level loop, which just
# random intervening delays before terminating.
# The print messages are just so you know it's doing

```python
def worker_process(queue, configurer):
    configurer(queue)
    name = multiprocessing.current_process().name
    print('Worker started: %s' % name)
    for i in range(10):
        time.sleep(random())
        logger = logging.getLogger(choice(LOGGERS))
        level = choice(LEVELS)
        message = choice(MESSAGES)
        logger.log(level, message)
        print('Worker finished: %s' % name)
```

# Here's where the demo gets orchestrated. Create the
# the listener, create ten workers and start them, wait
# then send a None to the queue to tell the listener

```python
def main():
    queue = multiprocessing.Queue(-1)
    listener = multiprocessing.Process(target=listener_process, args=(queue,
                                                                   queue.put_nowait(None))
    listener.join()
```
A variant of the above script keeps the logging in the main process, in a separate thread:

```python
import logging
import logging.config
import logging.handlers
from multiprocessing import Process, Queue
import random
import threading
import time

def logger_thread(q):
    while True:
        record = q.get()
        if record is None:
            break
        logger = logging.getLogger(record.name)
        logger.handle(record)

def worker_process(q):
    qh = logging.handlers.QueueHandler(q)
    root = logging.getLogger()
    root.setLevel(logging.DEBUG)
    root.addHandler(qh)
    levels = [logging.DEBUG, logging.INFO, logging.WARNING, logging.CRITICAL]
    loggers = ['foo', 'foo.bar', 'foo.bar.baz', 'spam', 'spam.ham', 'spam.ham.eggs']
    for i in range(100):
        lvl = random.choice(levels)
        logger = logging.getLogger(random.choice(loggers))
        logger.log(lvl, 'Message no. %d', i)

if __name__ == '__main__':
    q = Queue()
    d = {
```
'version': 1,
'formatters': {
    'detailed': {
        'class': 'logging.Formatter',
        'format': '%(asctime)s	%(name)-15s	%(levelname)-8s	%(processName)-10s	%(message)s'
    }
},

        'mode': 'w',
        'level': 'ERROR',
        'formatter': 'detailed',
    },
},
'loggers': {
    'foo': {
        'handlers': ['foofile']
    },
},
{'root': {
    'level': 'DEBUG',
    'handlers': ['console', 'file', 'errors']
},
}
workers = []
for i in range(5):
    wp = Process(target=worker_process, name='worker%d' % i)
    workers.append(wp)
    wp.start()
logging.config.dictConfig(d)
lp = threading.Thread(target=logger_thread, args=())
lp.start()
# At this point, the main process could do some
# Once it's done that, it can wait for the workers
for wp in workers:
    wp.join()
# And now tell the logging thread to finish up,
q.put(None)
lp.join()

This variant shows how you can e.g. apply configuration for particular loggers - e.g. the foo logger has a special handler which stores all events in the foo subsystem in a file mplog-foo.log. This will be used by the logging machinery in the main process (even though the logging events are generated in the worker processes) to direct the messages to the appropriate destinations.
Using file rotation

Sometimes you want to let a log file grow to a certain size, then open a new file and log to that. You may want to keep a certain number of these files, and when that many files have been created, rotate the files so that the number of files and the size of the files both remain bounded. For this usage pattern, the logging package provides a RotatingFileHandler:

```python
import glob
import logging
import logging.handlers

LOG_FILENAME = 'logging_rotatingfile_example.out'

# Set up a specific logger with our desired output level
my_logger = logging.getLogger('MyLogger')
my_logger.setLevel(logging.DEBUG)

# Add the log message handler to the logger
handler = logging.handlers.RotatingFileHandler(
    LOG_FILENAME, maxBytes=20, backupCount

my_logger.addHandler(handler)

# Log some messages
for i in range(20):
    my_logger.debug('i = %d' % i)

# See what files are created
logfiles = glob.glob('%s*' % LOG_FILENAME)

for filename in logfiles:
    print(filename)
```
The result should be 6 separate files, each with part of the log history for the application:

logging_rotatingfile_example.out
logging_rotatingfile_example.out.1
logging_rotatingfile_example.out.2
logging_rotatingfile_example.out.3
logging_rotatingfile_example.out.4
logging_rotatingfile_example.out.5

The most current file is always logging_rotatingfile_example.out, and each time it reaches the size limit it is renamed with the suffix .1. Each of the existing backup files is renamed to increment the suffix (.1 becomes .2, etc.) and the .6 file is erased.

Obviously this example sets the log length much too small as an extreme example. You would want to set maxBytes to an appropriate value.
Use of alternative formatting styles

When logging was added to the Python standard library, the only way of formatting messages with variable content was to use the %-formatting method. Since then, Python has gained two new formatting approaches: `string.Template` (added in Python 2.4) and `str.format()` (added in Python 2.6).

Logging (as of 3.2) provides improved support for these two additional formatting styles. The Formatter class been enhanced to take an additional, optional keyword parameter named `style`. This defaults to '%', but other possible values are '{' and '$', which correspond to the other two formatting styles. Backwards compatibility is maintained by default (as you would expect), but by explicitly specifying a style parameter, you get the ability to specify format strings which work with `str.format()` or `string.Template`. Here's an example console session to show the possibilities:

```python
>>> import logging
>>> root = logging.getLogger()  
>>> root.setLevel(logging.DEBUG)  
>>> handler = logging.StreamHandler()  
>>> bf = logging.Formatter('{asctime} {name} {levelname:8s} {message}')
...                                style='{'}
>>> handler.setFormatter(bf)  
>>> root.addHandler(handler)  
>>> logger = logging.getLogger('foo.bar')  
>>> logger.debug('This is a DEBUG message')
2010-10-28 15:11:55,341 foo.bar DEBUG  This is a DEBUG message
>>> logger.critical('This is a CRITICAL message')
2010-10-28 15:12:11,526 foo.bar CRITICAL This is a CRITICAL message
>>> df = logging.Formatter('${asctime} $name ${levelname} $message')
...                                style='$')
```
>>> handler.setFormatter(df)
>>> logger.debug('This is a DEBUG message')
2010-10-28 15:13:06,924 foo.bar DEBUG This is a DEBUG message
>>> logger.critical('This is a CRITICAL message')
2010-10-28 15:13:11,494 foo.bar CRITICAL This is a CRITICAL message

Note that the formatting of logging messages for final output to logs is completely independent of how an individual logging message is constructed. That can still use %-formatting, as shown here:

```python
>>> logger.error('This is an%s %s %s', 'other,', 'ERROR,
2010-10-28 15:19:29,833 foo.bar ERROR This is another,
```

Logging calls (logger.debug(), logger.info() etc.) only take positional parameters for the actual logging message itself, with keyword parameters used only for determining options for how to handle the actual logging call (e.g. the `exc_info` keyword parameter to indicate that traceback information should be logged, or the `extra` keyword parameter to indicate additional contextual information to be added to the log). So you cannot directly make logging calls using `str.format()` or `string.Template` syntax, because internally the logging package uses %-formatting to merge the format string and the variable arguments. There would no changing this while preserving backward compatibility, since all logging calls which are out there in existing code will be using %-format strings.

There is, however, a way that you can use {}- and $- formatting to construct your individual log messages. Recall that for a message you can use an arbitrary object as a message format string, and that the logging package will call `str()` on that object to get the actual format
string. Consider the following two classes:

```python
class BraceMessage:
    def __init__(self, fmt, *args, **kwargs):
        self.fmt = fmt
        self.args = args
        self.kwargs = kwargs

    def __str__(self):
        return self.fmt.format(*self.args, **self.kwargs)

class DollarMessage:
    def __init__(self, fmt, **kwargs):
        self.fmt = fmt
        self.kwargs = kwargs

    def __str__(self):
        from string import Template
        return Template(self.fmt).substitute(**self.kwargs)
```

Either of these can be used in place of a format string, to allow {}- or $-formatting to be used to build the actual “message” part which appears in the formatted log output in place of “%(message)s” or “{message}” or “$message”. It’s a little unwieldy to use the class names whenever you want to log something, but it’s quite palatable if you use an alias such as __ (double underscore – not to be confused with _, the single underscore used as a synonym/alias for gettext.gettext() or its brethren).

The above classes are not included in Python, though they’re easy enough to copy and paste into your own code. They can be used as follows (assuming that they’re declared in a module called wherever):
>>> from wherever import BraceMessage as __  
>>> print(__('Message with {0} {name}', 2, name='placeholders')) 
Message with 2 placeholders

>>> class Point: pass
...
>>> p = Point()
>>> p.x = 0.5
>>> p.y = 0.5
>>> print(__('Message with coordinates: ({point.x:.2f}, {point.y:.2f})', point=p))
Message with coordinates: (0.50, 0.50)

>>> from wherever import DollarMessage as __
>>> print(__('Message with $num $what', num=2, what='placeholders'))
Message with 2 placeholders

While the above examples use print() to show how the formatting works, you would of course use logger.debug() or similar to actually log using this approach.

One thing to note is that you pay no significant performance penalty with this approach: the actual formatting happens not when you make the logging call, but when (and if) the logged message is actually about to be output to a log by a handler. So the only slightly unusual thing which might trip you up is that the parentheses go around the format string and the arguments, not just the format string. That’s because the __ notation is just syntax sugar for a constructor call to one of the XXXMessage classes.

If you prefer, you can use a LoggerAdapter to achieve a similar effect to the above, as in the following example:

import logging
class Message(object):
    def __init__(self, fmt, args):
        self.fmt = fmt
        self.args = args

    def __str__(self):
        return self.fmt.format(*self.args)

class StyleAdapter(logging.LoggerAdapter):
    def __init__(self, logger, extra=None):
        super(StyleAdapter, self).__init__(logger, extra)

    def log(self, level, msg, *args, **kwargs):
        if self.isEnabledFor(level):  
            msg, kwargs = self.process(msg, kwargs)
            self.logger._log(level, Message(msg, args)

logger = StyleAdapter(logging.getLogger(__name__))

def main():
    logger.debug('Hello, {}', 'world!')

if __name__ == '__main__':
    logging.basicConfig(level=logging.DEBUG)
    main()

The above script should log the message Hello, world! when run with Python 3.2 or later.
Customizing LogRecord

Every logging event is represented by a LogRecord instance. When an event is logged and not filtered out by a logger's level, a LogRecord is created, populated with information about the event and then passed to the handlers for that logger (and its ancestors, up to and including the logger where further propagation up the hierarchy is disabled). Before Python 3.2, there were only two places where this creation was done:

- **Logger.makeRecord()**, which is called in the normal process of logging an event. This invoked LogRecord directly to create an instance.
- **makeLogRecord()**, which is called with a dictionary containing attributes to be added to the LogRecord. This is typically invoked when a suitable dictionary has been received over the network (e.g. in pickle form via a SocketHandler, or in JSON form via an HTTPHandler).

This has usually meant that if you need to do anything special with a LogRecord, you've had to do one of the following.

- Create your own Logger subclass, which overrides Logger.makeRecord(), and set it using setLoggerClass() before any loggers that you care about are instantiated.
- Add a Filter to a logger or handler, which does the necessary special manipulation you need when its filter() method is called.

The first approach would be a little unwieldy in the scenario where (say) several different libraries wanted to do different things. Each would attempt to set its own Logger subclass, and the one which did
this last would win.

The second approach works reasonably well for many cases, but does not allow you to e.g. use a specialized subclass of LogRecord. Library developers can set a suitable filter on their loggers, but they would have to remember to do this every time they introduced a new logger (which they would do simply by adding new packages or modules and doing

```python
logger = logging.getLogger(__name__)
```

at module level). It's probably one too many things to think about. Developers could also add the filter to a NullHandler attached to their top-level logger, but this would not be invoked if an application developer attached a handler to a lower-level library logger – so output from that handler would not reflect the intentions of the library developer.

In Python 3.2 and later, LogRecord creation is done through a factory, which you can specify. The factory is just a callable you can set with `setLogRecordFactory()`, and interrogate with `getLogRecordFactory()`. The factory is invoked with the same signature as the LogRecord constructor, as LogRecord is the default setting for the factory.

This approach allows a custom factory to control all aspects of LogRecord creation. For example, you could return a subclass, or just add some additional attributes to the record once created, using a pattern similar to this:

```python
old_factory = logging.getLogRecordFactory()

def record_factory(*args, **kwargs):
```
This pattern allows different libraries to chain factories together, and as long as they don't overwrite each other's attributes or unintentionally overwrite the attributes provided as standard, there should be no surprises. However, it should be borne in mind that each link in the chain adds run-time overhead to all logging operations, and the technique should only be used when the use of a Filter does not provide the desired result.
Subclassing QueueHandler - a ZeroMQ example

You can use a QueueHandler subclass to send messages to other kinds of queues, for example a ZeroMQ 'publish' socket. In the example below, the socket is created separately and passed to the handler (as its 'queue'):

```python
import zmq # using pyzmq, the Python binding for ZeroMQ
import json # for serializing records portably

ctx = zmq.Context()
sock = zmq.Socket(ctx, zmq.PUB) # or zmq.PUSH, or other
sock.bind('tcp://*:5556') # or wherever

class ZeroMQSocketHandler(QueueHandler):
    def enqueue(self, record):
        data = json.dumps(record.__dict__)
        self.queue.send(data)

handler = ZeroMQSocketHandler(sock)
```

Of course there are other ways of organizing this, for example passing in the data needed by the handler to create the socket:

```python
class ZeroMQSocketHandler(QueueHandler):
    def __init__(self, uri, socktype=zmq.PUB, ctx=None):
        self.ctx = ctx or zmq.Context()
        socket = zmq.Socket(self.ctx, socktype)
        socket.bind(uri)
        QueueHandler.__init__(self, socket)

    def enqueue(self, record):
```
data = json.dumps(record.__dict__)
self.queue.send(data)

def close(self):
    self.queue.close()
Subclassing QueueListener - a ZeroMQ example

You can also subclass QueueListener to get messages from other kinds of queues, for example a ZeroMQ 'subscribe' socket. Here's an example:

```python
class ZeroMQSocketListener(QueueListener):
    def __init__(self, uri, *handlers, **kwargs):
        self.ctx = kwargs.get('ctx') or zmq.Context()
        socket = zmq.Socket(self.ctx, zmq.SUB)
        socket.setsockopt(zmq.SUBSCRIBE, '')  # subscribe to everything
        socket.connect(uri)

    def dequeue(self):
        msg = self.queue.recv()
        return logging.makeLogRecord(json.loads(msg))
```

An example dictionary-based configuration

Below is an example of a logging configuration dictionary - it's taken from the documentation on the Django project. This dictionary is passed to dictConfig() to put the configuration into effect:

```python
LOGGING = {
    'version': 1,
    'disable_existing_loggers': True,
    'formatters': {
        'verbose': {
            'format': '%(levelname)s %(asctime)s %(module)s %(process)d %(thread)d %(message)s',
        },
        'simple': {
            'format': '%(levelname)s %(message)s',
        },
    },
    'filters': {
        'special': {
            '()': 'project.logging.SpecialFilter',
            'foo': 'bar',
        },
    },
    'handlers': {
        'null': {
            'level': 'DEBUG',
            'class': 'django.utils.log.NullHandler',
        },
        'console':{
            'level':'DEBUG',
            'class':'logging.StreamHandler',
            'formatter': 'simple'
        },
        'mail_admins': {
            'level': 'ERROR',
```
For more information about this configuration, you can see the relevant section of the Django documentation.
Using a rotator and namer to customize log rotation processing

An example of how you can define a namer and rotator is given in the following snippet, which shows zlib-based compression of the log file:

```python
def namer(name):
    return name + "\.gz"

def rotator(source, dest):
    with open(source, "rb") as sf:
        data = sf.read()
        compressed = zlib.compress(data, 9)
    with open(dest, "wb") as df:
        df.write(compressed)
        os.remove(source)

rh = logging.handlers.RotatingFileHandler(...)  
rh.rotator = rotator  
rh.namer = namer
```

These are not “true" .gz files, as they are bare compressed data, with no “container” such as you’d find in an actual gzip file. This snippet is just for illustration purposes.
A more elaborate multiprocessing example

The following working example shows how logging can be used with multiprocessing using configuration files. The configurations are fairly simple, but serve to illustrate how more complex ones could be implemented in a real multiprocessing scenario.

In the example, the main process spawns a listener process and some worker processes. Each of the main process, the listener and the workers have three separate configurations (the workers all share the same configuration). We can see logging in the main process, how the workers log to a QueueHandler and how the listener implements a QueueListener and a more complex logging configuration, and arranges to dispatch events received via the queue to the handlers specified in the configuration. Note that these configurations are purely illustrative, but you should be able to adapt this example to your own scenario.

Here’s the script - the docstrings and the comments hopefully explain how it works:

```python
import logging
import logging.config
import logging.handlers
from multiprocessing import Process, Queue, Event, current_process
import os
import random
import time

class MyHandler:
    
    """
    A simple handler for logging events. It runs in 
    dispatches events to loggers based on the name in
```
which then get dispatched, by the logging system configured for those loggers.

```python
def handle(self, record):
    logger = logging.getLogger(record.name)
    # The process name is transformed just to show that it's the listener doing the logging to files and console
    record.processName = '%s (for %s)' % (current_process, logger.handle(record))

def listener_process(q, stop_event, config):
    
    This could be done in the main process, but is just done in a separate process for illustrative purposes.

    This initialises logging according to the specified configuration, starts the listener and waits for the main process via the event. The listener is then stopped, and the process exits.

    logging.config.dictConfig(config)
    listener = logging.handlers.QueueListener(q, MyHandler)
    listener.start()
    if os.name == 'posix':
        # On POSIX, the setup logger will have been parent process, but should have been disabled following the dictConfig call.
        # On Windows, since fork isn't used, the setup logger won't exist in the child, so it would be created and would appear - hence the "if posix" clause
        logger = logging.getLogger('setup')
        logger.critical('Should not appear, because of disabled logger...')
    stop_event.wait()
    listener.stop()

def worker_process(config):
    
    A number of these are spawned for the purpose of
practice, they could be a heterogenous bunch of ones which are identical to each other.

This initialises logging according to the specified configuration, and logs a hundred messages with random levels to random loggers.

A small sleep is added to allow other processes a chance to run. This is not strictly needed, but it mixes the output from the different processes a bit more than if it's left out.

```python
logging.config.dictConfig(config)
levels = [logging.DEBUG, logging.INFO, logging.WARNING, logging.CRITICAL]
loggers = ['foo', 'foo.bar', 'foo.bar.baz', 'spam', 'spam.ham', 'spam.ham.eggs']
if os.name == 'posix':
    # On POSIX, the setup logger will have been configured in the parent process, but should have been disabled following the dictConfig call.
    # On Windows, since fork isn't used, the setup logger won't exist in the child, so it would be created and would appear - hence the "if posix" clause.
    logger = logging.getLogger('setup')
    logger.critical('Should not appear, because dictConfig call disabled it...')
for i in range(100):
    lvl = random.choice(levels)
    logger = logging.getLogger(random.choice(loggers))
    logger.log(lvl, 'Message no. %d', i)
    time.sleep(0.01)
```

def main():
    q = Queue()
    # The main process gets a simple configuration which prints to the console.
    config_initial = {
        'version': 1,
        'formatters': {
```
{'detailed': {
    'class': 'logging.Formatter',
    'format': '%(asctime)s %(name)-15s %(levelname)-8s %(processName)-10s %(message)s'
},
}
,
'handlers': {
    'console': {
        'class': 'logging.StreamHandler',
        'level': 'INFO',
    },
},
,'root': {
    'level': 'DEBUG',
    'handlers': ['console']
}
}

# The worker process configuration is just a Queue handler attached to the root logger, which allows all messages to be sent to the queue. We disable existing loggers to disable the "setup" logger used in the parent process. This is needed on POSIX because the logger will be there in the child following a fork().
config_worker = {
    'version': 1,
    'disable_existing_loggers': True,
    'handlers': {
        'queue': {
            'class': 'logging.handlers.QueueHandler',
            'queue': q,
        },
    },
    'root': {
        'level': 'DEBUG',
        'handlers': ['queue']
    },
}

# The listener process configuration shows that the full flexibility of logging configuration is available to dispatch events to handlers whatever
# you want.
# We disable existing loggers to disable the "setup" logger used in the parent process. This is needed on POSIX because the logger will be there in the child following a fork().

```python
config_listener = {
    'version': 1,
    'disable_existing_loggers': True,
    'formatters': {
        'detailed': {
            'class': 'logging.Formatter',
            'format': '%(asctime)s %(name)-15s %(levelname)-8s %(processName)-10s %(message)s'
        },
        'simple': {
            'class': 'logging.Formatter',
            'format': '%(name)-15s %(levelname)-8s %(processName)-10s %(message)s'
        }
    },
    'handlers': {
        'console': {
            'class': 'logging.StreamHandler',
            'level': 'INFO',
            'formatter': 'simple',
        },
        'file': {
            'class': 'logging.FileHandler',
            'filename': 'mplog.log',
            'mode': 'w',
            'formatter': 'detailed',
        },
        'foofile': {
            'class': 'logging.FileHandler',
            'filename': 'mplog-foo.log',
            'mode': 'w',
            'formatter': 'detailed',
        },
        'errors': {
            'class': 'logging.FileHandler',
```
''filename': 'mplog-errors.log',
'mode': 'w',
'level': 'ERROR',
'formatter': 'detailed',
},
},
'loggers': {
'foo': {
'handlers': ['foofile']
}
},
'root': {
'level': 'DEBUG',
'handlers': ['console', 'file', 'errors'
}
},
}

# Log some initial events, just to show that logging normally.
logging.config.dictConfig(config_initial)
logger = logging.getLogger('setup')
logger.info('About to create workers ...')
workers = []
for i in range(5):
    wp = Process(target=worker_process, name='worker%d' % i,
                  args=(config_worker,))
    workers.append(wp)
    wp.start()
    logger.info('Started worker: %s', wp.name)
logger.info('About to create listener ...')
stop_event = Event()
lp = Process(target=listener_process, name='listener',
             args=(q, stop_event, config_listener))
lp.start()
logger.info('Started listener')

# We now hang around for the workers to finish their tasks
for wp in workers:
    wp.join()
# Workers all done, listening can now stop.
# Logging in the parent still works normally.
logger.info('Telling listener to stop ...')
stop_event.set()
lp.join()
logger.info('All done.')

if __name__ == '__main__':
    main()
Inserting a BOM into messages sent to a SysLogHandler

RFC 5424 requires that a Unicode message be sent to a syslog daemon as a set of bytes which have the following structure: an optional pure-ASCII component, followed by a UTF-8 Byte Order Mark (BOM), followed by Unicode encoded using UTF-8. (See the relevant section of the specification.)

In Python 3.1, code was added to SysLogHandler to insert a BOM into the message, but unfortunately, it was implemented incorrectly, with the BOM appearing at the beginning of the message and hence not allowing any pure-ASCII component to appear before it.

As this behaviour is broken, the incorrect BOM insertion code is being removed from Python 3.2.4 and later. However, it is not being replaced, and if you want to produce RFC 5424-compliant messages which include a BOM, an optional pure-ASCII sequence before it and arbitrary Unicode after it, encoded using UTF-8, then you need to do the following:

1. Attach a Formatter instance to your SysLogHandler instance, with a format string such as:

   'ASCII section\ufeffUnicode section'

   The Unicode code point U+FEFF, when encoded using UTF-8, will be encoded as a UTF-8 BOM – the byte-string b'\xef\xbb\xbf'.

2. Replace the ASCII section with whatever placeholders you like, but make sure that the data that appears in there after substitution
is always ASCII (that way, it will remain unchanged after UTF-8 encoding).

3. Replace the Unicode section with whatever placeholders you like; if the data which appears there after substitution contains characters outside the ASCII range, that’s fine – it will be encoded using UTF-8.

The formatted message will be encoded using UTF-8 encoding by SysLogHandler. If you follow the above rules, you should be able to produce RFC 5424-compliant messages. If you don’t, logging may not complain, but your messages will not be RFC 5424-compliant, and your syslog daemon may complain.
Implementing structured logging

Although most logging messages are intended for reading by humans, and thus not readily machine-parseable, there might be circumstances where you want to output messages in a structured format which is capable of being parsed by a program (without needing complex regular expressions to parse the log message). This is straightforward to achieve using the logging package. There are a number of ways in which this could be achieved, but the following is a simple approach which uses JSON to serialise the event in a machine-parseable manner:

```python
import json
import logging

class StructuredMessage(object):
    def __init__(self, message, **kwargs):
        self.message = message
        self.kwargs = kwargs

    def __str__(self):
        return '%s >>> %s' % (self.message, json.dumps(self.kwargs))

_ = StructuredMessage  # optional, to improve readability
logging.basicConfig(level=logging.INFO, format='%(message)s')
logging.info(_('message 1', foo='bar', bar='baz', num=123))
```

If the above script is run, it prints:

```
message 1 >>> {"fnum": 123.456, "num": 123, "bar": "baz", "foo": "bar"}
```
Note that the order of items might be different according to the version of Python used.

If you need more specialised processing, you can use a custom JSON encoder, as in the following complete example:

```python
from __future__ import unicode_literals

import json
import logging

# This next bit is to ensure the script runs unchanged
try:
    unicode
except NameError:
    unicode = str

class Encoder(json.JSONEncoder):
    def default(self, o):
        if isinstance(o, set):
            return tuple(o)
        elif isinstance(o, unicode):
            return o.encode('unicode_escape').decode
        return super(Encoder, self).default(o)

class StructuredMessage(object):
    def __init__(self, message, **kwargs):
        self.message = message
        self.kwvars = kwargs

    def __str__(self):
        s = Encoder().encode(self.kwvars)
        return '%s >>> %s' % (self.message, s)

_ = StructuredMessage  # optional, to improve readability
```
```python
def main():
    logging.basicConfig(level=logging.INFO, format='%(message)s')
    logging.info(_('message 1'), set_value=set([1, 2, 3]))

if __name__ == '__main__':
    main()
```

When the above script is run, it prints:

```
message 1 >>> {'snowman': '\u2603', 'set_value': [1, 2]}
```

Note that the order of items might be different according to the version of Python used.
Customizing handlers with `dictConfig()`

There are times when you want to customize logging handlers in particular ways, and if you use `dictConfig()` you may be able to do this without subclassing. As an example, consider that you may want to set the ownership of a log file. On POSIX, this is easily done using `shutil.chown()`, but the file handlers in the stdlib don't offer built-in support. You can customize handler creation using a plain function such as:

```python
def owned_file_handler(filename, mode='a', encoding=None, owner=None):
    if owner:
        if not os.path.exists(filename):
            open(filename, 'a').close()
        shutil.chown(filename, *owner)
    return logging.FileHandler(filename, mode, encoding)
```

You can then specify, in a logging configuration passed to `dictConfig()`, that a logging handler be created by calling this function:

```python
LOGGING = {
    'version': 1,
    'disable_existing_loggers': False,
    'formatters': {
        'default': {
            'format': '%(asctime)s  %(levelname)s  %(name)s  %(message)s'
        },
    },
    'handlers': {
        'file':{
```
In this example I am setting the ownership using the `pulse` user and group, just for the purposes of illustration. Putting it together into a working script, `chowntest.py`:

```python
import logging, logging.config, os, shutil

def owned_file_handler(filename, mode='a', encoding='utf-8', owner=None):
    if owner:
        if not os.path.exists(filename):
            open(filename, 'a').close()
            shutil.chown(filename, *owner)
        return logging.FileHandler(filename, mode, encoding)

LOGGING = {
    'version': 1,
    'disable_existing_loggers': False,
    'root': {
        'handlers': ['file'],
        'level': 'DEBUG',
    },
}
```
'formatters': {
    'default': {
        'format': '%(asctime)s %(levelname)s %(name)s %(message)s',
    },
},
'handlers': {
    'file': {
        # The values below are popped from this
data dictionary and used to create the handler, set the handler's level and
its formatter.
        '()': owned_file_handler,
        'level': 'DEBUG',
        'formatter': 'default',
        # The values below are passed to the handler creator callable
        # as keyword arguments.
        'owner': ['pulse', 'pulse'],
        'filename': 'chowntest.log',
        'mode': 'w',
        'encoding': 'utf-8',
    },
},
'root': {
    'handlers': ['file'],
    'level': 'DEBUG',
}
}

logging.config.dictConfig(LOGGING)
logger = logging.getLogger('mylogger')
logger.debug('A debug message')

To run this, you will probably need to run as root:

$ sudo python3.3 chowntest.py
$ cat chowntest.log
2013-11-05 09:34:51,128 DEBUG mylogger A debug message
Note that this example uses Python 3.3 because that's where `shutil.chown()` makes an appearance. This approach should work with any Python version that supports `dictConfig()` - namely, Python 2.7, 3.2 or later. With pre-3.3 versions, you would need to implement the actual ownership change using e.g. `os.chown()`.

In practice, the handler-creating function may be in a utility module somewhere in your project. Instead of the line in the configuration:

```
't()': owned_file_handler,
```

you could use e.g.:

```
't()': 'ext://project.util.owned_file_handler',
```

where `project.util` can be replaced with the actual name of the package where the function resides. In the above working script, using `'ext://__main__.owned_file_handler'` should work. Here, the actual callable is resolved by `dictConfig()` from the `ext://` specification.

This example hopefully also points the way to how you could implement other types of file change - e.g. setting specific POSIX permission bits - in the same way, using `os.chmod()`.

Of course, the approach could also be extended to types of handler other than a `FileHandler` - for example, one of the rotating file handlers, or a different type of handler altogether.
Using particular formatting styles throughout your application

In Python 3.2, the **Formatter** gained a **style** keyword parameter which, while defaulting to `%` for backward compatibility, allowed the specification of `{` or `$` to support the formatting approaches supported by `str.format()` and `string.Template`. Note that this governs the formatting of logging messages for final output to logs, and is completely orthogonal to how an individual logging message is constructed.

Logging calls (`debug()`, `info()` etc.) only take positional parameters for the actual logging message itself, with keyword parameters used only for determining options for how to handle the logging call (e.g. the `exc_info` keyword parameter to indicate that traceback information should be logged, or the `extra` keyword parameter to indicate additional contextual information to be added to the log). So you cannot directly make logging calls using `str.format()` or `string.Template` syntax, because internally the logging package uses %-formatting to merge the format string and the variable arguments. There would no changing this while preserving backward compatibility, since all logging calls which are out there in existing code will be using %-format strings.

There have been suggestions to associate format styles with specific loggers, but that approach also runs into backward compatibility problems because any existing code could be using a given logger name and using %-formatting.

For logging to work interoperably between any third-party libraries and your code, decisions about formatting need to be made at the level of
the individual logging call. This opens up a couple of ways in which alternative formatting styles can be accommodated.

Using LogRecord factories

In Python 3.2, along with the Formatter changes mentioned above, the logging package gained the ability to allow users to set their own LogRecord subclasses, using the setLogRecordFactory() function. You can use this to set your own subclass of LogRecord, which does the Right Thing by overriding the getMessage() method. The base class implementation of this method is where the msg % args formatting happens, and where you can substitute your alternate formatting; however, you should be careful to support all formatting styles and allow %-formatting as the default, to ensure interoperability with other code. Care should also be taken to call str(self.msg), just as the base implementation does.

Refer to the reference documentation on setLogRecordFactory() and LogRecord for more information.

Using custom message objects

There is another, perhaps simpler way that you can use {}- and $-formatting to construct your individual log messages. You may recall (from Using arbitrary objects as messages) that when logging you can use an arbitrary object as a message format string, and that the logging package will call str() on that object to get the actual format string. Consider the following two classes:

```python
class BraceMessage(object):
    def __init__(self, fmt, *args, **kwargs):
```

self.fmt = fmt
self.args = args
self.kwargs = kwargs

def __str__(self):
    return self.fmt.format(*self.args, **self.kwargs)

class DollarMessage(object):
    def __init__(self, fmt, **kwargs):
        self.fmt = fmt
        self.kwargs = kwargs

def __str__(self):
    from string import Template
    return Template(self.fmt).substitute(**self.kwargs)

Either of these can be used in place of a format string, to allow {}- or $-
formatting to be used to build the actual “message” part which appears
in the formatted log output in place of “%(message)s” or “{message}”
or “$message”. If you find it a little unwieldy to use the class names
whenever you want to log something, you can make it more palatable
if you use an alias such as M or _ for the message (or perhaps __, if
you are using _ for localization).

Examples of this approach are given below. Firstly, formatting with
str.format():

```python
>>> __ = BraceMessage
>>> print(__('Message with {0} {1}', 2, 'placeholders'))
Message with 2 placeholders
>>> class Point: pass
...
>>> p = Point()
>>> p.x = 0.5
>>> p.y = 0.5
```
Secondly, formatting with `string.Template`:

```python
>>> __ = DollarMessage
>>> print(__('Message with $num $what', num=2, what='Message with 2 placeholders'))
Message with 2 placeholders
```

One thing to note is that you pay no significant performance penalty with this approach: the actual formatting happens not when you make the logging call, but when (and if) the logged message is actually about to be output to a log by a handler. So the only slightly unusual thing which might trip you up is that the parentheses go around the format string and the arguments, not just the format string. That's because the `__` notation is just syntax sugar for a constructor call to one of the XXXMessage classes shown above.
Configuring filters with `dictConfig()`

You can configure filters using `dictConfig()`, though it might not be obvious at first glance how to do it (hence this recipe). Since `Filter` is the only filter class included in the standard library, and it is unlikely to cater to many requirements (it's only there as a base class), you will typically need to define your own `Filter` subclass with an overridden `filter()` method. To do this, specify the `()` key in the configuration dictionary for the filter, specifying a callable which will be used to create the filter (a class is the most obvious, but you can provide any callable which returns a `Filter` instance). Here is a complete example:

```python
import logging
import logging.config
import sys

class MyFilter(logging.Filter):
    def __init__(self, param=None):
        self.param = param

    def filter(self, record):
        if self.param is None:
            allow = True
        else:
            allow = self.param not in record.msg
        if allow:
            record.msg = 'changed: ' + record.msg
        return allow

LOGGING = {
    'version': 1,
    'filters': {
```
```
{'myfilter': {
    '()': MyFilter,
    'param': 'noshow',
},
'handlers': {
    'console': {
        'class': 'logging.StreamHandler',
        'filters': ['myfilter']
    }
},
'root': {
    'level': 'DEBUG',
    'handlers': ['console']
},
}

if __name__ == '__main__':
    logging.config.dictConfig(LOGGING)
    logging.debug('hello')
    logging.debug('hello - noshow')

This example shows how you can pass configuration data to the callable which constructs the instance, in the form of keyword parameters. When run, the above script will print:

changed: hello

which shows that the filter is working as configured.

A couple of extra points to note:

- If you can’t refer to the callable directly in the configuration (e.g. if it lives in a different module, and you can’t import it directly where the configuration dictionary is), you can use the form `ext://...` as described in *Access to external objects*. For example, you
could have used the text `ext://__main__.MyFilter` instead of `MyFilter` in the above example.

- As well as for filters, this technique can also be used to configure custom handlers and formatters. See *User-defined objects* for more information on how logging supports using user-defined objects in its configuration, and see the other cookbook recipe *Customizing handlers with dictConfig()* above.
Regular Expression HOWTO

Author: A.M. Kuchling <amk@amk.ca>

Abstract

This document is an introductory tutorial to using regular expressions in Python with the `re` module. It provides a gentler introduction than the corresponding section in the Library Reference.
Introduction

Regular expressions (called REs, or regexes, or regex patterns) are essentially a tiny, highly specialized programming language embedded inside Python and made available through the `re` module. Using this little language, you specify the rules for the set of possible strings that you want to match; this set might contain English sentences, or e-mail addresses, or TeX commands, or anything you like. You can then ask questions such as “Does this string match the pattern?”, or “Is there a match for the pattern anywhere in this string?”. You can also use REs to modify a string or to split it apart in various ways.

Regular expression patterns are compiled into a series of bytecodes which are then executed by a matching engine written in C. For advanced use, it may be necessary to pay careful attention to how the engine will execute a given RE, and write the RE in a certain way in order to produce bytecode that runs faster. Optimization isn’t covered in this document, because it requires that you have a good understanding of the matching engine's internals.

The regular expression language is relatively small and restricted, so not all possible string processing tasks can be done using regular expressions. There are also tasks that can be done with regular expressions, but the expressions turn out to be very complicated. In these cases, you may be better off writing Python code to do the processing; while Python code will be slower than an elaborate regular expression, it will also probably be more understandable.
Simple Patterns

We'll start by learning about the simplest possible regular expressions. Since regular expressions are used to operate on strings, we'll begin with the most common task: matching characters.

For a detailed explanation of the computer science underlying regular expressions (deterministic and non-deterministic finite automata), you can refer to almost any textbook on writing compilers.

Matching Characters

Most letters and characters will simply match themselves. For example, the regular expression `test` will match the string `test` exactly. (You can enable a case-insensitive mode that would let this RE match `Test` or `TEST` as well; more about this later.)

There are exceptions to this rule; some characters are special *metacharacters*, and don’t match themselves. Instead, they signal that some out-of-the-ordinary thing should be matched, or they affect other portions of the RE by repeating them or changing their meaning. Much of this document is devoted to discussing various metacharacters and what they do.

Here's a complete list of the metacharacters; their meanings will be discussed in the rest of this HOWTO.

```
. ^ $ * + ? { } [ ] \ | ( )
```

The first metacharacters we'll look at are `[` and `]`. They're used for specifying a character class, which is a set of characters that you wish to match. Characters can be listed individually, or a range of
characters can be indicated by giving two characters and separating them by a ' - '. For example, [abc] will match any of the characters a, b, or c; this is the same as [a-c], which uses a range to express the same set of characters. If you wanted to match only lowercase letters, your RE would be [a-z].

Metacharacters are not active inside classes. For example, [akm$] will match any of the characters 'a', 'k', 'm', or '$'; '$' is usually a metacharacter, but inside a character class it's stripped of its special nature.

You can match the characters not listed within the class by complementing the set. This is indicated by including a '^' as the first character of the class; '^' outside a character class will simply match the '^' character. For example, [^5] will match any character except '5'.

Perhaps the most important metacharacter is the backslash, \\. As in Python string literals, the backslash can be followed by various characters to signal various special sequences. It's also used to escape all the metacharacters so you can still match them in patterns; for example, if you need to match a [ or \, you can precede them with a backslash to remove their special meaning: \\[ or \\.

Some of the special sequences beginning with '\\' represent predefined sets of characters that are often useful, such as the set of digits, the set of letters, or the set of anything that isn't whitespace.

Let's take an example: \w matches any alphanumeric character. If the regex pattern is expressed in bytes, this is equivalent to the class [a-zA-Z0-9_]. If the regex pattern is a string, \w will match all the characters marked as letters in the Unicode database provided by the
unicodedata module. You can use the more restricted definition of \w in a string pattern by supplying the re.ASCII flag when compiling the regular expression.

The following list of special sequences isn’t complete. For a complete list of sequences and expanded class definitions for Unicode string patterns, see the last part of Regular Expression Syntax in the Standard Library reference. In general, the Unicode versions match any character that’s in the appropriate category in the Unicode database.

\d
Matches any decimal digit; this is equivalent to the class [0-9].

\D
Matches any non-digit character; this is equivalent to the class [^0-9].

\s
Matches any whitespace character; this is equivalent to the class [\t\n\r\f\v].

\S
Matches any non-whitespace character; this is equivalent to the class [^\t\n\r\f\v].

\w
Matches any alphanumeric character; this is equivalent to the class [a-zA-Z0-9_].

\W
Matches any non-alphanumeric character; this is equivalent to the class [^a-zA-Z0-9_].

These sequences can be included inside a character class. For example, [\s,\.] is a character class that will match any whitespace
character, or ' , ' or ' . '.

The final metacharacter in this section is '. It matches anything except a newline character, and there’s an alternate mode (re.DOTALL) where it will match even a newline. '. ' is often used where you want to match “any character”.

Repeating Things

Being able to match varying sets of characters is the first thing regular expressions can do that isn’t already possible with the methods available on strings. However, if that was the only additional capability of regexes, they wouldn’t be much of an advance. Another capability is that you can specify that portions of the RE must be repeated a certain number of times.

The first metacharacter for repeating things that we’ll look at is *. * doesn’t match the literal character *; instead, it specifies that the previous character can be matched zero or more times, instead of exactly once.

For example, ca*t will match ct (0 a characters), cat (1 a), caaat (3 a characters), and so forth. The RE engine has various internal limitations stemming from the size of C’s int type that will prevent it from matching over 2 billion a characters; patterns are usually not written to match that much data.

Repetitions such as * are greedy; when repeating a RE, the matching engine will try to repeat it as many times as possible. If later portions of the pattern don’t match, the matching engine will then back up and try again with few repetitions.
A step-by-step example will make this more obvious. Let’s consider the expression $a[\text{bcd}]^*b$. This matches the letter 'a', zero or more letters from the class $[\text{bcd}]$, and finally ends with a 'b'. Now imagine matching this RE against the string $abcbd$.

<table>
<thead>
<tr>
<th>Step</th>
<th>Matched</th>
<th>Explanation</th>
</tr>
</thead>
<tbody>
<tr>
<td>1</td>
<td>a</td>
<td>The a in the RE matches.</td>
</tr>
<tr>
<td>2</td>
<td>abcbd</td>
<td>The engine matches $[\text{bcd}]^*$, going as far as it can, which is to the end of the string.</td>
</tr>
<tr>
<td>3</td>
<td>Failure</td>
<td>The engine tries to match b, but the current position is at the end of the string, so it fails.</td>
</tr>
<tr>
<td>4</td>
<td>abcb</td>
<td>Back up, so that $[\text{bcd}]^*$ matches one less character.</td>
</tr>
<tr>
<td>5</td>
<td>Failure</td>
<td>Try b again, but the current position is at the last character, which is a 'd'.</td>
</tr>
<tr>
<td>6</td>
<td>abc</td>
<td>Back up again, so that $[\text{bcd}]^*$ is only matching bc.</td>
</tr>
<tr>
<td>6</td>
<td>abcb</td>
<td>Try b again. This time the character at the current position is 'b', so it succeeds.</td>
</tr>
</tbody>
</table>

The end of the RE has now been reached, and it has matched $abcb$. This demonstrates how the matching engine goes as far as it can at first, and if no match is found it will then progressively back up and retry the rest of the RE again and again. It will back up until it has tried zero matches for $[\text{bcd}]^*$, and if that subsequently fails, the engine will conclude that the string doesn’t match the RE at all.

Another repeating metacharacter is +, which matches one or more times. Pay careful attention to the difference between * and +; * matches zero or more times, so whatever’s being repeated may not be
present at all, while + requires at least one occurrence. To use a similar example, ca+t will match cat (1 a), caaat (3 a's), but won’t match ct.

There are two more repeating qualifiers. The question mark character, ?, matches either once or zero times; you can think of it as marking something as being optional. For example, home-?brew matches either homebrew or home-brew.

The most complicated repeated qualifier is \{m, n\}, where m and n are decimal integers. This qualifier means there must be at least m repetitions, and at most n. For example, a/\{1,3\}b will match a/b, a///b, and a/////b. It won’t match ab, which has no slashes, or a///////b, which has four.

You can omit either m or n; in that case, a reasonable value is assumed for the missing value. Omitting m is interpreted as a lower limit of 0, while omitting n results in an upper bound of infinity — actually, the upper bound is the 2-billion limit mentioned earlier, but that might as well be infinity.

Readers of a reductionist bent may notice that the three other qualifiers can all be expressed using this notation. \{0,\} is the same as *, \{1,\} is equivalent to +, and \{0, 1\} is the same as ?. It’s better to use *, +, or ? when you can, simply because they’re shorter and easier to read.
Using Regular Expressions

Now that we’ve looked at some simple regular expressions, how do we actually use them in Python? The re module provides an interface to the regular expression engine, allowing you to compile REs into objects and then perform matches with them.

Compiling Regular Expressions

Regular expressions are compiled into pattern objects, which have methods for various operations such as searching for pattern matches or performing string substitutions.

```python
>>> import re
>>> p = re.compile('ab*')
>>> p
re.compile('ab*')
```

`re.compile()` also accepts an optional flags argument, used to enable various special features and syntax variations. We’ll go over the available settings later, but for now a single example will do:

```python
>>> p = re.compile('ab*', re.IGNORECASE)
```

The RE is passed to `re.compile()` as a string. REs are handled as strings because regular expressions aren't part of the core Python language, and no special syntax was created for expressing them. (There are applications that don’t need REs at all, so there’s no need to bloat the language specification by including them.) Instead, the re module is simply a C extension module included with Python, just like the socket or zlib modules.
Putting REs in strings keeps the Python language simpler, but has one disadvantage which is the topic of the next section.

**The Backslash Plague**

As stated earlier, regular expressions use the backslash character (\') to indicate special forms or to allow special characters to be used without invoking their special meaning. This conflicts with Python’s usage of the same character for the same purpose in string literals.

Let’s say you want to write a RE that matches the string \section, which might be found in a LaTeX file. To figure out what to write in the program code, start with the desired string to be matched. Next, you must escape any backslashes and other metacharacters by preceding them with a backslash, resulting in the string \\section. The resulting string that must be passed to `re.compile()` must be \section. However, to express this as a Python string literal, both backslashes must be escaped again.

<table>
<thead>
<tr>
<th>Characters</th>
<th>Stage</th>
</tr>
</thead>
<tbody>
<tr>
<td>\section</td>
<td>Text string to be matched</td>
</tr>
<tr>
<td>\section</td>
<td>Escaped backslash for <code>re.compile()</code></td>
</tr>
<tr>
<td>&quot;\\section&quot;</td>
<td>Escaped backslashes for a string literal</td>
</tr>
</tbody>
</table>

In short, to match a literal backslash, one has to write `'\\'` as the RE string, because the regular expression must be `\\`, and each backslash must be expressed as `\\` inside a regular Python string literal. In REs that feature backslashes repeatedly, this leads to lots of repeated backslashes and makes the resulting strings difficult to understand.
The solution is to use Python's raw string notation for regular expressions; backslashes are not handled in any special way in a string literal prefixed with \texttt{r'}, so \texttt{r"\n"} is a two-character string containing \texttt{\'} and \texttt{'n'}, while \texttt{"\n"} is a one-character string containing a newline. Regular expressions will often be written in Python code using this raw string notation.

<table>
<thead>
<tr>
<th>Regular String</th>
<th>Raw string</th>
</tr>
</thead>
<tbody>
<tr>
<td>&quot;ab*&quot;</td>
<td>r&quot;ab*&quot;</td>
</tr>
<tr>
<td>&quot;\section&quot;</td>
<td>r&quot;\section&quot;</td>
</tr>
<tr>
<td>&quot;\w+\s+\1&quot;</td>
<td>r&quot;\w+\s+\1&quot;</td>
</tr>
</tbody>
</table>

Performing Matches

Once you have an object representing a compiled regular expression, what do you do with it? Pattern objects have several methods and attributes. Only the most significant ones will be covered here; consult the \texttt{re} docs for a complete listing.

<table>
<thead>
<tr>
<th>Method/Attribute</th>
<th>Purpose</th>
</tr>
</thead>
<tbody>
<tr>
<td>\texttt{match()}</td>
<td>Determine if the RE matches at the beginning of the string.</td>
</tr>
<tr>
<td>\texttt{search()}</td>
<td>Scan through a string, looking for any location where this RE matches.</td>
</tr>
<tr>
<td>\texttt{findall()}</td>
<td>Find all substrings where the RE matches, and returns them as a list.</td>
</tr>
<tr>
<td>\texttt{finditer()}</td>
<td>Find all substrings where the RE matches, and returns them as an \texttt{iterator}.</td>
</tr>
</tbody>
</table>

\texttt{match()} and \texttt{search()} return \texttt{None} if no match can be found. If
they're successful, a *match object* instance is returned, containing information about the match: where it starts and ends, the substring it matched, and more.

You can learn about this by interactively experimenting with the `re` module. If you have `tkinter` available, you may also want to look at `Tools/demo/redemo.py`, a demonstration program included with the Python distribution. It allows you to enter REs and strings, and displays whether the RE matches or fails. `redemo.py` can be quite useful when trying to debug a complicated RE. Phil Schwartz's `Kodos` is also an interactive tool for developing and testing RE patterns.

This HOWTO uses the standard Python interpreter for its examples. First, run the Python interpreter, import the `re` module, and compile a RE:

```python
>>> import re
>>> p = re.compile('[a-z]+')
>>> p
re.compile('[a-z]+')
```

Now, you can try matching various strings against the RE `[a-z]+`. An empty string shouldn't match at all, since `+` means ‘one or more repetitions’. `match()` should return `None` in this case, which will cause the interpreter to print no output. You can explicitly print the result of `match()` to make this clear.

```python
>>> p.match('')
>>> print(p.match(''))
None
```

Now, let's try it on a string that it should match, such as `tempo`. In this case, `match()` will return a *match object*, so you should store the
result in a variable for later use.

```python
>>> m = p.match('tempo')
<_sre.SRE_Match object; span=(0, 5), match='tempo'>
```

Now you can query the `match object` for information about the matching string. `match object` instances also have several methods and attributes; the most important ones are:

<table>
<thead>
<tr>
<th>Method/Attribute</th>
<th>Purpose</th>
</tr>
</thead>
<tbody>
<tr>
<td><code>group()</code></td>
<td>Return the string matched by the RE</td>
</tr>
<tr>
<td><code>start()</code></td>
<td>Return the starting position of the match</td>
</tr>
<tr>
<td><code>end()</code></td>
<td>Return the ending position of the match</td>
</tr>
<tr>
<td><code>span()</code></td>
<td>Return a tuple containing the (start, end) positions of the match</td>
</tr>
</tbody>
</table>

Trying these methods will soon clarify their meaning:

```python
>>> m.group()
'tempo'
>>> m.start(), m.end()
(0, 5)
>>> m.span()
(0, 5)
```

group() returns the substring that was matched by the RE. start() and end() return the starting and ending index of the match. span() returns both start and end indexes in a single tuple. Since the match() method only checks if the RE matches at the start of a string, start() will always be zero. However, the search() method of patterns scans through the string, so the match may not
start at zero in that case.

```python
>>> print(p.match(': message'))
None
>>> m = p.search(': message'); print(m)
<_sre.SRE_Match object; span=(4, 11), match='message'>
>>> m.group()
'message'
>>> m.span()
(4, 11)
```

In actual programs, the most common style is to store the `match object` in a variable, and then check if it was `None`. This usually looks like:

```python
p = re.compile(...)
m = p.match('string goes here')
if m:
    print('Match found: ', m.group())
else:
    print('No match')
```

Two pattern methods return all of the matches for a pattern. `findall()` returns a list of matching strings:

```python
>>> p = re.compile('\d+')
>>> p.findall('12 drummers drumming, 11 pipers piping, 10 lords a-leaping')
['12', '11', '10']
```

`findall()` has to create the entire list before it can be returned as the result. The `finditer()` method returns a sequence of `match object` instances as an iterator:
Module-Level Functions

You don’t have to create a pattern object and call its methods; the `re` module also provides top-level functions called `match()`, `search()`, `findall()`, `sub()`, and so forth. These functions take the same arguments as the corresponding pattern method with the RE string added as the first argument, and still return either `None` or a `match object` instance.

Under the hood, these functions simply create a pattern object for you and call the appropriate method on it. They also store the compiled object in a cache, so future calls using the same RE won’t need to parse the pattern again and again.

Should you use these module-level functions, or should you get the pattern and call its methods yourself? If you’re accessing a regex within a loop, pre-compiling it will save a few function calls. Outside of
loops, there's not much difference thanks to the internal cache.

**Compilation Flags**

Compilation flags let you modify some aspects of how regular expressions work. Flags are available in the `re` module under two names, a long name such as `IGNORECASE` and a short, one-letter form such as `I`. (If you're familiar with Perl's pattern modifiers, the one-letter forms use the same letters; the short form of `re.VERBOSE` is `re.X`, for example.) Multiple flags can be specified by bitwise OR-ing them; `re.I | re.M` sets both the `I` and `M` flags, for example.

Here's a table of the available flags, followed by a more detailed explanation of each one.

<table>
<thead>
<tr>
<th>Flag</th>
<th>Meaning</th>
</tr>
</thead>
<tbody>
<tr>
<td>ASCII, A</td>
<td>Makes several escapes like <code>\w</code>, <code>\b</code>, <code>\s</code> and <code>\d</code> match only on ASCII characters with the respective property.</td>
</tr>
<tr>
<td>DOTALL, S</td>
<td>Make <code>.</code> match any character, including newlines</td>
</tr>
<tr>
<td>IGNORECASE, I</td>
<td>Do case-insensitive matches</td>
</tr>
<tr>
<td>LOCALE, L</td>
<td>Do a locale-aware match</td>
</tr>
<tr>
<td>MULTILINE, M</td>
<td>Multi-line matching, affecting <code>^</code> and <code>$</code></td>
</tr>
<tr>
<td>VERBOSE, X (for <code>extended</code>)</td>
<td>Enable verbose REs, which can be organized more cleanly and understandably.</td>
</tr>
</tbody>
</table>

**I**

**IGNORECASE**
Perform case-insensitive matching; character class and literal strings will match letters by ignoring case. For example, `[A-Z]` will match lowercase letters, too, and `Spam` will match `Spam`, `spam`, or `spAM`. This lowercasing doesn't take the current locale into account; it will if you also set the `LOCALE` flag.

**L**

**LOCALE**

Make `\w`, `\W`, `\b`, and `\B`, dependent on the current locale instead of the Unicode database.

Locales are a feature of the C library intended to help in writing programs that take account of language differences. For example, if you’re processing French text, you’d want to be able to write `\w+` to match words, but `\w` only matches the character class `[A-Za-z]`; it won’t match ‘é’ or ‘ç’. If your system is configured properly and a French locale is selected, certain C functions will tell the program that ‘é’ should also be considered a letter. Setting the `LOCALE` flag when compiling a regular expression will cause the resulting compiled object to use these C functions for `\w`; this is slower, but also enables `\w+` to match French words as you’d expect.

**M**

**MULTILINE**

(^
and $ haven’t been explained yet; they’ll be introduced in section *More Metacharacters*.)

Usually `^` matches only at the beginning of the string, and `$` matches only at the end of the string and immediately before the newline (if any) at the end of the string. When this flag is specified, `^` matches at the beginning of the string and at the beginning of
each line within the string, immediately following each newline. Similarly, the $ metacharacter matches either at the end of the string and at the end of each line (immediately preceding each newline).

**S DOTALL**

Makes the '.' special character match any character at all, including a newline; without this flag, '.' will match anything except a newline.

**A ASCII**

Make \w, \W, \b, \B, \s and \S perform ASCII-only matching instead of full Unicode matching. This is only meaningful for Unicode patterns, and is ignored for byte patterns.

**X VERBOSE**

This flag allows you to write regular expressions that are more readable by granting you more flexibility in how you can format them. When this flag has been specified, whitespace within the RE string is ignored, except when the whitespace is in a character class or preceded by an unescaped backslash; this lets you organize and indent the RE more clearly. This flag also lets you put comments within a RE that will be ignored by the engine; comments are marked by a '#' that's neither in a character class or preceded by an unescaped backslash.

For example, here's a RE that uses re.VERBOSE; see how much easier it is to read?
Without the verbose setting, the RE would look like this:

```python
charref = re.compile(r"""
\&#[#] # Start of a numeric entity
 ( 
    0[0-7]+ # Octal form
    | [0-9]+ # Decimal form
    | x[0-9a-fA-F]+ # Hexadecimal form
 )
 ; # Trailing semicolon
"""", re.VERBOSE)
```

In the above example, Python's automatic concatenation of string literals has been used to break up the RE into smaller pieces, but it's still more difficult to understand than the version using `re.VERBOSE`.
More Pattern Power

So far we've only covered a part of the features of regular expressions. In this section, we'll cover some new metacharacters, and how to use groups to retrieve portions of the text that was matched.

More Metacharacters

There are some metacharacters that we haven't covered yet. Most of them will be covered in this section.

Some of the remaining metacharacters to be discussed are zero-width assertions. They don’t cause the engine to advance through the string; instead, they consume no characters at all, and simply succeed or fail. For example, \b is an assertion that the current position is located at a word boundary; the position isn’t changed by the \b at all. This means that zero-width assertions should never be repeated, because if they match once at a given location, they can obviously be matched an infinite number of times.

|  

Alternation, or the “or” operator. If A and B are regular expressions, A|B will match any string that matches either A or B. | has very low precedence in order to make it work reasonably when you're alternating multi-character strings. Crow|Servo will match either Crow or Servo, not Cro, a 'w' or an 'S', and ervo.

To match a literal '|', use \\|, or enclose it inside a character class, as in [\|].

^
Matches at the beginning of lines. Unless the MULTILINE flag has been set, this will only match at the beginning of the string. In MULTILINE mode, this also matches immediately after each newline within the string.

For example, if you wish to match the word From only at the beginning of a line, the RE to use is ^From.

```python
>>> print(re.search('^From', 'From Here to Eternity'))
<_sre.SRE_Match object; span=(0, 4), match='From'>
>>> print(re.search('^From', 'Reciting From Memory'))
None
```

Matches at the end of a line, which is defined as either the end of the string, or any location followed by a newline character.

```python
>>> print(re.search('}$', '{block}'))
<_sre.SRE_Match object; span=(6, 7), match='}'>
>>> print(re.search('}$', '{block} '))
None
>>> print(re.search('}$', '{block}\n'))
<_sre.SRE_Match object; span=(6, 7), match='}'>
```

To match a literal '$', use \$ or enclose it inside a character class, as in [$].

\A

Matches only at the start of the string. When not in MULTILINE mode, \A and ^ are effectively the same. In MULTILINE mode, they’re different: \A still matches only at the beginning of the string, but ^ may match at any location inside the string that follows a newline character.
\Z

Matches only at the end of the string.

\b

Word boundary. This is a zero-width assertion that matches only at
the beginning or end of a word. A word is defined as a sequence of
alphanumeric characters, so the end of a word is indicated by
whitespace or a non-alphanumeric character.

The following example matches `class` only when it's a complete
word; it won’t match when it's contained inside another word.

```python
>>> p = re.compile(r'\bclass\b')
>>> print(p.search('no class at all'))
<_sre.SRE_Match object; span=(3, 8), match='class'>
>>> print(p.search('the declassified algorithm'))
None
>>> print(p.search('one subclass is'))
None
```

There are two subtleties you should remember when using this
special sequence. First, this is the worst collision between Python’s
string literals and regular expression sequences. In Python’s string
literals, `\b` is the backspace character, ASCII value 8. If you’re not
using raw strings, then Python will convert the `\b` to a backspace,
and your RE won’t match as you expect it to. The following
example looks the same as our previous RE, but omits the `'r'` in
front of the RE string.

```python
>>> p = re.compile('\bclass\b')
>>> print(p.search('no class at all'))
None
>>> print(p.search('\b' + 'class' + '\b'))
<_sre.SRE_Match object; span=(0, 7), match='\x08c'
```
Second, inside a character class, where there's no use for this assertion, \b represents the backspace character, for compatibility with Python's string literals.

\B

Another zero-width assertion, this is the opposite of \b, only matching when the current position is not at a word boundary.

Grouping

Frequently you need to obtain more information than just whether the RE matched or not. Regular expressions are often used to dissect strings by writing a RE divided into several subgroups which match different components of interest. For example, an RFC-822 header line is divided into a header name and a value, separated by a ':', like this:

```
From: author@example.com
User-Agent: Thunderbird 1.5.0.9 (X11/20061227)
MIME-Version: 1.0
To: editor@example.com
```

This can be handled by writing a regular expression which matches an entire header line, and has one group which matches the header name, and another group which matches the header's value.

Groups are marked by the '(', ')' metacharacters. '(', and ')' have much the same meaning as they do in mathematical expressions; they group together the expressions contained inside them, and you can repeat the contents of a group with a repeating qualifier, such as *, +, ?, or {m,n}. For example, (ab)* will match zero or more repetitions of ab.
```python
>>> p = re.compile('(ab)*')
>>> print(p.match('ababababab').span())
(0, 10)
```

Groups indicated with `((, ))` also capture the starting and ending index of the text that they match; this can be retrieved by passing an argument to `group()`, `start()`, `end()`, and `span()`.

Groups are numbered starting with 0. Group 0 is always present; it’s the whole RE, so `match object` methods all have group 0 as their default argument. Later we’ll see how to express groups that don’t capture the span of text that they match.

```python
>>> p = re.compile('(a)b')
>>> m = p.match('ab')
>>> m.group()
'ab'
>>> m.group(0)
'ab'
```

Subgroups are numbered from left to right, from 1 upward. Groups can be nested; to determine the number, just count the opening parenthesis characters, going from left to right.

```python
>>> p = re.compile('(a(b)c)d')
>>> m = p.match('abcd')
>>> m.group(0)
'abcd'
>>> m.group(1)
'abc'
>>> m.group(2)
'b'
```

`group()` can be passed multiple group numbers at a time, in which case it will return a tuple containing the corresponding values for those
The `groups()` method returns a tuple containing the strings for all the subgroups, from 1 up to however many there are.

```
>>> m.groups()
('abc', 'b')
```

Backreferences in a pattern allow you to specify that the contents of an earlier capturing group must also be found at the current location in the string. For example, `\1` will succeed if the exact contents of group 1 can be found at the current position, and fails otherwise. Remember that Python’s string literals also use a backslash followed by numbers to allow including arbitrary characters in a string, so be sure to use a raw string when incorporating backreferences in a RE.

For example, the following RE detects doubled words in a string.

```
>>> p = re.compile(r'\b\w+\s+\1')
>>> p.search('Paris in the the the spring').group()
'the the'
```

Backreferences like this aren’t often useful for just searching through a string — there are few text formats which repeat data in this way — but you’ll soon find out that they’re very useful when performing string substitutions.

**Non-capturing and Named Groups**

Elaborate REs may use many groups, both to capture substrings of
interest, and to group and structure the RE itself. In complex REs, it becomes difficult to keep track of the group numbers. There are two features which help with this problem. Both of them use a common syntax for regular expression extensions, so we’ll look at that first.

Perl 5 is well-known for its powerful additions to standard regular expressions. For these new features the Perl developers couldn't choose new single-keystroke metacharacters or new special sequences beginning with \ without making Perl's regular expressions confusingly different from standard REs. If they chose & as a new metacharacter, for example, old expressions would be assuming that & was a regular character and wouldn’t have escaped it by writing \& or [\&].

The solution chosen by the Perl developers was to use (?...) as the extension syntax. ? immediately after a parenthesis was a syntax error because the ? would have nothing to repeat, so this didn't introduce any compatibility problems. The characters immediately after the ? indicate what extension is being used, so (?=foo) is one thing (a positive lookahead assertion) and (?:foo) is something else (a non-capturing group containing the subexpression foo).

Python supports several of Perl's extensions and adds an extension syntax to Perl's extension syntax. If the first character after the question mark is a P, you know that it's an extension that's specific to Python.

Now that we’ve looked at the general extension syntax, we can return to the features that simplify working with groups in complex REs.

Sometimes you'll want to use a group to denote a part of a regular expression, but aren’t interested in retrieving the group’s contents. You
can make this fact explicit by using a non-capturing group: (?:...), where you can replace the ... with any other regular expression.

```python
>>> m = re.match("([abc])+", "abc")
>>> m.groups()
('c',)
>>> m = re.match("(?:[abc])+", "abc")
>>> m.groups()
()
```

Except for the fact that you can't retrieve the contents of what the group matched, a non-capturing group behaves exactly the same as a capturing group; you can put anything inside it, repeat it with a repetition metacharacter such as *, and nest it within other groups (capturing or non-capturing). (?:...) is particularly useful when modifying an existing pattern, since you can add new groups without changing how all the other groups are numbered. It should be mentioned that there's no performance difference in searching between capturing and non-capturing groups; neither form is any faster than the other.

A more significant feature is named groups: instead of referring to them by numbers, groups can be referenced by a name.

The syntax for a named group is one of the Python-specific extensions: (?P<name>...). name is, obviously, the name of the group. Named groups behave exactly like capturing groups, and additionally associate a name with a group. The **match object** methods that deal with capturing groups all accept either integers that refer to the group by number or strings that contain the desired group's name. Named groups are still given numbers, so you can retrieve information about a group in two ways:
Named groups are handy because they let you use easily-remembered names, instead of having to remember numbers. Here’s an example RE from the imaplib module:

```
InternalDate = re.compile(r'INTERNALDATE "
  r'(?P<day>\[123][0-9])-(?P<mon>[A-Z][a-z][a-z]a-
  r'(?P<year>[0-9][0-9][0-9][0-9])
    r' (?P<hour>[0-9][0-9]):(?P<min>[0-9][0-9]):(?P<sec>[0-9][0-9])
  r' (?P<zonen>[+])(?P<zoneh>[0-9][0-9])(?P<zonem>[0-9][0-9])
"')
```

It’s obviously much easier to retrieve `m.group('zonem')`, instead of having to remember to retrieve group 9.

The syntax for backreferences in an expression such as `(\...)`\1 refers to the number of the group. There’s naturally a variant that uses the group name instead of the number. This is another Python extension: `(\?P=name)` indicates that the contents of the group called `name` should again be matched at the current point. The regular expression for finding doubled words, `(\b\w+)s+\1` can also be written as `(\?P<word>\b\w+)s+(\?P=word)`:  

```
>>> p = re.compile(r'(\?P<word>\b\w+)s+(\?P=word)')
>>> p.search('Paris in the the spring').group()
'the the'
```
Lookahead Assertions

Another zero-width assertion is the lookahead assertion. Lookahead assertions are available in both positive and negative form, and look like this:

(?!...)

Negative lookahead assertion. This is the opposite of the positive assertion; it succeeds if the contained expression doesn’t match at the current position in the string.

To make this concrete, let’s look at a case where a lookahead is useful. Consider a simple pattern to match a filename and split it apart into a base name and an extension, separated by a `. `. For example, in `news.rc`, `news` is the base name, and `rc` is the filename’s extension.

The pattern to match this is quite simple:

`.*[.].*$`

Notice that the `.` needs to be treated specially because it’s a metacharacter, so it’s inside a character class to only match that specific character. Also notice the trailing `$`; this is added to ensure that all the rest of the string must be included in the extension. This regular expression matches `foo.bar` and `autoexec.bat` and `sendmail.cf` and `printers.conf`. 
Now, consider complicating the problem a bit; what if you want to match filenames where the extension is not bat? Some incorrect attempts:

```
.*[.][^b].*$
```

The first attempt above tries to exclude bat by requiring that the first character of the extension is not a b. This is wrong, because the pattern also doesn’t match foo.bar.

```
.*[.]([^b].?.|[^a].?.|..[^t])$
```

The expression gets messier when you try to patch up the first solution by requiring one of the following cases to match: the first character of the extension isn’t b; the second character isn’t a; or the third character isn’t t. This accepts foo.bar and rejects autoexec.bat, but it requires a three-letter extension and won’t accept a filename with a two-letter extension such as sendmail.cf. We’ll complicate the pattern again in an effort to fix it.

```
.*[.]([^b].?.|[^a].?.|..[^t])$
```

In the third attempt, the second and third letters are all made optional in order to allow matching extensions shorter than three characters, such as sendmail.cf.

The pattern’s getting really complicated now, which makes it hard to read and understand. Worse, if the problem changes and you want to exclude both bat and exe as extensions, the pattern would get even more complicated and confusing.

A negative lookahead cuts through all this confusion:

```
.*[.](?!bat$).*$
```

The negative lookahead means: if the
expression bat doesn’t match at this point, try the rest of the pattern; if bat$ does match, the whole pattern will fail. The trailing $ is required to ensure that something like sample.batch, where the extension only starts with bat, will be allowed.

Excluding another filename extension is now easy; simply add it as an alternative inside the assertion. The following pattern excludes filenames that end in either bat or exe:

`.\.*\.(?!bat$|exe$).*$`
Modifying Strings

Up to this point, we’ve simply performed searches against a static string. Regular expressions are also commonly used to modify strings in various ways, using the following pattern methods:

<table>
<thead>
<tr>
<th>Method/Attribute</th>
<th>Purpose</th>
</tr>
</thead>
<tbody>
<tr>
<td><code>split()</code></td>
<td>Split the string into a list, splitting it wherever the RE matches</td>
</tr>
<tr>
<td><code>sub()</code></td>
<td>Find all substrings where the RE matches, and replace them with a different string</td>
</tr>
<tr>
<td><code>subn()</code></td>
<td>Does the same thing as <code>sub()</code>, but returns the new string and the number of replacements</td>
</tr>
</tbody>
</table>

### Splitting Strings

The `split()` method of a pattern splits a string apart wherever the RE matches, returning a list of the pieces. It’s similar to the `split()` method of strings but provides much more generality in the delimiters that you can split by; string `split()` only supports splitting by whitespace or by a fixed string. As you’d expect, there’s a module-level `re.split()` function, too.

```
.split(string[, maxsplit=0])
```

Split `string` by the matches of the regular expression. If capturing parentheses are used in the RE, then their contents will also be returned as part of the resulting list. If `maxsplit` is nonzero, at most `maxsplit` splits are performed.

You can limit the number of splits made, by passing a value for `maxsplit`. When `maxsplit` is nonzero, at most `maxsplit` splits will be
made, and the remainder of the string is returned as the final element of the list. In the following example, the delimiter is any sequence of non-alphanumeric characters.

```python
>>> p = re.compile(r'\W+')
>>> p.split('This is a test, short and sweet, of split()')
['This', 'is', 'a', 'test', 'short', 'and', 'sweet', 'of split()']
```

Sometimes you’re not only interested in what the text between delimiters is, but also need to know what the delimiter was. If capturing parentheses are used in the RE, then their values are also returned as part of the list. Compare the following calls:

```python
>>> p = re.compile(r'\W+')
>>> p2 = re.compile(r'(?<delim>\W+)')
>>> p.split('This... is a test.')
['This', 'is', 'a', 'test', '']
>>> p2.split('This... is a test.')
['This', '...', 'is', '', 'a', '', 'test', '.', '']
```

The module-level function `re.split()` adds the RE to be used as the first argument, but is otherwise the same.

```python
>>> re.split('(?<delim>\W+)', 'Words, words, words.')
['Words', 'words', 'words', '']
>>> re.split('(?<delim>\W+),', 'Words, words, words.')
['Words', '', '', 'words', '', '', 'words', '', '', '.']
>>> re.split('(?<delim>\W+),', 'Words, words, words.', 1)
['Words', 'words, words.']
```

Search and Replace
Another common task is to find all the matches for a pattern, and replace them with a different string. The `sub()` method takes a replacement value, which can be either a string or a function, and the string to be processed.

```
sub(replacement, string[, count=0])
```

Returns the string obtained by replacing the leftmost non-overlapping occurrences of the RE in `string` by the replacement `replacement`. If the pattern isn’t found, `string` is returned unchanged.

The optional argument `count` is the maximum number of pattern occurrences to be replaced; `count` must be a non-negative integer. The default value of 0 means to replace all occurrences.

Here’s a simple example of using the `sub()` method. It replaces colour names with the word `colour`:

```python
>>> p = re.compile( '(blue|white|red)' )
>>> p.sub( 'colour', 'blue socks and red shoes' )
'colour socks and colour shoes'
```

The `subn()` method does the same work, but returns a 2-tuple containing the new string value and the number of replacements that were performed:

```python
>>> p = re.compile( '(blue|white|red)' )
>>> p.subn( 'colour', 'blue socks and red shoes' )
('colour socks and colour shoes', 2)
>>> p.subn( 'colour', 'no colours at all' )
```
Empty matches are replaced only when they're not adjacent to a previous match.

```python
>>> p = re.compile('x*')
>>> p.sub('-', 'abxd')
'-a-b-d-
```

If `replacement` is a string, any backslash escapes in it are processed. That is, `\n` is converted to a single newline character, `\r` is converted to a carriage return, and so forth. Unknown escapes such as `\j` are left alone. Backreferences, such as `\6`, are replaced with the substring matched by the corresponding group in the RE. This lets you incorporate portions of the original text in the resulting replacement string.

This example matches the word `section` followed by a string enclosed in `{`, `}`, and changes `section` to `subsection`:

```python
>>> p = re.compile('section{ ( [^}]*) }', re.VERBOSE)
>>> p.sub(r'subsection{\1}', 'section{First} section{subsection{First} subsection{second}')
```

There's also a syntax for referring to named groups as defined by the `(?P<name>...)` syntax. `\g<name>` will use the substring matched by the group named `name`, and `\g<number>` uses the corresponding group number. `\g<2>` is therefore equivalent to `\2`, but isn't ambiguous in a replacement string such as `\g<2>0` (\20 would be interpreted as a reference to group 20, not a reference to group 2 followed by the literal character '0'). The following substitutions are all equivalent, but use all three variations of the replacement string.
replacement can also be a function, which gives you even more control. If replacement is a function, the function is called for every non-overlapping occurrence of pattern. On each call, the function is passed a match object argument for the match and can use this information to compute the desired replacement string and return it.

In the following example, the replacement function translates decimals into hexadecimal:

```
>>> def hexrepl(match):
...     "Return the hex string for a decimal number"
...     value = int(match.group())
...     return hex(value)
...
>>> p = re.compile(r'\d+')
>>> p.sub(hexrepl, 'Call 65490 for printing, 49152 for user code.'
'Call 0xffd2 for printing, 0xc000 for user code.'
```

When using the module-level re.sub() function, the pattern is passed as the first argument. The pattern may be provided as an object or as a string; if you need to specify regular expression flags, you must either use a pattern object as the first parameter, or use embedded modifiers in the pattern string, e.g. sub("(?i)b+", "x", "b"b"b"b"b"b" "B"B"B"B") returns 'x x'.
Common Problems

Regular expressions are a powerful tool for some applications, but in some ways their behaviour isn’t intuitive and at times they don’t behave the way you may expect them to. This section will point out some of the most common pitfalls.

Use String Methods

Sometimes using the `re` module is a mistake. If you’re matching a fixed string, or a single character class, and you’re not using any `re` features such as the IGNORECASE flag, then the full power of regular expressions may not be required. Strings have several methods for performing operations with fixed strings and they’re usually much faster, because the implementation is a single small C loop that’s been optimized for the purpose, instead of the large, more generalized regular expression engine.

One example might be replacing a single fixed string with another one; for example, you might replace `word` with `deed`. `re.sub()` seems like the function to use for this, but consider the `replace()` method. Note that `replace()` will also replace `word` inside words, turning `swordfish` into `sdeedfish`, but the naive RE `word` would have done that, too. (To avoid performing the substitution on parts of words, the pattern would have to be `\bword\b`, in order to require that `word` have a word boundary on either side. This takes the job beyond `replace()`'s abilities.)

Another common task is deleting every occurrence of a single character from a string or replacing it with another single character.
You might do this with something like `re.sub('\n', '', S)`, but `translate()` is capable of doing both tasks and will be faster than any regular expression operation can be.

In short, before turning to the `re` module, consider whether your problem can be solved with a faster and simpler string method.

**match() versus search()**

The `match()` function only checks if the RE matches at the beginning of the string while `search()` will scan forward through the string for a match. It's important to keep this distinction in mind. Remember, `match()` will only report a successful match which will start at 0; if the match wouldn’t start at zero, `match()` will *not* report it.

```python
>>> print(re.match('super', 'superstition').span())
(0, 5)
>>> print(re.match('super', 'insuperable'))
None
```

On the other hand, `search()` will scan forward through the string, reporting the first match it finds.

```python
>>> print(re.search('super', 'superstition').span())
(0, 5)
>>> print(re.search('super', 'insuperable').span())
(2, 7)
```

Sometimes you'll be tempted to keep using `re.match()`, and just add `.*` to the front of your RE. Resist this temptation and use `re.search()` instead. The regular expression compiler does some analysis of REs in order to speed up the process of looking for a
match. One such analysis figures out what the first character of a match must be; for example, a pattern starting with Crow must match starting with a 'C'. The analysis lets the engine quickly scan through the string looking for the starting character, only trying the full match if a 'C' is found.

Adding .* defeats this optimization, requiring scanning to the end of the string and then backtracking to find a match for the rest of the RE. Use re.search() instead.

**Greedy versus Non-Greedy**

When repeating a regular expression, as in a*, the resulting action is to consume as much of the pattern as possible. This fact often bites you when you're trying to match a pair of balanced delimiters, such as the angle brackets surrounding an HTML tag. The naive pattern for matching a single HTML tag doesn't work because of the greedy nature of .*.

```python
>>> s = '<html><head><title>Title</title>'
>>> len(s)
32
>>> print(re.match('<.*>', s).span())
(0, 32)
>>> print(re.match('<.*>', s).group())
<html><head><title>Title</title>
```

The RE matches the '<' in <html>, and the .* consumes the rest of the string. There's still more left in the RE, though, and the > can't match at the end of the string, so the regular expression engine has to backtrack character by character until it finds a match for the >. The final match extends from the '<' in <html> to the '>' in </title>,
which isn't what you want.

In this case, the solution is to use the non-greedy qualifiers *?, +?, ??, or \{m,n}\?, which match as little text as possible. In the above example, the '>' is tried immediately after the first '<' matches, and when it fails, the engine advances a character at a time, retrying the '>' at every step. This produces just the right result:

```python
>>> print(re.match('<.*?>', s).group())
<html>
```

(Note that parsing HTML or XML with regular expressions is painful. Quick-and-dirty patterns will handle common cases, but HTML and XML have special cases that will break the obvious regular expression; by the time you’ve written a regular expression that handles all of the possible cases, the patterns will be very complicated. Use an HTML or XML parser module for such tasks.)

**Using re.VERBOSE**

By now you’ve probably noticed that regular expressions are a very compact notation, but they’re not terribly readable. REs of moderate complexity can become lengthy collections of backslashes, parentheses, and metacharacters, making them difficult to read and understand.

For such REs, specifying the `re.VERBOSE` flag when compiling the regular expression can be helpful, because it allows you to format the regular expression more clearly.

The `re.VERBOSE` flag has several effects. Whitespace in the regular expression that *isn’t* inside a character class is ignored. This means
that an expression such as `dog | cat` is equivalent to the less readable `dog|cat`, but `[a b]` will still match the characters 'a', 'b', or a space. In addition, you can also put comments inside a RE; comments extend from a `#` character to the next newline. When used with triple-quoted strings, this enables REs to be formatted more neatly:

```
pat = re.compile(r'''\s*
    (?P<header>[^:]+) \s*: \s*(?P<value>.*?)\s*$
''', re.VERBOSE)
```

This is far more readable than:

```
pat = re.compile(r'\s*(?P<header>[^:]+) \s*: (?P<value>.*?)\s*$'
```

Feedback

Regular expressions are a complicated topic. Did this document help you understand them? Were there parts that were unclear, or Problems you encountered that weren't covered here? If so, please send suggestions for improvements to the author.

The most complete book on regular expressions is almost certainly Jeffrey Friedl's Mastering Regular Expressions, published by O'Reilly. Unfortunately, it exclusively concentrates on Perl and Java’s flavours of regular expressions, and doesn't contain any Python material at all, so it won't be useful as a reference for programming in Python. (The first edition covered Python’s now-removed regex module, which won't help you much.) Consider checking it out from your library.
Socket Programming HOWTO

**Author:** Gordon McMillan

**Abstract**

Sockets are used nearly everywhere, but are one of the most severely misunderstood technologies around. This is a 10,000 foot overview of sockets. It's not really a tutorial - you'll still have work to do in getting things operational. It doesn't cover the fine points (and there are a lot of them), but I hope it will give you enough background to begin using them decently.
Sockets

I'm only going to talk about INET (i.e. IPv4) sockets, but they account for at least 99% of the sockets in use. And I'll only talk about STREAM (i.e. TCP) sockets - unless you really know what you're doing (in which case this HOWTO isn't for you!), you'll get better behavior and performance from a STREAM socket than anything else. I will try to clear up the mystery of what a socket is, as well as some hints on how to work with blocking and non-blocking sockets. But I'll start by talking about blocking sockets. You'll need to know how they work before dealing with non-blocking sockets.

Part of the trouble with understanding these things is that “socket” can mean a number of subtly different things, depending on context. So first, let's make a distinction between a “client” socket - an endpoint of a conversation, and a “server” socket, which is more like a switchboard operator. The client application (your browser, for example) uses “client” sockets exclusively; the web server it's talking to uses both “server” sockets and “client” sockets.

History

Of the various forms of IPC, sockets are by far the most popular. On any given platform, there are likely to be other forms of IPC that are faster, but for cross-platform communication, sockets are about the only game in town.

They were invented in Berkeley as part of the BSD flavor of Unix. They spread like wildfire with the Internet. With good reason — the combination of sockets with INET makes talking to arbitrary machines around the world unbelievably easy (at least compared to other
schemes).
Creating a Socket

Roughly speaking, when you clicked on the link that brought you to this page, your browser did something like the following:

```python
# create an INET, STREAMing socket
s = socket.socket(socket.AF_INET, socket.SOCK_STREAM)
# now connect to the web server on port 80 - the normal http port
s.connect(('www.python.org', 80))
```

When the `connect` completes, the socket `s` can be used to send in a request for the text of the page. The same socket will read the reply, and then be destroyed. That's right, destroyed. Client sockets are normally only used for one exchange (or a small set of sequential exchanges).

What happens in the web server is a bit more complex. First, the web server creates a "server socket":

```python
# create an INET, STREAMing socket
serversocket = socket.socket(socket.AF_INET, socket.SOCK_STREAM)
# bind the socket to a public host, and a well-known port
serversocket.bind((socket.gethostname(), 80))
# become a server socket
serversocket.listen(5)
```

A couple things to notice: we used `socket.gethostname()` so that the socket would be visible to the outside world. If we had used `s.bind(('localhost', 80))` or `s.bind(('127.0.0.1', 80))` we would still have a “server” socket, but one that was only visible within the same machine. `s.bind(('', 80))` specifies that
the socket is reachable by any address the machine happens to have.

A second thing to note: low number ports are usually reserved for “well known” services (HTTP, SNMP etc). If you’re playing around, use a nice high number (4 digits).

Finally, the argument to `listen` tells the socket library that we want it to queue up as many as 5 connect requests (the normal max) before refusing outside connections. If the rest of the code is written properly, that should be plenty.

Now that we have a “server” socket, listening on port 80, we can enter the mainloop of the web server:

```python
while True:
    # accept connections from outside
    (clientsocket, address) = serversocket.accept()
    # now do something with the clientsocket
    # in this case, we'll pretend this is a threaded
    ct = client_thread(clientsocket)
    ct.run()
```

There's actually 3 general ways in which this loop could work - dispatching a thread to handle `clientsocket`, create a new process to handle `clientsocket`, or restructure this app to use non-blocking sockets, and multiplex between our “server” socket and any active `clientsockets` using `select`. More about that later. The important thing to understand now is this: this is all a “server” socket does. It doesn't send any data. It doesn't receive any data. It just produces “client” sockets. Each `clientsocket` is created in response to some other “client” socket doing a `connect()` to the host and port we're bound to. As soon as we've created that `clientsocket`, we go back to listening for more connections. The two “clients” are free to chat it
up - they are using some dynamically allocated port which will be recycled when the conversation ends.

**IPC**

If you need fast IPC between two processes on one machine, you should look into pipes or shared memory. If you do decide to use AF_INET sockets, bind the “server” socket to 'localhost'. On most platforms, this will take a shortcut around a couple of layers of network code and be quite a bit faster.

**See also:** The *multiprocessing* integrates cross-platform IPC into a higher-level API.
Using a Socket

The first thing to note, is that the web browser’s “client” socket and the web server’s “client” socket are identical beasts. That is, this is a “peer to peer” conversation. Or to put it another way, as the designer, you will have to decide what the rules of etiquette are for a conversation. Normally, the connecting socket starts the conversation, by sending in a request, or perhaps a signon. But that’s a design decision - it’s not a rule of sockets.

Now there are two sets of verbs to use for communication. You can use send and recv, or you can transform your client socket into a file-like beast and use read and write. The latter is the way Java presents its sockets. I’m not going to talk about it here, except to warn you that you need to use flush on sockets. These are buffered “files”, and a common mistake is to write something, and then read for a reply. Without a flush in there, you may wait forever for the reply, because the request may still be in your output buffer.

Now we come to the major stumbling block of sockets - send and recv operate on the network buffers. They do not necessarily handle all the bytes you hand them (or expect from them), because their major focus is handling the network buffers. In general, they return when the associated network buffers have been filled (send) or emptied (recv). They then tell you how many bytes they handled. It is your responsibility to call them again until your message has been completely dealt with.

When a recv returns 0 bytes, it means the other side has closed (or is in the process of closing) the connection. You will not receive any more data on this connection. Ever. You may be able to send data
successfully; I'll talk more about this later.

A protocol like HTTP uses a socket for only one transfer. The client sends a request, then reads a reply. That's it. The socket is discarded. This means that a client can detect the end of the reply by receiving 0 bytes.

But if you plan to reuse your socket for further transfers, you need to realize that there is no EOT on a socket. I repeat: if a socket send or recv returns after handling 0 bytes, the connection has been broken. If the connection has not been broken, you may wait on a recv forever, because the socket will not tell you that there's nothing more to read (for now). Now if you think about that a bit, you'll come to realize a fundamental truth of sockets: messages must either be fixed length (yuck), or be delimited (shrug), or indicate how long they are (much better), or end by shutting down the connection. The choice is entirely yours, (but some ways are righter than others).

Assuming you don't want to end the connection, the simplest solution is a fixed length message:

class mysocket:
    """demonstration class only
    - coded for clarity, not efficiency
    """

def __init__(self, sock=None):
    if sock is None:
        self.sock = socket.socket(socket.AF_INET, socket.SOCK_STREAM)
    else:
        self.sock = sock

def connect(self, host, port):
```python
def mysend(self, msg):
    totalsent = 0
    while totalsent < MSGLEN:
        sent = self.sock.send(msg[totalsent:])
        if sent == 0:
            raise RuntimeError("socket connection broken")
        totalsent = totalsent + sent

def myreceive(self):
    msg = b'
    while len(msg) < MSGLEN:
        chunk = self.sock.recv(MSGLEN-len(msg))
        if chunk == b'':
            raise RuntimeError("socket connection broken")
        msg = msg + chunk
    return msg
```

The sending code here is usable for almost any messaging scheme - in Python you send strings, and you can use `len()` to determine its length (even if it has embedded \0 characters). It's mostly the receiving code that gets more complex. (And in C, it's not much worse, except you can't use `strlen` if the message has embedded \0s.)

The easiest enhancement is to make the first character of the message an indicator of message type, and have the type determine the length. Now you have two `recv`s - the first to get (at least) that first character so you can look up the length, and the second in a loop to get the rest. If you decide to go the delimited route, you'll be receiving in some arbitrary chunk size, (4096 or 8192 is frequently a good match for network buffer sizes), and scanning what you've received for a delimiter.
One complication to be aware of: if your conversational protocol allows multiple messages to be sent back to back (without some kind of reply), and you pass `recv` an arbitrary chunk size, you may end up reading the start of a following message. You'll need to put that aside and hold onto it, until it's needed.

Prefixing the message with it's length (say, as 5 numeric characters) gets more complex, because (believe it or not), you may not get all 5 characters in one `recv`. In playing around, you'll get away with it; but in high network loads, your code will very quickly break unless you use two `recv` loops - the first to determine the length, the second to get the data part of the message. Nasty. This is also when you'll discover that `send` does not always manage to get rid of everything in one pass. And despite having read this, you will eventually get bit by it!

In the interests of space, building your character, (and preserving my competitive position), these enhancements are left as an exercise for the reader. Let's move on to cleaning up.

**Binary Data**

It is perfectly possible to send binary data over a socket. The major problem is that not all machines use the same formats for binary data. For example, a Motorola chip will represent a 16 bit integer with the value 1 as the two hex bytes 00 01. Intel and DEC, however, are byte-reversed - that same 1 is 01 00. Socket libraries have calls for converting 16 and 32 bit integers - `ntohl, htonl, ntohs, htons` where “n” means network and “h” means host, “s” means short and “l” means long. Where network order is host order, these do nothing, but where the machine is byte-reversed, these swap the bytes around appropriately.
In these days of 32 bit machines, the ascii representation of binary data is frequently smaller than the binary representation. That's because a surprising amount of the time, all those longs have the value 0, or maybe 1. The string “0” would be two bytes, while binary is four. Of course, this doesn’t fit well with fixed-length messages. Decisions, decisions.
Disconnecting

Strictly speaking, you’re supposed to use `shutdown` on a socket before you `close` it. The `shutdown` is an advisory to the socket at the other end. Depending on the argument you pass it, it can mean “I’m not going to send anymore, but I’ll still listen”, or “I’m not listening, good riddance!”. Most socket libraries, however, are so used to programmers neglecting to use this piece of etiquette that normally a `close` is the same as `shutdown(); close()`. So in most situations, an explicit `shutdown` is not needed.

One way to use `shutdown` effectively is in an HTTP-like exchange. The client sends a request and then does a `shutdown(1)`. This tells the server “This client is done sending, but can still receive.” The server can detect “EOF” by a receive of 0 bytes. It can assume it has the complete request. The server sends a reply. If the `send` completes successfully then, indeed, the client was still receiving.

Python takes the automatic shutdown a step further, and says that when a socket is garbage collected, it will automatically do a `close` if it’s needed. But relying on this is a very bad habit. If your socket just disappears without doing a `close`, the socket at the other end may hang indefinitely, thinking you’re just being slow. Please `close` your sockets when you’re done.

When Sockets Die

Probably the worst thing about using blocking sockets is what happens when the other side comes down hard (without doing a `close`). Your socket is likely to hang. TCP is a reliable protocol, and it will wait a
long, long time before giving up on a connection. If you're using threads, the entire thread is essentially dead. There's not much you can do about it. As long as you aren't doing something dumb, like holding a lock while doing a blocking read, the thread isn't really consuming much in the way of resources. Do not try to kill the thread - part of the reason that threads are more efficient than processes is that they avoid the overhead associated with the automatic recycling of resources. In other words, if you do manage to kill the thread, your whole process is likely to be screwed up.
Non-blocking Sockets

If you’ve understood the preceding, you already know most of what you need to know about the mechanics of using sockets. You’ll still use the same calls, in much the same ways. It’s just that, if you do it right, your app will be almost inside-out.

In Python, you use `socket.setblocking(0)` to make it non-blocking. In C, it’s more complex, (for one thing, you’ll need to choose between the BSD flavor `O_NONBLOCK` and the almost indistinguishable Posix flavor `O_NDELAY`, which is completely different from `TCP_NODELAY`), but it’s the exact same idea. You do this after creating the socket, but before using it. (Actually, if you’re nuts, you can switch back and forth.)

The major mechanical difference is that `send`, `recv`, `connect` and `accept` can return without having done anything. You have (of course) a number of choices. You can check return code and error codes and generally drive yourself crazy. If you don’t believe me, try it sometime. Your app will grow large, buggy and suck CPU. So let’s skip the brain-dead solutions and do it right.

Use `select`.

In C, coding `select` is fairly complex. In Python, it's a piece of cake, but it's close enough to the C version that if you understand `select` in Python, you'll have little trouble with it in C:

```python
ready_to_read, ready_to_write, in_error = 
select.select( 
    potential_readers, 
    potential_writers,
```
You pass `select` three lists: the first contains all sockets that you might want to try reading; the second all the sockets you might want to try writing to, and the last (normally left empty) those that you want to check for errors. You should note that a socket can go into more than one list. The `select` call is blocking, but you can give it a timeout. This is generally a sensible thing to do - give it a nice long timeout (say a minute) unless you have good reason to do otherwise.

In return, you will get three lists. They contain the sockets that are actually readable, writable and in error. Each of these lists is a subset (possibly empty) of the corresponding list you passed in.

If a socket is in the output readable list, you can be as-close-to-certain-as-we-ever-get-in-this-business that a `recv` on that socket will return `something`. Same idea for the writable list. You'll be able to send `something`. Maybe not all you want to, but `something` is better than nothing. (Actually, any reasonably healthy socket will return as writable - it just means outbound network buffer space is available.)

If you have a “server” socket, put it in the potential_readers list. If it comes out in the readable list, your `accept` will (almost certainly) work. If you have created a new socket to `connect` to someone else, put it in the potential_writers list. If it shows up in the writable list, you have a decent chance that it has connected.

Actually, `select` can be handy even with blocking sockets. It’s one way of determining whether you will block - the socket returns as readable when there’s something in the buffers. However, this still doesn’t help with the problem of determining whether the other end is done, or just busy with something else.
**Portability alert:** On Unix, `select` works both with the sockets and files. Don’t try this on Windows. On Windows, `select` works with sockets only. Also note that in C, many of the more advanced socket options are done differently on Windows. In fact, on Windows I usually use threads (which work very, very well) with my sockets.
Python lists have a built-in `list.sort()` method that modifies the list in-place. There is also a `sorted()` built-in function that builds a new sorted list from an iterable.

In this document, we explore the various techniques for sorting data using Python.
A simple ascending sort is very easy: just call the `sorted()` function. It returns a new sorted list:

```
>>> sorted([5, 2, 3, 1, 4])
[1, 2, 3, 4, 5]
```

You can also use the `list.sort()` method. It modifies the list in-place (and returns `None` to avoid confusion). Usually it's less convenient than `sorted()` - but if you don't need the original list, it's slightly more efficient.

```
>>> a = [5, 2, 3, 1, 4]
>>> a.sort()
>>> a
[1, 2, 3, 4, 5]
```

Another difference is that the `list.sort()` method is only defined for lists. In contrast, the `sorted()` function accepts any iterable.

```
[1, 2, 3, 4, 5]
```
Key Functions

Both `list.sort()` and `sorted()` have a `key` parameter to specify a function to be called on each list element prior to making comparisons.

For example, here's a case-insensitive string comparison:

```python
>>> sorted("This is a test string from Andrew".split)[
'a', 'Andrew', 'from', 'is', 'string', 'test', 'This'
]
```

The value of the `key` parameter should be a function that takes a single argument and returns a key to use for sorting purposes. This technique is fast because the key function is called exactly once for each input record.

A common pattern is to sort complex objects using some of the object's indices as keys. For example:

```python
>>> student_tuples = [
    ('john', 'A', 15),
    ('jane', 'B', 12),
    ('dave', 'B', 10),
]
>>> sorted(student_tuples, key=lambda student: student[2], reverse=True)
[('dave', 'B', 10), ('jane', 'B', 12), ('john', 'A', 15)]
```

The same technique works for objects with named attributes. For example:

```python
>>> class Student:
    def __init__(self, name, grade, age):
```
self.name = name
self.grade = grade
self.age = age
def __repr__(self):
    return repr((self.name, self.grade, self.age))

>>> student_objects = [
    Student('john', 'A', 15),
    Student('jane', 'B', 12),
    Student('dave', 'B', 10),
]
>>> sorted(student_objects, key=lambda student: student[1])
[('dave', 'B', 10), ('jane', 'B', 12), ('john', 'A', 15)]
Operator Module Functions

The key-function patterns shown above are very common, so Python provides convenience functions to make accessor functions easier and faster. The `operator` module has `itemgetter()`, `attrgetter()`, and a `methodcaller()` function.

Using those functions, the above examples become simpler and faster:

```python
>>> from operator import itemgetter, attrgetter
>>> sorted(student_tuples, key=itemgetter(2))
[('dave', 'B', 10), ('jane', 'B', 12), ('john', 'A', 15)]
```

```python
>>> sorted(student_objects, key=attrgetter('age'))
[('dave', 'B', 10), ('jane', 'B', 12), ('john', 'A', 15)]
```

The `operator` module functions allow multiple levels of sorting. For example, to sort by `grade` then by `age`:

```python
>>> sorted(student_tuples, key=itemgetter(1,2))
[('john', 'A', 15), ('dave', 'B', 10), ('jane', 'B', 12)]
```

```python
>>> sorted(student_objects, key=attrgetter('grade', 'age'))
[('john', 'A', 15), ('dave', 'B', 10), ('jane', 'B', 12)]
```
Ascending and Descending

Both `list.sort()` and `sorted()` accept a `reverse` parameter with a boolean value. This is used to flag descending sorts. For example, to get the student data in reverse age order:

```python
>>> sorted(student_tuples, key=itemgetter(2), reverse=True)
[('john', 'A', 15), ('jane', 'B', 12), ('dave', 'B', 10)]

>>> sorted(student_objects, key=attrgetter('age'), reverse=True)
[('john', 'A', 15), ('jane', 'B', 12), ('dave', 'B', 10)]
```
Sort Stability and Complex Sorts

Sorts are guaranteed to be stable. That means that when multiple records have the same key, their original order is preserved.

```python
data = [('red', 1), ('blue', 1), ('red', 2), ('blue', 2), ('red', 1), ('red', 2)]
sorted(data, key=itemgetter(0))
[('blue', 1), ('blue', 2), ('red', 1), ('red', 2)]
```

Notice how the two records for blue retain their original order so that ('blue', 1) is guaranteed to precede ('blue', 2).

This wonderful property lets you build complex sorts in a series of sorting steps. For example, to sort the student data by descending grade and then ascending age, do the age sort first and then sort again using grade:

```python
s = sorted(student_objects, key=attrgetter('age'))
sorted(s, key=attrgetter('grade'), reverse=True)
[('dave', 'B', 10), ('jane', 'B', 12), ('john', 'A', 15)]
```

The Timsort algorithm used in Python does multiple sorts efficiently because it can take advantage of any ordering already present in a dataset.
The Old Way Using Decorate-Sort-Undecorate

This idiom is called Decorate-Sort-Undecorate after its three steps:

- First, the initial list is decorated with new values that control the sort order.
- Second, the decorated list is sorted.
- Finally, the decorations are removed, creating a list that contains only the initial values in the new order.

For example, to sort the student data by grade using the DSU approach:

```python
>>> decorated = [(student.grade, i, student) for i, student in decorated]
>>> decorated.sort()
>>> [student for grade, i, student in decorated]
[('john', 'A', 15), ('jane', 'B', 12), ('dave', 'B', 10)]
```

This idiom works because tuples are compared lexicographically; the first items are compared; if they are the same then the second items are compared, and so on.

It is not strictly necessary in all cases to include the index \( i \) in the decorated list, but including it gives two benefits:

- The sort is stable – if two items have the same key, their order will be preserved in the sorted list.
- The original items do not have to be comparable because the ordering of the decorated tuples will be determined by at most the first two items. So for example the original list could contain complex numbers which cannot be sorted directly.
Another name for this idiom is Schwartzian transform, after Randal L. Schwartz, who popularized it among Perl programmers.

Now that Python sorting provides key-functions, this technique is not often needed.
The Old Way Using the `cmp` Parameter

Many constructs given in this HOWTO assume Python 2.4 or later. Before that, there was no `sorted()` builtin and `list.sort()` took no keyword arguments. Instead, all of the Py2.x versions supported a `cmp` parameter to handle user specified comparison functions.

In Py3.0, the `cmp` parameter was removed entirely (as part of a larger effort to simplify and unify the language, eliminating the conflict between rich comparisons and the `__cmp__()` magic method).

In Py2.x, sort allowed an optional function which can be called for doing the comparisons. That function should take two arguments to be compared and then return a negative value for less-than, return zero if they are equal, or return a positive value for greater-than. For example, we can do:

```python
>>> def numeric_compare(x, y):
    return x - y
>>> sorted([5, 2, 4, 1, 3], cmp=numeric_compare)
[1, 2, 3, 4, 5]
```

Or you can reverse the order of comparison with:

```python
>>> def reverse_numeric(x, y):
    return y - x
>>> sorted([5, 2, 4, 1, 3], cmp=reverse_numeric)
[5, 4, 3, 2, 1]
```

When porting code from Python 2.x to 3.x, the situation can arise when you have the user supplying a comparison function and you need to convert that to a key function. The following wrapper makes that easy to do:
def cmp_to_key(mycmp):
    'Convert a cmp= function into a key= function'

class K:
    def __init__(self, obj, *args):
        self.obj = obj
    def __lt__(self, other):
        return mycmp(self.obj, other.obj) < 0
    def __gt__(self, other):
        return mycmp(self.obj, other.obj) > 0
    def __eq__(self, other):
        return mycmp(self.obj, other.obj) == 0
    def __le__(self, other):
        return mycmp(self.obj, other.obj) <= 0
    def __ge__(self, other):
        return mycmp(self.obj, other.obj) >= 0
    def __ne__(self, other):
        return mycmp(self.obj, other.obj) != 0

return K

To convert to a key function, just wrap the old comparison function:

```python
>>> sorted([5, 2, 4, 1, 3], key=cmp_to_key(reverse_numeric))
[5, 4, 3, 2, 1]
```

In Python 3.2, the `functools.cmp_to_key()` function was added to the `functools` module in the standard library.
Odd and Ends

- For locale aware sorting, use `locale.strxfrm()` for a key function or `locale.strcoll()` for a comparison function.

- The `reverse` parameter still maintains sort stability (so that records with equal keys retain the original order). Interestingly, that effect can be simulated without the parameter by using the builtin `reversed()` function twice:

```python
>>> data = [('red', 1), ('blue', 1), ('red', 2),
         >>> assert sorted(data, reverse=True) == list(reversed(data))
```

- The sort routines are guaranteed to use `__lt__()` when making comparisons between two objects. So, it is easy to add a standard sort order to a class by defining an `__lt__()` method:

```python
>>> Student.__lt__ = lambda self, other: self.age < other.age
>>> sorted(student_objects)
[('dave', 'B', 10), ('jane', 'B', 12), ('john', 'A', 15)]
```

- Key functions need not depend directly on the objects being sorted. A key function can also access external resources. For instance, if the student grades are stored in a dictionary, they can be used to sort a separate list of student names:

```python
>>> students = ['dave', 'john', 'jane']
>>> newgrades = {'john': 'F', 'jane': 'A', 'dave': 'D'}
>>> sorted(students, key=newgrades.__getitem__)
['jane', 'dave', 'john']
```
Unicode HOWTO

Release: 1.12

This HOWTO discusses Python support for Unicode, and explains various problems that people commonly encounter when trying to work with Unicode.
Introduction to Unicode

History of Character Codes

In 1968, the American Standard Code for Information Interchange, better known by its acronym ASCII, was standardized. ASCII defined numeric codes for various characters, with the numeric values running from 0 to 127. For example, the lowercase letter ‘a’ is assigned 97 as its code value.

ASCII was an American-developed standard, so it only defined unaccented characters. There was an ‘e’, but no ‘é’ or ‘í’. This meant that languages which required accented characters couldn’t be faithfully represented in ASCII. (Actually the missing accents matter for English, too, which contains words such as ‘naïve’ and ‘café’, and some publications have house styles which require spellings such as ‘coöperate’.)

For a while people just wrote programs that didn’t display accents. In the mid-1980s an Apple II BASIC program written by a French speaker might have lines like these:

```
PRINT "FICHIER EST COMPLETE."  
PRINT "CARACTERE NON ACCEPTE."  
```

Those messages should contain accents (completé, caractère, accepté), and they just look wrong to someone who can read French.

In the 1980s, almost all personal computers were 8-bit, meaning that bytes could hold values ranging from 0 to 255. ASCII codes only went up to 127, so some machines assigned values between 128 and 255 to accented characters. Different machines had different codes,
however, which led to problems exchanging files. Eventually various commonly used sets of values for the 128–255 range emerged. Some were true standards, defined by the International Standards Organization, and some were *de facto* conventions that were invented by one company or another and managed to catch on.

255 characters aren’t very many. For example, you can’t fit both the accented characters used in Western Europe and the Cyrillic alphabet used for Russian into the 128–255 range because there are more than 127 such characters.

You could write files using different codes (all your Russian files in a coding system called KOI8, all your French files in a different coding system called Latin1), but what if you wanted to write a French document that quotes some Russian text? In the 1980s people began to want to solve this problem, and the Unicode standardization effort began.

Unicode started out using 16-bit characters instead of 8-bit characters. 16 bits means you have $2^{16} = 65,536$ distinct values available, making it possible to represent many different characters from many different alphabets; an initial goal was to have Unicode contain the alphabets for every single human language. It turns out that even 16 bits isn’t enough to meet that goal, and the modern Unicode specification uses a wider range of codes, 0 through 1,114,111 (0x10FFFF in base 16).

There’s a related ISO standard, ISO 10646. Unicode and ISO 10646 were originally separate efforts, but the specifications were merged with the 1.1 revision of Unicode.

(This discussion of Unicode’s history is highly simplified. The precise historical details aren’t necessary for understanding how to use
Definitions

A **character** is the smallest possible component of a text. ‘A’, ‘B’, ‘C’, etc., are all different characters. So are ‘È’ and ‘Í’. Characters are abstractions, and vary depending on the language or context you’re talking about. For example, the symbol for ohms (Ω) is usually drawn much like the capital letter omega (Ω) in the Greek alphabet (they may even be the same in some fonts), but these are two different characters that have different meanings.

The Unicode standard describes how characters are represented by **code points**. A code point is an integer value, usually denoted in base 16. In the standard, a code point is written using the notation U+12CA to mean the character with value 0x12ca (4,810 decimal). The Unicode standard contains a lot of tables listing characters and their corresponding code points:

<table>
<thead>
<tr>
<th>Code Point</th>
<th>Character</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>0061</td>
<td>'a';</td>
<td>LATIN SMALL LETTER A</td>
</tr>
<tr>
<td>0062</td>
<td>'b';</td>
<td>LATIN SMALL LETTER B</td>
</tr>
<tr>
<td>0063</td>
<td>'c';</td>
<td>LATIN SMALL LETTER C</td>
</tr>
<tr>
<td>...</td>
<td></td>
<td></td>
</tr>
<tr>
<td>007B</td>
<td>'{';</td>
<td>LEFT CURLY BRACKET</td>
</tr>
</tbody>
</table>

Strictly, these definitions imply that it’s meaningless to say ‘this is character U+12CA’. U+12CA is a code point, which represents some particular character; in this case, it represents the character ‘ETHIOPIC SYLLABLE WI’. In informal contexts, this distinction between code points and characters will sometimes be forgotten.
A character is represented on a screen or on paper by a set of graphical elements that's called a **glyph**. The glyph for an uppercase A, for example, is two diagonal strokes and a horizontal stroke, though the exact details will depend on the font being used. Most Python code doesn't need to worry about glyphs; figuring out the correct glyph to display is generally the job of a GUI toolkit or a terminal's font renderer.

## Encodings

To summarize the previous section: a Unicode string is a sequence of code points, which are numbers from 0 through `0x10FFFF` (1,114,111 decimal). This sequence needs to be represented as a set of bytes (meaning, values from 0 through 255) in memory. The rules for translating a Unicode string into a sequence of bytes are called an **encoding**.

The first encoding you might think of is an array of 32-bit integers. In this representation, the string “Python” would look like this:

```
P y t h o n
```

<table>
<thead>
<tr>
<th>P</th>
<th>y</th>
<th>t</th>
<th>h</th>
<th>o</th>
<th>n</th>
</tr>
</thead>
<tbody>
<tr>
<td>0x50</td>
<td>00</td>
<td>00</td>
<td>00</td>
<td>79</td>
<td>00</td>
</tr>
<tr>
<td>00</td>
<td>00</td>
<td>00</td>

</tbody>
</table>

This representation is straightforward but using it presents a number of problems.

1. It's not portable; different processors order the bytes differently.
2. It's very wasteful of space. In most texts, the majority of the code points are less than 127, or less than 255, so a lot of space is occupied by `0x00` bytes. The above string takes 24 bytes compared to the 6 bytes needed for an ASCII representation.
Increased RAM usage doesn’t matter too much (desktop computers have gigabytes of RAM, and strings aren’t usually that large), but expanding our usage of disk and network bandwidth by a factor of 4 is intolerable.

3. It’s not compatible with existing C functions such as `strlen()`, so a new family of wide string functions would need to be used.

4. Many Internet standards are defined in terms of textual data, and can’t handle content with embedded zero bytes.

Generally people don’t use this encoding, instead choosing other encodings that are more efficient and convenient. UTF-8 is probably the most commonly supported encoding; it will be discussed below.

Encodings don’t have to handle every possible Unicode character, and most encodings don’t. The rules for converting a Unicode string into the ASCII encoding, for example, are simple; for each code point:

1. If the code point is < 128, each byte is the same as the value of the code point.
2. If the code point is 128 or greater, the Unicode string can’t be represented in this encoding. (Python raises a `UnicodeEncodeError` exception in this case.)

Latin-1, also known as ISO-8859-1, is a similar encoding. Unicode code points 0–255 are identical to the Latin-1 values, so converting to this encoding simply requires converting code points to byte values; if a code point larger than 255 is encountered, the string can’t be encoded into Latin-1.

Encodings don’t have to be simple one-to-one mappings like Latin-1. Consider IBM’s EBCDIC, which was used on IBM mainframes. Letter values weren’t in one block: ‘a’ through ‘i’ had values from 129 to 137, but ‘j’ through ‘r’ were 145 through 153. If you wanted to use EBCDIC as an encoding, you’d probably use some sort of lookup table to
perform the conversion, but this is largely an internal detail.

UTF-8 is one of the most commonly used encodings. UTF stands for “Unicode Transformation Format”, and the ‘8’ means that 8-bit numbers are used in the encoding. (There are also a UTF-16 and UTF-32 encodings, but they are less frequently used than UTF-8.) UTF-8 uses the following rules:

1. If the code point is < 128, it’s represented by the corresponding byte value.
2. If the code point is >= 128, it’s turned into a sequence of two, three, or four bytes, where each byte of the sequence is between 128 and 255.

UTF-8 has several convenient properties:

1. It can handle any Unicode code point.
2. A Unicode string is turned into a string of bytes containing no embedded zero bytes. This avoids byte-ordering issues, and means UTF-8 strings can be processed by C functions such as `strcpy()` and sent through protocols that can’t handle zero bytes.
3. A string of ASCII text is also valid UTF-8 text.
4. UTF-8 is fairly compact; the majority of commonly used characters can be represented with one or two bytes.
5. If bytes are corrupted or lost, it’s possible to determine the start of the next UTF-8-encoded code point and resynchronize. It’s also unlikely that random 8-bit data will look like valid UTF-8.

References

The Unicode Consortium site has character charts, a glossary, and PDF versions of the Unicode specification. Be prepared for some difficult reading. A chronology of the origin and development of
Unicode is also available on the site.

To help understand the standard, Jukka Korpela has written an introductory guide to reading the Unicode character tables.

Another good introductory article was written by Joel Spolsky. If this introduction didn’t make things clear to you, you should try reading this alternate article before continuing.

Wikipedia entries are often helpful; see the entries for “character encoding” and UTF-8, for example.
Python’s Unicode Support

Now that you’ve learned the rudiments of Unicode, we can look at Python’s Unicode features.

The String Type

Since Python 3.0, the language features a `str` type that contain Unicode characters, meaning any string created using "unicode rocks!", 'unicode rocks!', or the triple-quoted string syntax is stored as Unicode.

The default encoding for Python source code is UTF-8, so you can simply include a Unicode character in a string literal:

```
try:
    with open('/tmp/input.txt', 'r') as f:
        ...
except IOError:
    # 'File not found' error message.
    print("Fichier non trouvé")
```

You can use a different encoding from UTF-8 by putting a specially-formatted comment as the first or second line of the source code:

```
# -*- coding: <encoding name> -*-
```

Side note: Python 3 also supports using Unicode characters in identifiers:

```
répertoire = "/tmp/records.log"
with open(répertoire, "w") as f:
```
f.write("test\n")

If you can't enter a particular character in your editor or want to keep the source code ASCII-only for some reason, you can also use escape sequences in string literals. (Depending on your system, you may see the actual capital-delta glyph instead of a u escape.)

```python
>>> "\N{GREEK CAPITAL LETTER DELTA}"  # Using the character name
'\u0394'
>>> "\u0394"  # Using a 16-bit hex value
'\u0394'
>>> "\U00000394"  # Using a 32-bit hex value
'\u0394'
```

In addition, one can create a string using the `decode()` method of `bytes`. This method takes an `encoding` argument, such as UTF-8, and optionally an `errors` argument.

The `errors` argument specifies the response when the input string can't be converted according to the encoding's rules. Legal values for this argument are 'strict' (raise a `UnicodeDecodeError` exception), 'replace' (use U+FFFD, REPLACEMENT CHARACTER), or 'ignore' (just leave the character out of the Unicode result). The following examples show the differences:

```python
>>> b'\x80abc'.decode("utf-8", "strict")
Traceback (most recent call last):
  ...  
UnicodeDecodeError: 'utf-8' codec can't decode byte invalid start byte
>>> b'\x80abc'.decode("utf-8", "replace")
'\ufffdabc'
>>> b'\x80abc'.decode("utf-8", "ignore")
'abc'
```
(In this code example, the Unicode replacement character has been replaced by a question mark because it may not be displayed on some systems.)

Encodings are specified as strings containing the encoding’s name. Python 3.2 comes with roughly 100 different encodings; see the Python Library Reference at Standard Encodings for a list. Some encodings have multiple names; for example, 'latin-1', 'iso_8859_1' and '8859' are all synonyms for the same encoding.

One-character Unicode strings can also be created with the \texttt{chr()} built-in function, which takes integers and returns a Unicode string of length 1 that contains the corresponding code point. The reverse operation is the built-in \texttt{ord()} function that takes a one-character Unicode string and returns the code point value:

\begin{verbatim}
>>> chr(57344)
'\ue000'
>>> ord('\ue000')
57344
\end{verbatim}

\textbf{Converting to Bytes}

The opposite method of \texttt{bytes.decode()} is \texttt{str.encode()}, which returns a \texttt{bytes} representation of the Unicode string, encoded in the requested \textit{encoding}.

The \texttt{errors} parameter is the same as the parameter of the \texttt{decode()} method but supports a few more possible handlers. As well as 'strict', 'ignore', and 'replace' (which in this case inserts a question mark instead of the unencodable character), there is also
The following example shows the different results:

```python
>>> u = chr(40960) + 'abcd' + chr(1972)
>>> u.encode('utf-8')
b'\xea\x80\x80abcd\xde\xb4'
>>> u.encode('ascii')
Traceback (most recent call last):
  ... UnicodeEncodeError: 'ascii' codec can't encode character ' ' in position 0: ordinal not in range(128)
>>> u.encode('ascii', 'ignore')
b'abcd'
>>> u.encode('ascii', 'replace')
b'?abcd?'
>>> u.encode('ascii', 'xmlcharrefreplace')
b'ꕗabcd〒'
>>> u.encode('ascii', 'backslashreplace')
b'\ua000abcd\u07b4'
```

The low-level routines for registering and accessing the available encodings are found in the `codecs` module. Implementing new encodings also requires understanding the `codecs` module. However, the encoding and decoding functions returned by this module are usually more low-level than is comfortable, and writing new encodings is a specialized task, so the module won’t be covered in this HOWTO.

**Unicode Literals in Python Source Code**

In Python source code, specific Unicode code points can be written using the \\u escape sequence, which is followed by four hex digits.
giving the code point. The `\U` escape sequence is similar, but expects eight hex digits, not four:

```python
>>> s = "a\xac\u1234\u20ac\U00008000"
... # ^^^^ two-digit hex escape
... # ^^^^^^^^ four-digit Unicode escape
... # ^^^^^^^^^^ eight-digit Unicode escape
>>> [ord(c) for c in s]
[97, 172, 4660, 8364, 32768]
```

Using escape sequences for code points greater than 127 is fine in small doses, but becomes an annoyance if you’re using many accented characters, as you would in a program with messages in French or some other accent-using language. You can also assemble strings using the `chr()` built-in function, but this is even more tedious.

Ideally, you’d want to be able to write literals in your language’s natural encoding. You could then edit Python source code with your favorite editor which would display the accented characters naturally, and have the right characters used at runtime.

Python supports writing source code in UTF-8 by default, but you can use almost any encoding if you declare the encoding being used. This is done by including a special comment as either the first or second line of the source file:

```bash
#!/usr/bin/env python
# -*- coding: latin-1 -*-

u = 'abcdé'
print(ord(u[-1]))
```

The syntax is inspired by Emacs’s notation for specifying variables.
local to a file. Emacs supports many different variables, but Python only supports ‘coding’. The -*- symbols indicate to Emacs that the comment is special; they have no significance to Python but are a convention. Python looks for `coding: name` or `coding=name` in the comment.

If you don't include such a comment, the default encoding used will be UTF-8 as already mentioned. See also [PEP 263](https://www.python.org/dev/peps/pep-0263/) for more information.

### Unicode Properties

The Unicode specification includes a database of information about code points. For each defined code point, the information includes the character's name, its category, the numeric value if applicable (Unicode has characters representing the Roman numerals and fractions such as one-third and four-fifths). There are also properties related to the code point's use in bidirectional text and other display-related properties.

The following program displays some information about several characters, and prints the numeric value of one particular character:

```python
import unicodedata

u = chr(233) + chr(0x0bf2) + chr(3972) + chr(6000) +
for i, c in enumerate(u):
    print(i, '%04x' % ord(c), unicodedata.category(c),
print(unicodedata.name(c))

# Get numeric value of second character
print(unicodedata.numeric(u[1]))
```

When run, this prints:

<table>
<thead>
<tr>
<th>Dec</th>
<th>Hex</th>
<th>Category</th>
<th>Character</th>
</tr>
</thead>
<tbody>
<tr>
<td>0</td>
<td>00e9</td>
<td>Ll Latin Small Letter E With Acute</td>
<td>0</td>
</tr>
<tr>
<td>1</td>
<td>0bf2</td>
<td>No Tamil Number One Thousand</td>
<td>1</td>
</tr>
<tr>
<td>2</td>
<td>0f84</td>
<td>Mn Tibetan Mark Halanta</td>
<td>2</td>
</tr>
<tr>
<td>3</td>
<td>1770</td>
<td>Lo Tagbanwa Letter Sa</td>
<td>3</td>
</tr>
<tr>
<td>4</td>
<td>33af</td>
<td>So Square Rad Over S Squared</td>
<td>4</td>
</tr>
<tr>
<td></td>
<td></td>
<td></td>
<td>1000.0</td>
</tr>
</tbody>
</table>

The category codes are abbreviations describing the nature of the character. These are grouped into categories such as “Letter”, “Number”, “Punctuation”, or “Symbol”, which in turn are broken up into subcategories. To take the codes from the above output, 'Ll' means ‘Letter, lowercase’, 'No' means “Number, other”, 'Mn' is “Mark, nonspacing”, and 'So' is “Symbol, other”. See the General Category Values section of the Unicode Character Database documentation for a list of category codes.

**Unicode Regular Expressions**

The regular expressions supported by the `re` module can be provided either as bytes or strings. Some of the special character sequences such as `\d` and `\w` have different meanings depending on whether the pattern is supplied as bytes or a string. For example, `\d` will match the characters `[0-9]` in bytes but in strings will match any character that's in the 'Nd' category.

The string in this example has the number 57 written in both Thai and Arabic numerals:

```python
import re
p = re.compile('^\d+')
```
```python
s = "Over \u0e55\u0e57 57 flavours"
m = p.search(s)
print(repr(m.group()))
```

When executed, `\d+` will match the Thai numerals and print them out. If you supply the `re.ASCII` flag to `compile()`, `\d+` will match the substring “57” instead.

Similarly, `\w` matches a wide variety of Unicode characters but only `[a-zA-Z0-9_]` in bytes or if `re.ASCII` is supplied, and `\s` will match either Unicode whitespace characters or `[ \t\n\r\f\v]`.

Marc-André Lemburg gave a presentation titled “Python and Unicode” ([PDF slides](https://robots.lmb.univ-mrs.fr/~lemburg/codes/python.pdf)) at EuroPython 2002. The slides are an excellent overview of the design of Python 2’s Unicode features (where the Unicode string type is called `unicode` and literals start with `u`).
Reading and Writing Unicode Data

Once you’ve written some code that works with Unicode data, the next problem is input/output. How do you get Unicode strings into your program, and how do you convert Unicode into a form suitable for storage or transmission?

It’s possible that you may not need to do anything depending on your input sources and output destinations; you should check whether the libraries used in your application support Unicode natively. XML parsers often return Unicode data, for example. Many relational databases also support Unicode-valued columns and can return Unicode values from an SQL query.

Unicode data is usually converted to a particular encoding before it gets written to disk or sent over a socket. It’s possible to do all the work yourself: open a file, read an 8-bit bytes object from it, and convert the bytes with `bytes.decode(encoding)`. However, the manual approach is not recommended.

One problem is the multi-byte nature of encodings; one Unicode character can be represented by several bytes. If you want to read the file in arbitrary-sized chunks (say, 1024 or 4096 bytes), you need to write error-handling code to catch the case where only part of the bytes encoding a single Unicode character are read at the end of a chunk. One solution would be to read the entire file into memory and then perform the decoding, but that prevents you from working with files that are extremely large; if you need to read a 2 GiB file, you need 2 GiB of RAM. (More, really, since for at least a moment you’d need to have both the encoded string and its Unicode version in memory.)

The solution would be to use the low-level decoding interface to catch
the case of partial coding sequences. The work of implementing this has already been done for you: the built-in `open()` function can return a file-like object that assumes the file's contents are in a specified encoding and accepts Unicode parameters for methods such as `read()` and `write()`. This works through `open()`'s `encoding` and `errors` parameters which are interpreted just like those in `str.encode()` and `bytes.decode()`.

Reading Unicode from a file is therefore simple:

```python
with open('unicode.txt', encoding='utf-8') as f:
    for line in f:
        print(repr(line))
```

It's also possible to open files in update mode, allowing both reading and writing:

```python
with open('test', encoding='utf-8', mode='w+') as f:
    f.write('blah blah blah
')
    f.seek(0)
    print(repr(f.readline()[:1]))
```

The Unicode character `U+FEFF` is used as a byte-order mark (BOM), and is often written as the first character of a file in order to assist with autodetection of the file's byte ordering. Some encodings, such as UTF-16, expect a BOM to be present at the start of a file; when such an encoding is used, the BOM will be automatically written as the first character and will be silently dropped when the file is read. There are variants of these encodings, such as ‘utf-16-le’ and ‘utf-16-be’ for little-endian and big-endian encodings, that specify one particular byte ordering and don’t skip the BOM.

In some areas, it is also convention to use a “BOM” at the start of
UTF-8 encoded files; the name is misleading since UTF-8 is not byte-order dependent. The mark simply announces that the file is encoded in UTF-8. Use the ‘utf-8-sig’ codec to automatically skip the mark if present for reading such files.

**Unicode filenames**

Most of the operating systems in common use today support filenames that contain arbitrary Unicode characters. Usually this is implemented by converting the Unicode string into some encoding that varies depending on the system. For example, Mac OS X uses UTF-8 while Windows uses a configurable encoding; on Windows, Python uses the name “mbcs” to refer to whatever the currently configured encoding is. On Unix systems, there will only be a filesystem encoding if you’ve set the `LANG` or `LC_CTYPE` environment variables; if you haven’t, the default encoding is UTF-8.

The `sys.getfilesystemencoding()` function returns the encoding to use on your current system, in case you want to do the encoding manually, but there’s not much reason to bother. When opening a file for reading or writing, you can usually just provide the Unicode string as the filename, and it will be automatically converted to the right encoding for you:

```python
filename = 'filename\u4500abc'
with open(filename, 'w') as f:
    f.write('blah\n')
```

Functions in the `os` module such as `os.stat()` will also accept Unicode filenames.

The `os.listdir()` function returns filenames and raises an issue:
should it return the Unicode version of filenames, or should it return bytes containing the encoded versions? `os.listdir()` will do both, depending on whether you provided the directory path as bytes or a Unicode string. If you pass a Unicode string as the path, filenames will be decoded using the filesystem's encoding and a list of Unicode strings will be returned, while passing a byte path will return the filenames as bytes. For example, assuming the default filesystem encoding is UTF-8, running the following program:

```python
fn = 'filename\u4500abc'
f = open(fn, 'w')
f.close()

import os
print(os.listdir(b'.'))
print(os.listdir('.'))
```

will produce the following output:

```
amk:~$ python t.py
[b'filename\xe4\x94\x80abc', ...]
['filename\u4500abc', ...]
```

The first list contains UTF-8-encoded filenames, and the second list contains the Unicode versions.

Note that on most occasions, the Unicode APIs should be used. The bytes APIs should only be used on systems where undecodable file names can be present, i.e. Unix systems.

**Tips for Writing Unicode-aware Programs**

This section provides some suggestions on writing software that deals
with Unicode.

The most important tip is:

Software should only work with Unicode strings internally, decoding the input data as soon as possible and encoding the output only at the end.

If you attempt to write processing functions that accept both Unicode and byte strings, you will find your program vulnerable to bugs wherever you combine the two different kinds of strings. There is no automatic encoding or decoding: if you do e.g. `str + bytes`, a `TypeError` will be raised.

When using data coming from a web browser or some other untrusted source, a common technique is to check for illegal characters in a string before using the string in a generated command line or storing it in a database. If you're doing this, be careful to check the decoded string, not the encoded bytes data; some encodings may have interesting properties, such as not being bijective or not being fully ASCII-compatible. This is especially true if the input data also specifies the encoding, since the attacker can then choose a clever way to hide malicious text in the encoded bytestream.

Converting Between File Encodings

The `StreamRecoder` class can transparently convert between encodings, taking a stream that returns data in encoding #1 and behaving like a stream returning data in encoding #2.

For example, if you have an input file `f` that's in Latin-1, you can wrap it with a `StreamRecoder` to return bytes encoded in UTF-8:

```python
new_f = codecs.StreamRecoder(f,
```
Files in an Unknown Encoding

What can you do if you need to make a change to a file, but don't know the file's encoding? If you know the encoding is ASCII-compatible and only want to examine or modify the ASCII parts, you can open the file with the surrogateescape error handler:

```
with open(fname, 'r', encoding="ascii", errors="surrogateescape") as f:
    data = f.read()

# make changes to the string 'data'
with open(fname + '.new', 'w', encoding="ascii", errors="surrogateescape") as f:
    f.write(data)
```

The surrogateescape error handler will decode any non-ASCII bytes as code points in the Unicode Private Use Area ranging from U+DC80 to U+DCFF. These private code points will then be turned back into the same bytes when the surrogateescape error handler is used when encoding the data and writing it back out.

HOWTO Fetch Internet Resources Using The urllib Package

Author: Michael Foord

Note: There is a French translation of an earlier revision of this HOWTO, available at urllib2 - Le Manuel manquant.
Introduction

`urllib.request` is a Python module for fetching URLs (Uniform Resource Locators). It offers a very simple interface, in the form of the `urlopen` function. This is capable of fetching URLs using a variety of different protocols. It also offers a slightly more complex interface for handling common situations - like basic authentication, cookies, proxies and so on. These are provided by objects called handlers and openers.

`urllib.request` supports fetching URLs for many “URL schemes” (identified by the string before the “:” in URL - for example “ftp” is the URL scheme of “ftp://python.org/”) using their associated network protocols (e.g. FTP, HTTP). This tutorial focuses on the most common case, HTTP.

For straightforward situations `urlopen` is very easy to use. But as soon as you encounter errors or non-trivial cases when opening HTTP URLs, you will need some understanding of the HyperText Transfer Protocol. The most comprehensive and authoritative reference to HTTP is **RFC 2616**. This is a technical document and not intended to be easy to read. This HOWTO aims to illustrate using `urllib`, with enough detail about HTTP to help you through. It is not intended to replace the `urllib.request` docs, but is supplementary to them.
Fetching URLs

The simplest way to use urllib.request is as follows:

```python
import urllib.request
response = urllib.request.urlopen('http://python.org/
html = response.read()
```

If you wish to retrieve a resource via URL and store it in a temporary location, you can do so via the `urllib.request.urlretrieve()` function:

```python
import urllib.request
local_filename, headers = urllib.request.urlretrieve()
html = open(local_filename)
```

Many uses of urllib will be that simple (note that instead of an ‘http:’ URL we could have used an URL starting with ‘ftp:’, ‘file:’, etc.). However, it’s the purpose of this tutorial to explain the more complicated cases, concentrating on HTTP.

HTTP is based on requests and responses - the client makes requests and servers send responses. urllib.request mirrors this with a `Request` object which represents the HTTP request you are making. In its simplest form you create a Request object that specifies the URL you want to fetch. Calling `urlopen` with this Request object returns a response object for the URL requested. This response is a file-like object, which means you can for example call `.read()` on the response:

```python
import urllib.request
```
req = urllib.request.Request('http://www.voidspace.org.uk')
response = urllib.request.urlopen(req)
the_page = response.read()

Note that urllib.request makes use of the same Request interface to handle all URL schemes. For example, you can make an FTP request like so:

req = urllib.request.Request('ftp://example.com/')

In the case of HTTP, there are two extra things that Request objects allow you to do: First, you can pass data to be sent to the server. Second, you can pass extra information (“metadata”) about the data or the about request itself, to the server - this information is sent as HTTP “headers”. Let's look at each of these in turn.

Data

Sometimes you want to send data to a URL (often the URL will refer to a CGI (Common Gateway Interface) script [1] or other web application). With HTTP, this is often done using what’s known as a POST request. This is often what your browser does when you submit a HTML form that you filled in on the web. Not all POSTs have to come from forms: you can use a POST to transmit arbitrary data to your own application. In the common case of HTML forms, the data needs to be encoded in a standard way, and then passed to the Request object as the data argument. The encoding is done using a function from the urllib.parse library.

import urllib.parse
import urllib.request
url = 'http://www.someserver.com/cgi-bin/register.cgi'
values = {'name' : 'Michael Foord',
          'location' : 'Northampton',
          'language' : 'Python'}

data = urllib.parse.urlencode(values)  # data should be bytes
req = urllib.request.Request(url, data)
response = urllib.request.urlopen(req)
the_page = response.read()

Note that other encodings are sometimes required (e.g. for file upload from HTML forms - see HTML Specification, Form Submission for more details).

If you do not pass the data argument, urllib uses a GET request. One way in which GET and POST requests differ is that POST requests often have “side-effects”: they change the state of the system in some way (for example by placing an order with the website for a hundredweight of tinned spam to be delivered to your door). Though the HTTP standard makes it clear that POSTs are intended to always cause side-effects, and GET requests never to cause side-effects, nothing prevents a GET request from having side-effects, nor a POST requests from having no side-effects. Data can also be passed in an HTTP GET request by encoding it in the URL itself.

This is done as follows:

```python
>>> import urllib.request
>>> import urllib.parse
>>> data = {}
>>> data['name'] = 'Somebody Here'
>>> data['location'] = 'Northampton'
>>> data['language'] = 'Python'
```
Notice that the full URL is created by adding a ? to the URL, followed by the encoded values.

**Headers**

We'll discuss here one particular HTTP header, to illustrate how to add headers to your HTTP request.

Some websites [2] dislike being browsed by programs, or send different versions to different browsers [3]. By default urllib identifies itself as Python-urllib/x.y (where x and y are the major and minor version numbers of the Python release, e.g. Python-urllib/2.5), which may confuse the site, or just plain not work. The way a browser identifies itself is through the User-Agent header [4]. When you create a Request object you can pass a dictionary of headers in. The following example makes the same request as above, but identifies itself as a version of Internet Explorer [5].

```python
import urllib.parse
import urllib.request

url = 'http://www.someserver.com/cgi-bin/register.cgi'
user_agent = 'Mozilla/4.0 (compatible; MSIE 5.5; Windows)
values = {'name': 'Michael Foord',
        'location': 'Northampton',
        'language': 'Python'}
```
headers = { 'User-Agent' : user_agent }

data = urllib.parse.urlencode(values)
data = data.encode('utf-8')
req = urllib.request.Request(url, data, headers)
response = urllib.request.urlopen(req)
the_page = response.read()

The response also has two useful methods. See the section on info and geturl which comes after we have a look at what happens when things go wrong.
Handling Exceptions

`urlopen` raises `URLError` when it cannot handle a response (though as usual with Python APIs, built-in exceptions such as `ValueError`, `TypeError` etc. may also be raised).

`HTTPError` is the subclass of `URLError` raised in the specific case of HTTP URLs.

The exception classes are exported from the `urllib.error` module.

**URLError**

Often, `URLError` is raised because there is no network connection (no route to the specified server), or the specified server doesn’t exist. In this case, the exception raised will have a ‘reason’ attribute, which is a tuple containing an error code and a text error message.

e.g.

```python
>>> req = urllib.request.Request('http://www.pretend_server.org')
>>> try:
...     urllib.request.urlopen(req)
... except urllib.error.URLError as e:
...     print(e.reason)
... (4, 'getaddrinfo failed')
```

**HTTPError**

Every HTTP response from the server contains a numeric “status code”. Sometimes the status code indicates that the server is unable...
to fulfil the request. The default handlers will handle some of these responses for you (for example, if the response is a “redirection” that requests the client fetch the document from a different URL, urllib will handle that for you). For those it can’t handle, urlopen will raise an HTTPError. Typical errors include ‘404’ (page not found), ‘403’ (request forbidden), and ‘401’ (authentication required).

See section 10 of RFC 2616 for a reference on all the HTTP error codes.

The HTTPError instance raised will have an integer ‘code’ attribute, which corresponds to the error sent by the server.

Error Codes

Because the default handlers handle redirects (codes in the 300 range), and codes in the 100-299 range indicate success, you will usually only see error codes in the 400-599 range.

http.server.BaseHTTPRequestHandler.responses is a useful dictionary of response codes in that shows all the response codes used by RFC 2616. The dictionary is reproduced here for convenience.

```python
# Table mapping response codes to messages; entries # form {code: (shortmessage, longmessage)}.
responses = {
    100: ('Continue', 'Request received, please continue'),
    101: ('Switching Protocols', 'Switching to new protocol; obey Upgrade header'),
    200: ('OK', 'Request fulfilled, document follows'),
    201: ('Created', 'Document created, URL follows'),
    202: ('Accepted', 'Request accepted, processing continues of
```
203: ('Non-Authoritative Information', 'Request fulfilled, nothing more'
204: ('No Content', 'Request fulfilled, nothing follows'
205: ('Reset Content', 'Clear input form for further input.
206: ('Partial Content', 'Partial content follows.'
300: ('Multiple Choices', 'Object has several resources -- see URI list'
301: ('Moved Permanently', 'Object moved permanently -- see URI list'
302: ('Found', 'Object moved temporarily -- see URI list'
303: ('See Other', 'Object moved -- see Method and URL list'
304: ('Not Modified', 'Document has not changed since given time'
305: ('Use Proxy', 'You must use proxy specified in Location to access this resource.'
307: ('Temporary Redirect', 'Object moved temporarily -- see URI list'
400: ('Bad Request', 'Bad request syntax or unsupported method'
401: ('Unauthorized', 'No permission -- see authorization scheme'
402: ('Payment Required', 'No payment -- see charging schemes'
403: ('Forbidden', 'Request forbidden -- authorization will not help'
404: ('Not Found', 'Nothing matches the given URI'
405: ('Method Not Allowed', 'Specified method is invalid for this server'
406: ('Not Acceptable', 'URI not available in preferred format'
407: ('Proxy Authentication Required', 'You must authenticate with this proxy before proceeding.'
408: ('Request Timeout', 'Request timed out; try again later'
409: ('Conflict', 'Request conflict.'
410: ('Gone', 'URI no longer exists and has been permanently removed'
411: ('Length Required', 'Client must specify Content-Length.'
When an error is raised the server responds by returning an HTTP error code and an error page. You can use the HTTPError instance as a response on the page returned. This means that as well as the code attribute, it also has read, geturl, and info, methods as returned by the urllib.response module:

```python
given
```
Wrapping it Up

So if you want to be prepared for HTTPError or URLError there are two basic approaches. I prefer the second approach.

Number 1

```python
from urllib.request import Request, urlopen
from urllib.error import URLError, HTTPError
req = Request(someurl)
try:
    response = urlopen(req)
except HTTPError as e:
    print('The server couldn’t fulfill the request.
    Error code: ', e.code)
except URLError as e:
    print('We failed to reach a server.
    Reason: ', e.reason)
else:
    # everything is fine
```

Note: The except HTTPError must come first, otherwise except URLError will also catch an HTTPError.

Number 2

```python
from urllib.request import Request, urlopen
```
from urllib.error import URLError
req = Request(someurl)
try:
    response = urlopen(req)
except URLError as e:
    if hasattr(e, 'reason'):
        print('We failed to reach a server.
        print('Reason: ', e.reason)
    elif hasattr(e, 'code'):
        print('The server couldn\'t fulfill the request.
        print('Error code: ', e.code)
else:
    # everything is fine
info and geturl

The response returned by urlopen (or the HTTPError instance) has two useful methods info() and geturl() and is defined in the module `urllib.response`.

**geturl** - this returns the real URL of the page fetched. This is useful because urlopen (or the opener object used) may have followed a redirect. The URL of the page fetched may not be the same as the URL requested.

**info** - this returns a dictionary-like object that describes the page fetched, particularly the headers sent by the server. It is currently an http.client.HTTPMessage instance.

Typical headers include ‘Content-length’, ‘Content-type’, and so on. See the Quick Reference to HTTP Headers for a useful listing of HTTP headers with brief explanations of their meaning and use.
Openers and Handlers

When you fetch a URL you use an opener (an instance of the perhaps confusingly-named `urllib.request.OpenerDirector`). Normally we have been using the default opener - via `urlopen` - but you can create custom openers. Openers use handlers. All the “heavy lifting” is done by the handlers. Each handler knows how to open URLs for a particular URL scheme (http, ftp, etc.), or how to handle an aspect of URL opening, for example HTTP redirections or HTTP cookies.

You will want to create openers if you want to fetch URLs with specific handlers installed, for example to get an opener that handles cookies, or to get an opener that does not handle redirections.

To create an opener, instantiate an `OpenerDirector`, and then call `.add_handler(some_handler_instance)` repeatedly.

Alternatively, you can use `build_opener`, which is a convenience function for creating opener objects with a single function call. `build_opener` adds several handlers by default, but provides a quick way to add more and/or override the default handlers.

Other sorts of handlers you might want to can handle proxies, authentication, and other common but slightly specialised situations.

`install_opener` can be used to make an opener object the (global) default opener. This means that calls to `urlopen` will use the opener you have installed.

Opener objects have an `open` method, which can be called directly to fetch urls in the same way as the `urlopen` function: there's no need to call `install_opener`, except as a convenience.
Basic Authentication

To illustrate creating and installing a handler we will use the HTTPBasicAuthHandler. For a more detailed discussion of this subject – including an explanation of how Basic Authentication works - see the Basic Authentication Tutorial.

When authentication is required, the server sends a header (as well as the 401 error code) requesting authentication. This specifies the authentication scheme and a ‘realm’. The header looks like: "WWW-Authenticate: SCHEME realm="REALM"."

e.g.

WWW-Authenticate: Basic realm="cPanel Users"

The client should then retry the request with the appropriate name and password for the realm included as a header in the request. This is ‘basic authentication’. In order to simplify this process we can create an instance of HTTPBasicAuthHandler and an opener to use this handler.

The HTTPBasicAuthHandler uses an object called a password manager to handle the mapping of URLs and realms to passwords and usernames. If you know what the realm is (from the authentication header sent by the server), then you can use a HTTPPasswordMgr. Frequently one doesn’t care what the realm is. In that case, it is convenient to use HTTPPasswordMgrWithDefaultRealm. This allows you to specify a default username and password for a URL. This will be supplied in the absence of you providing an alternative combination for a specific realm. We indicate this by providing None
as the realm argument to the `add_password` method.

The top-level URL is the first URL that requires authentication. URLs “deeper” than the URL you pass to `.add_password()` will also match.

```python
# create a password manager
password_mgr = urllib.request.HTTPPasswordMgrWithDefaultRealm()

# Add the username and password.
# If we knew the realm, we could use it instead of None.
top_level_url = "http://example.com/foo/"
password_mgr.add_password(None, top_level_url, username, password)

handler = urllib.request.HTTPBasicAuthHandler(password_mgr)

# create "opener" (OpenerDirector instance)
opener = urllib.request.build_opener(handler)

# use the opener to fetch a URL
opener.open(a_url)

# Install the opener.
# Now all calls to urllib.request.urlopen use our opener.
urllib.request.install_opener(opener)
```

**Note:** In the above example we only supplied our HTTPBasicAuthHandler to build_opener. By default openers have the handlers for normal situations – ProxyHandler (if a proxy setting such as an http_proxy environment variable is set), UnknownHandler, HTTPHandler, HTTPDefaultErrorHandler, HTTPRedirectHandler, FTPHandler, FileHandler, DataHandler, HTTPErrorProcessor.
top_level_url is in fact either a full URL (including the ‘http’ scheme component and the hostname and optionally the port number) e.g. “http://example.com/” or an “authority” (i.e. the hostname, optionally including the port number) e.g. “example.com” or “example.com:8080” (the latter example includes a port number). The authority, if present, must NOT contain the “userinfo” component - for example “joe@password:example.com” is not correct.
Proxies

urllib will auto-detect your proxy settings and use those. This is through the ProxyHandler, which is part of the normal handler chain when a proxy setting is detected. Normally that’s a good thing, but there are occasions when it may not be helpful [6]. One way to do this is to setup our own ProxyHandler, with no proxies defined. This is done using similar steps to setting up a Basic Authentication handler:

```python
>>> proxy_support = urllib.request.ProxyHandler({})
>>> opener = urllib.request.build_opener(proxy_support)
>>> urllib.request.install_opener(opener)
```

**Note:** Currently urllib.request does not support fetching of https locations through a proxy. However, this can be enabled by extending urllib.request as shown in the recipe [7].
Sockets and Layers

The Python support for fetching resources from the web is layered. urllib uses the `http.client` library, which in turn uses the socket library.

As of Python 2.3 you can specify how long a socket should wait for a response before timing out. This can be useful in applications which have to fetch web pages. By default the socket module has no timeout and can hang. Currently, the socket timeout is not exposed at the `http.client` or `urllib.request` levels. However, you can set the default timeout globally for all sockets using

```python
import socket
import urllib.request

# timeout in seconds
timeout = 10
socket.setdefaulttimeout(timeout)

# this call to urllib.request.urlopen now uses the default timeout we have set in the socket module
req = urllib.request.Request('http://www.voidspace.org.uk')
response = urllib.request.urlopen(req)
```
Footnotes

This document was reviewed and revised by John Lee.

[1] For an introduction to the CGI protocol see "Writing Web Applications in Python."

Like Google for example. The proper way to use google from a program is to use PyGoogle of course. See Voidspace Google for some examples of using the Google API.

Browser sniffing is a very bad practise for website design - building sites using web standards is much more sensible. Unfortunately a lot of sites still send different versions to different browsers.

[3] The user agent for MSIE 6 is ‘Mozilla/4.0 (compatible; MSIE 6.0; Windows NT 5.1; SV1; .NET CLR 1.1.4322)’

[4] For details of more HTTP request headers, see "Quick Reference to HTTP Headers."

In my case I have to use a proxy to access the internet at work. If you attempt to fetch localhost URLs through this proxy it blocks them. IE is set to use the proxy, which urllib picks up on. In order to test scripts with a localhost server, I have to prevent urllib from using the proxy.

HOWTO Use Python in the web

Author: Marek Kubica

Abstract

This document shows how Python fits into the web. It presents some ways to integrate Python with a web server, and general practices useful for developing web sites.

Programming for the Web has become a hot topic since the rise of “Web 2.0”, which focuses on user-generated content on web sites. It has always been possible to use Python for creating web sites, but it was a rather tedious task. Therefore, many frameworks and helper tools have been created to assist developers in creating faster and more robust sites. This HOWTO describes some of the methods used to combine Python with a web server to create dynamic content. It is not meant as a complete introduction, as this topic is far too broad to be covered in one single document. However, a short overview of the most popular libraries is provided.

See also: While this HOWTO tries to give an overview of Python in the web, it cannot always be as up to date as desired. Web development in Python is rapidly moving forward, so the wiki page on Web Programming may be more in sync with recent development.
The Low-Level View

When a user enters a web site, their browser makes a connection to the site’s web server (this is called the request). The server looks up the file in the file system and sends it back to the user’s browser, which displays it (this is the response). This is roughly how the underlying protocol, HTTP, works.

Dynamic web sites are not based on files in the file system, but rather on programs which are run by the web server when a request comes in, and which generate the content that is returned to the user. They can do all sorts of useful things, like display the postings of a bulletin board, show your email, configure software, or just display the current time. These programs can be written in any programming language the server supports. Since most servers support Python, it is easy to use Python to create dynamic web sites.

Most HTTP servers are written in C or C++, so they cannot execute Python code directly – a bridge is needed between the server and the program. These bridges, or rather interfaces, define how programs interact with the server. There have been numerous attempts to create the best possible interface, but there are only a few worth mentioning.

Not every web server supports every interface. Many web servers only support old, now-obsolete interfaces; however, they can often be extended using third-party modules to support newer ones.

Common Gateway Interface

This interface, most commonly referred to as “CGI”, is the oldest, and is supported by nearly every web server out of the box. Programs
using CGI to communicate with their web server need to be started by the server for every request. So, every request starts a new Python interpreter – which takes some time to start up – thus making the whole interface only usable for low load situations.

The upside of CGI is that it is simple – writing a Python program which uses CGI is a matter of about three lines of code. This simplicity comes at a price: it does very few things to help the developer.

Writing CGI programs, while still possible, is no longer recommended. With WSGI, a topic covered later in this document, it is possible to write programs that emulate CGI, so they can be run as CGI if no better option is available.

See also: The Python standard library includes some modules that are helpful for creating plain CGI programs:

- **cgi** – Handling of user input in CGI scripts
- **cgitb** – Displays nice tracebacks when errors happen in CGI applications, instead of presenting a “500 Internal Server Error” message

The Python wiki features a page on CGI scripts with some additional information about CGI in Python.

Simple script for testing CGI

To test whether your web server works with CGI, you can use this short and simple CGI program:

```
#!/usr/bin/env python
# -*- coding: UTF-8 -*-

# enable debugging
```
import cgitb
cgitb.enable()

print("Content-Type: text/plain;charset=utf-8")
print()
print("Hello World!")

Depending on your web server configuration, you may need to save this code with a `.py` or `.cgi` extension. Additionally, this file may also need to be in a `cgi-bin` folder, for security reasons.

You might wonder what the `cgitb` line is about. This line makes it possible to display a nice traceback instead of just crashing and displaying an “Internal Server Error” in the user’s browser. This is useful for debugging, but it might risk exposing some confidential data to the user. You should not use `cgitb` in production code for this reason. You should always catch exceptions, and display proper error pages – end-users don’t like to see nondescript “Internal Server Errors” in their browsers.

**Setting up CGI on your own server**

If you don’t have your own web server, this does not apply to you. You can check whether it works as-is, and if not you will need to talk to the administrator of your web server. If it is a big host, you can try filing a ticket asking for Python support.

If you are your own administrator or want to set up CGI for testing purposes on your own computers, you have to configure it by yourself. There is no single way to configure CGI, as there are many web servers with different configuration options. Currently the most widely used free web server is Apache HTTPd, or Apache for short. Apache
can be easily installed on nearly every system using the system's package management tool. **lighttpd** is another alternative and is said to have better performance. On many systems this server can also be installed using the package management tool, so manually compiling the web server may not be needed.

- On Apache you can take a look at the [Dynamic Content with CGI](#) tutorial, where everything is described. Most of the time it is enough just to set `ExecCGI`. The tutorial also describes the most common gotchas that might arise.
- On lighttpd you need to use the **CGI module**, which can be configured in a straightforward way. It boils down to setting `cgi.assign` properly.

**Common problems with CGI scripts**

Using CGI sometimes leads to small annoyances while trying to get these scripts to run. Sometimes a seemingly correct script does not work as expected, the cause being some small hidden problem that's difficult to spot.

Some of these potential problems are:

- The Python script is not marked as executable. When CGI scripts are not executable most web servers will let the user download it, instead of running it and sending the output to the user. For CGI scripts to run properly on Unix-like operating systems, the `+x` bit needs to be set. Using `chmod a+x your_script.py` may solve this problem.
- On a Unix-like system, the line endings in the program file must be Unix style line endings. This is important because the web server checks the first line of the script (called shebang) and tries to run the program specified there. It gets easily confused by Windows line endings (Carriage Return & Line Feed, also called
CRLF), so you have to convert the file to Unix line endings (only Line Feed, LF). This can be done automatically by uploading the file via FTP in text mode instead of binary mode, but the preferred way is just telling your editor to save the files with Unix line endings. Most editors support this.

- Your web server must be able to read the file, and you need to make sure the permissions are correct. On unix-like systems, the server often runs as user and group www-data, so it might be worth a try to change the file ownership, or making the file world readable by using chmod a+r your_script.py.

- The web server must know that the file you're trying to access is a CGI script. Check the configuration of your web server, as it may be configured to expect a specific file extension for CGI scripts.

- On Unix-like systems, the path to the interpreter in the shebang (#!/usr/bin/env python) must be correct. This line calls /usr/bin/env to find Python, but it will fail if there is no /usr/bin/env, or if Python is not in the web server's path. If you know where your Python is installed, you can also use that full path. The commands whereis python and type -p python could help you find where it is installed. Once you know the path, you can change the shebang accordingly: #!/usr/bin/python.

- The file must not contain a BOM (Byte Order Mark). The BOM is meant for determining the byte order of UTF-16 and UTF-32 encodings, but some editors write this also into UTF-8 files. The BOM interferes with the shebang line, so be sure to tell your editor not to write the BOM.

- If the web server is using mod_python, mod_python may be having problems. mod_python is able to handle CGI scripts by itself, but it can also be a source of issues.
People coming from PHP often find it hard to grasp how to use Python in the web. Their first thought is mostly mod_python, because they think that this is the equivalent to mod_php. Actually, there are many differences. What mod_python does is embed the interpreter into the Apache process, thus speeding up requests by not having to start a Python interpreter for each request. On the other hand, it is not “Python intermixed with HTML” in the way that PHP is often intermixed with HTML. The Python equivalent of that is a template engine. mod_python itself is much more powerful and provides more access to Apache internals. It can emulate CGI, work in a “Python Server Pages” mode (similar to JSP) which is “HTML intermingled with Python”, and it has a “Publisher” which designates one file to accept all requests and decide what to do with them.

mod_python does have some problems. Unlike the PHP interpreter, the Python interpreter uses caching when executing files, so changes to a file will require the web server to be restarted. Another problem is the basic concept – Apache starts child processes to handle the requests, and unfortunately every child process needs to load the whole Python interpreter even if it does not use it. This makes the whole web server slower. Another problem is that, because mod_python is linked against a specific version of libpython, it is not possible to switch from an older version to a newer (e.g. 2.4 to 2.5) without recompiling mod_python. mod_python is also bound to the Apache web server, so programs written for mod_python cannot easily run on other web servers.

These are the reasons why mod_python should be avoided when writing new programs. In some circumstances it still might be a good idea to use mod_python for deployment, but WSGI makes it possible to run WSGI programs under mod_python as well.
FastCGI and SCGI

FastCGI and SCGI try to solve the performance problem of CGI in another way. Instead of embedding the interpreter into the web server, they create long-running background processes. There is still a module in the web server which makes it possible for the web server to “speak” with the background process. As the background process is independent of the server, it can be written in any language, including Python. The language just needs to have a library which handles the communication with the webserver.

The difference between FastCGI and SCGI is very small, as SCGI is essentially just a “simpler FastCGI”. As the web server support for SCGI is limited, most people use FastCGI instead, which works the same way. Almost everything that applies to SCGI also applies to FastCGI as well, so we'll only cover the latter.

These days, FastCGI is never used directly. Just like mod_python, it is only used for the deployment of WSGI applications.

See also:

- FastCGI, SCGI, and Apache: Background and Future is a discussion on why the concept of FastCGI and SCGI is better than that of mod_python.

Setting up FastCGI

Each web server requires a specific module.

- Apache has both mod_fastcgi and mod_fcgid. mod_fastcgi is the original one, but it has some licensing issues, which is why it is sometimes considered non-free. mod_fcgid is a smaller,
compatible alternative. One of these modules needs to be loaded by Apache.

- lighttpd ships its own FastCGI module as well as an SCGI module.
- nginx also supports FastCGI.

Once you have installed and configured the module, you can test it with the following WSGI-application:

```python
#!/usr/bin/env python
# -*- coding: UTF-8 -*-

import sys, os
from html import escape
from flup.server.fcgi import WSGIServer

def app(environ, start_response):
    start_response('200 OK', [('Content-Type', 'text/html')])
    yield '<h1>FastCGI Environment</h1>'
    yield '<table>
    for k, v in sorted(environ.items()):
        yield '<tr><th>{0}</th><td>{1}</td></tr>'.format(escape(k), escape(v))
    yield '</table>'

WSGIServer(app).run()
```

This is a simple WSGI application, but you need to install flup first, as flup handles the low level FastCGI access.

**See also:** There is some documentation on setting up Django with FastCGI, most of which can be reused for other WSGI-compliant frameworks and libraries. Only the `manage.py` part has to be
changed, the example used here can be used instead. Django does more or less the exact same thing.

**mod_wsgi**

`mod_wsgi` is an attempt to get rid of the low level gateways. Given that FastCGI, SCGI, and mod_python are mostly used to deploy WSGI applications, `mod_wsgi` was started to directly embed WSGI applications into the Apache web server. `mod_wsgi` is specifically designed to host WSGI applications. It makes the deployment of WSGI applications much easier than deployment using other low level methods, which need glue code. The downside is that `mod_wsgi` is limited to the Apache web server; other servers would need their own implementations of `mod_wsgi`.

`mod_wsgi` supports two modes: embedded mode, in which it integrates with the Apache process, and daemon mode, which is more FastCGI-like. Unlike FastCGI, `mod_wsgi` handles the worker-processes by itself, which makes administration easier.
Step back: WSGI

WSGI has already been mentioned several times, so it has to be something important. In fact it really is, and now it is time to explain it.

The *Web Server Gateway Interface*, or WSGI for short, is defined in [PEP 333](https://www.python.org/dev/peps/pep-0333/) and is currently the best way to do Python web programming. While it is great for programmers writing frameworks, a normal web developer does not need to get in direct contact with it. When choosing a framework for web development it is a good idea to choose one which supports WSGI.

The big benefit of WSGI is the unification of the application programming interface. When your program is compatible with WSGI – which at the outer level means that the framework you are using has support for WSGI – your program can be deployed via any web server interface for which there are WSGI wrappers. You do not need to care about whether the application user uses mod_python or FastCGI or mod_wsgi – with WSGI your application will work on any gateway interface. The Python standard library contains its own WSGI server, *wsgiref*, which is a small web server that can be used for testing.

A really great WSGI feature is middleware. Middleware is a layer around your program which can add various functionality to it. There is quite a bit of [middleware](https://www.python.org/dev/peps/pep-0333/) already available. For example, instead of writing your own session management (HTTP is a stateless protocol, so to associate multiple HTTP requests with a single user your application must create and manage such state via a session), you can just download middleware which does that, plug it in, and get on with coding the unique parts of your application. The same thing with compression – there is existing middleware which handles compressing your HTML using gzip to save on your server's
bandwidth. Authentication is another a problem easily solved using existing middleware.

Although WSGI may seem complex, the initial phase of learning can be very rewarding because WSGI and the associated middleware already have solutions to many problems that might arise while developing web sites.

WSGI Servers

The code that is used to connect to various low level gateways like CGI or mod_python is called a WSGI server. One of these servers is flup, which supports FastCGI and SCGI, as well as AJP. Some of these servers are written in Python, as flup is, but there also exist others which are written in C and can be used as drop-in replacements.

There are many servers already available, so a Python web application can be deployed nearly anywhere. This is one big advantage that Python has compared with other web technologies.

See also: A good overview of WSGI-related code can be found in the WSGI homepage, which contains an extensive list of WSGI servers which can be used by any application supporting WSGI.

You might be interested in some WSGI-supporting modules already contained in the standard library, namely:

- wsgiref – some tiny utilities and servers for WSGI

Case study: MoinMoin
What does WSGI give the web application developer? Let’s take a look at an application that’s been around for a while, which was written in Python without using WSGI.

One of the most widely used wiki software packages is MoinMoin. It was created in 2000, so it predates WSGI by about three years. Older versions needed separate code to run on CGI, mod_python, FastCGI and standalone.

It now includes support for WSGI. Using WSGI, it is possible to deploy MoinMoin on any WSGI compliant server, with no additional glue code. Unlike the pre-WSGI versions, this could include WSGI servers that the authors of MoinMoin know nothing about.
Model-View-Controller

The term MVC is often encountered in statements such as “framework foo supports MVC”. MVC is more about the overall organization of code, rather than any particular API. Many web frameworks use this model to help the developer bring structure to their program. Bigger web applications can have lots of code, so it is a good idea to have an effective structure right from the beginning. That way, even users of other frameworks (or even other languages, since MVC is not Python-specific) can easily understand the code, given that they are already familiar with the MVC structure.

MVC stands for three components:

- The *model*. This is the data that will be displayed and modified. In Python frameworks, this component is often represented by the classes used by an object-relational mapper.
- The *view*. This component’s job is to display the data of the model to the user. Typically this component is implemented via templates.
- The *controller*. This is the layer between the user and the model. The controller reacts to user actions (like opening some specific URL), tells the model to modify the data if necessary, and tells the view code what to display.

While one might think that MVC is a complex design pattern, in fact it is not. It is used in Python because it has turned out to be useful for creating clean, maintainable web sites.

**Note:** While not all Python frameworks explicitly support MVC, it is often trivial to create a web site which uses the MVC pattern by separating the data logic (the model) from the user interaction logic.
(the controller) and the templates (the view). That's why it is important not to write unnecessary Python code in the templates – it works against the MVC model and creates chaos in the code base, making it harder to understand and modify.

**See also:** The English Wikipedia has an article about the Model-View-Controller pattern. It includes a long list of web frameworks for various programming languages.
Ingredients for Websites

Websites are complex constructs, so tools have been created to help web developers make their code easier to write and more maintainable. Tools like these exist for all web frameworks in all languages. Developers are not forced to use these tools, and often there is no “best” tool. It is worth learning about the available tools because they can greatly simplify the process of developing a web site.

See also: There are far more components than can be presented here. The Python wiki has a page about these components, called Web Components.

Templates

Mixing of HTML and Python code is made possible by a few libraries. While convenient at first, it leads to horribly unmaintainable code. That’s why templates exist. Templates are, in the simplest case, just HTML files with placeholders. The HTML is sent to the user’s browser after filling in the placeholders.

Python already includes a way to build simple templates:

```python
# a simple template
template = "<html><body><h1>Hello {who}!</h1></body>
print(template.format(who="Reader"))
```

To generate complex HTML based on non-trivial model data, conditional and looping constructs like Python’s for and if are generally needed. Template engines support templates of this complexity.
There are a lot of template engines available for Python which can be used with or without a framework. Some of these define a plain-text programming language which is easy to learn, partly because it is limited in scope. Others use XML, and the template output is guaranteed to be always be valid XML. There are many other variations.

Some frameworks ship their own template engine or recommend one in particular. In the absence of a reason to use a different template engine, using the one provided by or recommended by the framework is a good idea.

Popular template engines include:

- Mako
- Genshi
- Jinja

See also: There are many template engines competing for attention, because it is pretty easy to create them in Python. The page Templating in the wiki lists a big, ever-growing number of these. The three listed above are considered “second generation” template engines and are a good place to start.

Data persistence

Data persistence, while sounding very complicated, is just about storing data. This data might be the text of blog entries, the postings on a bulletin board or the text of a wiki page. There are, of course, a number of different ways to store information on a web server.

Often, relational database engines like MySQL or PostgreSQL are used because of their good performance when handling very large
databases consisting of millions of entries. There is also a small database engine called SQLite, which is bundled with Python in the sqlite3 module, and which uses only one file. It has no other dependencies. For smaller sites SQLite is just enough.

Relational databases are queried using a language called SQL. Python programmers in general do not like SQL too much, as they prefer to work with objects. It is possible to save Python objects into a database using a technology called ORM (Object Relational Mapping). ORM translates all object-oriented access into SQL code under the hood, so the developer does not need to think about it. Most frameworks use ORMs, and it works quite well.

A second possibility is storing data in normal, plain text files (sometimes called “flat files”). This is very easy for simple sites, but can be difficult to get right if the web site is performing many updates to the stored data.

A third possibility are object oriented databases (also called “object databases”). These databases store the object data in a form that closely parallels the way the objects are structured in memory during program execution. (By contrast, ORMs store the object data as rows of data in tables and relations between those rows.) Storing the objects directly has the advantage that nearly all objects can be saved in a straightforward way, unlike in relational databases where some objects are very hard to represent.

Frameworks often give hints on which data storage method to choose. It is usually a good idea to stick to the data store recommended by the framework unless the application has special requirements better satisfied by an alternate storage mechanism.
- **Persistence Tools** lists possibilities on how to save data in the file system. Some of these modules are part of the standard library.
- **Database Programming** helps with choosing a method for saving data.
- **SQLAlchemy**, the most powerful OR-Mapper for Python, and **Elixir**, which makes SQLAlchemy easier to use.
- **SQLObject**, another popular OR-Mapper.
- **ZODB** and **Durus**, two object oriented databases.
Frameworks

The process of creating code to run web sites involves writing code to provide various services. The code to provide a particular service often works the same way regardless of the complexity or purpose of the web site in question. Abstracting these common solutions into reusable code produces what are called “frameworks” for web development. Perhaps the most well-known framework for web development is Ruby on Rails, but Python has its own frameworks. Some of these were partly inspired by Rails, or borrowed ideas from Rails, but many existed a long time before Rails.

Originally Python web frameworks tended to incorporate all of the services needed to develop web sites as a giant, integrated set of tools. No two web frameworks were interoperable: a program developed for one could not be deployed on a different one without considerable re-engineering work. This led to the development of “minimalist” web frameworks that provided just the tools to communicate between the Python code and the http protocol, with all other services to be added on top via separate components. Some ad hoc standards were developed that allowed for limited interoperability between frameworks, such as a standard that allowed different template engines to be used interchangeably.

Since the advent of WSGI, the Python web framework world has been evolving toward interoperability based on the WSGI standard. Now many web frameworks, whether “full stack” (providing all the tools one needs to deploy the most complex web sites) or minimalist, or anything in between, are built from collections of reusable components that can be used with more than one framework.

The majority of users will probably want to select a “full stack”
framework that has an active community. These frameworks tend to be well documented, and provide the easiest path to producing a fully functional web site in minimal time.

Some notable frameworks

There are an incredible number of frameworks, so they cannot all be covered here. Instead we will briefly touch on some of the most popular.

Django

Django is a framework consisting of several tightly coupled elements which were written from scratch and work together very well. It includes an ORM which is quite powerful while being simple to use, and has a great online administration interface which makes it possible to edit the data in the database with a browser. The template engine is text-based and is designed to be usable for page designers who cannot write Python. It supports template inheritance and filters (which work like Unix pipes). Django has many handy features bundled, such as creation of RSS feeds or generic views, which make it possible to create web sites almost without writing any Python code.

It has a big, international community, the members of which have created many web sites. There are also a lot of add-on projects which extend Django’s normal functionality. This is partly due to Django’s well written online documentation and the Django book.

Note: Although Django is an MVC-style framework, it names the elements differently, which is described in the Django FAQ.

TurboGears
Another popular web framework for Python is **TurboGears**. TurboGears takes the approach of using already existing components and combining them with glue code to create a seamless experience. TurboGears gives the user flexibility in choosing components. For example the ORM and template engine can be changed to use packages different from those used by default.

The documentation can be found in the **TurboGears wiki**, where links to screencasts can be found. TurboGears has also an active user community which can respond to most related questions. There is also a **TurboGears book** published, which is a good starting point.

The newest version of TurboGears, version 2.0, moves even further in direction of WSGI support and a component-based architecture. TurboGears 2 is based on the WSGI stack of another popular component-based web framework, **Pylons**.

**Zope**

The Zope framework is one of the “old original” frameworks. Its current incarnation in Zope2 is a tightly integrated full-stack framework. One of its most interesting feature is its tight integration with a powerful object database called the **ZODB** (Zope Object Database). Because of its highly integrated nature, Zope wound up in a somewhat isolated ecosystem: code written for Zope wasn’t very usable outside of Zope, and vice-versa. To solve this problem the Zope 3 effort was started. Zope 3 re-engineers Zope as a set of more cleanly isolated components. This effort was started before the advent of the WSGI standard, but there is WSGI support for Zope 3 from the **Repoze** project. Zope components have many years of production use behind them, and the Zope 3 project gives access to these components to the wider Python community. There is even a separate framework based
on the Zope components: Grok.

Zope is also the infrastructure used by the Plone content management system, one of the most powerful and popular content management systems available.

Other notable frameworks

Of course these are not the only frameworks that are available. There are many other frameworks worth mentioning.

Another framework that's already been mentioned is Pylons. Pylons is much like TurboGears, but with an even stronger emphasis on flexibility, which comes at the cost of being more difficult to use. Nearly every component can be exchanged, which makes it necessary to use the documentation of every single component, of which there are many. Pylons builds upon Paste, an extensive set of tools which are handy for WSGI.

And that's still not everything. The most up-to-date information can always be found in the Python wiki.

See also: The Python wiki contains an extensive list of web frameworks.

Most frameworks also have their own mailing lists and IRC channels, look out for these on the projects’ web sites. There is also a general “Python in the Web” IRC channel on freenode called #python.web.
Argparse Tutorial

**author:** Tshepang Lekhonkhobe

This tutorial is intended to be a gentle introduction to *argparse*, the recommended command-line parsing module in the Python standard library.

**Note:** There are two other modules that fulfill the same task, namely *getopt* (an equivalent for getopt() from the C language) and the deprecated *optparse*. Note also that *argparse* is based on *optparse*, and therefore very similar in terms of usage.
Concepts

Let’s show the sort of functionality that we are going to explore in this introductory tutorial by making use of the `ls` command:

```bash
$ ls
cpython devguide prog.py pypy rm-unused-function
$ ls pypy
ctypes_configure demo dotviewer include lib_pypy
$ ls -l
```

```bash
...
```

```bash
$ ls --help
```

Usage: ls [OPTION][FILE]...
List information about the FILEs (the current directory by default, if none of -cftuvSUX nor --sort is specified.

A few concepts we can learn from the four commands:

- The `ls` command is useful when run without any options at all. It defaults to displaying the contents of the current directory.
- If we want beyond what it provides by default, we tell it a bit more. In this case, we want it to display a different directory, `pypy`. What we did is specify what is known as a positional argument. It’s named so because the program should know what to do with the value, solely based on where it appears on the command line. This concept is more relevant to a command like `cp`, whose most basic usage is `cp SRC DEST`. The first position is *what you want copied*, and the second position is *where you want it copied to*. 

• Now, say we want to change behaviour of the program. In our example, we display more info for each file instead of just showing the file names. The `-l` in that case is known as an optional argument.
• That's a snippet of the help text. It's very useful in that you can come across a program you have never used before, and can figure out how it works simply by reading its help text.
The basics

Let us start with a very simple example which does (almost) nothing:

```python
import argparse
parser = argparse.ArgumentParser()
parser.parse_args()
```

Following is a result of running the code:

```
$ python3 prog.py
$ python3 prog.py --help
usage: prog.py [-h]

optional arguments:
  -h, --help    show this help message and exit
```

```
$ python3 prog.py --verbose
usage: prog.py [-h]
prog.py: error: unrecognized arguments: --verbose
```

```
$ python3 prog.py foo
usage: prog.py [-h]
prog.py: error: unrecognized arguments: foo
```

Here is what is happening:

- Running the script without any options results in nothing displayed to stdout. Not so useful.
- The second one starts to display the usefulness of the `argparse` module. We have done almost nothing, but already we get a nice help message.
- The `--help` option, which can also be shortened to `-h`, is the only option we get for free (i.e. no need to specify it). Specifying anything else results in an error. But even then, we do get a useful usage message, also for free.
Introducing Positional arguments

An example:

```python
import argparse
parser = argparse.ArgumentParser()
parser.add_argument("echo")
args = parser.parse_args()
print(args.echo)
```

And running the code:

```bash
$ python3 prog.py
usage: prog.py [-h] echo
prog.py: error: the following arguments are required
$ python3 prog.py --help
usage: prog.py [-h] echo

positional arguments:
  echo

optional arguments:
  -h, --help  show this help message and exit
```

Here is what's happening:

- We've added the `add_argument()` method, which is what we use to specify which command-line options the program is willing to accept. In this case, I've named it `echo` so that it's in line with its function.
- Calling our program now requires us to specify an option.
- The `parse_args()` method actually returns some data from the
options specified, in this case, `echo`.
- The variable is some form of ‘magic’ that `argparse` performs for free (i.e. no need to specify which variable that value is stored in). You will also notice that its name matches the string argument given to the method, `echo`.

Note however that, although the help display looks nice and all, it currently is not as helpful as it can be. For example we see that we got `echo` as a positional argument, but we don’t know what it does, other than by guessing or by reading the source code. So, let’s make it a bit more useful:

```python
import argparse
parser = argparse.ArgumentParser()
parser.add_argument("echo", help="echo the string you use here")
args = parser.parse_args()
print(args.echo)
```

And we get:

```
$ python3 prog.py -h
usage: prog.py [-h] echo

positional arguments:
  echo                  echo the string you use here

optional arguments:
  -h, --help  show this help message and exit
```

Now, how about doing something even more useful:

```python
import argparse
parser = argparse.ArgumentParser()
parser.add_argument("square", help="display a square")
```
args = parser.parse_args()
print(args.square**2)

Following is a result of running the code:

```
$ python3 prog.py 4
16
$ python3 prog.py four
usage: prog.py [-h] square
prog.py: error: argument square: invalid int value:
```

That didn't go so well. That's because **argparse** treats the options we give it as strings, unless we tell it otherwise. So, let's tell **argparse** to treat that input as an integer:

```
import argparse
parser = argparse.ArgumentParser()
parser.add_argument("square", help="display a square", type=int)
args = parser.parse_args()
print(args.square**2)
```

Following is a result of running the code:

```
$ python3 prog.py 4
16
$ python3 prog.py four
usage: prog.py [-h] square
prog.py: error: argument square: invalid int value:
```

That went well. The program now even helpfully quits on bad illegal input before proceeding.
Introducing Optional arguments

So far we, have been playing with positional arguments. Let us have a look on how to add optional ones:

```python
import argparse
parser = argparse.ArgumentParser()
parser.add_argument("--verbosity", help="increase output verbosity")
args = parser.parse_args()
if args.verbosity:
    print("verbosity turned on")
```

And the output:

```
$ python3 prog.py --verbosity 1
verbosity turned on
$ python3 prog.py
$ python3 prog.py --help
usage: prog.py [-h] [--verbosity VERBOSITY]

optional arguments:
  -h, --help            show this help message and exit
  --verbosity VERBOSITY increase output verbosity

$ python3 prog.py --verbosity
usage: prog.py [-h] [--verbosity VERBOSITY]
prog.py: error: argument --verbosity: expected one argument
```

Here is what is happening:

- The program is written so as to display something when `--verbosity` is specified and display nothing when not.
- To show that the option is actually optional, there is no error when
running the program without it. Note that by default, if an optional argument isn't used, the relevant variable, in this case args.verbosity, is given None as a value, which is the reason it fails the truth test of the if statement.

- The help message is a bit different.
- When using the --verbosity option, one must also specify some value, any value.

The above example accepts arbitrary integer values for --verbosity, but for our simple program, only two values are actually useful, True or False. Let's modify the code accordingly:

```python
import argparse
parser = argparse.ArgumentParser()
parser.add_argument("--verbose", help="increase output verbosity", action="store_true")
args = parser.parse_args()
if args.verbose:
    print("verbosity turned on")
```

And the output:

```
$ python3 prog.py --verbose
verbosity turned on
$ python3 prog.py --verbose 1
usage: prog.py [-h] [--verbose]
prog.py: error: unrecognized arguments: 1
$ python3 prog.py --help
usage: prog.py [-h] [--verbose]

optional arguments:
  -h, --help    show this help message and exit
  --verbose     increase output verbosity
```
Here is what is happening:

- The option is now more of a flag than something that requires a value. We even changed the name of the option to match that idea. Note that we now specify a new keyword, `action`, and give it the value "store_true". This means that, if the option is specified, assign the value `True` to `args.verbose`. Not specifying it implies `False`.
- It complains when you specify a value, in true spirit of what flags actually are.
- Notice the different help text.

**Short options**

If you are familiar with command line usage, you will notice that I haven’t yet touched on the topic of short versions of the options. It’s quite simple:

```python
import argparse
parser = argparse.ArgumentParser()
parser.add_argument("-v", "--verbose", help="increase output verbosity",
                   action="store_true")
args = parser.parse_args()
if args.verbose:
    print("verbosity turned on")
```

And here goes:

```
$ python3 prog.py -v
verbosity turned on
$ python3 prog.py --help
usage: prog.py [-h] [-v]
optional arguments:
```
Note that the new ability is also reflected in the help text.
Combining Positional and Optional arguments

Our program keeps growing in complexity:

```python
import argparse
parser = argparse.ArgumentParser()
parser.add_argument("square", type=int,
                    help="display a square of a given number")
parser.add_argument("-v", "--verbose",
                    action="store_true",
                    help="increase output verbosity")
args = parser.parse_args()
answer = args.square ** 2
if args.verbose:
    print("the square of {} equals {}".format(args.square, answer))
else:
    print(answer)
```

And now the output:

```
$ python3 prog.py
usage: prog.py [-h] [-v] square
prog.py: error: the following arguments are required
$ python3 prog.py 4
16
$ python3 prog.py 4 --verbose
the square of 4 equals 16
$ python3 prog.py --verbose 4
the square of 4 equals 16
```

- We’ve brought back a positional argument, hence the complaint.
- Note that the order does not matter.
How about we give this program of ours back the ability to have multiple verbosity values, and actually get to use them:

```python
import argparse
parser = argparse.ArgumentParser()
parser.add_argument("square", type=int,
                    help="display a square of a given number")
parser.add_argument("-v", "--verbosity", type=int,
                    help="increase output verbosity")
args = parser.parse_args()
answer = args.square**2
if args.verbosity == 2:
    print("the square of {} equals {}".format(args.square, answer))
elif args.verbosity == 1:
    print("{}^2 == {}".format(args.square, answer))
else:
    print(answer)
```

And the output:

```
$ python3 prog.py 4
16
$ python3 prog.py 4 -v
usage: prog.py [-h] [-v VERBOSITY] square
prog.py: error: argument -v/--verbosity: expected one argument
$ python3 prog.py 4 -v 1
4^2 == 16
$ python3 prog.py 4 -v 2
the square of 4 equals 16
$ python3 prog.py 4 -v 3
16
```

These all look good except the last one, which exposes a bug in our program. Let's fix it by restricting the values the `--verbosity` option
can accept:

```python
import argparse
parser = argparse.ArgumentParser()
parser.add_argument("square", type=int,
                   help="display a square of a given number")
parser.add_argument("-v", "--verbosity", type=int,
                   choices=[0, 1, 2],
                   help="increase output verbosity")
args = parser.parse_args()
answer = args.square**2
if args.verbosity == 2:
    print("the square of {} equals {}".format(args.square, answer))
elif args.verbosity == 1:
    print("{}^2 == {}".format(args.square, answer))
else:
    print(answer)
```

And the output:

```
$ python3 prog.py 4 -v 3
usage: prog.py [-h] [-v {0,1,2}] square
prog.py: error: argument -v/--verbosity: invalid choice: 3 (choose from 0, 1, 2)
$ python3 prog.py 4 -h
usage: prog.py [-h] [-v {0,1,2}] square

positional arguments:
  square                    display a square of a given number

optional arguments:
  -h, --help                show this help message and exit
  -v {0,1,2}, --verbosity {0,1,2}  increase output verbosity
```

Note that the change also reflects both in the error message as well as the help string.
Now, let's use a different approach of playing with verbosity, which is pretty common. It also matches the way the CPython executable handles its own verbosity argument (check the output of `python --help`):

```python
import argparse
parser = argparse.ArgumentParser()
parser.add_argument("square", type=int,
                    help="display the square of a given number")
parser.add_argument("-v", "--verbosity",
                    action="count",
                    help="increase output verbosity")
args = parser.parse_args()
answer = args.square**2
if args.verbosity == 2:
    print("the square of {} equals {}").format(args.square, answer)
elif args.verbosity == 1:
    print("{}^2 == {}".format(args.square, answer))
else:
    print(answer)
```

We have introduced another action, “count”, to count the number of occurrences of a specific optional arguments:

```bash
$ python3 prog.py 4
16
$ python3 prog.py 4 -v
4^2 == 16
$ python3 prog.py 4 -vv
the square of 4 equals 16
$ python3 prog.py 4 --verbosity --verbosity
the square of 4 equals 16
$ python3 prog.py 4 -v 1
usage: prog.py [-h] [-v] square
prog.py: error: unrecognized arguments: 1
$ python3 prog.py 4 -h
```
usage: prog.py [-h] [-v] square

positional arguments:
square display a square of a given number

optional arguments:
-h, --help show this help message and exit
-v, --verbosity increase output verbosity

$ python3 prog.py 4 -vvv
16

- Yes, it's now more of a flag (similar to `action="store_true"`) in the previous version of our script. That should explain the complaint.
- It also behaves similar to “store_true” action.
- Now here's a demonstration of what the “count” action gives. You've probably seen this sort of usage before.
- And, just like the “store_true” action, if you don't specify the `-v` flag, that flag is considered to have None value.
- As should be expected, specifying the long form of the flag, we should get the same output.
- Sadly, our help output isn’t very informative on the new ability our script has acquired, but that can always be fixed by improving the documentation for our script (e.g. via the help keyword argument).
- That last output exposes a bug in our program.

Let's fix:

```python
import argparse
parser = argparse.ArgumentParser()
parser.add_argument("square", type=int,
                    help="display a square of a given number")
parser.add_argument("-v", "--verbosity", action="count",
                    help="increase output verbosity")
```
```python
class Args:
    def __init__(self, square, verbosity):
        self.square = square
        self.verbosity = verbosity

    def to_json(self):
        return json.dumps(self, default=lambda o: o.__dict__,
                          sort_keys=True, indent=4)

    def __str__(self):
        return 'Args(square={}, verbosity={})'.format(self.square, self.verbosity)

def main():
    parser = argparse.ArgumentParser()
    parser.add_argument('square', type=int,
                        help='display a square of a given number
                        [default: 10]')
    parser.add_argument('-v', '--verbosity', action='count',
                        help='increase output verbosity')
    args = parser.parse_args()

    answer = args.square ** 2

    if args.verbosity >= 2:
        print('the square of {} equals {}'.format(args.square, answer))
    elif args.verbosity >= 1:
        print('{}^2 == {}'.format(args.square, answer))
    else:
        print(answer)

if __name__ == '__main__':
    main()
```

And this is what it gives:

```
$ python3 prog.py 4 -vvv
the square of 4 equals 16
$ python3 prog.py 4 -vvvv
the square of 4 equals 16
$ python3 prog.py 4
Traceback (most recent call last):
  File "prog.py", line 11, in <module>
    if args.verbosity >= 2:
TypeError: unorderable types: NoneType() >= int()
```

- First output went well, and fixes the bug we had before. That is, we want any value >= 2 to be as verbose as possible.
- Third output not so good.

Let's fix that bug:

```python
import argparse
parser = argparse.ArgumentParser()
parser.add_argument("square", type=int,
    help="display a square of a given number [default: 10]")
parser.add_argument("-v", "--verbosity", action="count",
    help="increase output verbosity")
args = parser.parse_args()
```
answer = args.square**2
if args.verbosity >= 2:
    print("the square of {} equals {}".format(args.square, answer))
elif args.verbosity >= 1:
    print("{}^2 == {}".format(args.square, answer))
else:
    print(answer)

We've just introduced yet another keyword, default. We've set it to 0 in order to make it comparable to the other int values. Remember that by default, if an optional argument isn't specified, it gets the None value, and that cannot be compared to an int value (hence the TypeError exception).

And:

```
$ python3 prog.py 4
16
```

You can go quite far just with what we've learned so far, and we have only scratched the surface. The argparse module is very powerful, and we'll explore a bit more of it before we end this tutorial.
Getting a little more advanced

What if we wanted to expand our tiny program to perform other powers, not just squares:

```python
import argparse
parser = argparse.ArgumentParser()
parser.add_argument("x", type=int, help="the base")
parser.add_argument("y", type=int, help="the exponent")
parser.add_argument("-v", "--verbosity", action="count")
args = parser.parse_args()
answer = args.x**args.y
if args.verbosity >= 2:
    print("{} to the power {} equals {}".format(args.x, args.y, answer))
elif args.verbosity >= 1:
    print("{}^{} == {}".format(args.x, args.y, answer))
else:
    print(answer)
```

Output:

```
$ python3 prog.py
usage: prog.py [-h] [-v] x y
prog.py: error: the following arguments are required
$ python3 prog.py -h
usage: prog.py [-h] [-v] x y

positional arguments:
    x            the base
    y            the exponent

optional arguments:
    -h, --help       show this help message and exit
    -v, --verbosity
```
Notice that so far we've been using verbosity level to change the text that gets displayed. The following example instead uses verbosity level to display more text instead:

```python
import argparse
parser = argparse.ArgumentParser()
parser.add_argument("x", type=int, help="the base")
parser.add_argument("y", type=int, help="the exponent")
parser.add_argument("-v", "--verbosity", action="count")
args = parser.parse_args()
answer = args.x**args.y
if args.verbosity >= 2:
    print("Running '{}'".format(__file__)))
if args.verbosity >= 1:
    print("{}^{} == ".format(args.x, args.y), end=""
print(answer)
```

Output:

```
$ python3 prog.py 4 2
16
$ python3 prog.py 4 2 -v
4^2 == 16
$ python3 prog.py 4 2 -vv
Running 'prog.py'
4^2 == 16
```

Conflicting options

So far, we have been working with two methods of an
argparse.ArgumentParser instance. Let's introduce a third one, add_mutually_exclusive_group(). It allows for us to specify options that conflict with each other. Let's also change the rest of the program so that the new functionality makes more sense: we'll introduce the **--quiet** option, which will be the opposite of the **--verbose** one:

```python
import argparse

parser = argparse.ArgumentParser()
group = parser.add_mutually_exclusive_group()
group.add_argument("-v", "--verbose", action="store_true")
group.add_argument("-q", "--quiet", action="store_true")
parser.add_argument("x", type=int, help="the base")
parser.add_argument("y", type=int, help="the exponent")

args = parser.parse_args()
answer = args.x**args.y

if args.quiet:
    print(answer)
elif args.verbose:
    print("{} to the power {} equals {}").format(args.x, args.y, answer)
else:
    print("{}^{} == {}".format(args.x, args.y, answer))
```

Our program is now simpler, and we've lost some functionality for the sake of demonstration. Anyways, here's the output:

```
$ python3 prog.py 4 2
4^2 == 16
$ python3 prog.py 4 2 -q
16
$ python3 prog.py 4 2 -v
4 to the power 2 equals 16
```
That should be easy to follow. I’ve added that last output so you can see the sort of flexibility you get, i.e. mixing long form options with short form ones.

Before we conclude, you probably want to tell your users the main purpose of your program, just in case they don’t know:

```python
import argparse

parser = argparse.ArgumentParser(description="calculate X to the power of Y")
group = parser.add_mutually_exclusive_group()
group.add_argument("-v", "--verbose", action="store_true")
group.add_argument("-q", "--quiet", action="store_true")
parser.add_argument("x", type=int, help="the base")
parser.add_argument("y", type=int, help="the exponent")
args = parser.parse_args()
answer = args.x**args.y

if args.quiet:
    print(answer)
elif args.verbose:
    print("{} to the power {} equals {}".format(args.x, args.y, answer))
else:
    print("{}^{} == {}".format(args.x, args.y, answer))
```

Note that slight difference in the usage text. Note the `[v | q]`, which tells us that we can either use `-v` or `-q`, but not both at the
same time:

```bash
$ python3 prog.py --help
usage: prog.py [-h] [-v | -q] x y

calculate X to the power of Y

positional arguments:
  x            the base
  y            the exponent

optional arguments:
  -h, --help   show this help message and exit
  -v, --verbose
  -q, --quiet
```
Conclusion

The `argparse` module offers a lot more than shown here. Its docs are quite detailed and thorough, and full of examples. Having gone through this tutorial, you should easily digest them without feeling overwhelmed.
An introduction to the ipaddress module

author: Peter Moody
author: Nick Coghlan

Overview

This document aims to provide a gentle introduction to the ipaddress module. It is aimed primarily at users that aren't already familiar with IP networking terminology, but may also be useful to network engineers wanting an overview of how ipaddress represents IP network addressing concepts.
Creating Address/Network/Interface objects

Since `ipaddress` is a module for inspecting and manipulating IP addresses, the first thing you'll want to do is create some objects. You can use `ipaddress` to create objects from strings and integers.

A Note on IP Versions

For readers that aren’t particularly familiar with IP addressing, it’s important to know that the Internet Protocol is currently in the process of moving from version 4 of the protocol to version 6. This transition is occurring largely because version 4 of the protocol doesn’t provide enough addresses to handle the needs of the whole world, especially given the increasing number of devices with direct connections to the internet.

Explaining the details of the differences between the two versions of the protocol is beyond the scope of this introduction, but readers need to at least be aware that these two versions exist, and it will sometimes be necessary to force the use of one version or the other.

IP Host Addresses

Addresses, often referred to as “host addresses” are the most basic unit when working with IP addressing. The simplest way to create addresses is to use the `ipaddress.ip_address()` factory function, which automatically determines whether to create an IPv4 or IPv6 address based on the passed in value:
Addresses can also be created directly from integers. Values that will fit within 32 bits are assumed to be IPv4 addresses:

```python
>>> ipaddress.ip_address('192.0.2.1')
IPv4Address('192.0.2.1')
>>> ipaddress.ip_address('2001:db8::1')
IPv6Address('2001:db8::1')
```

To force the use of IPv4 or IPv6 addresses, the relevant classes can be invoked directly. This is particularly useful to force creation of IPv6 addresses for small integers:

```python
>>> ipaddress.ip_address(3221225985)
IPv4Address('192.0.2.1')
>>> ipaddress.ip_address(42540766411285928569039849)
IPv6Address('2001:db8::1')
```

**Defining Networks**

Host addresses are usually grouped together into IP networks, so `ipaddress` provides a way to create, inspect and manipulate network definitions. IP network objects are constructed from strings that define the range of host addresses that are part of that network. The simplest form for that information is a “network address/network prefix” pair, where the prefix defines the number of leading bits that are compared to determine whether or not an address is part of the network and the
network address defines the expected value of those bits.

As for addresses, a factory function is provided that determines the correct IP version automatically:

```
>>> ipaddress.ip_network('192.0.2.0/24')
IPv4Network('192.0.2.0/24')
>>> ipaddress.ip_network('2001:db8::/96')
IPv6Network('2001:db8::/96')
```

Network objects cannot have any host bits set. The practical effect of this is that `192.0.2.1/24` does not describe a network. Such definitions are referred to as interface objects since the ip-on-a-network notation is commonly used to describe network interfaces of a computer on a given network and are described further in the next section.

By default, attempting to create a network object with host bits set will result in `ValueError` being raised. To request that the additional bits instead be coerced to zero, the flag `strict=False` can be passed to the constructor:

```
>>> ipaddress.ip_network('192.0.2.1/24')
Traceback (most recent call last):
...
ValueError: 192.0.2.1/24 has host bits set
>>> ipaddress.ip_network('192.0.2.1/24', strict=False)
IPv4Network('192.0.2.0/24')
```

While the string form offers significantly more flexibility, networks can also be defined with integers, just like host addresses. In this case, the network is considered to contain only the single address identified by the integer, so the network prefix includes the entire network address:
As with addresses, creation of a particular kind of network can be forced by calling the class constructor directly instead of using the factory function.

### Host Interfaces

As mentioned just above, if you need to describe an address on a particular network, neither the address nor the network classes are sufficient. Notation like 192.0.2.1/24 is commonly used by network engineers and the people who write tools for firewalls and routers as shorthand for “the host 192.0.2.1 on the network 192.0.2.0/24”. Accordingly, `ipaddress` provides a set of hybrid classes that associate an address with a particular network. The interface for creation is identical to that for defining network objects, except that the address portion isn’t constrained to being a network address.

```python
>>> ipaddress.ip_interface('192.0.2.1/24')
IPv4Interface('192.0.2.1/24')

>>> ipaddress.ip_interface('2001:db8::1/96')
IPv6Interface('2001:db8::1/96')
```

Integer inputs are accepted (as with networks), and use of a particular IP version can be forced by calling the relevant constructor directly.
Inspecting Address/Network/Interface Objects

You’ve gone to the trouble of creating an IPv(4|6) (Address|Network|Interface) object, so you probably want to get information about it. `ipaddress` tries to make doing this easy and intuitive.

Extracting the IP version:

```python
>>> addr4 = ipaddress.ip_address('192.0.2.1')
>>> addr6 = ipaddress.ip_address('2001:db8::1')
>>> addr6.version
6
>>> addr4.version
4
```

Obtaining the network from an interface:

```python
>>> host4 = ipaddress.ip_interface('192.0.2.1/24')
>>> host4.network
IPv4Network('192.0.2.0/24')
>>> host6 = ipaddress.ip_interface('2001:db8::1/96')
>>> host6.network
IPv6Network('2001:db8::/96')
```

Finding out how many individual addresses are in a network:

```python
>>> net4 = ipaddress.ip_network('192.0.2.0/24')
>>> net4.num_addresses
256
>>> net6 = ipaddress.ip_network('2001:db8::/96')
>>> net6.num_addresses
```
Iterating through the “usable” addresses on a network:

```python
>>> net4 = ipaddress.ip_network('192.0.2.0/24')
>>> for x in net4.hosts():
...     print(x)
192.0.2.1
192.0.2.2
192.0.2.3
192.0.2.4
...
192.0.2.252
192.0.2.253
192.0.2.254
```

Obtaining the netmask (i.e. set bits corresponding to the network prefix) or the hostmask (any bits that are not part of the netmask):

```python
>>> net4 = ipaddress.ip_network('192.0.2.0/24')
>>> net4.netmask
IPv4Address('255.255.255.0')
>>> net4.hostmask
IPv4Address('0.0.0.255')
>>> net6 = ipaddress.ip_network('2001:db8::0/96')
>>> net6.netmask
>>> net6.hostmask
IPv6Address('::ffff:ffff')
```

Exploding or compressing the address:

```python
>>> addr6.exploded
'2001:0db8:0000:0000:0000:0000:0000:0001'
>>> addr6.compressed
'2001:db8::1'
```
While IPv4 doesn't support explosion or compression, the associated objects still provide the relevant properties so that version neutral code can easily ensure the most concise or most verbose form is used for IPv6 addresses while still correctly handling IPv4 addresses.
Networks as lists of Addresses

It's sometimes useful to treat networks as lists. This means it is possible to index them like this:

```python
>>> net4[1]
IPv4Address('192.0.2.1')
>>> net4[-1]
IPv4Address('192.0.2.255')
>>> net6[1]
IPv6Address('2001:db8::1')
>>> net6[-1]
IPv6Address('2001:db8::ffff:ffff')
```

It also means that network objects lend themselves to using the list membership test syntax like this:

```python
if address in network:
    # do something
```

Containment testing is done efficiently based on the network prefix:

```python
>>> addr4 = ipaddress.ip_address('192.0.2.1')
>>> addr4 in ipaddress.ip_network('192.0.2.0/24')
True
>>> addr4 in ipaddress.ip_network('192.0.3.0/24')
False
```
Comparisons

`ipaddress` provides some simple, hopefully intuitive ways to compare objects, where it makes sense:

```python
>>> ipaddress.ip_address('192.0.2.1') < ipaddress.ip_address('192.0.2.2')
True
```

A `TypeError` exception is raised if you try to compare objects of different versions or different types.
Using IP Addresses with other modules

Other modules that use IP addresses (such as `socket`) usually won't accept objects from this module directly. Instead, they must be coerced to an integer or string that the other module will accept:

```
>>> addr4 = ipaddress.ip_address('192.0.2.1')
>>> str(addr4)
'192.0.2.1'
>>> int(addr4)
3221225985
```
Getting more detail when instance creation fails

When creating address/network/interface objects using the version-agnostic factory functions, any errors will be reported as `ValueError` with a generic error message that simply says the passed in value was not recognized as an object of that type. The lack of a specific error is because it's necessary to know whether the value is `supposed` to be IPv4 or IPv6 in order to provide more detail on why it has been rejected.

To support use cases where it is useful to have access to this additional detail, the individual class constructors actually raise the `ValueError` subclasses `ipaddress.AddressValueError` and `ipaddress.NetmaskValueError` to indicate exactly which part of the definition failed to parse correctly.

The error messages are significantly more detailed when using the class constructors directly. For example:

```python
>>> ipaddress.ip_address("192.168.0.256")
ValueError: '192.168.0.256' does not appear to be an IPv4 or IPv6 address

>>> ipaddress.IPv4Address("192.168.0.256")
ipaddress.AddressValueError: Octet 256 (> 255) not permitted in '192.168.0.256'

>>> ipaddress.ip_network("192.168.0.1/64")
ValueError: '192.168.0.1/64' does not appear to be an IPv4 or IPv6 network
```
>>> ipaddress.IPv4Network("192.168.0.1/64")
Traceback (most recent call last):
...
ipaddress.NetmaskValueError: '64' is not a valid net

However, both of the module specific exceptions have ValueError as their parent class, so if you’re not concerned with the particular type of error, you can still write code like the following:

try:
    network = ipaddress.IPv4Network(address)
except ValueError:
    print('address/netmask is invalid for IPv4:', address)
Argument Clinic How-To

**author:** Larry Hastings

**Abstract**

Argument Clinic is a preprocessor for CPython C files. Its purpose is to automate all the boilerplate involved with writing argument parsing code for “builtins”. This document shows you how to convert your first C function to work with Argument Clinic, and then introduces some advanced topics on Argument Clinic usage.

Currently Argument Clinic is considered internal-only for CPython. Its use is not supported for files outside CPython, and no guarantees are made regarding backwards compatibility for future versions. In other words: if you maintain an external C extension for CPython, you're welcome to experiment with Argument Clinic in your own code. But the version of Argument Clinic that ships with CPython 3.5 could be totally incompatible and break all your code.
The Goals Of Argument Clinic

Argument Clinic’s primary goal is to take over responsibility for all argument parsing code inside CPython. This means that, when you convert a function to work with Argument Clinic, that function should no longer do any of its own argument parsing—the code generated by Argument Clinic should be a “black box” to you, where CPython calls in at the top, and your code gets called at the bottom, with `PyObject *args` (and maybe `PyObject *kwargs`) magically converted into the C variables and types you need.

In order for Argument Clinic to accomplish its primary goal, it must be easy to use. Currently, working with CPython’s argument parsing library is a chore, requiring maintaining redundant information in a surprising number of places. When you use Argument Clinic, you don’t have to repeat yourself.

Obviously, no one would want to use Argument Clinic unless it’s solving their problem—and without creating new problems of its own. So it’s paramount that Argument Clinic generate correct code. It’d be nice if the code was faster, too, but at the very least it should not introduce a major speed regression. (Eventually Argument Clinic should make a major speedup possible—we could rewrite its code generator to produce tailor-made argument parsing code, rather than calling the general-purpose CPython argument parsing library. That would make for the fastest argument parsing possible!)

Additionally, Argument Clinic must be flexible enough to work with any approach to argument parsing. Python has some functions with some very strange parsing behaviors; Argument Clinic’s goal is to support all of them.
Finally, the original motivation for Argument Clinic was to provide introspection “signatures” for CPython builtins. It used to be, the introspection query functions would throw an exception if you passed in a builtin. With Argument Clinic, that’s a thing of the past!

One idea you should keep in mind, as you work with Argument Clinic: the more information you give it, the better job it’ll be able to do. Argument Clinic is admittedly relatively simple right now. But as it evolves it will get more sophisticated, and it should be able to do many interesting and smart things with all the information you give it.
Basic Concepts And Usage

Argument Clinic ships with CPython; you’ll find it in Tools/clinic/clinic.py. If you run that script, specifying a C file as an argument:

```
% python3 Tools/clinic/clinic.py foo.c
```

Argument Clinic will scan over the file looking for lines that look exactly like this:

```
/*[clinic input]
```

When it finds one, it reads everything up to a line that looks exactly like this:

```
[clinic start generated code]*/
```

Everything in between these two lines is input for Argument Clinic. All of these lines, including the beginning and ending comment lines, are collectively called an Argument Clinic “block”.

When Argument Clinic parses one of these blocks, it generates output. This output is rewritten into the C file immediately after the block, followed by a comment containing a checksum. The Argument Clinic block now looks like this:

```
/*[clinic input]
... clinic input goes here ...
[clinic start generated code]*/
... clinic output goes here ...
/*[clinic end generated code: checksum=...]*/
```
If you run Argument Clinic on the same file a second time, Argument Clinic will discard the old output and write out the new output with a fresh checksum line. However, if the input hasn’t changed, the output won’t change either.

You should never modify the output portion of an Argument Clinic block. Instead, change the input until it produces the output you want. (That’s the purpose of the checksum—to detect if someone changed the output, as these edits would be lost the next time Argument Clinic writes out fresh output.)

For the sake of clarity, here’s the terminology we’ll use with Argument Clinic:

- The first line of the comment (/*[clinic input]*) is the start line.
- The last line of the initial comment ([clinic start generated code]*) is the end line.
- The last line (/*[clinic end generated code: checksum=...]*/) is the checksum line.
- In between the start line and the end line is the input.
- In between the end line and the checksum line is the output.
- All the text collectively, from the start line to the checksum line inclusively, is the block. (A block that hasn’t been successfully processed by Argument Clinic yet doesn’t have output or a checksum line, but it’s still considered a block.)
Converting Your First Function

The best way to get a sense of how Argument Clinic works is to convert a function to work with it. Here, then, are the bare minimum steps you’d need to follow to convert a function to work with Argument Clinic. Note that for code you plan to check in to CPython, you really should take the conversion farther, using some of the advanced concepts you’ll see later on in the document (like “return converters” and “self converters”). But we’ll keep it simple for this walkthrough so you can learn.

Let’s dive in!

0. Make sure you’re working with a freshly updated checkout of the CPython trunk.

1. Find a Python builtin that calls either `PyArg_ParseTuple()` or `PyArg_ParseTupleAndKeywords()`, and hasn’t been converted to work with Argument Clinic yet. For my example I’m using `_pickle.Pickler.dump()`.

2. If the call to the `PyArg_Parse` function uses any of the following format units:

   0&
   0!
   es
   es#
   et
   et#

or if it has multiple calls to `PyArg_ParseTuple()`, you should choose a different function. Argument Clinic does support all of
these scenarios. But these are advanced topics—let’s do something simpler for your first function.

Also, if the function has multiple calls to `PyArg_ParseTuple()` or `PyArg_ParseTupleAndKeywords()` where it supports different types for the same argument, or if the function uses something besides `PyArg_Parse` functions to parse its arguments, it probably isn’t suitable for conversion to Argument Clinic. Argument Clinic doesn’t support generic functions or polymorphic parameters.

3. Add the following boilerplate above the function, creating our block:

```c
/*[clinic input] [clinic start generated code]*/
```

4. Cut the docstring and paste it in between the `[clinic]` lines, removing all the junk that makes it a properly quoted C string. When you’re done you should have just the text, based at the left margin, with no line wider than 80 characters. (Argument Clinic will preserve indents inside the docstring.)

If the old docstring had a first line that looked like a function signature, throw that line away. (The docstring doesn’t need it anymore—when you use `help()` on your builtin in the future, the first line will be built automatically based on the function’s signature.)

Sample:

```c
/*[clinic input] Write a pickled representation of obj to the open
```
5. If your docstring doesn’t have a “summary” line, Argument Clinic will complain. So let’s make sure it has one. The “summary” line should be a paragraph consisting of a single 80-column line at the beginning of the docstring.

(Our example docstring consists solely of a summary line, so the sample code doesn’t have to change for this step.)

6. Above the docstring, enter the name of the function, followed by a blank line. This should be the Python name of the function, and should be the full dotted path to the function—it should start with the name of the module, include any sub-modules, and if the function is a method on a class it should include the class name too.

Sample:

/* [clinic input] _pickle.Pickler.dump Write a pickled representation of obj to the open [clinic start generated code]*/

7. If this is the first time that module or class has been used with Argument Clinic in this C file, you must declare the module and/or class. Proper Argument Clinic hygiene prefers declaring these in a separate block somewhere near the top of the C file, in the same way that include files and statics go at the top. (In our sample code we’ll just show the two blocks next to each other.)

The name of the class and module should be the same as the one
seen by Python. Check the name defined in the `PyModuleDef` or `PyTypeObject` as appropriate.

When you declare a class, you must also specify two aspects of its type in C: the type declaration you’d use for a pointer to an instance of this class, and a pointer to the `PyTypeObject` for this class.

Sample:

```c
/*[clinic input]
module _pickle
class _pickle.Pickler "PicklerObject *" "&Pickler;
[clinic start generated code]*/

/*[clinic input]
_pickle.Pickler.dump

Write a pickled representation of obj to the open
[clinic start generated code]*/
```

8. Declare each of the parameters to the function. Each parameter should get its own line. All the parameter lines should be indented from the function name and the docstring.

The general form of these parameter lines is as follows:

```
name_of_parameter: converter
```

If the parameter has a default value, add that after the converter:

```
name_of_parameter: converter = default_value
```

Argument Clinic’s support for “default values” is quite
sophisticated; please see *the section below on default values* for more information.

Add a blank line below the parameters.

What’s a “converter”? It establishes both the type of the variable used in C, and the method to convert the Python value into a C value at runtime. For now you’re going to use what’s called a “legacy converter”—a convenience syntax intended to make porting old code into Argument Clinic easier.

For each parameter, copy the “format unit” for that parameter from the `PyArg_Parse()` format argument and specify *that* as its converter, as a quoted string. ("format unit" is the formal name for the one-to-three character substring of the `format` parameter that tells the argument parsing function what the type of the variable is and how to convert it. For more on format units please see *Parsing arguments and building values.*)

For multicharacter format units like `z#`, use the entire two-or-three character string.

Sample:

```c
/*[clinic input]
module _pickle
FromClass _pickle.Pickler "PicklerObject *" "&Pickler
[clinic start generated code]*/

<!--[clinic input]
_pickle.Pickler.dump
    obj: 'O'
Write a pickled representation of obj to the open
```
9. If your function has `|` in the format string, meaning some parameters have default values, you can ignore it. Argument Clinic infers which parameters are optional based on whether or not they have default values.

If your function has `$` in the format string, meaning it takes keyword-only arguments, specify `*` on a line by itself before the first keyword-only argument, indented the same as the parameter lines.

(`_pickle.Pickler.dump` has neither, so our sample is unchanged.)

10. If the existing C function calls `PyArg_ParseTuple()` (as opposed to `PyArg_ParseTupleAndKeywords()`), then all its arguments are positional-only.

To mark all parameters as positional-only in Argument Clinic, add a `/` on a line by itself after the last parameter, indented the same as the parameter lines.

Currently this is all-or-nothing; either all parameters are positional-only, or none of them are. (In the future Argument Clinic may relax this restriction.)

Sample:
11. It's helpful to write a per-parameter docstring for each parameter. But per-parameter docstrings are optional; you can skip this step if you prefer.

Here's how to add a per-parameter docstring. The first line of the per-parameter docstring must be indented further than the parameter definition. The left margin of this first line establishes the left margin for the whole per-parameter docstring; all the text you write will be outdented by this amount. You can write as much text as you like, across multiple lines if you wish.

Sample:
Write a pickled representation of obj to the open file.

12. Save and close the file, then run Tools/clinic/clinic.py on it. With luck everything worked and your block now has output! Reopen the file in your text editor to see:

```
/*[clinic input]
module _pickle

class _pickle.Pickler "PicklerObject *" "&Pickler

/*[clinic start generated code]*/
/*[clinic end generated code: checksum=da39a3ee5e6b4b0d3255bfef95601890afd80709]

/*[clinic input]
_picklle.Pickler.dump

    obj: 'O'
        The object to be pickled.
/

Write a pickled representation of obj to the open file.

PyDoc_STRVAR(_pickle_Pickler_dump__doc__,
"Write a pickled representation of obj to the open file."
... static PyObject *
_picklle_Pickler_dump_impl(PicklerObject *self, Py

/*[clinic end generated code: checksum=3bd30745bf206a48f8b576a1da3d90f55a0a4187]
```

Obviously, if Argument Clinic didn’t produce any output, it’s because it found an error in your input. Keep fixing your errors and retrying until Argument Clinic processes your file without
complaint.

13. Double-check that the argument-parsing code Argument Clinic generated looks basically the same as the existing code.

First, ensure both places use the same argument-parsing function. The existing code must call either `PyArg_ParseTuple()` or `PyArg_ParseTupleAndKeywords()`; ensure that the code generated by Argument Clinic calls the exact same function.

Second, the format string passed in to `PyArg_ParseTuple()` or `PyArg_ParseTupleAndKeywords()` should be exactly the same as the hand-written one in the existing function, up to the colon or semi-colon.

(Argument Clinic always generates its format strings with a `:` followed by the name of the function. If the existing code’s format string ends with `;`, to provide usage help, this change is harmless—don’t worry about it.)

Third, for parameters whose format units require two arguments (like a length variable, or an encoding string, or a pointer to a conversion function), ensure that the second argument is exactly the same between the two invocations.

Fourth, inside the output portion of the block you’ll find a preprocessor macro defining the appropriate static `PyMethodDef` structure for this builtin:

```c
#define __PICKLE_PICKLER_DUMP_METHODDEF \ 
{"dump", (PyCFunction)__pickle_Pickler_dump, METH_O}
```
This static structure should be exactly the same as the existing static `PyMethodDef` structure for this builtin.

If any of these items differ in any way, adjust your Argument Clinic function specification and rerun `Tools/clinic/clinic.py` until they are the same.

14. Notice that the last line of its output is the declaration of your "impl" function. This is where the builtin’s implementation goes. Delete the existing prototype of the function you’re modifying, but leave the opening curly brace. Now delete its argument parsing code and the declarations of all the variables it dumps the arguments into. Notice how the Python arguments are now arguments to this impl function; if the implementation used different names for these variables, fix it.

Let’s reiterate, just because it’s kind of weird. Your code should now look like this:

```c
static return_type
your_function_impl(...)
/*[clinic end generated code: checksum=...]*/
{
...}
```

Argument Clinic generated the checksum line and the function prototype just above it. You should write the opening (and closing) curly braces for the function, and the implementation inside.

Sample:

```c
/*[clinic input]
module _pickle
class _pickle.Pickler "PicklerObject *" "&Pickler
```
_pickle.Pickler.dump

    obj: '0'
    The object to be pickled.

Write a pickled representation of obj to the open

PyDoc_STRVAR(__pickle_Pickler_dump__doc__, "Write a pickled representation of obj to the open"\n
... static PyObject *
_pickle_Pickler_dump_impl(PicklerObject *self, Py

{ /* Check whether the Pickler was initialized
Developers often forget to call __init__(
    would trigger a segfault without this check

    if (self->write == NULL) {
        PyErr_Format(PicklingError,
            "Pickler.__init__() was not
        Py_TYPE(self)->tp_name);

            return NULL;
        }

    if (_Pickler_ClearBuffer(self) < 0)
        return NULL;

    ...
15. Remember the macro with the **PyMethodDef** structure for this function? Find the existing **PyMethodDef** structure for this function and replace it with a reference to the macro. (If the builtin is at module scope, this will probably be very near the end of the file; if the builtin is a class method, this will probably be below but relatively near to the implementation.)

Note that the body of the macro contains a trailing comma. So when you replace the existing static **PyMethodDef** structure with the macro, *don’t* add a comma to the end.

Sample:

```c
static struct PyMethodDef Pickler_methods[] = {
    __PICKLE_PICKLER_DUMP_METHODDEF
    __PICKLE_PICKLER_CLEAR_MEMO_METHODDEF
    {NULL, NULL}  /* sentinel */
};
```

16. Compile, then run the relevant portions of the regression-test suite. This change should not introduce any new compile-time warnings or errors, and there should be no externally-visible change to Python's behavior.

Well, except for one difference: `inspect.signature()` run on your function should now provide a valid signature!

Congratulations, you’ve ported your first function to work with Argument Clinic!
Advanced Topics

Now that you've had some experience working with Argument Clinic, it's time for some advanced topics.

Symbolic default values

The default value you provide for a parameter can't be any arbitrary expression. Currently the following are explicitly supported:

- Numeric constants (integer and float)
- String constants
- `True`, `False`, and `None`
- Simple symbolic constants like `sys.maxsize`, which must start with the name of the module

In case you're curious, this is implemented in `from_builtins()` in `Lib/inspect.py`.

(In the future, this may need to get even more elaborate, to allow full expressions like `CONSTANT - 1`.)

Renaming the C functions and variables generated by Argument Clinic

Argument Clinic automatically names the functions it generates for you. Occasionally this may cause a problem, if the generated name collides with the name of an existing C function. There's an easy solution: override the names used for the C functions. Just add the keyword "as" to your function declaration line, followed by the function name you wish to use. Argument Clinic will use that function
name for the base (generated) function, then add "_impl" to the end and use that for the name of the impl function.

For example, if we wanted to rename the C function names generated for pickle.Pickler.dump, it'd look like this:

```c
/*[clinic input]
.pickle.Pickler.dump as pickler_dumper
...
```

The base function would now be named `pickler_dumper()`, and the impl function would now be named `pickler_dumper_impl()`.

Similarly, you may have a problem where you want to give a parameter a specific Python name, but that name may be inconvenient in C. Argument Clinic allows you to give a parameter different names in Python and in C, using the same "as" syntax:

```c
/*[clinic input]
pickle.Pickler.dump

    obj: object
    file as file_obj: object
    protocol: object = NULL
    *
    fix_imports: bool = True
```

Here, the name used in Python (in the signature and the keywords array) would be `file`, but the C variable would be named `file_obj`.

You can use this to rename the `self` parameter too!

Converting functions using PyArg_UnpackTuple
To convert a function parsing its arguments with `PyArg_UnpackTuple()`, simply write out all the arguments, specifying each as an object. You may specify the type argument to cast the type as appropriate. All arguments should be marked positional-only (add a / on a line by itself after the last argument).

Currently the generated code will use `PyArg_ParseTuple()`, but this will change soon.

**Optional Groups**

Some legacy functions have a tricky approach to parsing their arguments: they count the number of positional arguments, then use a switch statement to call one of several different `PyArg_ParseTuple()` calls depending on how many positional arguments there are. (These functions cannot accept keyword-only arguments.) This approach was used to simulate optional arguments back before `PyArg_ParseTupleAndKeywords()` was created.

While functions using this approach can often be converted to use `PyArg_ParseTupleAndKeywords()`, optional arguments, and default values, it's not always possible. Some of these legacy functions have behaviors `PyArg_ParseTupleAndKeywords()` doesn't directly support. The most obvious example is the built-in function `range()`, which has an optional argument on the left side of its required argument! Another example is `curses.window.addch()`, which has a group of two arguments that must always be specified together. (The arguments are called x and y; if you call the function passing in x, you must also pass in y–and if you don’t pass in x you may not pass in y either.)
In any case, the goal of Argument Clinic is to support argument parsing for all existing CPython builtins without changing their semantics. Therefore Argument Clinic supports this alternate approach to parsing, using what are called *optional groups*. Optional groups are groups of arguments that must all be passed in together. They can be to the left or the right of the required arguments. They can *only* be used with positional-only parameters.

**Note:** Optional groups are *only* intended for use when converting functions that make multiple calls to `PyArg_ParseTuple()`! Functions that use *any* other approach for parsing arguments should *almost never* be converted to Argument Clinic using optional groups. Functions using optional groups currently cannot have accurate signatures in Python, because Python just doesn’t understand the concept. Please avoid using optional groups wherever possible.

To specify an optional group, add a `[` on a line by itself before the parameters you wish to group together, and a `]` on a line by itself after these parameters. As an example, here’s how `curses.window.addch` uses optional groups to make the first two parameters and the last parameter optional:

```c
/*[clinic input]

curses.window.addch

[  
  x: int
  X-coordinate.
  y: int
  Y-coordinate.
]
```
ch: object
    Character to add.

[  
    attr: long
        Attributes for the character.
]  /

...  

Notes:

- For every optional group, one additional parameter will be passed into the impl function representing the group. The parameter will be an int named `group_{direction}_{number}`, where `{direction}` is either right or left depending on whether the group is before or after the required parameters, and `{number}` is a monotonically increasing number (starting at 1) indicating how far away the group is from the required parameters. When the impl is called, this parameter will be set to zero if this group was unused, and set to non-zero if this group was used. (By used or unused, I mean whether or not the parameters received arguments in this invocation.)
- If there are no required arguments, the optional groups will behave as if they’re to the right of the required arguments.
- In the case of ambiguity, the argument parsing code favors parameters on the left (before the required parameters).
- Optional groups can only contain positional-only parameters.
- Optional groups are only intended for legacy code. Please do not use optional groups for new code.

Using real Argument Clinic converters, instead of “legacy converters”
To save time, and to minimize how much you need to learn to achieve your first port to Argument Clinic, the walkthrough above tells you to use “legacy converters”. “Legacy converters” are a convenience, designed explicitly to make porting existing code to Argument Clinic easier. And to be clear, their use is acceptable when porting code for Python 3.4.

However, in the long term we probably want all our blocks to use Argument Clinic’s real syntax for converters. Why? A couple reasons:

- The proper converters are far easier to read and clearer in their intent.
- There are some format units that are unsupported as “legacy converters”, because they require arguments, and the legacy converter syntax doesn’t support specifying arguments.
- In the future we may have a new argument parsing library that isn’t restricted to what `PyArg_ParseTuple()` supports; this flexibility won’t be available to parameters using legacy converters.

Therefore, if you don’t mind a little extra effort, please use the normal converters instead of legacy converters.

In a nutshell, the syntax for Argument Clinic (non-legacy) converters looks like a Python function call. However, if there are no explicit arguments to the function (all functions take their default values), you may omit the parentheses. Thus `bool` and `bool()` are exactly the same converters.

All arguments to Argument Clinic converters are keyword-only. All Argument Clinic converters accept the following arguments:

```
c_default
```

The default value for this parameter when defined in C.
Specifically, this will be the initializer for the variable declared in the “parse function”. See the section on default values for how to use this. Specified as a string.

**annotation**
The annotation value for this parameter. Not currently supported, because PEP 8 mandates that the Python library may not use annotations.

In addition, some converters accept additional arguments. Here is a list of these arguments, along with their meanings:

**bitwise**
Only supported for unsigned integers. The native integer value of this Python argument will be written to the parameter without any range checking, even for negative values.

**converter**
Only supported by the object converter. Specifies the name of a C “converter function” to use to convert this object to a native type.

**encoding**
Only supported for strings. Specifies the encoding to use when converting this string from a Python str (Unicode) value into a C char * value.

**length**
Only supported for strings. If true, requests that the length of the string be passed in to the impl function, just after the string parameter, in a parameter named `<parameter_name>_length`.

**nullable**
Only supported for strings. If true, this parameter may also be set to None, in which case the C parameter will be set to NULL.
subclass_of
Only supported for the object converter. Requires that the Python value be a subclass of a Python type, as expressed in C.

types
Only supported for the object (and self) converter. Specifies the C type that will be used to declare the variable. Default value is "PyObject *".

types
A string containing a list of Python types (and possibly pseudo-types); this restricts the allowable Python argument to values of these types. (This is not a general-purpose facility; as a rule it only supports specific lists of types as shown in the legacy converter table.)

zeroes
Only supported for strings. If true, embedded NUL bytes (\0) are permitted inside the value.

Please note, not every possible combination of arguments will work. Often these arguments are implemented internally by specific PyArg_ParseTuple format units, with specific behavior. For example, currently you cannot call str and pass in zeroes=True without also specifying an encoding; although it's perfectly reasonable to think this would work, these semantics don't map to any existing format unit. So Argument Clinic doesn't support it. (Or, at least, not yet.)

Below is a table showing the mapping of legacy converters into real Argument Clinic converters. On the left is the legacy converter, on the right is the text you’d replace it with.

<p>| 'B' | unsigned_char(bitwise=True) |</p>

</table>

As an example, here's our sample `pickle.Pickler.dump` using the proper converter:

```c
/*@clinic input*/
pickle.Pickler.dump

    obj: object
    The object to be pickled.
*/
```
Argument Clinic will show you all the converters it has available. For each converter it'll show you all the parameters it accepts, along with the default value for each parameter. Just run Tools/clinic/clinic.py --converters to see the full list.

Py_buffer

When using the Py_buffer converter (or the 's*', 'w*', '*'y', or 'z*' legacy converters), you must not call PyBuffer_Release() on the provided buffer. Argument Clinic generates code that does it for you (in the parsing function).

Advanced converters

Remember those format units you skipped for your first time because they were advanced? Here's how to handle those too.

The trick is, all those format units take arguments–either conversion functions, or types, or strings specifying an encoding. (But “legacy converters” don't support arguments. That's why we skipped them for your first function.) The argument you specified to the format unit is now an argument to the converter; this argument is either converter (for O&), subclass_of (for O!), or encoding (for all the format units that start with e).

When using subclass_of, you may also want to use the other custom argument for object(): type, which lets you set the type actually used for the parameter. For example, if you want to ensure
that the object is a subclass of `PyUnicode_Type`, you probably want to use the converter `object(type='PyUnicodeObject *', subclass_of='&PyUnicode_Type')`.

One possible problem with using Argument Clinic: it takes away some possible flexibility for the format units starting with `e`. When writing a `PyArg_Parse` call by hand, you could theoretically decide at runtime what encoding string to pass in to `PyArg_ParseTuple()`. But now this string must be hard-coded at Argument-Clinic-preprocessing-time. This limitation is deliberate; it made supporting this format unit much easier, and may allow for future optimizations. This restriction doesn’t seem unreasonable; CPython itself always passes in static hard-coded encoding strings for parameters whose format units start with `e`.

**Parameter default values**

Default values for parameters can be any of a number of values. At their simplest, they can be string, int, or float literals:

```python
foo: str = "abc"
bar: int = 123
bat: float = 45.6
```

They can also use any of Python’s built-in constants:

```python
yep: bool = True
nope: bool = False
nada: object = None
```

There’s also special support for a default value of `NULL`, and for simple expressions, documented in the following sections.
The NULL default value

For string and object parameters, you can set them to None to indicate that there’s no default. However, that means the C variable will be initialized to Py_None. For convenience’s sakes, there’s a special value called NULL for just this reason: from Python’s perspective it behaves like a default value of None, but the C variable is initialized with NULL.

Expressions specified as default values

The default value for a parameter can be more than just a literal value. It can be an entire expression, using math operators and looking up attributes on objects. However, this support isn’t exactly simple, because of some non-obvious semantics.

Consider the following example:

```python
foo: Py_ssize_t = sys.maxsize - 1
```

sys.maxsize can have different values on different platforms. Therefore Argument Clinic can’t simply evaluate that expression locally and hard-code it in C. So it stores the default in such a way that it will get evaluated at runtime, when the user asks for the function’s signature.

What namespace is available when the expression is evaluated? It’s evaluated in the context of the module the builtin came from. So, if your module has an attribute called “max_widgets”, you may simply use it:
foo: Py_ssize_t = max_widgets

If the symbol isn't found in the current module, it fails over to looking in `sys.modules`. That's how it can find `sys.maxsize` for example. (Since you don't know in advance what modules the user will load into their interpreter, it's best to restrict yourself to modules that are preloaded by Python itself.)

Evaluating default values only at runtime means Argument Clinic can't compute the correct equivalent C default value. So you need to tell it explicitly. When you use an expression, you must also specify the equivalent expression in C, using the `c_default` parameter to the converter:

```python
foo: Py_ssize_t(c_default="PY_SSIZE_T_MAX - 1") = sys
```

Another complication: Argument Clinic can't know in advance whether or not the expression you supply is valid. It parses it to make sure it looks legal, but it can't actually know. You must be very careful when using expressions to specify values that are guaranteed to be valid at runtime!

Finally, because expressions must be representable as static C values, there are many restrictions on legal expressions. Here's a list of Python features you're not permitted to use:

- Function calls.
- Inline if statements (`3 if foo else 5`).
- Automatic sequence unpacking (`*[1, 2, 3]`).
- List/set/dict comprehensions and generator expressions.
- Tuple/list/set/dict literals.
Using a return converter

By default the impl function Argument Clinic generates for you returns `PyObject *`. But your C function often computes some C type, then converts it into the `PyObject *` at the last moment. Argument Clinic handles converting your inputs from Python types into native C types—why not have it convert your return value from a native C type into a Python type too?

That’s what a “return converter” does. It changes your impl function to return some C type, then adds code to the generated (non-impl) function to handle converting that value into the appropriate `PyObject *`.

The syntax for return converters is similar to that of parameter converters. You specify the return converter like it was a return annotation on the function itself. Return converters behave much the same as parameter converters; they take arguments, the arguments are all keyword-only, and if you’re not changing any of the default arguments you can omit the parentheses.

(If you use both "as" and a return converter for your function, the "as" should come before the return converter.)

There’s one additional complication when using return converters: how do you indicate an error has occurred? Normally, a function returns a valid (non-NULL) pointer for success, and NULL for failure. But if you use an integer return converter, all integers are valid. How can Argument Clinic detect an error? Its solution: each return converter implicitly looks for a special value that indicates an error. If you return that value, and an error has been set (`PyErr_Occurred()` returns a true value), then the generated code will propagate the error.
Otherwise it will encode the value you return like normal.

Currently Argument Clinic supports only a few return converters:

```python
bool
int
unsigned int
long
unsigned int
size_t
Py_ssize_t
float
double
DecodeFSDefault
```

None of these take parameters. For the first three, return -1 to indicate error. For `DecodeFSDefault`, the return type is `char *`; return a NULL pointer to indicate an error.

(There’s also an experimental `NoneType` converter, which lets you return `Py_None` on success or `NULL` on failure, without having to increment the reference count on `Py_None`. I’m not sure it adds enough clarity to be worth using.)

To see all the return converters Argument Clinic supports, along with their parameters (if any), just run `Tools/clinic/clinic.py --converters` for the full list.

**Cloning existing functions**

If you have a number of functions that look similar, you may be able to use Clinic’s “clone” feature. When you clone an existing function, you reuse:
• its parameters, including
  ◦ their names,
  ◦ their converters, with all parameters,
  ◦ their default values,
  ◦ their per-parameter docstrings,
  ◦ their *kind* (whether they're positional only, positional or keyword, or keyword only), and
• its return converter.

The only thing not copied from the original function is its docstring; the syntax allows you to specify a new docstring.

Here's the syntax for cloning a function:

```plaintext
/*[clinic input]*/
module.class.new_function [as c_basename] = module.class.

Docstring for new_function goes here.
[clinic start generated code]*/
```

(The functions can be in different modules or classes. I wrote `module.class` in the sample just to illustrate that you must use the full path to both functions.)

Sorry, there's no syntax for partially-cloning a function, or cloning a function then modifying it. Cloning is an all-or nothing proposition.

Also, the function you are cloning from must have been previously defined in the current file.

**Calling Python code**

The rest of the advanced topics require you to write Python code
which lives inside your C file and modifies Argument Clinic's runtime state. This is simple: you simply define a Python block.

A Python block uses different delimiter lines than an Argument Clinic function block. It looks like this:

```*/
/*[python input]
# python code goes here
[python start generated code]*/
```

All the code inside the Python block is executed at the time it's parsed. All text written to stdout inside the block is redirected into the “output” after the block.

As an example, here’s a Python block that adds a static integer variable to the C code:

```*/
/*[python input]
print('static int __ignored_unused_variable__ = 0;')
[python start generated code]*/
static int __ignored_unused_variable__ = 0;
/*[python checksum:...]*/
```

Using a “self converter”

Argument Clinic automatically adds a “self” parameter for you using a default converter. It automatically sets the type of this parameter to the “pointer to an instance” you specified when you declared the type. However, you can override Argument Clinic’s converter and specify one yourself. Just add your own self parameter as the first parameter in a block, and ensure that its converter is an instance of self_converter or a subclass thereof.
What's the point? This lets you override the type of `self`, or give it a different default name.

How do you specify the custom type you want to cast `self` to? If you only have one or two functions with the same type for `self`, you can directly use Argument Clinic's existing `self` converter, passing in the type you want to use as the `type` parameter:

```cpp
/*[clinic input]
_pickle.Pickler.dump
    self: self(type="PicklerObject *")
    obj: object
/
Write a pickled representation of the given object to
[clinic start generated code]*/
```

On the other hand, if you have a lot of functions that will use the same type for `self`, it's best to create your own converter, subclassing `self_converter` but overwriting the `type` member:

```cpp
/*[python input]
class PicklerObject_converter(self_converter):
    type = "PicklerObject *
[python start generated code]*/
```

```cpp
/*[clinic input]
_pickle.Pickler.dump
    self: PicklerObject
    obj: object
```
Write a pickled representation of the given object to [clinic start generated code]*/

Writing a custom converter

As we hinted at in the previous section... you can write your own converters! A converter is simply a Python class that inherits from CConverter. The main purpose of a custom converter is if you have a parameter using the O& format unit–parsing this parameter means calling a PyArg_ParseTuple() “converter function”.

Your converter class should be named *something*_converter. If the name follows this convention, then your converter class will be automatically registered with Argument Clinic; its name will be the name of your class with the _converter suffix stripped off. (This is accomplished with a metaclass.)

You shouldn’t subclass CConverter.__init__. Instead, you should write a converter_init() function. converter_init() always accepts a self parameter; after that, all additional parameters must be keyword-only. Any arguments passed in to the converter in Argument Clinic will be passed along to your converter_init().

There are some additional members of CConverter you may wish to specify in your subclass. Here’s the current list:

**type**

The C type to use for this variable. type should be a Python string specifying the type, e.g. int. If this is a pointer type, the type string should end with '*'.

/*
**default**
The Python default value for this parameter, as a Python value. Or the magic value unspecified if there is no default.

**py_default**
default as it should appear in Python code, as a string. Or None if there is no default.

**c_default**
default as it should appear in C code, as a string. Or None if there is no default.

**c_ignored_default**
The default value used to initialize the C variable when there is no default, but not specifying a default may result in an “uninitialized variable” warning. This can easily happen when using option groups–although properly-written code will never actually use this value, the variable does get passed in to the impl, and the C compiler will complain about the “use” of the uninitialized value. This value should always be a non-empty string.

**converter**
The name of the C converter function, as a string.

**impl_by_reference**
A boolean value. If true, Argument Clinic will add a & in front of the name of the variable when passing it into the impl function.

**parse_by_reference**
A boolean value. If true, Argument Clinic will add a & in front of the name of the variable when passing it into PyArg_ParseTuple().

Here's the simplest example of a custom converter, from Modules/zlibmodule.c:

```c
/*[python input]

class uint_converter(CConverter):
```
This block adds a converter to Argument Clinic named `uint`. Parameters declared as `uint` will be declared as type `unsigned int`, and will be parsed by the `'0&'` format unit, which will call the `uint_converter` converter function. `uint` variables automatically support default values.

More sophisticated custom converters can insert custom C code to handle initialization and cleanup. You can see more examples of custom converters in the CPython source tree; grep the C files for the string `CConverter`.

### Writing a custom return converter

Writing a custom return converter is much like writing a custom converter. Except it’s somewhat simpler, because return converters are themselves much simpler.

Return converters must subclass `CReturnConverter`. There are no examples yet of custom return converters, because they are not widely used yet. If you wish to write your own return converter, please read `Tools/clinic/clinic.py`, specifically the implementation of `CReturnConverter` and all its subclasses.

**METH_O and METH_NOARGS**
To convert a function using METH_O, make sure the function’s single argument is using the object converter, and mark the arguments as positional-only:

```c
/*[clinic input]
meth_o_sample
   argument: object
*/
```

To convert a function using METH_NOARGS, just don’t specify any arguments.

You can still use a self converter, a return converter, and specify a type argument to the object converter for METH_O.

**tp_new and tp_init functions**

You can convert `tp_new` and `tp_init` functions. Just name them `__new__` or `__init__` as appropriate. Notes:

- The function name generated for `__new__` doesn’t end in `__new__` like it would by default. It’s just the name of the class, converted into a valid C identifier.
- No PyMethodDef `#define` is generated for these functions.
- `__init__` functions return `int`, not `PyObject *`.
- Use the docstring as the class docstring.
- Although `__new__` and `__init__` functions must always accept both the `args` and `kwargs` objects, when converting you may specify any signature for these functions that you like. (If your function doesn’t support keywords, the parsing function generated will throw an exception if it receives any.)
Changing and redirecting Clinic’s output

It can be inconvenient to have Clinic’s output interspersed with your conventional hand-edited C code. Luckily, Clinic is configurable: you can buffer up its output for printing later (or earlier!), or write its output to a separate file. You can also add a prefix or suffix to every line of Clinic’s generated output.

While changing Clinic's output in this manner can be a boon to readability, it may result in Clinic code using types before they are defined, or your code attempting to use Clinic-generated code before it is defined. These problems can be easily solved by rearranging the declarations in your file, or moving where Clinic’s generated code goes. (This is why the default behavior of Clinic is to output everything into the current block; while many people consider this hampers readability, it will never require rearranging your code to fix definition-before-use problems.)

Let’s start with defining some terminology:

field
A field, in this context, is a subsection of Clinic’s output. For example, the `#define` for the `PyMethodDef` structure is a field, called `methoddef_define`. Clinic has seven different fields it can output per function definition:

```
docstring_prototype
docstring_definition
methoddef_define
impl_prototype
parser_prototype
parser_definition
impl_definition
```
All the names are of the form "<a>_<b>" where "<a>" is the semantic object represented (the parsing function, the impl function, the docstring, or the methoddef structure) and "<b>" represents what kind of statement the field is. Field names that end in "_prototype" represent forward declarations of that thing, without the actual body/data of the thing; field names that end in "_definition" represent the actual definition of the thing, with the body/data of the thing. ("methoddef" is special, it's the only one that ends with "_define", representing that it's a preprocessor #define.)

**destination**

A destination is a place Clinic can write output to. There are five built-in destinations:

**block**

The default destination: printed in the output section of the current Clinic block.

**buffer**

A text buffer where you can save text for later. Text sent here is appended to the end of any existing text. It’s an error to have any text left in the buffer when Clinic finishes processing a file.

**file**

A separate “clinic file” that will be created automatically by Clinic. The filename chosen for the file is `{basename}.clinic{extension}`, where basename and extension were assigned the output from os.path.splitext() run on the current file. (Example: the file destination for _pickle.c would be written to _pickle.clinic.c.)
Important: When using a **file** destination, you *must check in the generated file!*

**two-pass**
A buffer like `buffer`. However, a two-pass buffer can only be written once, and it prints out all text sent to it during all of processing, even from Clinic blocks *after* the

**suppress**
The text is suppressed–thrown away.

Clinic defines five new directives that let you reconfigure its output.

The first new directive is **dump**:

```
dump <destination>
```

This dumps the current contents of the named destination into the output of the current block, and empties it. This only works with `buffer` and **two-pass** destinations.

The second new directive is **output**. The most basic form of **output** is like this:

```
output <field> <destination>
```

This tells Clinic to output `field` to `destination`. **output** also supports a special meta-destination, called **everything**, which tells Clinic to output *all* fields to that `destination`.

**output** has a number of other functions:

```
output push
output pop
```
output preset <preset>

output push and output pop allow you to push and pop configurations on an internal configuration stack, so that you can temporarily modify the output configuration, then easily restore the previous configuration. Simply push before your change to save the current configuration, then pop when you wish to restore the previous configuration.

output preset sets Clinic's output to one of several built-in preset configurations, as follows:

**block**

Clinic’s original starting configuration. Writes everything immediately after the input block.

Suppress the parser_prototype and docstring_prototype, write everything else to block.

**file**

Designed to write everything to the “clinic file” that it can. You then #include this file near the top of your file. You may need to rearrange your file to make this work, though usually this just means creating forward declarations for various typedef and PyTypeObject definitions.

Suppress the parser_prototype and docstring_prototype, write the impl_definition to block, and write everything else to file.

The default filename is " {dirname}/clinic/{basename}.h".
buffer

Save up all most of the output from Clinic, to be written into your file near the end. For Python files implementing modules or builtin types, it's recommended that you dump the buffer just above the static structures for your module or builtin type; these are normally very near the end. Using buffer may require even more editing than file, if your file has static PyMethodDef arrays defined in the middle of the file.

Suppress the parser_prototype, impl_prototype, and docstring_prototype, write the impl_definition to block, and write everything else to file.

two-pass

Similar to the buffer preset, but writes forward declarations to the two-pass buffer, and definitions to the buffer. This is similar to the buffer preset, but may require less editing than buffer. Dump the two-pass buffer near the top of your file, and dump the buffer near the end just like you would when using the buffer preset.

Suppresses the impl_prototype, write the impl_definition to block, write docstring_prototype, methoddef_define, and parser_prototype to two-pass, write everything else to buffer.

partial-buffer

Similar to the buffer preset, but writes more things to block, only writing the really big chunks of generated code to buffer. This avoids the definition-before-use problem of buffer completely, at the small cost of having slightly more
stuff in the block’s output. Dump the buffer near the end, just like you would when using the buffer preset.

Suppresses the impl_prototype, write the docstring_definition and parser_defintion to buffer, write everything else to block.

The third new directive is destination:

```plaintext
destination <name> <command> [...]
```

This performs an operation on the destination named `<name>`.

There are two defined subcommands: new and clear.

The `new` subcommand works like this:

```plaintext
destination <name> new <type>
```

This creates a new destination with name `<name>` and type `<type>`.

There are five destination types:

- `suppress`
  - Throws the text away.
- `block`
  - Writes the text to the current block. This is what Clinic originally did.
- `buffer`
  - A simple text buffer, like the “buffer” builtin destination above.
- `file`
  - A text file. The file destination takes an extra argument, a template to use for building the filename, like so:
destination <name> new <type> <file_template>

The template can use three strings internally that will be replaced by bits of the filename:

{path}
The full path to the file, including directory and full filename.

{dirname}
The name of the directory the file is in.

{basename}
Just the name of the file, not including the directory.

{basename_root}
Basename with the extension clipped off (everything up to but not including the last ‘.’).

{basename_extension}
The last ‘.’ and everything after it. If the basename does not contain a period, this will be the empty string.

If there are no periods in the filename, {basename} and {filename} are the same, and {extension} is empty. “{basename}{extension}” is always exactly the same as “{filename}”.

two-pass
A two-pass buffer, like the “two-pass” builtin destination above.

The clear subcommand works like this:

destination <name> clear

It removes all the accumulated text up to this point in the destination. (I
don’t know what you’d need this for, but I thought maybe it’d be useful while someone’s experimenting.)

The fourth new directive is set:

```plaintext
set line_prefix "string"
set line_suffix "string"
```

set lets you set two internal variables in Clinic. line_prefix is a string that will be prepended to every line of Clinic’s output; line_suffix is a string that will be appended to every line of Clinic’s output.

Both of these support two format strings:

```
{block comment start}
  Turns into the string /*, the start-comment text sequence for C files.
{block comment end}
  Turns into the string */, the end-comment text sequence for C files.
```

The final new directive is one you shouldn’t need to use directly, called preserve:

```
preserve
```

This tells Clinic that the current contents of the output should be kept, unmodified. This is used internally by Clinic when dumping output into file files; wrapping it in a Clinic block lets Clinic use its existing checksum functionality to ensure the file was not modified by hand before it gets overwritten.
The #ifdef trick

If you’re converting a function that isn’t available on all platforms, there’s a trick you can use to make life a little easier. The existing code probably looks like this:

```c
#ifdef HAVE_FUNCTIONNAME
static module_functionname(...)
{
...
}
#endif /* HAVE_FUNCTIONNAME */
```

And then in the PyMethodDef structure at the bottom the existing code will have:

```c
#ifdef HAVE_FUNCTIONNAME
{ 'functionname', ... },
#endif /* HAVE_FUNCTIONNAME */
```

In this scenario, you should enclose the body of your impl function inside the #ifdef, like so:

```c
#ifdef HAVE_FUNCTIONNAME
/*[clinic input]
module.functionname
...
[clinic start generated code]*/
static module_functionname(...)
{
...
}
#endif /* HAVE_FUNCTIONNAME */
```
Then, remove those three lines from the `PyMethodDef` structure, replacing them with the macro Argument Clinic generated:

```
MODULE_FUNCTIONNAME_METHODDEF
```

(You can find the real name for this macro inside the generated code. Or you can calculate it yourself: it's the name of your function as defined on the first line of your block, but with periods changed to underscores, uppercased, and "_METHODDEF" added to the end.)

Perhaps you're wondering: what if `HAVE_FUNCTIONNAME` isn't defined? The `MODULE_FUNCTIONNAME_METHODDEF` macro won't be defined either!

Here's where Argument Clinic gets very clever. It actually detects that the Argument Clinic block might be deactivated by the `#ifdef`. When that happens, it generates a little extra code that looks like this:

```
#ifndef MODULE_FUNCTIONNAME_METHODDEF
#define MODULE_FUNCTIONNAME_METHODDEF
#endif /* !defined(MODULE_FUNCTIONNAME_METHODDEF) */
```

That means the macro always works. If the function is defined, this turns into the correct structure, including the trailing comma. If the function is undefined, this turns into nothing.

However, this causes one ticklish problem: where should Argument Clinic put this extra code when using the “block” output preset? It can’t go in the output block, because that could be decativated by the `#ifdef`. (That's the whole point!)

In this situation, Argument Clinic writes the extra code to the “buffer” destination. This may mean that you get a complaint from Argument
Clinic:

Warning in file "Modules/posixmodule.c" on line 12357
Destination buffer 'buffer' not empty at end of file

When this happens, just open your file, find the dump buffer block that Argument Clinic added to your file (it'll be at the very bottom), then move it above the PyMethodDef structure where that macro is used.

Using Argument Clinic in Python files

It's actually possible to use Argument Clinic to preprocess Python files. There's no point to using Argument Clinic blocks, of course, as the output wouldn't make any sense to the Python interpreter. But using Argument Clinic to run Python blocks lets you use Python as a Python preprocessor!

Since Python comments are different from C comments, Argument Clinic blocks embedded in Python files look slightly different. They look like this:

```python
#/*[python input]
#print("def foo(): pass")
#[python start generated code]*/
def foo(): pass
#/*[python checksum:...]*/
```

General Information

What is Python?

Python is an interpreted, interactive, object-oriented programming language. It incorporates modules, exceptions, dynamic typing, very high level dynamic data types, and classes. Python combines remarkable power with very clear syntax. It has interfaces to many system calls and libraries, as well as to various window systems, and is extensible in C or C++. It is also usable as an extension language for applications that need a programmable interface. Finally, Python is portable: it runs on many Unix variants, on the Mac, and on Windows 2000 and later.

To find out more, start with The Python Tutorial. The Beginner’s Guide to Python links to other introductory tutorials and resources for learning Python.

What is the Python Software Foundation?

The Python Software Foundation is an independent non-profit organization that holds the copyright on Python versions 2.1 and newer. The PSF’s mission is to advance open source technology related to the Python programming language and to publicize the use of Python. The PSF’s home page is at http://www.python.org/psf/.

Donations to the PSF are tax-exempt in the US. If you use Python and find it helpful, please contribute via the PSF donation page.

Are there copyright restrictions on the use of Python?
You can do anything you want with the source, as long as you leave the copyrights in and display those copyrights in any documentation about Python that you produce. If you honor the copyright rules, it's OK to use Python for commercial use, to sell copies of Python in source or binary form (modified or unmodified), or to sell products that incorporate Python in some form. We would still like to know about all commercial use of Python, of course.

See the PSF license page to find further explanations and a link to the full text of the license.

The Python logo is trademarked, and in certain cases permission is required to use it. Consult the Trademark Usage Policy for more information.

**Why was Python created in the first place?**

Here's a *very* brief summary of what started it all, written by Guido van Rossum:

I had extensive experience with implementing an interpreted language in the ABC group at CWI, and from working with this group I had learned a lot about language design. This is the origin of many Python features, including the use of indentation for statement grouping and the inclusion of very-high-level data types (although the details are all different in Python).

I had a number of gripes about the ABC language, but also liked many of its features. It was impossible to extend the ABC language (or its implementation) to remedy my complaints – in fact its lack of extensibility was one of its biggest problems. I had some experience with using Modula-2+ and talked with the designers of Modula-3 and read the Modula-3 report. Modula-3 is
the origin of the syntax and semantics used for exceptions, and some other Python features.

I was working in the Amoeba distributed operating system group at CWI. We needed a better way to do system administration than by writing either C programs or Bourne shell scripts, since Amoeba had its own system call interface which wasn't easily accessible from the Bourne shell. My experience with error handling in Amoeba made me acutely aware of the importance of exceptions as a programming language feature.

It occurred to me that a scripting language with a syntax like ABC but with access to the Amoeba system calls would fill the need. I realized that it would be foolish to write an Amoeba-specific language, so I decided that I needed a language that was generally extensible.

During the 1989 Christmas holidays, I had a lot of time on my hand, so I decided to give it a try. During the next year, while still mostly working on it in my own time, Python was used in the Amoeba project with increasing success, and the feedback from colleagues made me add many early improvements.

In February 1991, after just over a year of development, I decided to post to USENET. The rest is in the Misc/HISTORY file.

What is Python good for?

Python is a high-level general-purpose programming language that can be applied to many different classes of problems.

The language comes with a large standard library that covers areas such as string processing (regular expressions, Unicode, calculating
differences between files), Internet protocols (HTTP, FTP, SMTP, XML-RPC, POP, IMAP, CGI programming), software engineering (unit testing, logging, profiling, parsing Python code), and operating system interfaces (system calls, filesystems, TCP/IP sockets). Look at the table of contents for *The Python Standard Library* to get an idea of what’s available. A wide variety of third-party extensions are also available. Consult *the Python Package Index* to find packages of interest to you.

**How does the Python version numbering scheme work?**

Python versions are numbered A.B.C or A.B. A is the major version number – it is only incremented for really major changes in the language. B is the minor version number, incremented for less earth-shattering changes. C is the micro-level – it is incremented for each bugfix release. See [PEP 6](https://www.python.org/dev/peps/pep-0006/) for more information about bugfix releases.

Not all releases are bugfix releases. In the run-up to a new major release, a series of development releases are made, denoted as alpha, beta, or release candidate. Alphas are early releases in which interfaces aren’t yet finalized; it’s not unexpected to see an interface change between two alpha releases. Betas are more stable, preserving existing interfaces but possibly adding new modules, and release candidates are frozen, making no changes except as needed to fix critical bugs.

Alpha, beta and release candidate versions have an additional suffix. The suffix for an alpha version is “aN” for some small number N, the suffix for a beta version is “bN” for some small number N, and the suffix for a release candidate version is “cN” for some small number N. In other words, all versions labeled 2.0aN precede the versions
labeled 2.0bN, which precede versions labeled 2.0cN, and those precede 2.0.

You may also find version numbers with a “+” suffix, e.g. “2.2+”. These are unreleased versions, built directly from the Subversion trunk. In practice, after a final minor release is made, the Subversion trunk is incremented to the next minor version, which becomes the “a0” version, e.g. “2.4a0”.

See also the documentation for `sys.version`, `sys.hexversion`, and `sys.version_info`.

**How do I obtain a copy of the Python source?**

The source distribution is a gzipped tar file containing the complete C source, Sphinx-formatted documentation, Python library modules, example programs, and several useful pieces of freely distributable software. The source will compile and run out of the box on most UNIX platforms.

Consult the Developer FAQ for more information on getting the source code and compiling it.

**How do I get documentation on Python?**

The standard documentation for the current stable version of Python is available at [http://docs.python.org/](http://docs.python.org/). PDF, plain text, and downloadable
HTML versions are also available at http://docs.python.org/download.html.

The documentation is written in reStructuredText and processed by the Sphinx documentation tool. The reStructuredText source for the documentation is part of the Python source distribution.

I’ve never programmed before. Is there a Python tutorial?

There are numerous tutorials and books available. The standard documentation includes The Python Tutorial.

Consult the Beginner’s Guide to find information for beginning Python programmers, including lists of tutorials.

Is there a newsgroup or mailing list devoted to Python?

There is a newsgroup, comp.lang.python, and a mailing list, python-list. The newsgroup and mailing list are gatewayed into each other – if you can read news it’s unnecessary to subscribe to the mailing list. comp.lang.python is high-traffic, receiving hundreds of postings every day, and Usenet readers are often more able to cope with this volume.

Announcements of new software releases and events can be found in comp.lang.python.announce, a low-traffic moderated list that receives about five postings per day. It’s available as the python-announce mailing list.

More info about other mailing lists and newsgroups can be found at http://www.python.org/community/lists/.
How do I get a beta test version of Python?

Alpha and beta releases are available from http://www.python.org/download/. All releases are announced on the comp.lang.python and comp.lang.python.announce newsgroups and on the Python home page at http://www.python.org/; an RSS feed of news is available.

You can also access the development version of Python through Subversion. See http://docs.python.org/devguide/faq for details.

How do I submit bug reports and patches for Python?

To report a bug or submit a patch, please use the Roundup installation at http://bugs.python.org/.

You must have a Roundup account to report bugs; this makes it possible for us to contact you if we have follow-up questions. It will also enable Roundup to send you updates as we act on your bug. If you had previously used SourceForge to report bugs to Python, you can obtain your Roundup password through Roundup’s password reset procedure.

For more information on how Python is developed, consult the Python Developer’s Guide.

Are there any published articles about Python that I can reference?

It’s probably best to cite your favorite book about Python.
The very first article about Python was written in 1991 and is now quite outdated.

Are there any books on Python?

Yes, there are many, and more are being published. See the python.org wiki at http://wiki.python.org/moin/PythonBooks for a list.

You can also search online bookstores for “Python” and filter out the Monty Python references; or perhaps search for “Python” and “language”.

Where in the world is www.python.org located?

The Python project’s infrastructure is located all over the world. www.python.org is currently in Amsterdam, graciously hosted by XS4ALL. Upfront Systems hosts bugs.python.org. Most other Python services like PyPI and hg.python.org are hosted by Oregon State University Open Source Lab.

Why is it called Python?

When he began implementing Python, Guido van Rossum was also reading the published scripts from “Monty Python's Flying Circus”, a BBC comedy series from the 1970s. Van Rossum thought he needed a name that was short, unique, and slightly mysterious, so he decided to call the language Python.
Do I have to like “Monty Python’s Flying Circus”?

No, but it helps. :)

Python in the real world

How stable is Python?

Very stable. New, stable releases have been coming out roughly every 6 to 18 months since 1991, and this seems likely to continue. Currently there are usually around 18 months between major releases.

The developers issue “bugfix” releases of older versions, so the stability of existing releases gradually improves. Bugfix releases, indicated by a third component of the version number (e.g. 2.5.3, 2.6.2), are managed for stability; only fixes for known problems are included in a bugfix release, and it’s guaranteed that interfaces will remain the same throughout a series of bugfix releases.

The latest stable releases can always be found on the Python download page. There are two recommended production-ready versions at this point in time, because at the moment there are two branches of stable releases: 2.x and 3.x. Python 3.x may be less useful than 2.x, since currently there is more third party software available for Python 2 than for Python 3. Python 2 code will generally not run unchanged in Python 3.

How many people are using Python?

There are probably tens of thousands of users, though it’s difficult to obtain an exact count.

Python is available for free download, so there are no sales figures, and it’s available from many different sites and packaged with many Linux distributions, so download statistics don’t tell the whole story either.
The comp.lang.python newsgroup is very active, but not all Python users post to the group or even read it.

**Have any significant projects been done in Python?**

See [http://python.org/about/success](http://python.org/about/success) for a list of projects that use Python. Consulting the proceedings for past Python conferences will reveal contributions from many different companies and organizations.

High-profile Python projects include the Mailman mailing list manager and the Zope application server. Several Linux distributions, most notably Red Hat, have written part or all of their installer and system administration software in Python. Companies that use Python internally include Google, Yahoo, and Lucasfilm Ltd.

**What new developments are expected for Python in the future?**

See [http://www.python.org/dev/peps/](http://www.python.org/dev/peps/) for the Python Enhancement Proposals (PEPs). PEPs are design documents describing a suggested new feature for Python, providing a concise technical specification and a rationale. Look for a PEP titled “Python X.Y Release Schedule”, where X.Y is a version that hasn’t been publicly released yet.

New development is discussed on the python-dev mailing list.

**Is it reasonable to propose incompatible changes to Python?**
In general, no. There are already millions of lines of Python code around the world, so any change in the language that invalidates more than a very small fraction of existing programs has to be frowned upon. Even if you can provide a conversion program, there’s still the problem of updating all documentation; many books have been written about Python, and we don’t want to invalidate them all at a single stroke.

Providing a gradual upgrade path is necessary if a feature has to be changed. **PEP 5** describes the procedure followed for introducing backward-incompatible changes while minimizing disruption for users.

**Is Python Y2K (Year 2000) Compliant?**

As of August, 2003 no major problems have been reported and Y2K compliance seems to be a non-issue.

Python does very few date calculations and for those it does perform relies on the C library functions. Python generally represents times either as seconds since 1970 or as a `(year, month, day, ...)` tuple where the year is expressed with four digits, which makes Y2K bugs unlikely. So as long as your C library is okay, Python should be okay. Of course, it’s possible that a particular application written in Python makes assumptions about 2-digit years.

Because Python is available free of charge, there are no absolute guarantees. If there are unforeseen problems, liability is the user’s problem rather than the developers’, and there is nobody you can sue for damages. The Python copyright notice contains the following disclaimer:

4. PSF is making Python 2.3 available to Licensee on an “AS IS” basis. PSF MAKES NO REPRESENTATIONS OR WARRANTIES,
EXPRESS OR IMPLIED. BY WAY OF EXAMPLE, BUT NOT LIMITATION, PSF MAKES NO AND DISCLAIMS ANY REPRESENTATION OR WARRANTY OF MERCHANTABILITY OR FITNESS FOR ANY PARTICULAR PURPOSE OR THAT THE USE OF PYTHON 2.3 WILL NOT INFRINGE ANY THIRD PARTY RIGHTS.

5. PSF SHALL NOT BE LIABLE TO LICENSEE OR ANY OTHER USERS OF PYTHON 2.3 FOR ANY INCIDENTAL, SPECIAL, OR CONSEQUENTIAL DAMAGES OR LOSS AS A RESULT OF MODIFYING, DISTRIBUTING, OR OTHERWISE USING PYTHON 2.3, OR ANY DERIVATIVE THEREOF, EVEN IF ADVISED OF THE POSSIBILITY THEREOF.

The good news is that if you encounter a problem, you have full source available to track it down and fix it. This is one advantage of an open source programming environment.

Is Python a good language for beginning programmers?

Yes.

It is still common to start students with a procedural and statically typed language such as Pascal, C, or a subset of C++ or Java. Students may be better served by learning Python as their first language. Python has a very simple and consistent syntax and a large standard library and, most importantly, using Python in a beginning programming course lets students concentrate on important programming skills such as problem decomposition and data type design. With Python, students can be quickly introduced to basic concepts such as loops and procedures. They can probably even work
with user-defined objects in their very first course.

For a student who has never programmed before, using a statically typed language seems unnatural. It presents additional complexity that the student must master and slows the pace of the course. The students are trying to learn to think like a computer, decompose problems, design consistent interfaces, and encapsulate data. While learning to use a statically typed language is important in the long term, it is not necessarily the best topic to address in the students' first programming course.

Many other aspects of Python make it a good first language. Like Java, Python has a large standard library so that students can be assigned programming projects very early in the course that do something. Assignments aren't restricted to the standard four-function calculator and check balancing programs. By using the standard library, students can gain the satisfaction of working on realistic applications as they learn the fundamentals of programming. Using the standard library also teaches students about code reuse. Third-party modules such as PyGame are also helpful in extending the students' reach.

Python's interactive interpreter enables students to test language features while they're programming. They can keep a window with the interpreter running while they enter their program's source in another window. If they can't remember the methods for a list, they can do something like this:

```python
>>> L = []
>>> dir(L)
['append', 'count', 'extend', 'index', 'insert', 'pop', 'remove', 'reverse', 'sort']
>>> help(L.append)
```
Help on built-in function append:

```python
append(...)  
L.append(object) -- append object to end
```  
```python
>>> L.append(1)
>>> L
[1]
```

With the interpreter, documentation is never far from the student as he’s programming.

There are also good IDEs for Python. IDLE is a cross-platform IDE for Python that is written in Python using Tkinter. PythonWin is a Windows-specific IDE. Emacs users will be happy to know that there is a very good Python mode for Emacs. All of these programming environments provide syntax highlighting, auto-indenting, and access to the interactive interpreter while coding. Consult the Python wiki for a full list of Python editing environments.

If you want to discuss Python’s use in education, you may be interested in joining the edu-sig mailing list.

General Questions

Is there a source code level debugger with breakpoints, single-stepping, etc.?

Yes.

The pdb module is a simple but adequate console-mode debugger for Python. It is part of the standard Python library, and is documented in the Library Reference Manual. You can also write your own debugger by using the code for pdb as an example.

The IDLE interactive development environment, which is part of the standard Python distribution (normally available as Tools/scripts/idle), includes a graphical debugger. There is documentation for the IDLE debugger at http://www.python.org/idle/doc/idle2.html#Debugger.

PythonWin is a Python IDE that includes a GUI debugger based on pdb. The Pythonwin debugger colors breakpoints and has quite a few cool features such as debugging non-Pythonwin programs. Pythonwin is available as part of the Python for Windows Extensions project and as a part of the ActivePython distribution (see http://www.activestate.com/Products/ActivePython/index.html).

Boa Constructor is an IDE and GUI builder that uses wxWidgets. It offers visual frame creation and manipulation, an object inspector, many views on the source like object browsers, inheritance hierarchies, doc string generated html documentation, an advanced debugger, integrated help, and Zope support.

Eric is an IDE built on PyQt and the Scintilla editing component.
Pydb is a version of the standard Python debugger pdb, modified for use with DDD (Data Display Debugger), a popular graphical debugger front end. Pydb can be found at http://bashdb.sourceforge.net/pydb/ and DDD can be found at http://www.gnu.org/software/ddd.

There are a number of commercial Python IDEs that include graphical debuggers. They include:

- Wing IDE (http://wingware.com/)
- Komodo IDE (http://www.activestate.com/Products/Komodo)

**Is there a tool to help find bugs or perform static analysis?**

Yes.

PyChecker is a static analysis tool that finds bugs in Python source code and warns about code complexity and style. You can get PyChecker from http://pychecker.sf.net.

Pylint is another tool that checks if a module satisfies a coding standard, and also makes it possible to write plug-ins to add a custom feature. In addition to the bug checking that PyChecker performs, Pylint offers some additional features such as checking line length, whether variable names are well-formed according to your coding standard, whether declared interfaces are fully implemented, and more. http://www.logilab.org/card/pylint_manual provides a full list of Pylint’s features.

**How can I create a stand-alone binary from a Python script?**
You don’t need the ability to compile Python to C code if all you want is a stand-alone program that users can download and run without having to install the Python distribution first. There are a number of tools that determine the set of modules required by a program and bind these modules together with a Python binary to produce a single executable.

One is to use the freeze tool, which is included in the Python source tree as `Tools/freeze`. It converts Python byte code to C arrays; a C compiler you can embed all your modules into a new program, which is then linked with the standard Python modules.

It works by scanning your source recursively for import statements (in both forms) and looking for the modules in the standard Python path as well as in the source directory (for built-in modules). It then turns the bytecode for modules written in Python into C code (array initializers that can be turned into code objects using the marshal module) and creates a custom-made config file that only contains those built-in modules which are actually used in the program. It then compiles the generated C code and links it with the rest of the Python interpreter to form a self-contained binary which acts exactly like your script.

Obviously, freeze requires a C compiler. There are several other utilities which don’t. One is Thomas Heller’s py2exe (Windows only) at

http://www.py2exe.org/

Another is Christian Tismer’s SQFREEZE which appends the byte code to a specially-prepared Python interpreter that can find the byte code in the executable.

Other tools include Fredrik Lundh’s Squeeze and Anthony Tuininga’s
Are there coding standards or a style guide for Python programs?

Yes. The coding style required for standard library modules is documented as **PEP 8**.
Core Language

Why am I getting an UnboundLocalError when the variable has a value?

It can be a surprise to get the UnboundLocalError in previously working code when it is modified by adding an assignment statement somewhere in the body of a function.

This code:

```python
>>> x = 10
>>> def bar():
...     print(x)
>>> bar()
10
```

works, but this code:

```python
>>> x = 10
>>> def foo():
...     print(x)
...     x += 1
```

results in an UnboundLocalError:

```python
>>> foo()
Traceback (most recent call last):
...
UnboundLocalError: local variable 'x' referenced before assignment
```

This is because when you make an assignment to a variable in a scope, that variable becomes local to that scope and shadows any
similarly named variable in the outer scope. Since the last statement in foo assigns a new value to \( x \), the compiler recognizes it as a local variable. Consequently when the earlier \( \text{print}(x) \) attempts to print the uninitialized local variable and an error results.

In the example above you can access the outer scope variable by declaring it global:

```python
>>> x = 10
>>> def foobar():
...    global x
...    print(x)
...    x += 1
>>> foobar()
10
```

This explicit declaration is required in order to remind you that (unlike the superficially analogous situation with class and instance variables) you are actually modifying the value of the variable in the outer scope:

```python
>>> print(x)
11
```

You can do a similar thing in a nested scope using the \texttt{nonlocal} keyword:

```python
>>> def foo():
...    x = 10
...    def bar():
...        nonlocal x
...        print(x)
...        x += 1
...    bar()
...    print(x)
>>> foo()
```
What are the rules for local and global variables in Python?

In Python, variables that are only referenced inside a function are implicitly global. If a variable is assigned a new value anywhere within the function’s body, it’s assumed to be a local. If a variable is ever assigned a new value inside the function, the variable is implicitly local, and you need to explicitly declare it as ‘global’.

Though a bit surprising at first, a moment’s consideration explains this. On one hand, requiring `global` for assigned variables provides a bar against unintended side-effects. On the other hand, if `global` was required for all global references, you’d be using `global` all the time. You’d have to declare as global every reference to a built-in function or to a component of an imported module. This clutter would defeat the usefulness of the `global` declaration for identifying side-effects.

Why do lambdas defined in a loop with different values all return the same result?

Assume you use a for loop to define a few different lambdas (or even plain functions), e.g.:

```python
>>> squares = []
>>> for x in range(5):
...     squares.append(lambda: x**2)
```

This gives you a list that contains 5 lambdas that calculate \( x^2 \). You
might expect that, when called, they would return, respectively, 0, 1, 4, 9, and 16. However, when you actually try you will see that they all return 16:

```python
>>> squares[2]()
16
>>> squares[4]()
16
```

This happens because `x` is not local to the lambdas, but is defined in the outer scope, and it is accessed when the lambda is called — not when it is defined. At the end of the loop, the value of `x` is 4, so all the functions now return `4**2`, i.e. 16. You can also verify this by changing the value of `x` and see how the results of the lambdas change:

```python
>>> x = 8
>>> squares[2]()
64
```

In order to avoid this, you need to save the values in variables local to the lambdas, so that they don’t rely on the value of the global `x`:

```python
>>> squares = []
>>> for x in range(5):
...     squares.append(lambda n=x: n**2)
```

Here, `n=x` creates a new variable `n` local to the lambda and computed when the lambda is defined so that it has the same value that `x` had at that point in the loop. This means that the value of `n` will be 0 in the first lambda, 1 in the second, 2 in the third, and so on. Therefore each lambda will now return the correct result:
>>> squares[2]()
4
>>> squares[4]()
16

Note that this behaviour is not peculiar to lambdas, but applies to regular functions too.

**How do I share global variables across modules?**

The canonical way to share information across modules within a single program is to create a special module (often called config or cfg). Just import the config module in all modules of your application; the module then becomes available as a global name. Because there is only one instance of each module, any changes made to the module object get reflected everywhere. For example:

**config.py:**

```python
x = 0  # Default value of the 'x' configuration setting
```

**mod.py:**

```python
import config
cfg.x = 1
```

**main.py:**

```python
import config
import mod
print(config.x)
```

Note that using a module is also the basis for implementing the
Singleton design pattern, for the same reason.

**What are the “best practices” for using import in a module?**

In general, don’t use `from modulename import *`. Doing so clutters the importer’s namespace. Some people avoid this idiom even with the few modules that were designed to be imported in this manner. Modules designed in this manner include `tkinter`, and `threading`.

Import modules at the top of a file. Doing so makes it clear what other modules your code requires and avoids questions of whether the module name is in scope. Using one import per line makes it easy to add and delete module imports, but using multiple imports per line uses less screen space.

It’s good practice if you import modules in the following order:

1. standard library modules – e.g. `sys`, `os`, `getopt`, `re`
2. third-party library modules (anything installed in Python’s site-packages directory) – e.g. `mx.DateTime`, `ZODB`, `PIL.Image`, etc.
3. locally-developed modules

Never use relative package imports. If you’re writing code that’s in the `package.sub.m1` module and want to import `package.sub.m2`, do not just write `from . import m2`, even though it’s legal. Write `from package.sub import m2` instead. See PEP 328 for details.

It is sometimes necessary to move imports to a function or class to avoid problems with circular imports. Gordon McMillan says:

Circular imports are fine where both modules use the “import
"form of import. They fail when the 2nd module wants to grab a name out of the first ("from module import name") and the import is at the top level. That's because names in the 1st are not yet available, because the first module is busy importing the 2nd.

In this case, if the second module is only used in one function, then the import can easily be moved into that function. By the time the import is called, the first module will have finished initializing, and the second module can do its import.

It may also be necessary to move imports out of the top level of code if some of the modules are platform-specific. In that case, it may not even be possible to import all of the modules at the top of the file. In this case, importing the correct modules in the corresponding platform-specific code is a good option.

Only move imports into a local scope, such as inside a function definition, if it's necessary to solve a problem such as avoiding a circular import or are trying to reduce the initialization time of a module. This technique is especially helpful if many of the imports are unnecessary depending on how the program executes. You may also want to move imports into a function if the modules are only ever used in that function. Note that loading a module the first time may be expensive because of the one time initialization of the module, but loading a module multiple times is virtually free, costing only a couple of dictionary lookups. Even if the module name has gone out of scope, the module is probably available in `sys.modules`.

If only instances of a specific class use a module, then it is reasonable to import the module in the class's `__init__` method and then assign the module to an instance variable so that the module is always available (via that instance variable) during the life of the object. Note that to delay an import until the class is instantiated, the import must
be inside a method. Putting the import inside the class but outside of any method still causes the import to occur when the module is initialized.

**How can I pass optional or keyword parameters from one function to another?**

Collect the arguments using the `*` and `**` specifiers in the function's parameter list; this gives you the positional arguments as a tuple and the keyword arguments as a dictionary. You can then pass these arguments when calling another function by using `*` and `**`:

```python
def f(x, *args, **kwargs):
  ...  
  kwargs['width'] = '14.3c'
  ... 
  g(x, *args, **kwargs)
```

**What is the difference between arguments and parameters?**

*Parameters* are defined by the names that appear in a function definition, whereas *arguments* are the values actually passed to a function when calling it. Parameters define what types of arguments a function can accept. For example, given the function definition:

```python
def func(foo, bar=None, **kwargs):
  pass
```

`foo, bar and kwargs` are parameters of `func`. However, when calling `func`, for example:
func(42, bar=314, extra=somevar)

the values 42, 314, and somevar are arguments.

How do I write a function with output parameters (call by reference)?

Remember that arguments are passed by assignment in Python. Since assignment just creates references to objects, there's no alias between an argument name in the caller and callee, and so no call-by-reference per se. You can achieve the desired effect in a number of ways.

1. By returning a tuple of the results:

```python
def func2(a, b):
    a = 'new-value'  # a and b are local names
    b = b + 1        # assigned to new objects
    return a, b      # return new values

x, y = 'old-value', 99
x, y = func2(x, y)
print(x, y)          # output: new-value 100
```

This is almost always the clearest solution.

2. By using global variables. This isn't thread-safe, and is not recommended.

3. By passing a mutable (changeable in-place) object:

```python
def func1(a):
    a[0] = 'new-value'   # 'a' references a mutable object
```
4. By passing in a dictionary that gets mutated:

```python
def func3(args):
    args['a'] = 'new-value'  # args is a mutable dict
    args['b'] = args['b'] + 1  # change it in-place

args = {'a': 'old-value', 'b': 99}
func3(args)
print(args['a'], args['b'])
```

5. Or bundle up values in a class instance:

```python
class callByRef:
    def __init__(self, **args):
        for (key, value) in args.items():
            setattr(self, key, value)

    def func4(args):
        args.a = 'new-value'  # args is a mutable dict
        args.b = args.b + 1  # change object in-place

args = callByRef(a='old-value', b=99)
func4(args)
print(args.a, args.b)
```

There's almost never a good reason to get this complicated.

Your best choice is to return a tuple containing the multiple results.
How do you make a higher order function in Python?

You have two choices: you can use nested scopes or you can use callable objects. For example, suppose you wanted to define `linear(a, b)` which returns a function `f(x)` that computes the value `a*x+b`. Using nested scopes:

```python
def linear(a, b):
    def result(x):
        return a * x + b
    return result
```

Or using a callable object:

```python
class linear:
    def __init__(self, a, b):
        self.a, self.b = a, b
    def __call__(self, x):
        return self.a * x + self.b
```

In both cases,

```python
taxes = linear(0.3, 2)
```

gives a callable object where `taxes(10e6) == 0.3 * 10e6 + 2`.

The callable object approach has the disadvantage that it is a bit slower and results in slightly longer code. However, note that a collection of callables can share their signature via inheritance:
**class exponential**(*linear)*:

```python
    # __init__ inherited
def __call__(self, x):
        return self.a * (x ** self.b)
```

Object can encapsulate state for several methods:

**class counter**:

```python
    value = 0
def set(self, x):
        self.value = x
def up(self):
        self.value = self.value + 1
def down(self):
        self.value = self.value - 1
```

count = counter()
inc, dec, reset = count.up, count.down, count.set

Here `inc()`, `dec()` and `reset()` act like functions which share the same counting variable.

**How do I copy an object in Python?**

In general, try `copy.copy()` or `copy.deepcopy()` for the general case. Not all objects can be copied, but most can.

Some objects can be copied more easily. Dictionaries have a `copy()` method:
newdict = olddict.copy()

Sequences can be copied by slicing:

new_l = l[:]

How can I find the methods or attributes of an object?

For an instance x of a user-defined class, `dir(x)` returns an alphabetized list of the names containing the instance attributes and methods and attributes defined by its class.

How can my code discover the name of an object?

Generally speaking, it can’t, because objects don’t really have names. Essentially, assignment always binds a name to a value; The same is true of `def` and `class` statements, but in that case the value is a callable. Consider the following code:

class A:
    pass

B = A

a = B()
b = a
print(b)  # __main__.A object at 0x16D07CC
print(a)  # __main__.A object at 0x16D07CC
Arguably the class has a name: even though it is bound to two names and invoked through the name B the created instance is still reported as an instance of class A. However, it is impossible to say whether the instance’s name is a or b, since both names are bound to the same value.

Generally speaking it should not be necessary for your code to “know the names” of particular values. Unless you are deliberately writing introspective programs, this is usually an indication that a change of approach might be beneficial.

In comp.lang.python, Fredrik Lundh once gave an excellent analogy in answer to this question:

   The same way as you get the name of that cat you found on your porch: the cat (object) itself cannot tell you its name, and it doesn’t really care – so the only way to find out what it’s called is to ask all your neighbours (namespaces) if it’s their cat (object)...

   ....and don’t be surprised if you’ll find that it’s known by many names, or no name at all!

**What’s up with the comma operator’s precedence?**

Comma is not an operator in Python. Consider this session:

```python
>>> "a" in "b", "a"
(False, 'a')
```

Since the comma is not an operator, but a separator between expressions the above is evaluated as if you had entered:
The same is true of the various assignment operators (\(=, \; +=\) etc). They are not truly operators but syntactic delimiters in assignment statements.

**Is there an equivalent of C’s "?:" ternary operator?**

Yes, there is. The syntax is as follows:

```
[on_true] if [expression] else [on_false]
```

```
x, y = 50, 25
small = x if x < y else y
```

Before this syntax was introduced in Python 2.5, a common idiom was to use logical operators:

```
[expression] and [on_true] or [on_false]
```

However, this idiom is unsafe, as it can give wrong results when \(on\_true\) has a false boolean value. Therefore, it is always better to use the \(\ldots\) if \(\ldots\) else \(\ldots\) form.

**Is it possible to write obfuscated one-liners in Python?**

Yes. Usually this is done by nesting \texttt{lambda} within \texttt{lambda}. See the
following three examples, due to Ulf Bartelt:

```
from functools import reduce

# Primes < 1000
print(list(filter(None, map(lambda y: y*reduce(lambda x, y: y%x, range(2, int(pow(y, 0.5)) + 1)), 1)), 1),

# First 10 Fibonacci numbers
print(list(map(lambda x, f=lambda x, f: f(x-1, f) + f(x-2, f(x, f)), range(10))))

# Mandelbrot set
print(((lambda Ru, Ro, Iu, Io, IM, Sx, Sy: reduce(lambda x, y: x+y, map(lambda x, xc=Ru, Iu=Iu, Io=Io, IM=IM, Sx=Sx, Sy=Sy: reduce(lambda x, y: x*y*x+y+xc, 2.0*x*y+yc, k-1, f): f(x, y)), range(Sx)))): L(Iu+y*(4.0)))(-2.1, 0.7, -1.2, 1.2, 30, 80, 24))
```

Don't try this at home, kids!
Numbers and strings

How do I specify hexadecimal and octal integers?

To specify an octal digit, precede the octal value with a zero, and then a lower or uppercase “o”. For example, to set the variable “a” to the octal value “10” (8 in decimal), type:

```
>>> a = 0o10
>>> a
8
```

Hexadecimal is just as easy. Simply precede the hexadecimal number with a zero, and then a lower or uppercase “x”. Hexadecimal digits can be specified in lower or uppercase. For example, in the Python interpreter:

```
>>> a = 0xa5
>>> a
165
>>> b = 0XB2
>>> b
178
```

Why does -22 // 10 return -3?

It’s primarily driven by the desire that \( i \ % \ j \) have the same sign as \( j \). If you want that, and also want:

\[
 i = (i \ // \ j) \ * \ j + (i \ % \ j)
\]

then integer division has to return the floor. C also requires that identity
to hold, and then compilers that truncate $i \div j$ need to make $i \% j$ have the same sign as $i$.

There are few real use cases for $i \% j$ when $j$ is negative. When $j$ is positive, there are many, and in virtually all of them it’s more useful for $i \% j$ to be $\geq 0$. If the clock says 10 now, what did it say 200 hours ago? $-190 \% 12 == 2$ is useful; $-190 \% 12 == -10$ is a bug waiting to bite.

**How do I convert a string to a number?**

For integers, use the built-in `int()` type constructor, e.g. `int('144') == 144`. Similarly, `float()` converts to floating-point, e.g. `float('144') == 144.0`.

By default, these interpret the number as decimal, so that `int('0144') == 144` and `int('0x144')` raises `ValueError`. `int(string, base)` takes the base to convert from as a second optional argument, so `int('0x144', 16) == 324`. If the base is specified as 0, the number is interpreted using Python’s rules: a leading ‘0’ indicates octal, and ‘0x’ indicates a hex number.

Do not use the built-in function `eval()` if all you need is to convert strings to numbers. `eval()` will be significantly slower and it presents a security risk: someone could pass you a Python expression that might have unwanted side effects. For example, someone could pass `__import__('os').system("rm -rf $HOME")` which would erase your home directory.

`eval()` also has the effect of interpreting numbers as Python expressions, so that e.g. `eval('09')` gives a syntax error because
Python does not allow leading ‘0’ in a decimal number (except ‘0’).

**How do I convert a number to a string?**

To convert, e.g., the number 144 to the string ‘144’, use the built-in type constructor `str()`. If you want a hexadecimal or octal representation, use the built-in functions `hex()` or `oct()`. For fancy formatting, see the *String Formatting* section, e.g. "{:04d}".format(144) yields '0144' and "{::.3f}".format(1/3) yields '0.333'.

**How do I modify a string in place?**

You can’t, because strings are immutable. In most situations, you should simply construct a new string from the various parts you want to assemble it from. However, if you need an object with the ability to modify in-place unicode data, try using a `io.StringIO` object or the `array` module:

```python
>>> import io
>>> s = "Hello, world"
>>> sio = io.StringIO(s)
>>> sio.getvalue()
'Hello, world'
>>> sio.seek(7)
7
>>> sio.write("there!")
6
>>> sio.getvalue()
'Hello, there!'

>>> import array
>>> a = array.array('u', s)
```
>>> print(a)
array('u', 'Hello, world')
>>> a[0] = 'y'
>>> print(a)
array('u', 'yello, world')
>>> a.tounicode()
yello, world

How do I use strings to call functions/methods?

There are various techniques.

- The best is to use a dictionary that maps strings to functions. The primary advantage of this technique is that the strings do not need to match the names of the functions. This is also the primary technique used to emulate a case construct:

```python
def a():
    pass

def b():
    pass

dispatch = {'go': a, 'stop': b}  # Note lack of 

dispatch[get_input()]()  # Note trailing parens
```

- Use the built-in function `getattr()`:

```python
import foo
getattr(foo, 'bar')()
```

Note that `getattr()` works on any object, including classes, class instances, modules, and so on.
This is used in several places in the standard library, like this:

```python
class Foo:
    def do_foo(self):
        ...

    def do_bar(self):
        ...

f = getattr(foo_instance, 'do_' + opname)
f()
```

- Use `locals()` or `eval()` to resolve the function name:

```python
def myFunc():
    print("hello")

fname = "myFunc"

f = locals()[fname]
f()

f = eval(fname)
f()
```

Note: Using `eval()` is slow and dangerous. If you don’t have absolute control over the contents of the string, someone could pass a string that resulted in an arbitrary function being executed.

**Is there an equivalent to Perl’s chomp() for removing trailing newlines from strings?**

You can use `S.rstrip("\r\n")` to remove all occurrences of any line terminator from the end of the string `S` without removing other
trailing whitespace. If the string \texttt{S} represents more than one line, with several empty lines at the end, the line terminators for all the blank lines will be removed:

given = ("line 1 \n... \n... \n")
given.rstrip("\n")

Since this is typically only desired when reading text one line at a time, using \texttt{S.rstrip()} this way works well.

**Is there a scanf() or sscanf() equivalent?**

Not as such.

For simple input parsing, the easiest approach is usually to split the line into whitespace-delimited words using the \texttt{split()} method of string objects and then convert decimal strings to numeric values using \texttt{int()} or \texttt{float()}. \texttt{split()} supports an optional “sep” parameter which is useful if the line uses something other than whitespace as a separator.

For more complicated input parsing, regular expressions are more powerful than C’s \texttt{sscanf()} and better suited for the task.

**What does ‘UnicodeDecodeError’ or ‘UnicodeEncodeError’ error mean?**

See the \textit{Unicode HOWTO}.
Performance

My program is too slow. How do I speed it up?

That’s a tough one, in general. First, here are a list of things to remember before diving further:

- Performance characteristics vary across Python implementations. This FAQ focusses on CPython.
- Behaviour can vary across operating systems, especially when talking about I/O or multi-threading.
- You should always find the hot spots in your program before attempting to optimize any code (see the profile module).
- Writing benchmark scripts will allow you to iterate quickly when searching for improvements (see the timeit module).
- It is highly recommended to have good code coverage (through unit testing or any other technique) before potentially introducing regressions hidden in sophisticated optimizations.

That being said, there are many tricks to speed up Python code. Here are some general principles which go a long way towards reaching acceptable performance levels:

- Making your algorithms faster (or changing to faster ones) can yield much larger benefits than trying to sprinkle micro-optimization tricks all over your code.
- Use the right data structures. Study documentation for the Built-in Types and the collections module.
- When the standard library provides a primitive for doing something, it is likely (although not guaranteed) to be faster than any alternative you may come up with. This is doubly true for primitives written in C, such as builtins and some extension types. For example, be sure to use either the list.sort() built-in
method or the related \texttt{sorted()} function to do sorting (and see the \texttt{sorting mini-HOWTO} for examples of moderately advanced usage).

- Abstractions tend to create indirections and force the interpreter to work more. If the levels of indirection outweigh the amount of useful work done, your program will be slower. You should avoid excessive abstraction, especially under the form of tiny functions or methods (which are also often detrimental to readability).

If you have reached the limit of what pure Python can allow, there are tools to take you further away. For example, \texttt{Cython} can compile a slightly modified version of Python code into a C extension, and can be used on many different platforms. Cython can take advantage of compilation (and optional type annotations) to make your code significantly faster than when interpreted. If you are confident in your C programming skills, you can also \texttt{write a C extension module} yourself.

\textbf{See also:} The wiki page devoted to performance tips.

\section*{What is the most efficient way to concatenate many strings together?}

\texttt{str} and \texttt{bytes} objects are immutable, therefore concatenating many strings together is inefficient as each concatenation creates a new object. In the general case, the total runtime cost is quadratic in the total string length.

To accumulate many \texttt{str} objects, the recommended idiom is to place them into a list and call \texttt{str.join()} at the end:

\begin{verbatim}
chunks = []
for s in my_strings:
    chunks.append(s)
\end{verbatim}
result = ''.join(chunks)

(another reasonably efficient idiom is to use io.StringIO)

To accumulate many bytes objects, the recommended idiom is to extend a bytearray object using in-place concatenation (the += operator):

```python
result = bytearray()
for b in my_bytes_objects:
    result += b
```
Sequences (Tuples/Lists)

How do I convert between tuples and lists?

The type constructor `tuple(seq)` converts any sequence (actually, any iterable) into a tuple with the same items in the same order.

For example, `tuple([1, 2, 3])` yields `(1, 2, 3)` and `tuple('abc')` yields `('a', 'b', 'c')`. If the argument is a tuple, it does not make a copy but returns the same object, so it is cheap to call `tuple()` when you aren't sure that an object is already a tuple.

The type constructor `list(seq)` converts any sequence or iterable into a list with the same items in the same order. For example, `list((1, 2, 3))` yields `[1, 2, 3]` and `list('abc')` yields `['a', 'b', 'c']`. If the argument is a list, it makes a copy just like `seq[:]` would.

What’s a negative index?

Python sequences are indexed with positive numbers and negative numbers. For positive numbers 0 is the first index 1 is the second index and so forth. For negative indices -1 is the last index and -2 is the penultimate (next to last) index and so forth. Think of `seq[-n]` as the same as `seq[len(seq)-n]`.

Using negative indices can be very convenient. For example `S[::1]` is all of the string except for its last character, which is useful for removing the trailing newline from a string.
How do I iterate over a sequence in reverse order?

Use the `reversed()` built-in function, which is new in Python 2.4:

```python
for x in reversed(sequence):
    ... # do something with x...
```

This won't touch your original sequence, but build a new copy with reversed order to iterate over.

With Python 2.3, you can use an extended slice syntax:

```python
for x in sequence[::-1]:
    ... # do something with x...
```

How do you remove duplicates from a list?

See the Python Cookbook for a long discussion of many ways to do this:

http://aspn.activestate.com/ASPN/Cookbook/Python/Recipe/52560

If you don’t mind reordering the list, sort it and then scan from the end of the list, deleting duplicates as you go:

```python
if mylist:
    mylist.sort()
    last = mylist[-1]
    for i in range(len(mylist)-2, -1, -1):
        if last == mylist[i]:
            del mylist[i]
        else:
            last = mylist[i]
```
If all elements of the list may be used as set keys (i.e. they are all *hashable*) this is often faster

```python
mylist = list(set(mylist))
```

This converts the list into a set, thereby removing duplicates, and then back into a list.

**How do you make an array in Python?**

Use a list:

```python
["this", 1, "is", "an", "array"]
```

Lists are equivalent to C or Pascal arrays in their time complexity; the primary difference is that a Python list can contain objects of many different types.

The *array* module also provides methods for creating arrays of fixed types with compact representations, but they are slower to index than lists. Also note that the Numeric extensions and others define array-like structures with various characteristics as well.

To get Lisp-style linked lists, you can emulate cons cells using tuples:

```python
lisp_list = ("like", ("this", ("example", None))
```

If mutability is desired, you could use lists instead of tuples. Here the analogue of lisp car is `lisp_list[0]` and the analogue of cdr is `lisp_list[1]`. Only do this if you’re sure you really need to, because it’s usually a lot slower than using Python lists.
How do I create a multidimensional list?

You probably tried to make a multidimensional array like this:

```
>>> A = [[None] * 2] * 3
```

This looks correct if you print it:

```
>>> A
[[None, None], [None, None], [None, None]]
```

But when you assign a value, it shows up in multiple places:

```
>>> A[0][0] = 5
>>> A
[[5, None], [5, None], [5, None]]
```

The reason is that replicating a list with `*` doesn’t create copies, it only creates references to the existing objects. The `*3` creates a list containing 3 references to the same list of length two. Changes to one row will show in all rows, which is almost certainly not what you want.

The suggested approach is to create a list of the desired length first and then fill in each element with a newly created list:

```
A = [None] * 3
for i in range(3):
    A[i] = [None] * 2
```

This generates a list containing 3 different lists of length two. You can also use a list comprehension:

```
w, h = 2, 3
A = [[None] * w for i in range(h)]
```
Or, you can use an extension that provides a matrix datatype; Numeric Python is the best known.

**How do I apply a method to a sequence of objects?**

Use a list comprehension:

```
result = [obj.method() for obj in mylist]
```

**Why does a_tuple[i] += ['item'] raise an exception when the addition works?**

This is because of a combination of the fact that augmented assignment operators are assignment operators, and the difference between mutable and immutable objects in Python.

This discussion applies in general when augmented assignment operators are applied to elements of a tuple that point to mutable objects, but we'll use a list and `+=` as our exemplar.

If you wrote:

```python
>>> a_tuple = (1, 2)
>>> a_tuple[0] += 1
Traceback (most recent call last):
  ...
TypeError: 'tuple' object does not support item assignment
```

The reason for the exception should be immediately clear: 1 is added to the object `a_tuple[0]` points to (1), producing the result object,
2, but when we attempt to assign the result of the computation, 2, to element 0 of the tuple, we get an error because we can’t change what an element of a tuple points to.

Under the covers, what this augmented assignment statement is doing is approximately this:

```python
>>> result = a_tuple[0] + 1
>>> a_tuple[0] = result
Traceback (most recent call last):
...  
TypeError: 'tuple' object does not support item assignment
```

It is the assignment part of the operation that produces the error, since a tuple is immutable.

When you write something like:

```python
>>> a_tuple = (['foo'], 'bar')
>>> a_tuple[0] += ['item']
Traceback (most recent call last):
...  
TypeError: 'tuple' object does not support item assignment
```

The exception is a bit more surprising, and even more surprising is the fact that even though there was an error, the append worked:

```python
>>> a_tuple[0]
['foo', 'item']
```

To see why this happens, you need to know that (a) if an object implements an `__iadd__` magic method, it gets called when the `+=` augmented assignment is executed, and its return value is what gets
used in the assignment statement; and (b) for lists, `__iadd__` is equivalent to calling `extend` on the list and returning the list. That's why we say that for lists, `+=` is a “shorthand” for `list.extend`:

```python
>>> a_list = []
>>> a_list += [1]
>>> a_list
[1]
```

This is equivalent to:

```python
>>> result = a_list.__iadd__([1])
>>> a_list = result
```

The object pointed to by `a_list` has been mutated, and the pointer to the mutated object is assigned back to `a_list`. The end result of the assignment is a no-op, since it is a pointer to the same object that `a_list` was previously pointing to, but the assignment still happens.

Thus, in our tuple example what is happening is equivalent to:

```python
>>> result = a_tuple[0].__iadd__(['item'])
>>> a_tuple[0] = result
Traceback (most recent call last):
  ...
TypeError: 'tuple' object does not support item assi
```

The `__iadd__` succeeds, and thus the list is extended, but even though `result` points to the same object that `a_tuple[0]` already points to, that final assignment still results in an error, because tuples are immutable.
Dictionaries

How can I get a dictionary to store and display its keys in a consistent order?

Use `collections.OrderedDict`.

I want to do a complicated sort: can you do a Schwartzian Transform in Python?

The technique, attributed to Randal Schwartz of the Perl community, sorts the elements of a list by a metric which maps each element to its “sort value”. In Python, just use the `key` argument for the `sort()` method:

```python
Isorted = L[:]
Isorted.sort(key=lambda s: int(s[10:15]))
```

The `key` argument is new in Python 2.4, for older versions this kind of sorting is quite simple to do with list comprehensions. To sort a list of strings by their uppercase values:

```python
tmp1 = [(x.upper(), x) for x in L]  # Schwartzian transform
tmp1.sort()
Usorted = [x[1] for x in tmp1]
```

To sort by the integer value of a subfield extending from positions 10-15 in each string:

```python
tmp2 = [(int(s[10:15]), s) for s in L]  # Schwartzian transform
tmp2.sort()
```
Isorted = [x[1] for x in tmp2]

For versions prior to 3.0, Isorted may also be computed by

```python
def intfield(s):
    return int(s[10:15])

def Icmp(s1, s2):
    return cmp(intfield(s1), intfield(s2))

Isorted = L[:]
Isorted.sort(Icmp)
```

but since this method calls `intfield()` many times for each element of L, it is slower than the Schwartzian Transform.

**How can I sort one list by values from another list?**

Merge them into an iterator of tuples, sort the resulting list, and then pick out the element you want.

```python
>>> list1 = ['what', 'I'm', 'sorting', 'by']
>>> list2 = ['something', 'else', 'to', 'sort']
>>> pairs = zip(list1, list2)
>>> pairs = sorted(pairs)
>>> pairs
[('I'm', 'else'), ('by', 'sort'), ('sorting', 'to'), ('what', 'something')]
```

An alternative for the last step is:

```python
>>> result = [x[1] for x in pairs]
>>> result
['else', 'sort', 'to', 'something']
```
If you find this more legible, you might prefer to use this instead of the final list comprehension. However, it is almost twice as slow for long lists. Why? First, the `append()` operation has to reallocate memory, and while it uses some tricks to avoid doing that each time, it still has to do it occasionally, and that costs quite a bit. Second, the expression “result.append” requires an extra attribute lookup, and third, there’s a speed reduction from having to make all those function calls.
Objects

What is a class?

A class is the particular object type created by executing a class statement. Class objects are used as templates to create instance objects, which embody both the data (attributes) and code (methods) specific to a datatype.

A class can be based on one or more other classes, called its base class(es). It then inherits the attributes and methods of its base classes. This allows an object model to be successively refined by inheritance. You might have a generic Mailbox class that provides basic accessor methods for a mailbox, and subclasses such as MboxMailbox, MaildirMailbox, OutlookMailbox that handle various specific mailbox formats.

What is a method?

A method is a function on some object x that you normally call as x.name(arguments...). Methods are defined as functions inside the class definition:

```python
class C:
    def meth (self, arg):
        return arg * 2 + self.attribute
```

What is self?

Self is merely a conventional name for the first argument of a method. A method defined as meth(self, a, b, c) should be called as
x.meth(a, b, c) for some instance x of the class in which the definition occurs; the called method will think it is called as meth(x, a, b, c).

See also *Why must ‘self’ be used explicitly in method definitions and calls?*

**How do I check if an object is an instance of a given class or of a subclass of it?**

Use the built-in function `isinstance(obj, cls)`. You can check if an object is an instance of any of a number of classes by providing a tuple instead of a single class, e.g. `isinstance(obj, (class1, class2, ...))`, and can also check whether an object is one of Python’s built-in types, e.g. `isinstance(obj, str)` or `isinstance(obj, (int, float, complex))`.

Note that most programs do not use `isinstance()` on user-defined classes very often. If you are developing the classes yourself, a more proper object-oriented style is to define methods on the classes that encapsulate a particular behaviour, instead of checking the object’s class and doing a different thing based on what class it is. For example, if you have a function that does something:

```python
def search(obj):
    if isinstance(obj, Mailbox):
        # ... code to search a mailbox
    elif isinstance(obj, Document):
        # ... code to search a document
    elif ...
```

A better approach is to define a `search()` method on all the classes
and just call it:

```python
class Mailbox:
    def search(self):
        # ... code to search a mailbox

class Document:
    def search(self):
        # ... code to search a document

obj.search()
```

What is delegation?

Delegation is an object oriented technique (also called a design pattern). Let's say you have an object `x` and want to change the behaviour of just one of its methods. You can create a new class that provides a new implementation of the method you’re interested in changing and delegates all other methods to the corresponding method of `x`.

Python programmers can easily implement delegation. For example, the following class implements a class that behaves like a file but converts all written data to uppercase:

```python
class UpperOut:
    def __init__(self, outfile):
        self._outfile = outfile

    def write(self, s):
        self._outfile.write(s.upper())

    def __getattr__(self, name):
```
return getattr(self._outfile, name)

Here the `UpperOut` class redefines the `write()` method to convert the argument string to uppercase before calling the underlying `self.__outfile.write()` method. All other methods are delegated to the underlying `self.__outfile` object. The delegation is accomplished via the `__getattr__` method; consult the language reference for more information about controlling attribute access.

Note that for more general cases delegation can get trickier. When attributes must be set as well as retrieved, the class must define a `__setattr__()` method too, and it must do so carefully. The basic implementation of `__setattr__()` is roughly equivalent to the following:

```python
class X:
    ...
    def __setattr__(self, name, value):
        self.__dict__[name] = value
    ...
```

Most `__setattr__()` implementations must modify `self.__dict__` to store local state for `self` without causing an infinite recursion.

**How do I call a method defined in a base class from a derived class that overrides it?**

Use the built-in `super()` function:

```python
class Derived(Base):
    def meth(self):
```
super(Derived, self).meth()

For version prior to 3.0, you may be using classic classes: For a class definition such as `class Derived(Base): ...` you can call method `meth()` defined in `Base` (or one of `Base`'s base classes) as `Base.meth(self, arguments...)`. Here, `Base.meth` is an unbound method, so you need to provide the `self` argument.

How can I organize my code to make it easier to change the base class?

You could define an alias for the base class, assign the real base class to it before your class definition, and use the alias throughout your class. Then all you have to change is the value assigned to the alias. Incidentally, this trick is also handy if you want to decide dynamically (e.g. depending on availability of resources) which base class to use. Example:

```python
BaseAlias = <real base class>
class Derived(BaseAlias):
    def meth(self):
        BaseAlias.meth(self)
...```

How do I create static class data and static class methods?

Both static data and static methods (in the sense of C++ or Java) are supported in Python.

For static data, simply define a class attribute. To assign a new value
to the attribute, you have to explicitly use the class name in the assignment:

```python
class C:
    count = 0  # number of times C.__init__ called

    def __init__(self):
        C.count = C.count + 1

    def getcount(self):
        return C.count  # or return self.count
```

c.count also refers to C.count for any c such that `isinstance(c, C)` holds, unless overridden by c itself or by some class on the base-class search path from c.__class__ back to C.

Caution: within a method of C, an assignment like `self.count = 42` creates a new and unrelated instance named “count” in self's own dict. Rebinding of a class-static data name must always specify the class whether inside a method or not:

```python
C.count = 314
```

Static methods are possible:

```python
class C:
    @staticmethod
def static(arg1, arg2, arg3):
        # No 'self' parameter!
        ...
```

However, a far more straightforward way to get the effect of a static method is via a simple module-level function:
def getcount():
    return C.count

If your code is structured so as to define one class (or tightly related class hierarchy) per module, this supplies the desired encapsulation.

**How can I overload constructors (or methods) in Python?**

This answer actually applies to all methods, but the question usually comes up first in the context of constructors.

In C++ you’d write

```cpp
class C {
    C() { cout << "No arguments\n"; }
    C(int i) { cout << "Argument is " << i << "\n"; }
}
```

In Python you have to write a single constructor that catches all cases using default arguments. For example:

```python
class C:
    def __init__(self, i=None):
        if i is None:
            print("No arguments")
        else:
            print("Argument is", i)
```

This is not entirely equivalent, but close enough in practice.

You could also try a variable-length argument list, e.g.
The same approach works for all method definitions.

I try to use __spam and I get an error about _SomeClassName__spam.

Variable names with double leading underscores are “mangled” to provide a simple but effective way to define class private variables. Any identifier of the form __spam (at least two leading underscores, at most one trailing underscore) is textually replaced with _classname__spam, where classname is the current class name with any leading underscores stripped.

This doesn't guarantee privacy: an outside user can still deliberately access the “_classname__spam” attribute, and private values are visible in the object's __dict__. Many Python programmers never bother to use private variable names at all.

My class defines __del__ but it is not called when I delete the object.

There are several possible reasons for this.

The del statement does not necessarily call __del__() – it simply decrements the object's reference count, and if this reaches zero __del__() is called.

If your data structures contain circular links (e.g. a tree where each child has a parent reference and each parent has a list of children) the reference counts will never go back to zero. Once in a while Python
runs an algorithm to detect such cycles, but the garbage collector might run some time after the last reference to your data structure vanishes, so your \_\_del\_\_() method may be called at an inconvenient and random time. This is inconvenient if you're trying to reproduce a problem. Worse, the order in which object's \_\_del\_\_() methods are executed is arbitrary. You can run gc.collect() to force a collection, but there are pathological cases where objects will never be collected.

Despite the cycle collector, it's still a good idea to define an explicit close() method on objects to be called whenever you're done with them. The close() method can then remove attributes that refer to subobjects. Don't call \_\_del\_\_() directly – \_\_del\_\_() should call close() and close() should make sure that it can be called more than once for the same object.

Another way to avoid cyclical references is to use the weakref module, which allows you to point to objects without incrementing their reference count. Tree data structures, for instance, should use weak references for their parent and sibling references (if they need them!).

Finally, if your \_\_del\_\_() method raises an exception, a warning message is printed to sys.stderr.

**How do I get a list of all instances of a given class?**

Python does not keep track of all instances of a class (or of a built-in type). You can program the class's constructor to keep track of all instances by keeping a list of weak references to each instance.
Why does the result of `id()` appear to be not unique?

The `id()` built-in returns an integer that is guaranteed to be unique during the lifetime of the object. Since in CPython, this is the object's memory address, it happens frequently that after an object is deleted from memory, the next freshly created object is allocated at the same position in memory. This is illustrated by this example:

```python
>>> id(1000)
13901272
>>> id(2000)
13901272
```

The two ids belong to different integer objects that are created before, and deleted immediately after execution of the `id()` call. To be sure that objects whose id you want to examine are still alive, create another reference to the object:

```python
>>> a = 1000; b = 2000
>>> id(a)
13901272
>>> id(b)
13891296
```
Modules

How do I create a .pyc file?

When a module is imported for the first time (or when the source file has changed since the current compiled file was created) a .pyc file containing the compiled code should be created in a `__pycache__` subdirectory of the directory containing the .py file. The .pyc file will have a filename that starts with the same name as the .py file, and ends with .pyc, with a middle component that depends on the particular python binary that created it. (See PEP 3147 for details.)

One reason that a .pyc file may not be created is a permissions problem with the directory containing the source file, meaning that the `__pycache__` subdirectory cannot be created. This can happen, for example, if you develop as one user but run as another, such as if you are testing with a web server.

Unless the `PYTHONDONTCWRITEBYTECODE` environment variable is set, creation of a .pyc file is automatic if you’re importing a module and Python has the ability (permissions, free space, etc...) to create a `__pycache__` subdirectory and write the compiled module to that subdirectory.

Running Python on a top level script is not considered an import and no .pyc will be created. For example, if you have a top-level module `foo.py` that imports another module `xyz.py`, when you run `foo` (by typing `python foo.py` as a shell command), a .pyc will be created for `xyz` because `xyz` is imported, but no .pyc file will be created for `foo` since `foo.py` isn't being imported.
If you need to create a .pyc file for foo – that is, to create a .pyc file for a module that is not imported – you can, using the py_compile and compileall modules.

The py_compile module can manually compile any module. One way is to use the compile() function in that module interactively:

```python
>>> import py_compile
>>> py_compile.compile('foo.py')
```

This will write the .pyc to a __pycache__ subdirectory in the same location as foo.py (or you can override that with the optional parameter cfile).

You can also automatically compile all files in a directory or directories using the compileall module. You can do it from the shell prompt by running compileall.py and providing the path of a directory containing Python files to compile:

```bash
python -m compileall
```

**How do I find the current module name?**

A module can find out its own module name by looking at the predefined global variable __name__. If this has the value '__main__', the program is running as a script. Many modules that are usually used by importing them also provide a command-line interface or a self-test, and only execute this code after checking __name__:

```python
def main():
    print('Running test...')
```
if __name__ == '__main__':
    main()

How can I have modules that mutually import each other?

Suppose you have the following modules:

foo.py:

```python
from bar import bar_var
foo_var = 1
```

bar.py:

```python
from foo import foo_var
bar_var = 2
```

The problem is that the interpreter will perform the following steps:

- main imports foo
- Empty globals for foo are created
- foo is compiled and starts executing
- foo imports bar
- Empty globals for bar are created
- bar is compiled and starts executing
- bar imports foo (which is a no-op since there already is a module named foo)
- bar.foo_var = foo.foo_var

The last step fails, because Python isn't done with interpreting foo yet and the global symbol dictionary for foo is still empty.
The same thing happens when you use `import foo`, and then try to access `foo.foo_var` in global code.

There are (at least) three possible workarounds for this problem.

Guido van Rossum recommends avoiding all uses of `from <module> import ...`, and placing all code inside functions. Initializations of global variables and class variables should use constants or built-in functions only. This means everything from an imported module is referenced as `<module>.<name>`.

Jim Roskind suggests performing steps in the following order in each module:

- exports (globals, functions, and classes that don't need imported base classes)
- `import` statements
- active code (including globals that are initialized from imported values).

van Rossum doesn't like this approach much because the imports appear in a strange place, but it does work.

Matthias Urlichs recommends restructuring your code so that the recursive import is not necessary in the first place.

These solutions are not mutually exclusive.

```
__import__('x.y.z') returns <module 'x'>; how do I get z?
```

Try:
For more realistic situations, you may have to do something like

```python
m = __import__(s)
for i in s.split(".")[1:]:
    m = getattr(m, i)
```

See `importlib` for a convenience function called `import_module()`.

**When I edit an imported module and reimport it, the changes don’t show up. Why does this happen?**

For reasons of efficiency as well as consistency, Python only reads the module file on the first time a module is imported. If it didn’t, in a program consisting of many modules where each one imports the same basic module, the basic module would be parsed and re-parsed many times. To force re-reading of a changed module, do this:

```python
import importlib
import modname
importlib.reload(modname)
```

Warning: this technique is not 100% fool-proof. In particular, modules containing statements like

```python
from modname import some_objects
```

will continue to work with the old version of the imported objects. If the module contains class definitions, existing class instances will *not* be
updated to use the new class definition. This can result in the following paradoxical behaviour:

```python
>>> import importlib
>>> import cls
>>> c = cls.C()  # Create an instance
>>> importlib.reload(cls)
<module 'cls' from 'cls.py'>
>>> isinstance(c, cls.C)  # isinstance is false
False
```

The nature of the problem is made clear if you print out the “identity” of the class objects:

```python
>>> hex(id(c.__class__))
'0x7352a0'
>>> hex(id(cls.C))
'0x4198d0'
```
Design and History FAQ
Why does Python use indentation for grouping of statements?

Guido van Rossum believes that using indentation for grouping is extremely elegant and contributes a lot to the clarity of the average Python program. Most people learn to love this feature after a while.

Since there are no begin/end brackets there cannot be a disagreement between grouping perceived by the parser and the human reader. Occasionally C programmers will encounter a fragment of code like this:

```python
if (x <= y)
    x++;  
    y--; 
z++; 
```

Only the `x++` statement is executed if the condition is true, but the indentation leads you to believe otherwise. Even experienced C programmers will sometimes stare at it a long time wondering why `y` is being decremented even for `x > y`.

Because there are no begin/end brackets, Python is much less prone to coding-style conflicts. In C there are many different ways to place the braces. If you’re used to reading and writing code that uses one style, you will feel at least slightly uneasy when reading (or being required to write) another style.

Many coding styles place begin/end brackets on a line by themselves. This makes programs considerably longer and wastes valuable screen space, making it harder to get a good overview of a program. Ideally, a function should fit on one screen (say, 20-30 lines). 20 lines of Python
can do a lot more work than 20 lines of C. This is not solely due to the lack of begin/end brackets – the lack of declarations and the high-level data types are also responsible – but the indentation-based syntax certainly helps.
Why am I getting strange results with simple arithmetic operations?

See the next question.
Why are floating-point calculations so inaccurate?

Users are often surprised by results like this:

```python
>>> 1.2 - 1.0
0.19999999999999996
```

and think it is a bug in Python. It's not. This has little to do with Python, and much more to do with how the underlying platform handles floating-point numbers.

The `float` type in CPython uses a C `double` for storage. A `float` object's value is stored in binary floating-point with a fixed precision (typically 53 bits) and Python uses C operations, which in turn rely on the hardware implementation in the processor, to perform floating-point operations. This means that as far as floating-point operations are concerned, Python behaves like many popular languages including C and Java.

Many numbers that can be written easily in decimal notation cannot be expressed exactly in binary floating-point. For example, after:

```python
>>> x = 1.2
```

the value stored for `x` is a (very good) approximation to the decimal value 1.2, but is not exactly equal to it. On a typical machine, the actual stored value is:

```
1.0011001100110011001100110011001100110011001100110011
```
which is exactly:

1.19999999999999995559107901499373838305473327636718

The typical precision of 53 bits provides Python floats with 15-16 decimal digits of accuracy.

For a fuller explanation, please see the *floating point arithmetic* chapter in the Python tutorial.
Why are Python strings immutable?

There are several advantages.

One is performance: knowing that a string is immutable means we can allocate space for it at creation time, and the storage requirements are fixed and unchanging. This is also one of the reasons for the distinction between tuples and lists.

Another advantage is that strings in Python are considered as “elemental” as numbers. No amount of activity will change the value 8 to anything else, and in Python, no amount of activity will change the string “eight” to anything else.
Why must ‘self’ be used explicitly in method definitions and calls?

The idea was borrowed from Modula-3. It turns out to be very useful, for a variety of reasons.

First, it’s more obvious that you are using a method or instance attribute instead of a local variable. Reading `self.x` or `self.meth()` makes it absolutely clear that an instance variable or method is used even if you don’t know the class definition by heart. In C++, you can sort of tell by the lack of a local variable declaration (assuming globals are rare or easily recognizable) – but in Python, there are no local variable declarations, so you’d have to look up the class definition to be sure. Some C++ and Java coding standards call for instance attributes to have an `m_` prefix, so this explicitness is still useful in those languages, too.

Second, it means that no special syntax is necessary if you want to explicitly reference or call the method from a particular class. In C++, if you want to use a method from a base class which is overridden in a derived class, you have to use the `::` operator – in Python you can write `baseclass.methodname(self, <argument list>). This is particularly useful for `__init__()` methods, and in general in cases where a derived class method wants to extend the base class method of the same name and thus has to call the base class method somehow.

Finally, for instance variables it solves a syntactic problem with assignment: since local variables in Python are (by definition!) those variables to which a value is assigned in a function body (and that aren’t explicitly declared global), there has to be some way to tell the
interpreter that an assignment was meant to assign to an instance variable instead of to a local variable, and it should preferably be syntactic (for efficiency reasons). C++ does this through declarations, but Python doesn't have declarations and it would be a pity having to introduce them just for this purpose. Using the explicit `self.var` solves this nicely. Similarly, for using instance variables, having to write `self.var` means that references to unqualified names inside a method don't have to search the instance's directories. To put it another way, local variables and instance variables live in two different namespaces, and you need to tell Python which namespace to use.
Why can’t I use an assignment in an expression?

Many people used to C or Perl complain that they want to use this C idiom:

```c
while (line = readline(f)) {
    // do something with line
}
```

where in Python you’re forced to write this:

```python
while True:
    line = f.readline()
    if not line:
        break
    ... # do something with line
```

The reason for not allowing assignment in Python expressions is a common, hard-to-find bug in those other languages, caused by this construct:

```python
if (x = 0) {
    // error handling
}
else {
    // code that only works for nonzero x
}
```

The error is a simple typo: `x = 0`, which assigns 0 to the variable `x`, was written while the comparison `x == 0` is certainly what was intended.
Many alternatives have been proposed. Most are hacks that save some typing but use arbitrary or cryptic syntax or keywords, and fail the simple criterion for language change proposals: it should intuitively suggest the proper meaning to a human reader who has not yet been introduced to the construct.

An interesting phenomenon is that most experienced Python programmers recognize the `while True` idiom and don’t seem to be missing the assignment in expression construct much; it’s only newcomers who express a strong desire to add this to the language.

There’s an alternative way of spelling this that seems attractive but is generally less robust than the “while True” solution:

```python
line = f.readline()
while line:
    ... # do something with line...
    line = f.readline()
```

The problem with this is that if you change your mind about exactly how you get the next line (e.g. you want to change it into `sys.stdin.readline()`) you have to remember to change two places in your program – the second occurrence is hidden at the bottom of the loop.

The best approach is to use iterators, making it possible to loop through objects using the `for` statement. For example, `file objects` support the iterator protocol, so you can write simply:

```python
for line in f:
    ... # do something with line...
```
Why does Python use methods for some functionality (e.g. list.index()) but functions for other (e.g. len(list))?  

The major reason is history. Functions were used for those operations that were generic for a group of types and which were intended to work even for objects that didn’t have methods at all (e.g. tuples). It is also convenient to have a function that can readily be applied to an amorphous collection of objects when you use the functional features of Python (map(), zip() et al).

In fact, implementing len(), max(), min() as a built-in function is actually less code than implementing them as methods for each type. One can quibble about individual cases but it’s a part of Python, and it’s too late to make such fundamental changes now. The functions have to remain to avoid massive code breakage.

**Note:** For string operations, Python has moved from external functions (the string module) to methods. However, len() is still a function.
Why is `join()` a string method instead of a list or tuple method?

Strings became much more like other standard types starting in Python 1.6, when methods were added which give the same functionality that has always been available using the functions of the string module. Most of these new methods have been widely accepted, but the one which appears to make some programmers feel uncomfortable is:

```
"", "\n\t.join(['1', '2', '4', '8', '16'])
```

which gives the result:

```
"1, 2, 4, 8, 16"
```

There are two common arguments against this usage.

The first runs along the lines of: “It looks really ugly using a method of a string literal (string constant)”, to which the answer is that it might, but a string literal is just a fixed value. If the methods are to be allowed on names bound to strings there is no logical reason to make them unavailable on literals.

The second objection is typically cast as: “I am really telling a sequence to join its members together with a string constant”. Sadly, you aren’t. For some reason there seems to be much less difficulty with having `split()` as a string method, since in that case it is easy to see that

```
"1, 2, 4, 8, 16".split("", ")
```
is an instruction to a string literal to return the substrings delimited by the given separator (or, by default, arbitrary runs of white space).

`join()` is a string method because in using it you are telling the separator string to iterate over a sequence of strings and insert itself between adjacent elements. This method can be used with any argument which obeys the rules for sequence objects, including any new classes you might define yourself. Similar methods exist for bytes and bytearray objects.
How fast are exceptions?

A try/except block is extremely efficient if no exceptions are raised. Actually catching an exception is expensive. In versions of Python prior to 2.0 it was common to use this idiom:

```python
try:
    value = mydict[key]
except KeyError:
    mydict[key] = getvalue(key)
    value = mydict[key]
```

This only made sense when you expected the dict to have the key almost all the time. If that wasn’t the case, you coded it like this:

```python
if key in mydict:
    value = mydict[key]
else:
    value = mydict[key] = getvalue(key)
```

For this specific case, you could also use `value = dict.setdefault(key, getvalue(key))`, but only if the `getvalue()` call is cheap enough because it is evaluated in all cases.
Why isn’t there a switch or case statement in Python?

You can do this easily enough with a sequence of `if... elif... elif... else`. There have been some proposals for switch statement syntax, but there is no consensus (yet) on whether and how to do range tests. See PEP 275 for complete details and the current status.

For cases where you need to choose from a very large number of possibilities, you can create a dictionary mapping case values to functions to call. For example:

```python
def function_1(...):
    ...

functions = {'a': function_1,
              'b': function_2,
              'c': self.method_1, ...}

func = functions[value]
func()
```

For calling methods on objects, you can simplify yet further by using the `getattr()` built-in to retrieve methods with a particular name:

```python
def visit_a(self, ...):
    ...
    ...

def dispatch(self, value):
    method_name = 'visit_' + str(value)
    method = getattr(self, method_name)
```
It’s suggested that you use a prefix for the method names, such as `visit_` in this example. Without such a prefix, if values are coming from an untrusted source, an attacker would be able to call any method on your object.
Can’t you emulate threads in the interpreter instead of relying on an OS-specific thread implementation?

Answer 1: Unfortunately, the interpreter pushes at least one C stack frame for each Python stack frame. Also, extensions can call back into Python at almost random moments. Therefore, a complete threads implementation requires thread support for C.

Answer 2: Fortunately, there is Stackless Python, which has a completely redesigned interpreter loop that avoids the C stack.
Why can’t lambda expressions contain statements?

Python lambda expressions cannot contain statements because Python's syntactic framework can't handle statements nested inside expressions. However, in Python, this is not a serious problem. Unlike lambda forms in other languages, where they add functionality, Python lambdas are only a shorthand notation if you're too lazy to define a function.

Functions are already first class objects in Python, and can be declared in a local scope. Therefore the only advantage of using a lambda instead of a locally-defined function is that you don’t need to invent a name for the function – but that’s just a local variable to which the function object (which is exactly the same type of object that a lambda expression yields) is assigned!
Can Python be compiled to machine code, C or some other language?

Practical answer:

Cython and Pyrex compile a modified version of Python with optional annotations into C extensions. Weave makes it easy to intermingle Python and C code in various ways to increase performance. Nuitka is an up-and-coming compiler of Python into C++ code, aiming to support the full Python language.

Theoretical answer:

Not trivially. Python’s high level data types, dynamic typing of objects and run-time invocation of the interpreter (using eval() or exec()) together mean that a naïvely “compiled” Python program would probably consist mostly of calls into the Python run-time system, even for seemingly simple operations like \( x+1 \).

Several projects described in the Python newsgroup or at past Python conferences have shown that this approach is feasible, although the speedups reached so far are only modest (e.g. 2x). Jython uses the same strategy for compiling to Java bytecode. (Jim Hugunin has demonstrated that in combination with whole-program analysis, speedups of 1000x are feasible for small demo programs. See the proceedings from the 1997 Python conference for more information.)
How does Python manage memory?

The details of Python memory management depend on the implementation. The standard implementation of Python, CPython, uses reference counting to detect inaccessible objects, and another mechanism to collect reference cycles, periodically executing a cycle detection algorithm which looks for inaccessible cycles and deletes the objects involved. The gc module provides functions to perform a garbage collection, obtain debugging statistics, and tune the collector's parameters.

Other implementations (such as Jython or PyPy), however, can rely on a different mechanism such as a full-blown garbage collector. This difference can cause some subtle porting problems if your Python code depends on the behavior of the reference counting implementation.

In some Python implementations, the following code (which is fine in CPython) will probably run out of file descriptors:

```python
for file in very_long_list_of_files:
    f = open(file)
    c = f.read(1)
```

Indeed, using CPython's reference counting and destructor scheme, each new assignment to `f` closes the previous file. With a traditional GC, however, those file objects will only get collected (and closed) at varying and possibly long intervals.

If you want to write code that will work with any Python implementation, you should explicitly close the file or use the with statement; this will work regardless of memory management scheme:
for file in very_long_list_of_files:
    with open(file) as f:
        c = f.read(1)
Why doesn’t CPython use a more traditional garbage collection scheme?

For one thing, this is not a C standard feature and hence it’s not portable. (Yes, we know about the Boehm GC library. It has bits of assembler code for most common platforms, not for all of them, and although it is mostly transparent, it isn’t completely transparent; patches are required to get Python to work with it.)

Traditional GC also becomes a problem when Python is embedded into other applications. While in a standalone Python it’s fine to replace the standard malloc() and free() with versions provided by the GC library, an application embedding Python may want to have its own substitute for malloc() and free(), and may not want Python’s. Right now, CPython works with anything that implements malloc() and free() properly.
Why isn’t all memory freed when CPython exits?

Objects referenced from the global namespaces of Python modules are not always deallocated when Python exits. This may happen if there are circular references. There are also certain bits of memory that are allocated by the C library that are impossible to free (e.g. a tool like Purify will complain about these). Python is, however, aggressive about cleaning up memory on exit and does try to destroy every single object.

If you want to force Python to delete certain things on deallocation use the `atexit` module to run a function that will force those deletions.
Why are there separate tuple and list data types?

Lists and tuples, while similar in many respects, are generally used in fundamentally different ways. Tuples can be thought of as being similar to Pascal records or C structs; they’re small collections of related data which may be of different types which are operated on as a group. For example, a Cartesian coordinate is appropriately represented as a tuple of two or three numbers.

Lists, on the other hand, are more like arrays in other languages. They tend to hold a varying number of objects all of which have the same type and which are operated on one-by-one. For example, `os.listdir('.')` returns a list of strings representing the files in the current directory. Functions which operate on this output would generally not break if you added another file or two to the directory.

Tuples are immutable, meaning that once a tuple has been created, you can’t replace any of its elements with a new value. Lists are mutable, meaning that you can always change a list’s elements. Only immutable elements can be used as dictionary keys, and hence only tuples and not lists can be used as keys.
How are lists implemented?

Python’s lists are really variable-length arrays, not Lisp-style linked lists. The implementation uses a contiguous array of references to other objects, and keeps a pointer to this array and the array’s length in a list head structure.

This makes indexing a list $a[i]$ an operation whose cost is independent of the size of the list or the value of the index.

When items are appended or inserted, the array of references is resized. Some cleverness is applied to improve the performance of appending items repeatedly; when the array must be grown, some extra space is allocated so the next few times don’t require an actual resize.
How are dictionaries implemented?

Python’s dictionaries are implemented as resizable hash tables. Compared to B-trees, this gives better performance for lookup (the most common operation by far) under most circumstances, and the implementation is simpler.

Dictionaries work by computing a hash code for each key stored in the dictionary using the `hash()` built-in function. The hash code varies widely depending on the key and a per-process seed; for example, “Python” could hash to -539294296 while “python”, a string that differs by a single bit, could hash to 1142331976. The hash code is then used to calculate a location in an internal array where the value will be stored. Assuming that you’re storing keys that all have different hash values, this means that dictionaries take constant time – O(1), in computer science notation – to retrieve a key. It also means that no sorted order of the keys is maintained, and traversing the array as the `.keys()` and `.items()` do will output the dictionary’s content in some arbitrary jumbled order that can change with every invocation of a program.
Why must dictionary keys be immutable?

The hash table implementation of dictionaries uses a hash value calculated from the key value to find the key. If the key were a mutable object, its value could change, and thus its hash could also change. But since whoever changes the key object can’t tell that it was being used as a dictionary key, it can’t move the entry around in the dictionary. Then, when you try to look up the same object in the dictionary it won’t be found because its hash value is different. If you tried to look up the old value it wouldn’t be found either, because the value of the object found in that hash bin would be different.

If you want a dictionary indexed with a list, simply convert the list to a tuple first; the function `tuple(L)` creates a tuple with the same entries as the list `L`. Tuples are immutable and can therefore be used as dictionary keys.

Some unacceptable solutions that have been proposed:

- Hash lists by their address (object ID). This doesn’t work because if you construct a new list with the same value it won’t be found; e.g.:

  ```python
  mydict = {[1, 2]: '12'}
  print(mydict[[1, 2]])
  ```

  would raise a KeyError exception because the id of the `[1, 2]` used in the second line differs from that in the first line. In other words, dictionary keys should be compared using `==`, not using `is`.

- Make a copy when using a list as a key. This doesn’t work
because the list, being a mutable object, could contain a reference to itself, and then the copying code would run into an infinite loop.

- Allow lists as keys but tell the user not to modify them. This would allow a class of hard-to-track bugs in programs when you forgot or modified a list by accident. It also invalidates an important invariant of dictionaries: every value in \texttt{d.keys()} is usable as a key of the dictionary.

- Mark lists as read-only once they are used as a dictionary key. The problem is that it's not just the top-level object that could change its value; you could use a tuple containing a list as a key. Entering anything as a key into a dictionary would require marking all objects reachable from there as read-only – and again, self-referential objects could cause an infinite loop.

There is a trick to get around this if you need to, but use it at your own risk: You can wrap a mutable structure inside a class instance which has both a \texttt{__eq__()} and a \texttt{__hash__()} method. You must then make sure that the hash value for all such wrapper objects that reside in a dictionary (or other hash based structure), remain fixed while the object is in the dictionary (or other structure).

```python
class ListWrapper:
    def __init__(self, the_list):
        self.the_list = the_list
    def __eq__(self, other):
        return self.the_list == other.the_list
    def __hash__(self):
        l = self.the_list
        result = 98767 - len(l)*555
        for i, el in enumerate(l):
            try:
```
result = result + (hash(el) % 999999)

except Exception:
    result = (result % 777777) + i * 33

return result

Note that the hash computation is complicated by the possibility that some members of the list may be unhashable and also by the possibility of arithmetic overflow.

Furthermore it must always be the case that if o1 == o2 (ie o1.__eq__(o2) is True) then hash(o1) == hash(o2) (ie, o1.__hash__() == o2.__hash__()), regardless of whether the object is in a dictionary or not. If you fail to meet these restrictions dictionaries and other hash based structures will misbehave.

In the case of ListWrapper, whenever the wrapper object is in a dictionary the wrapped list must not change to avoid anomalies. Don’t do this unless you are prepared to think hard about the requirements and the consequences of not meeting them correctly. Consider yourself warned.
Why doesn’t list.sort() return the sorted list?

In situations where performance matters, making a copy of the list just to sort it would be wasteful. Therefore, `list.sort()` sorts the list in place. In order to remind you of that fact, it does not return the sorted list. This way, you won’t be fooled into accidentally overwriting a list when you need a sorted copy but also need to keep the unsorted version around.

If you want to return a new list, use the built-in `sorted()` function instead. This function creates a new list from a provided iterable, sorts it and returns it. For example, here’s how to iterate over the keys of a dictionary in sorted order:

```python
for key in sorted(mydict):
    ... # do whatever with mydict[key]...
```
How do you specify and enforce an interface spec in Python?

An interface specification for a module as provided by languages such as C++ and Java describes the prototypes for the methods and functions of the module. Many feel that compile-time enforcement of interface specifications helps in the construction of large programs.

Python 2.6 adds an `abc` module that lets you define Abstract Base Classes (ABCs). You can then use `isinstance()` and `issubclass()` to check whether an instance or a class implements a particular ABC. The `collections.abc` module defines a set of useful ABCs such as `Iterable`, `Container`, and `MutableMapping`.

For Python, many of the advantages of interface specifications can be obtained by an appropriate test discipline for components. There is also a tool, PyChecker, which can be used to find problems due to subclassing.

A good test suite for a module can both provide a regression test and serve as a module interface specification and a set of examples. Many Python modules can be run as a script to provide a simple “self test.” Even modules which use complex external interfaces can often be tested in isolation using trivial “stub” emulations of the external interface. The `doctest` and `unittest` modules or third-party test frameworks can be used to construct exhaustive test suites that exercise every line of code in a module.

An appropriate testing discipline can help build large complex applications in Python as well as having interface specifications would.
In fact, it can be better because an interface specification cannot test certain properties of a program. For example, the `append()` method is expected to add new elements to the end of some internal list; an interface specification cannot test that your `append()` implementation will actually do this correctly, but it’s trivial to check this property in a test suite.

Writing test suites is very helpful, and you might want to design your code with an eye to making it easily tested. One increasingly popular technique, test-directed development, calls for writing parts of the test suite first, before you write any of the actual code. Of course Python allows you to be sloppy and not write test cases at all.
Why are default values shared between objects?

This type of bug commonly bites neophyte programmers. Consider this function:

```python
def foo(mydict={}):  # Danger: shared reference to one dict for all calls...
    ... compute something ...
    mydict[key] = value
    return mydict
```

The first time you call this function, `mydict` contains a single item. The second time, `mydict` contains two items because when `foo()` begins executing, `mydict` starts out with an item already in it.

It is often expected that a function call creates new objects for default values. This is not what happens. Default values are created exactly once, when the function is defined. If that object is changed, like the dictionary in this example, subsequent calls to the function will refer to this changed object.

By definition, immutable objects such as numbers, strings, tuples, and `None`, are safe from change. Changes to mutable objects such as dictionaries, lists, and class instances can lead to confusion.

Because of this feature, it is good programming practice to not use mutable objects as default values. Instead, use `None` as the default value and inside the function, check if the parameter is `None` and create a new list/dictionary/whatever if it is. For example, don’t write:

```python
def foo(mydict={}):
```
but:

```python
def foo(mydict=None):
    if mydict is None:
        mydict = {}  # create a new dict for local namespace
```

This feature can be useful. When you have a function that’s time-consuming to compute, a common technique is to cache the parameters and the resulting value of each call to the function, and return the cached value if the same value is requested again. This is called “memoizing”, and can be implemented like this:

```python
# Callers will never provide a third parameter for this function.
def expensive(arg1, arg2, _cache={}):
    if (arg1, arg2) in _cache:
        return _cache[(arg1, arg2)]

    # Calculate the value
    result = ... expensive computation ...
    _cache[(arg1, arg2)] = result  # Store result in the cache
    return result
```

You could use a global variable containing a dictionary instead of the default value; it’s a matter of taste.
Why is there no goto?

You can use exceptions to provide a “structured goto” that even works across function calls. Many feel that exceptions can conveniently emulate all reasonable uses of the “go” or “goto” constructs of C, Fortran, and other languages. For example:

```python
class label(Exception): pass  # declare a label

try:
    ...
    if condition: raise label()  # goto label
    ...
except label:  # where to goto
    pass
    ...
```

This doesn't allow you to jump into the middle of a loop, but that's usually considered an abuse of goto anyway. Use sparingly.
Why can’t raw strings (r-strings) end with a backslash?

More precisely, they can’t end with an odd number of backslashes: the unpaired backslash at the end escapes the closing quote character, leaving an unterminated string.

Raw strings were designed to ease creating input for processors (chiefly regular expression engines) that want to do their own backslash escape processing. Such processors consider an unmatched trailing backslash to be an error anyway, so raw strings disallow that. In return, they allow you to pass on the string quote character by escaping it with a backslash. These rules work well when r-strings are used for their intended purpose.

If you’re trying to build Windows pathnames, note that all Windows system calls accept forward slashes too:

```python
f = open("/mydir/file.txt")  # works fine!
```

If you're trying to build a pathname for a DOS command, try e.g. one of

```python
dir = r"\this\is\my\dos\dir" "\\"
dir = r"\this\is\my\dos\dir\ "[:-1]
dir = "\\this\\is\\my\\dos\\dir\\"
```
Why doesn’t Python have a “with” statement for attribute assignments?

Python has a ‘with’ statement that wraps the execution of a block, calling code on the entrance and exit from the block. Some language have a construct that looks like this:

```python
with obj:
    a = 1  # equivalent to obj.a = 1
    total = total + 1  # obj.total = obj.total + 1
```

In Python, such a construct would be ambiguous.

Other languages, such as Object Pascal, Delphi, and C++, use static types, so it’s possible to know, in an unambiguous way, what member is being assigned to. This is the main point of static typing – the compiler always knows the scope of every variable at compile time.

Python uses dynamic types. It is impossible to know in advance which attribute will be referenced at runtime. Member attributes may be added or removed from objects on the fly. This makes it impossible to know, from a simple reading, what attribute is being referenced: a local one, a global one, or a member attribute?

For instance, take the following incomplete snippet:

```python
def foo(a):
    with a:
        print(x)
```

The snippet assumes that “a” must have a member attribute called “x”. However, there is nothing in Python that tells the interpreter this. What
should happen if “a” is, let us say, an integer? If there is a global variable named “x”, will it be used inside the with block? As you see, the dynamic nature of Python makes such choices much harder.

The primary benefit of “with” and similar language features (reduction of code volume) can, however, easily be achieved in Python by assignment. Instead of:

```python
function(args).mydict[index][index].a = 21
function(args).mydict[index][index].b = 42
function(args).mydict[index][index].c = 63
```

write this:

```python
ref = function(args).mydict[index][index]
ref.a = 21
ref.b = 42
ref.c = 63
```

This also has the side-effect of increasing execution speed because name bindings are resolved at run-time in Python, and the second version only needs to perform the resolution once.
Why are colons required for the if/while/def/class statements?

The colon is required primarily to enhance readability (one of the results of the experimental ABC language). Consider this:

```python
if a == b
    print(a)
```

versus

```python
if a == b:
    print(a)
```

Notice how the second one is slightly easier to read. Notice further how a colon sets off the example in this FAQ answer; it's a standard usage in English.

Another minor reason is that the colon makes it easier for editors with syntax highlighting; they can look for colons to decide when indentation needs to be increased instead of having to do a more elaborate parsing of the program text.
Why does Python allow commas at the end of lists and tuples?

Python lets you add a trailing comma at the end of lists, tuples, and dictionaries:

```python
[1, 2, 3,]
('a', 'b', 'c',)
d = {
    "A": [1, 5],
    "B": [6, 7],  # last trailing comma is optional
}
```

There are several reasons to allow this.

When you have a literal value for a list, tuple, or dictionary spread across multiple lines, it's easier to add more elements because you don't have to remember to add a comma to the previous line. The lines can also be reordered without creating a syntax error.

Accidentally omitting the comma can lead to errors that are hard to diagnose. For example:

```python
x = [
    "fee",
    "fie",
    "foo",
    "fum"
]
```

This list looks like it has four elements, but it actually contains three: “fee”, “fiefoo” and “fum”. Always adding the comma avoids this source
of error.

Allowing the trailing comma may also make programmatic code generation easier.

General Library Questions

How do I find a module or application to perform task X?

Check the Library Reference to see if there's a relevant standard library module. (Eventually you'll learn what's in the standard library and will be able to skip this step.)

For third-party packages, search the Python Package Index or try Google or another Web search engine. Searching for “Python” plus a keyword or two for your topic of interest will usually find something helpful.

Where is the math.py (socket.py, regex.py, etc.) source file?

If you can’t find a source file for a module it may be a built-in or dynamically loaded module implemented in C, C++ or other compiled language. In this case you may not have the source file or it may be something like mathmodule.c, somewhere in a C source directory (not on the Python Path).

There are (at least) three kinds of modules in Python:

1. modules written in Python (.py);
2. modules written in C and dynamically loaded (.dll, .pyd, .so, .sl, etc);
3. modules written in C and linked with the interpreter; to get a list of these, type:
```python
import sys
print(sys.builtin_module_names)
```

**How do I make a Python script executable on Unix?**

You need to do two things: the script file’s mode must be executable and the first line must begin with `#!` followed by the path of the Python interpreter.

The first is done by executing `chmod +x scriptfile` or perhaps `chmod 755 scriptfile`.

The second can be done in a number of ways. The most straightforward way is to write

```
#!/usr/local/bin/python
```

as the very first line of your file, using the pathname for where the Python interpreter is installed on your platform.

If you would like the script to be independent of where the Python interpreter lives, you can use the `env` program. Almost all Unix variants support the following, assuming the Python interpreter is in a directory on the user’s PATH:

```
#!/usr/bin/env python
```

*Don’t* do this for CGI scripts. The PATH variable for CGI scripts is often very very minimal, so you need to use the actual absolute pathname of the interpreter.
Occasionally, a user's environment is so full that the `/usr/bin/env` program fails; or there's no env program at all. In that case, you can try the following hack (due to Alex Rezinsky):

```sh
#!/bin/sh
"":
exec python $0 ${1+"$@"}
"
```

The minor disadvantage is that this defines the script’s `__doc__` string. However, you can fix that by adding

```python
__doc__ = """...Whatever...""
```

**Is there a curses/termcap package for Python?**

For Unix variants: The standard Python source distribution comes with a curses module in the `Modules` subdirectory, though it's not compiled by default. (Note that this is not available in the Windows distribution – there is no curses module for Windows.)

The `curses` module supports basic curses features as well as many additional functions from `ncurses` and `SYSV` curses such as colour, alternative character set support, pads, and mouse support. This means the module isn't compatible with operating systems that only have BSD curses, but there don't seem to be any currently maintained OSes that fall into this category.

For Windows: use the `consolelib` module.

**Is there an equivalent to C’s onexit() in Python?**
The `atexit` module provides a register function that is similar to C's `onexit()`.

**Why don’t my signal handlers work?**

The most common problem is that the signal handler is declared with the wrong argument list. It is called as

```python
handler(signum, frame)
```

so it should be declared with two arguments:

```python
def handler(signum, frame):
    ...
```
Common tasks

How do I test a Python program or component?

Python comes with two testing frameworks. The `doctest` module finds examples in the docstrings for a module and runs them, comparing the output with the expected output given in the docstring.

The `unittest` module is a fancier testing framework modelled on Java and Smalltalk testing frameworks.

To make testing easier, you should use good modular design in your program. Your program should have almost all functionality encapsulated in either functions or class methods – and this sometimes has the surprising and delightful effect of making the program run faster (because local variable accesses are faster than global accesses). Furthermore the program should avoid depending on mutating global variables, since this makes testing much more difficult to do.

The “global main logic” of your program may be as simple as

```python
if __name__ == '__main__':
    main_logic()
```

at the bottom of the main module of your program.

Once your program is organized as a tractable collection of functions and class behaviours you should write test functions that exercise the behaviours. A test suite that automates a sequence of tests can be associated with each module. This sounds like a lot of work, but since Python is so terse and flexible it's surprisingly easy. You can make
coding much more pleasant and fun by writing your test functions in parallel with the “production code”, since this makes it easy to find bugs and even design flaws earlier.

“Support modules” that are not intended to be the main module of a program may include a self-test of the module.

```python
if __name__ == '__main__':
    self_test()
```

Even programs that interact with complex external interfaces may be tested when the external interfaces are unavailable by using “fake” interfaces implemented in Python.

**How do I create documentation from doc strings?**

The *pydoc* module can create HTML from the doc strings in your Python source code. An alternative for creating API documentation purely from docstrings is *epydoc*. *Sphinx* can also include docstring content.

**How do I get a single keypress at a time?**

For Unix variants there are several solutions. It's straightforward to do this using curses, but curses is a fairly large module to learn.
Threads

How do I program using threads?

Be sure to use the `threading` module and not the `_thread` module. The `threading` module builds convenient abstractions on top of the low-level primitives provided by the `_thread` module.

Aahz has a set of slides from his threading tutorial that are helpful; see [http://www.pythoncraft.com/OSCON2001/](http://www.pythoncraft.com/OSCON2001/).

None of my threads seem to run: why?

As soon as the main thread exits, all threads are killed. Your main thread is running too quickly, giving the threads no time to do any work.

A simple fix is to add a sleep to the end of the program that's long enough for all the threads to finish:

```python
import threading, time

def thread_task(name, n):
    for i in range(n):
        print(name, i)

for i in range(10):
    T = threading.Thread(target=thread_task, args=(str(i),))
    T.start()

time.sleep(10)  # <---------------------------!
```

But now (on many platforms) the threads don’t run in parallel, but
appear to run sequentially, one at a time! The reason is that the OS thread scheduler doesn’t start a new thread until the previous thread is blocked.

A simple fix is to add a tiny sleep to the start of the run function:

```python
def thread_task(name, n):
    time.sleep(0.001)  # <----------------------!
    for i in range(n):
        print(name, i)

for i in range(10):
    T = threading.Thread(target=thread_task, args=(str(T.start()),))
    T.start()

time.sleep(10)
```

Instead of trying to guess a good delay value for `time.sleep()`, it’s better to use some kind of semaphore mechanism. One idea is to use the `queue` module to create a queue object, let each thread append a token to the queue when it finishes, and let the main thread read as many tokens from the queue as there are threads.

**How do I parcel out work among a bunch of worker threads?**

The easiest way is to use the new `concurrent.futures` module, especially the `ThreadPoolExecutor` class.

Or, if you want fine control over the dispatching algorithm, you can write your own logic manually. Use the `queue` module to create a queue containing a list of jobs. The `Queue` class maintains a list of objects and has a `.put(obj)` method that adds items to the queue.
and a .get() method to return them. The class will take care of the locking necessary to ensure that each job is handed out exactly once.

Here's a trivial example:

```python
import threading, queue, time

# The worker thread gets jobs off the queue. When the queue is empty, it assumes there will be no more work and exits. (Realistically workers will run until terminated.)
def worker():
    print('Running worker')
    time.sleep(0.1)
    while True:
        try:
            arg = q.get(block=False)
        except queue.Empty:
            print('Worker', threading.currentThread(), 'queue empty')
            break
        else:
            print('Worker', threading.currentThread(), 'running with argument', arg)
            time.sleep(0.5)

# Create queue
q = queue.Queue()

# Start a pool of 5 workers
for i in range(5):
    t = threading.Thread(target=worker, name='worker%i' % i)
    t.start()

# Begin adding work to the queue
for i in range(50):
    q.put(i)
```
# Give threads time to run

```
print('Main thread sleeping')
time.sleep(5)
```

When run, this will produce the following output:

```
Running worker
Running worker
Running worker
Running worker
Running worker
Main thread sleeping
Worker <Thread(worker 1, started 130283832797456)> running with argument 0
Worker <Thread(worker 2, started 130283824404752)> running with argument 1
Worker <Thread(worker 3, started 130283816012048)> running with argument 2
Worker <Thread(worker 4, started 130283807619344)> running with argument 3
Worker <Thread(worker 5, started 130283799226640)> running with argument 4
Worker <Thread(worker 1, started 130283832797456)> running with argument 5
...
```

Consult the module’s documentation for more details; the `Queue` class provides a featureful interface.

**What kinds of global value mutation are thread-safe?**

A *global interpreter lock* (GIL) is used internally to ensure that only one thread runs in the Python VM at a time. In general, Python offers to switch among threads only between bytecode instructions; how frequently it switches can be set via `sys.setswitchinterval()`. Each bytecode instruction and therefore all the C implementation code reached from each instruction is therefore atomic from the point of
view of a Python program.

In theory, this means an exact accounting requires an exact understanding of the PVM bytecode implementation. In practice, it means that operations on shared variables of built-in data types (ints, lists, dicts, etc) that “look atomic” really are.

For example, the following operations are all atomic (L, L1, L2 are lists, D, D1, D2 are dicts, x, y are objects, i, j are ints):

```python
L.append(x)
L1.extend(L2)
x = L[i]
x = L.pop()
L1[i:j] = L2
L.sort()
x = y
x.field = y
D[x] = y
D1.update(D2)
D.keys()
```

These aren’t:

```python
i = i+1
L.append(L[-1])
L[i] = L[j]
D[x] = D[x] + 1
```

Operations that replace other objects may invoke those other objects’ `__del__()` method when their reference count reaches zero, and that can affect things. This is especially true for the mass updates to dictionaries and lists. When in doubt, use a mutex!
Can’t we get rid of the Global Interpreter Lock?

The *global interpreter lock* (GIL) is often seen as a hindrance to Python’s deployment on high-end multiprocessor server machines, because a multi-threaded Python program effectively only uses one CPU, due to the insistence that (almost) all Python code can only run while the GIL is held.

Back in the days of Python 1.5, Greg Stein actually implemented a comprehensive patch set (the “free threading” patches) that removed the GIL and replaced it with fine-grained locking. Adam Olsen recently did a similar experiment in his *python-safethread* project. Unfortunately, both experiments exhibited a sharp drop in single-thread performance (at least 30% slower), due to the amount of fine-grained locking necessary to compensate for the removal of the GIL.

This doesn’t mean that you can’t make good use of Python on multi-CPU machines! You just have to be creative with dividing the work up between multiple *processes* rather than multiple *threads*. The *ProcessPoolExecutor* class in the new *concurrent.futures* module provides an easy way of doing so; the *multiprocessing* module provides a lower-level API in case you want more control over dispatching of tasks.

Judicious use of C extensions will also help; if you use a C extension to perform a time-consuming task, the extension can release the GIL while the thread of execution is in the C code and allow other threads to get some work done. Some standard library modules such as *zlib* and *hashlib* already do this.

It has been suggested that the GIL should be a per-interpreter-state lock rather than truly global; interpreters then wouldn’t be able to share
objects. Unfortunately, this isn’t likely to happen either. It would be a tremendous amount of work, because many object implementations currently have global state. For example, small integers and short strings are cached; these caches would have to be moved to the interpreter state. Other object types have their own free list; these free lists would have to be moved to the interpreter state. And so on.

And I doubt that it can even be done in finite time, because the same problem exists for 3rd party extensions. It is likely that 3rd party extensions are being written at a faster rate than you can convert them to store all their global state in the interpreter state.

And finally, once you have multiple interpreters not sharing any state, what have you gained over running each interpreter in a separate process?
Input and Output

How do I delete a file? (And other file questions...)

Use `os.remove(filename)` or `os.unlink(filename)`; for documentation, see the `os` module. The two functions are identical; `unlink()` is simply the name of the Unix system call for this function.

To remove a directory, use `os.rmdir()`; use `os.mkdir()` to create one. `os.makedirs(path)` will create any intermediate directories in `path` that don't exist. `os.removedirs(path)` will remove intermediate directories as long as they're empty; if you want to delete an entire directory tree and its contents, use `shutil.rmtree()`.

To rename a file, use `os.rename(old_path, new_path)`.

To truncate a file, open it using `f = open(filename, "rb+"), and use `f.truncate(offset); offset defaults to the current seek position. There's also `os.ftruncate(fd, offset)` for files opened with `os.open()`, where `fd` is the file descriptor (a small integer).

The `shutil` module also contains a number of functions to work on files including `copyfile()`, `copytree()`, and `rmtree()`.

How do I copy a file?

The `shutil` module contains a `copyfile()` function. Note that on MacOS 9 it doesn’t copy the resource fork and Finder info.

How do I read (or write) binary data?
To read or write complex binary data formats, it's best to use the `struct` module. It allows you to take a string containing binary data (usually numbers) and convert it to Python objects; and vice versa.

For example, the following code reads two 2-byte integers and one 4-byte integer in big-endian format from a file:

```python
import struct

with open(filename, "rb") as f:
    s = f.read(8)
    x, y, z = struct.unpack(">hhl", s)
```

The ‘>’ in the format string forces big-endian data; the letter ‘h’ reads one “short integer” (2 bytes), and ‘l’ reads one “long integer” (4 bytes) from the string.

For data that is more regular (e.g. a homogeneous list of ints or floats), you can also use the `array` module.

**Note:** To read and write binary data, it is mandatory to open the file in binary mode (here, passing "rb" to `open()`). If you use "r" instead (the default), the file will be open in text mode and `f.read()` will return `str` objects rather than `bytes` objects.

I can’t seem to use `os.read()` on a pipe created with `os.popen();` why?

`os.read()` is a low-level function which takes a file descriptor, a small integer representing the opened file. `os.popen()` creates a high-level file object, the same type returned by the built-in `open()`
function. Thus, to read \( n \) bytes from a pipe \( p \) created with \texttt{os.popen()}\), you need to use \texttt{p.read(n)}.

**How do I access the serial (RS232) port?**

For Win32, POSIX (Linux, BSD, etc.), Jython:

http://pyserial.sourceforge.net

For Unix, see a Usenet post by Mitch Chapman:

http://groups.google.com/groups?selm=34A04430.CF9@ohioee.com

**Why doesn’t closing sys.stdout (stdin, stderr) really close it?**

Python *file objects* are a high-level layer of abstraction on low-level C file descriptors.

For most file objects you create in Python via the built-in \texttt{open()} function, \texttt{f.close()} marks the Python file object as being closed from Python's point of view, and also arranges to close the underlying C file descriptor. This also happens automatically in \texttt{f}'s destructor, when \texttt{f} becomes garbage.

But stdin, stdout and stderr are treated specially by Python, because of the special status also given to them by C. Running \texttt{sys.stdout.close()} marks the Python-level file object as being closed, but does *not* close the associated C file descriptor.

To close the underlying C file descriptor for one of these three, you should first be sure that’s what you really want to do (e.g., you may
confuse extension modules trying to do I/O). If it is, use `os.close()`:

```python
os.close(stdin.fileno())
os.close(stdout.fileno())
os.close(stderr.fileno())
```

Or you can use the numeric constants 0, 1 and 2, respectively.
Network/Internet Programming

What WWW tools are there for Python?

See the chapters titled *Internet Protocols and Support* and *Internet Data Handling* in the Library Reference Manual. Python has many modules that will help you build server-side and client-side web systems.

How can I mimic CGI form submission (METHOD=POST)?

I would like to retrieve web pages that are the result of POSTing a form. Is there existing code that would let me do this easily?

Yes. Here's a simple example that uses urllib.request:

```python
#!/usr/local/bin/python

import urllib.request

### build the query string
qs = "First=Josephine&MI=Q&Last=Public"

### connect and send the server a path
req = urllib.request.urlopen('http://www.some-server.out-there' '/cgi-bin/some-cgi-script')
```
Note that in general for percent-encoded POST operations, query strings must be quoted using `urllib.parse.urlencode()`. For example, to send `name=Guy Steele, Jr.`:

```python
>>> import urllib.parse
>>> urllib.parse.urlencode({'name': 'Guy Steele, Jr.', 'name=Guy+Steele%2C+Jr.'})
```

**See also:** HOWTO Fetch Internet Resources Using The urllib Package for extensive examples.

**What module should I use to help with generating HTML?**

You can find a collection of useful links on the Web Programming wiki page.

**How do I send mail from a Python script?**

Use the standard library module `smtplib`.

Here's a very simple interactive mail sender that uses it. This method will work on any host that supports an SMTP listener.

```python
import sys, smtplib
fromaddr = input("From: ")
toaddrs  = input("To: ").split(',
print("Enter message, end with ^D:")
```
msg = ''
while True:
    line = sys.stdin.readline()
    if not line:
        break
    msg += line

# The actual mail send
server = smtplib.SMTP('localhost')
server.sendmail(fromaddr, toaddrs, msg)
server.quit()

A Unix-only alternative uses sendmail. The location of the sendmail program varies between systems; sometimes it is /usr/lib/sendmail, sometimes /usr/sbin/sendmail. The sendmail manual page will help you out. Here's some sample code:

SENDMAIL = '/usr/sbin/sendmail'  # sendmail location
import os
p = os.popen("%s -t -i" % SENDMAIL, "w")
p.write("To: receiver@example.com\n")
p.write("Subject: test\n")
p.write("\n")  # blank line separating headers from
p.write("Some text\n")
p.write("some more text\n")
sts = p.close()
if sts != 0:
    print("Sendmail exit status", sts)

How do I avoid blocking in the connect() method of a socket?

The select module is commonly used to help with asynchronous I/O on sockets.
To prevent the TCP connect from blocking, you can set the socket to non-blocking mode. Then when you do the `connect()`, you will either connect immediately (unlikely) or get an exception that contains the error number as `.errno`. `errno.EINPROGRESS` indicates that the connection is in progress, but hasn't finished yet. Different OSes will return different values, so you're going to have to check what's returned on your system.

You can use the `connect_ex()` method to avoid creating an exception. It will just return the `errno` value. To poll, you can call `connect_ex()` again later – `0` or `errno.EISCONN` indicate that you're connected – or you can pass this socket to `select` to check if it's writable.

**Note:** The `asyncore` module presents a framework-like approach to the problem of writing non-blocking networking code. The third-party `Twisted` library is a popular and feature-rich alternative.
Databases

Are there any interfaces to database packages in Python?

Yes.

Interfaces to disk-based hashes such as DBM and GDBM are also included with standard Python. There is also the sqlite3 module, which provides a lightweight disk-based relational database.

Support for most relational databases is available. See the DatabaseProgramming wiki page for details.

How do you implement persistent objects in Python?

The pickle library module solves this in a very general way (though you still can't store things like open files, sockets or windows), and the shelve library module uses pickle and (g)dbm to create persistent mappings containing arbitrary Python objects.
Mathematics and Numerics

How do I generate random numbers in Python?

The standard module `random` implements a random number generator. Usage is simple:

```python
import random
random.random()
```

This returns a random floating point number in the range [0, 1).

There are also many other specialized generators in this module, such as:

- `randrange(a, b)` chooses an integer in the range [a, b).
- `uniform(a, b)` chooses a floating point number in the range [a, b).
- `normalvariate(mean, sdev)` samples the normal (Gaussian) distribution.

Some higher-level functions operate on sequences directly, such as:

- `choice(S)` chooses random element from a given sequence
- `shuffle(L)` shuffles a list in-place, i.e. permutes it randomly

There’s also a Random class you can instantiate to create independent multiple random number generators.

  - How do I find undefined g++ symbols __builtin_new or __pure_virtual?
  - Can I create an object class with some methods implemented in C and others in Python (e.g. through inheritance)?
Can I create my own functions in C?

Yes, you can create built-in modules containing functions, variables, exceptions and even new types in C. This is explained in the document *Extending and Embedding the Python Interpreter*.

Most intermediate or advanced Python books will also cover this topic.
Can I create my own functions in C++?

Yes, using the C compatibility features found in C++. Place `extern "C" { ... }` around the Python include files and put `extern "C"` before each function that is going to be called by the Python interpreter. Global or static C++ objects with constructors are probably not a good idea.
Writing C is hard; are there any alternatives?

There are a number of alternatives to writing your own C extensions, depending on what you're trying to do.

Cython and its relative Pyrex are compilers that accept a slightly modified form of Python and generate the corresponding C code. Cython and Pyrex make it possible to write an extension without having to learn Python's C API.

If you need to interface to some C or C++ library for which no Python extension currently exists, you can try wrapping the library's data types and functions with a tool such as SWIG. SIP, CXX Boost, or Weave are also alternatives for wrapping C++ libraries.
How can I execute arbitrary Python statements from C?

The highest-level function to do this is `PyRun_SimpleString()` which takes a single string argument to be executed in the context of the module `__main__` and returns 0 for success and -1 when an exception occurred (including `SyntaxError`). If you want more control, use `PyRun_String()`: see the source for `PyRun_SimpleString()` in `Python/pythonrun.c`. 
How can I evaluate an arbitrary Python expression from C?

Call the function `PyRun_String()` from the previous question with the start symbol `Py_eval_input`; it parses an expression, evaluates it and returns its value.
How do I extract C values from a Python object?

That depends on the object's type. If it's a tuple, `PyTuple_Size()` returns its length and `PyTuple_GetItem()` returns the item at a specified index. Lists have similar functions, `PyListSize()` and `PyList_GetItem()`.

For bytes, `PyBytes_Size()` returns its length and `PyBytes_AsStringAndSize()` provides a pointer to its value and its length. Note that Python bytes objects may contain null bytes so C’s `strlen()` should not be used.

To test the type of an object, first make sure it isn’t `NULL`, and then use `PyBytes_Check()`, `PyTuple_Check()`, `PyList_Check()`, etc.

There is also a high-level API to Python objects which is provided by the so-called ‘abstract’ interface – read `Include/abstract.h` for further details. It allows interfacing with any kind of Python sequence using calls like `PySequence_Length()`, `PySequence_GetItem()`, etc.) as well as many other useful protocols such as numbers (`PyNumber_Index()` et. al.) and mappings in the PyMapping APIs.
How do I use Py_BuildValue() to create a tuple of arbitrary length?

You can't. Use PyTuple_Pack() instead.
How do I call an object’s method from C?

The `PyObject_CallMethod()` function can be used to call an arbitrary method of an object. The parameters are the object, the name of the method to call, a format string like that used with `Py_BuildValue()`, and the argument values:

```c
PyObject *
PyObject_CallMethod(PyObject *object, char *method_name, char *arg_format, ...);
```

This works for any object that has methods – whether built-in or user-defined. You are responsible for eventually `Py_DECREF()`'ing the return value.

To call, e.g., a file object’s “seek” method with arguments 10, 0 (assuming the file object pointer is “f”):

```c
res = PyObject_CallMethod(f, "seek", "(ii)", 10, 0);
if (res == NULL) {
    ... an exception occurred ...
}
else {
    Py_DECREF(res);
}
```

Note that since `PyObject_CallObject()` always wants a tuple for the argument list, to call a function without arguments, pass “()” for the format, and to call a function with one argument, surround the argument in parentheses, e.g. “(i)”.
How do I catch the output from `PyErr_Print()` (or anything that prints to `stdout/stderr`)?

In Python code, define an object that supports the `write()` method. Assign this object to `sys.stdout` and `sys.stderr`. Call `print_error`, or just allow the standard traceback mechanism to work. Then, the output will go wherever your `write()` method sends it.

The easiest way to do this is to use the `io.StringIO` class:

```python
>>> import io, sys
>>> sys.stdout = io.StringIO()
>>> print('foo')
>>> print('hello world!')
>>> sys.stderr.write(sys.stdout.getvalue())
foo
hello world!
```

A custom object to do the same would look like this:

```python
>>> import io, sys
>>> class StdoutCatcher(io.TextIOBase):
...     def __init__(self):
...         self.data = []
...     def write(self, stuff):
...         self.data.append(stuff)
... >>> import sys
>>> sys.stdout = StdoutCatcher()
>>> print('foo')
>>> print('hello world!')
>>> sys.stderr.write(''.join(sys.stdout.data))
```
foo
hello world!
How do I access a module written in Python from C?

You can get a pointer to the module object as follows:

```python
module = PyImport_ImportModule("<modulename>");
```

If the module hasn't been imported yet (i.e. it is not yet present in `sys.modules`), this initializes the module; otherwise it simply returns the value of `sys.modules["<modulename>"]`. Note that it doesn't enter the module into any namespace – it only ensures it has been initialized and is stored in `sys.modules`.

You can then access the module's attributes (i.e. any name defined in the module) as follows:

```python
attr = PyObject_GetAttrString(module, "<attrname>");
```

Calling `PyObject_SetAttrString()` to assign to variables in the module also works.
How do I interface to C++ objects from Python?

Depending on your requirements, there are many approaches. To do this manually, begin by reading *the “Extending and Embedding” document*. Realize that for the Python run-time system, there isn’t a whole lot of difference between C and C++ – so the strategy of building a new Python type around a C structure (pointer) type will also work for C++ objects.

For C++ libraries, see *Writing C is hard; are there any alternatives?*. 
I added a module using the Setup file and the make fails; why?

Setup must end in a newline, if there is no newline there, the build process fails. (Fixing this requires some ugly shell script hackery, and this bug is so minor that it doesn't seem worth the effort.)
How do I debug an extension?

When using GDB with dynamically loaded extensions, you can’t set a breakpoint in your extension until your extension is loaded.

In your `.gdbinit` file (or interactively), add the command:

```
br _PyImport_LoadDynamicModule
```

Then, when you run GDB:

```
$ gdb /local/bin/python
gdb) run myscript.py
gdb) continue  # repeat until your extension is loaded
gdb) finish    # so that your extension is loaded
gdb) br myfunction.c:50
gdb) continue
```
I want to compile a Python module on my Linux system, but some files are missing. Why?

Most packaged versions of Python don’t include the /usr/lib/python2.x/config/ directory, which contains various files required for compiling Python extensions.

For Red Hat, install the python-devel RPM to get the necessary files.

For Debian, run `apt-get install python-dev`. 
What does “SystemError: _PyImport_FixupExtension: module yourmodule not loaded” mean?

This means that you have created an extension module named “yourmodule”, but your module init function does not initialize with that name.

Every module init function will have a line similar to:

```python
module = Py_InitModule("yourmodule", yourmodule_functions)
```

If the string passed to this function is not the same name as your extension module, the `SystemError` exception will be raised.
How do I tell “incomplete input” from “invalid input”?

Sometimes you want to emulate the Python interactive interpreter’s behavior, where it gives you a continuation prompt when the input is incomplete (e.g. you typed the start of an “if” statement or you didn’t close your parentheses or triple string quotes), but it gives you a syntax error message immediately when the input is invalid.

In Python you can use the codeop module, which approximates the parser’s behavior sufficiently. IDLE uses this, for example.

The easiest way to do it in C is to call `PyRun_InteractiveLoop()` (perhaps in a separate thread) and let the Python interpreter handle the input for you. You can also set the `PyOS_ReadlineFunctionPointer()` to point at your custom input function. See `Modules/readline.c` and `Parser/myreadline.c` for more hints.

However sometimes you have to run the embedded Python interpreter in the same thread as your rest application and you can’t allow the `PyRun_InteractiveLoop()` to stop while waiting for user input. The one solution then is to call `PyParser_ParseString()` and test for `e.error` equal to `E_EOF`, which means the input is incomplete. Here’s a sample code fragment, untested, inspired by code from Alex Farber:

```
#include <Python.h>
#include <node.h>
#include <errcode.h>
#include <grammar.h>
#include <parsetok.h>
```
#include <compile.h>

int testcomplete(char *code)
    /* code should end in \n */
    /* return -1 for error, 0 for incomplete, 1 for complete */
{
    node *n;
    perrdetail e;

    n = PyParser_ParseString(code, &_PyParser_Grammar,
                            Py_file_input, &e);
    if (n == NULL) {
        if (e.error == E_EOF)
            return 0;
        return -1;
    }

    PyNode_Free(n);
    return 1;
}

Another solution is trying to compile the received string with Py_CompileString(). If it compiles without errors, try to execute the returned code object by calling PyEval_EvalCode(). Otherwise save the input for later. If the compilation fails, find out if it's an error or just more input is required - by extracting the message string from the exception tuple and comparing it to the string “unexpected EOF while parsing”. Here is a complete example using the GNU readline library (you may want to ignore SIGINT while calling readline()):

#include <stdio.h>
#include <readline.h>
#include <Python.h>
#include <object.h>

#include <compile.h>
#include <eval.h>

int main (int argc, char* argv[]) {
    int i, j, done = 0; /* length of line, code */
    char ps1[] = ">>> ";
    char ps2[] = "... ";
    char *prompt = ps1;
    char *msg, *line, *code = NULL;
    PyObject *src, *glb, *loc;

    Py_Initialize ();
    loc = PyDict_New ();
    glb = PyDict_New ();
    PyDict_SetItemString (glb, "__builtins__", PyEval_
code = realloc (code, i + j + 2);
if (NULL == code) /* out
    exit (1);

if (0 == j) /* co
    code[0] = '\0'; /* ke

strncat (code, line, i); /* ap
code[i + j] = '\n'; /* ap
code[i + j + 1] = '\0';

src = Py_CompileString (code, "<stdin>", Py_sini

if (NULL != src) /* co
{
    if (ps1 == prompt || /* ">
        '\n' == code[i + j - 1]) /* ",
    {
        dum = PyEval_EvalCode (src, glb, loc);
        Py_XDECREF (dum);
        Py_XDECREF (src);
        free (code);
        code = NULL;
        if (PyErr_Occurred ())
            PyErr_Print ();
            prompt = ps1;
    }
    /* sy
} else if (PyErr_ExceptionMatches (PyExc_SyntaxEr
{
    PyErr_Fetch (&exc, &val, &trb); /* cl

    if (PyArg_ParseTuple (val, "sO", &msg, &obj)
        !strcmp (msg, "unexpected EOF while pars
    {
        Py_XDECREF (exc);
Py_XDECREF (val);
Py_XDECREF (trb);
prompt = ps2;
}
else /* some other syntax error */ {
    PyErr_Restore (exc, val, trb);
    PyErr_Print ();
    free (code);
    code = NULL;
    prompt = ps1;
}
}
else /* some non-syntax error */ {
    PyErr_Print ();
    free (code);
    code = NULL;
    prompt = ps1;
}

free (line);
}
}

Py_XDECREF (glb);
Py_XDECREF (loc);
Py_F finalize();
exit(0);
How do I find undefined g++ symbols __builtin_new or __pure_virtual?

To dynamically load g++ extension modules, you must recompile Python, relink it using g++ (change LINKCC in the Python Modules Makefile), and link your extension module using g++ (e.g., g++ -shared -o mymodule.so mymodule.o).
Can I create an object class with some methods implemented in C and others in Python (e.g. through inheritance)?

In Python 2.2, you can inherit from built-in classes such as `int`, `list`, `dict`, etc.

The Boost Python Library (BPL, http://www.boost.org/libs/python/doc/index.html) provides a way of doing this from C++ (i.e. you can inherit from an extension class written in C++ using the BPL).

How do I run a Python program under Windows?

This is not necessarily a straightforward question. If you are already familiar with running programs from the Windows command line then everything will seem obvious; otherwise, you might need a little more guidance.

Unless you use some sort of integrated development environment, you will end up typing Windows commands into what is variously referred to as a “DOS window” or “Command prompt window”. Usually you can create such a window from your Start menu; under Windows 7 the menu selection is Start ➤ Programs ➤ Accessories ➤ Command Prompt. You should be able to recognize when you have started such a window because you will see a Windows “command prompt”, which usually looks like this:

```
C:\>
```

The letter may be different, and there might be other things after it, so you might just as easily see something like:

```
D:\YourName\Projects\Python>
```
depending on how your computer has been set up and what else you have recently done with it. Once you have started such a window, you are well on the way to running Python programs.

You need to realize that your Python scripts have to be processed by another program called the Python *interpreter*. The interpreter reads your script, compiles it into bytecodes, and then executes the bytecodes to run your program. So, how do you arrange for the interpreter to handle your Python?

First, you need to make sure that your command window recognises the word “python” as an instruction to start the interpreter. If you have opened a command window, you should try entering the command `python` and hitting return:

```
C:\Users\YourName> python
```

You should then see something like:

```
Python 3.3.0 (v3.3.0:bd8af890ebf2, Sep 29 2012, 10:5)
Type "help", "copyright", "credits" or "license" for
```

You have started the interpreter in “interactive mode”. That means you can enter Python statements or expressions interactively and have them executed or evaluated while you wait. This is one of Python's strongest features. Check it by entering a few expressions of your choice and seeing the results:

```
>>> print("Hello")
Hello
>>> "Hello" * 3
HelloHelloHello
```
Many people use the interactive mode as a convenient yet highly programmable calculator. When you want to end your interactive Python session, hold the Ctrl key down while you enter a Z, then hit the “Enter” key to get back to your Windows command prompt.

You may also find that you have a Start-menu entry such as Start ▶ Programs ▶ Python 3.3 ▶ Python (command line) that results in you seeing the >>> prompt in a new window. If so, the window will disappear after you enter the Ctrl-Z character; Windows is running a single “python” command in the window, and closes it when you terminate the interpreter.

If the python command, instead of displaying the interpreter prompt >>>, gives you a message like:

```
'python' is not recognized as an internal or external command
```

or:

```
Bad command or filename
```

then you need to make sure that your computer knows where to find the Python interpreter. To do this you will have to modify a setting called PATH, which is a list of directories where Windows will look for programs.

You should arrange for Python’s installation directory to be added to the PATH of every command window as it starts. If you installed Python...
fairly recently then the command

```
dir C:\py*
```

will probably tell you where it is installed; the usual location is something like `C:\Python33`. Otherwise you will be reduced to a search of your whole disk ... use Tools ▶ Find or hit the Search button and look for “python.exe”. Supposing you discover that Python is installed in the `C:\Python33` directory (the default at the time of writing), you should make sure that entering the command

```
c:\Python33\python
```

starts up the interpreter as above (and don’t forget you’ll need a “CTRL-Z” and an “Enter” to get out of it). Once you have verified the directory, you can add it to the system path to make it easier to start Python by just running the `python` command. This is currently an option in the installer as of CPython 3.3.

More information about environment variables can be found on the *Using Python on Windows* page.
How do I make Python scripts executable?

On Windows, the standard Python installer already associates the .py extension with a file type (Python.File) and gives that file type an open command that runs the interpreter (D:\Program Files\Python\python.exe "%1" %*). This is enough to make scripts executable from the command prompt as ‘foo.py’. If you’d rather be able to execute the script by simple typing ‘foo’ with no extension you need to add .py to the PATHEXT environment variable.
Why does Python sometimes take so long to start?

Usually Python starts very quickly on Windows, but occasionally there are bug reports that Python suddenly begins to take a long time to start up. This is made even more puzzling because Python will work fine on other Windows systems which appear to be configured identically.

The problem may be caused by a misconfiguration of virus checking software on the problem machine. Some virus scanners have been known to introduce startup overhead of two orders of magnitude when the scanner is configured to monitor all reads from the filesystem. Try checking the configuration of virus scanning software on your systems to ensure that they are indeed configured identically. McAfee, when configured to scan all file system read activity, is a particular offender.
How do I make an executable from a Python script?

See http://cx-freeze.sourceforge.net/ for a distutils extension that allows you to create console and GUI executables from Python code. py2exe, the most popular extension for building Python 2.x-based executables, does not yet support Python 3 but a version that does is in development.
Is a *.pyd file the same as a DLL?

Yes, .pyd files are dll's, but there are a few differences. If you have a DLL named(foo).pyd, then it must have a function PyInit_foo(). You can then write Python “import foo”, and Python will search for foo.pyd (as well as foo.py, foo.pyc) and if it finds it, will attempt to call PyInit_foo() to initialize it. You do not link your.exe with foo.lib, as that would cause Windows to require the DLL to be present.

Note that the search path for foo.py is PYTHONPATH, not the same as the path that Windows uses to search for foo.dll. Also, foo.pyd need not be present to run your program, whereas if you linked your program with a dll, the dll is required. Of course, foo.pyd is required if you want to say import foo. In a DLL, linkage is declared in the source code with __declspec(dllexport). In a .pyd, linkage is defined in a list of available functions.
How can I embed Python into a Windows application?

Embedding the Python interpreter in a Windows app can be summarized as follows:

1. Do _not_ build Python into your .exe file directly. On Windows, Python must be a DLL to handle importing modules that are themselves DLL's. (This is the first key undocumented fact.) Instead, link to `pythonNN.dll`; it is typically installed in C:\Windows\System. \textit{NN} is the Python version, a number such as “33” for Python 3.3.

You can link to Python in two different ways. Load-time linking means linking against `pythonNN.lib`, while run-time linking means linking against `pythonNN.dll`. (General note: `pythonNN.lib` is the so-called “import lib” corresponding to `pythonNN.dll`. It merely defines symbols for the linker.)

Run-time linking greatly simplifies link options; everything happens at run time. Your code must load `pythonNN.dll` using the Windows \texttt{LoadLibraryEx()} routine. The code must also use access routines and data in `pythonNN.dll` (that is, Python’s C API’s) using pointers obtained by the Windows \texttt{GetProcAddress()} routine. Macros can make using these pointers transparent to any C code that calls routines in Python’s C API.

Borland note: convert `pythonNN.lib` to OMF format using Coff2Omf.exe first.
2. If you use SWIG, it is easy to create a Python “extension module” that will make the app’s data and methods available to Python. SWIG will handle just about all the grungy details for you. The result is C code that you link into your .exe file (!) You do _not_ have to create a DLL file, and this also simplifies linking.

3. SWIG will create an init function (a C function) whose name depends on the name of the extension module. For example, if the name of the module is leo, the init function will be called initleo(). If you use SWIG shadow classes, as you should, the init function will be called initleoc(). This initializes a mostly hidden helper class used by the shadow class.

   The reason you can link the C code in step 2 into your .exe file is that calling the initialization function is equivalent to importing the module into Python! (This is the second key undocumented fact.)

4. In short, you can use the following code to initialize the Python interpreter with your extension module.

   ```
#include "python.h"
...
Py_Initialize();  // Initialize Python.
initmyAppc();  // Initialize (import) the helper
PyRun_SimpleString("import myApp");  // Import the 
```

5. There are two problems with Python’s C API which will become apparent if you use a compiler other than MSVC, the compiler used to build pythonNN.dll.

   Problem 1: The so-called “Very High Level” functions that take FILE * arguments will not work in a multi-compiler environment because each compiler’s notion of a struct FILE will be different.
From an implementation standpoint these are very _low_ level functions.

Problem 2: SWIG generates the following code when generating wrappers to void functions:

```c
Py_INCREF(Py_None);
_resultobj = Py_None;
return _resultobj;
```

Alas, Py_None is a macro that expands to a reference to a complex data structure called _Py_NoneStruct inside pythonNN.dll. Again, this code will fail in a mult-compiler environment. Replace such code by:

```c
return Py_BuildValue("");
```

It may be possible to use SWIG’s `%typemap` command to make the change automatically, though I have not been able to get this to work (I’m a complete SWIG newbie).

6. Using a Python shell script to put up a Python interpreter window from inside your Windows app is not a good idea; the resulting window will be independent of your app’s windowing system. Rather, you (or the wxPythonWindow class) should create a “native” interpreter window. It is easy to connect that window to the Python interpreter. You can redirect Python’s i/o to _any_ object that supports read and write, so all you need is a Python object (defined in your extension module) that contains read() and write() methods.
How do I keep editors from inserting tabs into my Python source?

The FAQ does not recommend using tabs, and the Python style guide, PEP 8, recommends 4 spaces for distributed Python code; this is also the Emacs python-mode default.

Under any editor, mixing tabs and spaces is a bad idea. MSVC is no different in this respect, and is easily configured to use spaces: Take Tools ▶️ Options ▶️ Tabs, and for file type “Default” set “Tab size” and “Indent size” to 4, and select the “Insert spaces” radio button.

If you suspect mixed tabs and spaces are causing problems in leading whitespace, run Python with the -t switch or run Tools/Scripts/tabnanny.py to check a directory tree in batch mode.
How do I check for a keypress without blocking?

Use the msvcrt module. This is a standard Windows-specific extension module. It defines a function `kbhit()` which checks whether a keyboard hit is present, and `getch()` which gets one character without echoing it.
How do I emulate os.kill() in Windows?

Prior to Python 2.7 and 3.2, to terminate a process, you can use `ctypes`:

```python
import ctypes

def kill(pid):
    """kill function for Win32""
    kernel32 = ctypes.windll.kernel32
    handle = kernel32.OpenProcess(1, 0, pid)
    return (0 != kernel32.TerminateProcess(handle, 0))
```

In 2.7 and 3.2, `os.kill()` is implemented similar to the above function, with the additional feature of being able to send CTRL+C and CTRL+BREAK to console subprocesses which are designed to handle those signals. See `os.kill()` for further details.
How do I extract the downloaded documentation on Windows?

Sometimes, when you download the documentation package to a Windows machine using a web browser, the file extension of the saved file ends up being .EXE. This is a mistake; the extension should be .TGZ.

Simply rename the downloaded file to have the .TGZ extension, and WinZip will be able to handle it. (If your copy of WinZip doesn’t, get a newer one from http://www.winzip.com.)

General GUI Questions
What platform-independent GUI toolkits exist for Python?

Depending on what platform(s) you are aiming at, there are several. Some of them haven’t been ported to Python 3 yet. At least Tkinter and Qt are known to be Python 3-compatible.

Tkinter

Standard builds of Python include an object-oriented interface to the Tcl/Tk widget set, called tkinter. This is probably the easiest to install (since it comes included with most binary distributions of Python) and use. For more info about Tk, including pointers to the source, see the Tcl/Tk home page. Tcl/Tk is fully portable to the MacOS, Windows, and Unix platforms.

wxWidgets

wxWidgets (http://www.wxwidgets.org) is a free, portable GUI class library written in C++ that provides a native look and feel on a number of platforms, with Windows, MacOS X, GTK, X11, all listed as current stable targets. Language bindings are available for a number of languages including Python, Perl, Ruby, etc.

wxPython (http://www.wxpython.org) is the Python binding for wxwidgets. While it often lags slightly behind the official wxWidgets releases, it also offers a number of features via pure Python extensions that are not available in other language bindings. There is an active wxPython user and developer community.

Both wxWidgets and wxPython are free, open source, software with
permissive licences that allow their use in commercial products as well as in freeware or shareware.

Qt

There are bindings available for the Qt toolkit (using either PyQt or PySide) and for KDE (PyKDE). PyQt is currently more mature than PySide, but you must buy a PyQt license from Riverbank Computing if you want to write proprietary applications. PySide is free for all applications.

Qt 4.5 upwards is licensed under the LGPL license; also, commercial licenses are available from Nokia.

Gtk+

The GObject introspection bindings for Python allow you to write GTK+ 3 applications. There is also a Python GTK+ 3 Tutorial.

The older PyGtk bindings for the Gtk+ 2 toolkit have been implemented by James Henstridge; see <http://www.pygtk.org>.

FLTK

Python bindings for the FLTK toolkit, a simple yet powerful and mature cross-platform windowing system, are available from the PyFLTK project.

FOX

A wrapper for the FOX toolkit called FXpy is available. FOX supports
both Unix variants and Windows.

**OpenGL**

For OpenGL bindings, see [PyOpenGL](#).
What platform-specific GUI toolkits exist for Python?

The Mac port by Jack Jansen has a rich and ever-growing set of modules that support the native Mac toolbox calls. The port supports MacOS X's Carbon libraries.

By installing the PyObjc Objective-C bridge, Python programs can use MacOS X's Cocoa libraries. See the documentation that comes with the Mac port.

Pythonwin by Mark Hammond includes an interface to the Microsoft Foundation Classes and a Python programming environment that's written mostly in Python using the MFC classes.
Tkinter questions

How do I freeze Tkinter applications?

Freeze is a tool to create stand-alone applications. When freezing Tkinter applications, the applications will not be truly stand-alone, as the application will still need the Tcl and Tk libraries.

One solution is to ship the application with the Tcl and Tk libraries, and point to them at run-time using the TCL_LIBRARY and TK_LIBRARY environment variables.

To get truly stand-alone applications, the Tcl scripts that form the library have to be integrated into the application as well. One tool supporting that is SAM (stand-alone modules), which is part of the Tix distribution (http://tix.sourceforge.net/).

Build Tix with SAM enabled, perform the appropriate call to Tclsam_init(), etc. inside Python's Modules/tkappinit.c, and link with libtclsam and libtksam (you might include the Tix libraries as well).

Can I have Tk events handled while waiting for I/O?

Yes, and you don’t even need threads! But you’ll have to restructure your I/O code a bit. Tk has the equivalent of Xt’s XtAddInput() call, which allows you to register a callback function which will be called from the Tk mainloop when I/O is possible on a file descriptor. Here’s what you need:

```python
from Tkinter import tkinter
```
The file may be a Python file or socket object (actually, anything with a fileno() method), or an integer file descriptor. The mask is one of the constants tkinter.READABLE or tkinter.WRITABLE. The callback is called as follows:

```
callback(file, mask)
```

You must unregister the callback when you're done, using

```
tkinter.deletefilehandler(file)
```

Note: since you don’t know how many bytes are available for reading, you can’t use the Python file object's read or readline methods, since these will insist on reading a predefined number of bytes. For sockets, the recv() or recvfrom() methods will work fine; for other files, use `os.read(file.fileno(), maxbytecount)`.

I can’t get key bindings to work in Tkinter: why?

An often-heard complaint is that event handlers bound to events with the bind() method don’t get handled even when the appropriate key is pressed.

The most common cause is that the widget to which the binding applies doesn’t have “keyboard focus”. Check out the Tk documentation for the focus command. Usually a widget is given the keyboard focus by clicking in it (but not for labels; see the takefocus option).
“Why is Python Installed on my Computer?” FAQ
What is Python?

Python is a programming language. It’s used for many different applications. It's used in some high schools and colleges as an introductory programming language because Python is easy to learn, but it's also used by professional software developers at places such as Google, NASA, and Lucasfilm Ltd.

If you wish to learn more about Python, start with the Beginner’s Guide to Python.
Why is Python installed on my machine?

If you find Python installed on your system but don’t remember installing it, there are several possible ways it could have gotten there.

- Perhaps another user on the computer wanted to learn programming and installed it; you’ll have to figure out who’s been using the machine and might have installed it.
- A third-party application installed on the machine might have been written in Python and included a Python installation. There are many such applications, from GUI programs to network servers and administrative scripts.
- Some Windows machines also have Python installed. At this writing we’re aware of computers from Hewlett-Packard and Compaq that include Python. Apparently some of HP/Compaq’s administrative tools are written in Python.
- Many Unix-compatible operating systems, such as Mac OS X and some Linux distributions, have Python installed by default; it’s included in the base installation.
Can I delete Python?

That depends on where Python came from.

If someone installed it deliberately, you can remove it without hurting anything. On Windows, use the Add/Remove Programs icon in the Control Panel.

If Python was installed by a third-party application, you can also remove it, but that application will no longer work. You should use that application's uninstaller rather than removing Python directly.

If Python came with your operating system, removing it is not recommended. If you remove it, whatever tools were written in Python will no longer run, and some of them might be important to you. Reinstalling the whole system would then be required to fix things again.
Glossary

>>> The default Python prompt of the interactive shell. Often seen for code examples which can be executed interactively in the interpreter.

... The default Python prompt of the interactive shell when entering code for an indented code block or within a pair of matching left and right delimiters (parentheses, square brackets or curly braces).

2to3
A tool that tries to convert Python 2.x code to Python 3.x code by handling most of the incompatibilities which can be detected by parsing the source and traversing the parse tree.

2to3 is available in the standard library as lib2to3; a standalone entry point is provided as Tools/scripts/2to3. See 2to3 - Automated Python 2 to 3 code translation.

abstract base class
Abstract base classes complement duck-typing by providing a way to define interfaces when other techniques like hasattr() would be clumsy or subtly wrong (for example with magic methods). ABCs introduce virtual subclasses, which are classes that don't inherit from a class but are still recognized by isinstance() and issubclass(); see the abc module documentation. Python comes with many built-in ABCs for data structures (in the collections.abc module), numbers (in the numbers module), streams (in the io module), import finders and loaders (in the importlib.abc module). You can create your own ABCs with the abc module.
**argument**

A value passed to a *function* (or *method*) when calling the function. There are two kinds of argument:

- *keyword argument*: an argument preceded by an identifier (e.g. `name=`) in a function call or passed as a value in a dictionary preceded by `**`. For example, 3 and 5 are both keyword arguments in the following calls to `complex()`:

  ```python
  complex(real=3, imag=5)
  complex(**{'real': 3, 'imag': 5})
  ```

- *positional argument*: an argument that is not a keyword argument. Positional arguments can appear at the beginning of an argument list and/or be passed as elements of an *iterable* preceded by `*`. For example, 3 and 5 are both positional arguments in the following calls:

  ```python
  complex(3, 5)
  complex(*[3, 5])
  ```

Arguments are assigned to the named local variables in a function body. See the *Calls* section for the rules governing this assignment. Syntactically, any expression can be used to represent an argument; the evaluated value is assigned to the local variable.

See also the *parameter* glossary entry, the FAQ question on the *difference between arguments and parameters*, and PEP 362.

**attribute**

A value associated with an object which is referenced by name using dotted expressions. For example, if an object `o` has an attribute `a` it would be referenced as `o.a`. 
**BDFL**

Benevolent Dictator For Life, a.k.a. Guido van Rossum, Python’s creator.

**binary file**

A *file object* able to read and write *bytes-like objects*.

**See also:** A *text file* reads and writes *str* objects.

**bytes-like object**

An object that supports the *Buffer Protocol*, like *bytes*, *bytearray* or *memoryview*. Bytes-like objects can be used for various operations that expect binary data, such as compression, saving to a binary file or sending over a socket. Some operations need the binary data to be mutable, in which case not all bytes-like objects can apply.

**bytecode**

Python source code is compiled into bytecode, the internal representation of a Python program in the CPython interpreter. The bytecode is also cached in `.pyc` and `.pyo` files so that executing the same file is faster the second time (recompilation from source to bytecode can be avoided). This “intermediate language” is said to run on a *virtual machine* that executes the machine code corresponding to each bytecode. Do note that bytecodes are not expected to work between different Python virtual machines, nor to be stable between Python releases.

A list of bytecode instructions can be found in the documentation for *the dis module*.

**class**

A template for creating user-defined objects. Class definitions normally contain method definitions which operate on instances of
coercion
The implicit conversion of an instance of one type to another during an operation which involves two arguments of the same type. For example, `int(3.15)` converts the floating point number to the integer 3, but in `3+4.5`, each argument is of a different type (one int, one float), and both must be converted to the same type before they can be added or it will raise a `TypeError`. Without coercion, all arguments of even compatible types would have to be normalized to the same value by the programmer, e.g., `float(3)+4.5` rather than just `3+4.5`.

complex number
An extension of the familiar real number system in which all numbers are expressed as a sum of a real part and an imaginary part. Imaginary numbers are real multiples of the imaginary unit (the square root of -1), often written `i` in mathematics or `j` in engineering. Python has built-in support for complex numbers, which are written with this latter notation; the imaginary part is written with a `j` suffix, e.g., `3+1j`. To get access to complex equivalents of the `math` module, use `cmath`. Use of complex numbers is a fairly advanced mathematical feature. If you're not aware of a need for them, it's almost certain you can safely ignore them.

context manager
An object which controls the environment seen in a `with` statement by defining `__enter__() ` and `__exit__() ` methods. See PEP 343.

CPython
The canonical implementation of the Python programming language, as distributed on python.org. The term “CPython” is used when necessary to distinguish this implementation from others.
such as Jython or IronPython.

**decorator**
A function returning another function, usually applied as a function transformation using the `@wrapper` syntax. Common examples for decorators are `classmethod()` and `staticmethod()`.

The decorator syntax is merely syntactic sugar, the following two function definitions are semantically equivalent:

```python
def f(...):
    ...

f = staticmethod(f)

@staticmethod
def f(...):
    ...
```

The same concept exists for classes, but is less commonly used there. See the documentation for function definitions and class definitions for more about decorators.

**descriptor**
Any object which defines the methods `__get__()`, `__set__()`, or `__delete__()`. When a class attribute is a descriptor, its special binding behavior is triggered upon attribute lookup. Normally, using `a.b` to get, set or delete an attribute looks up the object named `b` in the class dictionary for `a`, but if `b` is a descriptor, the respective descriptor method gets called. Understanding descriptors is a key to a deep understanding of Python because they are the basis for many features including functions, methods, properties, class methods, static methods, and reference to super classes.
For more information about descriptors’ methods, see *Implementing Descriptors*.

**dictionary**

An associative array, where arbitrary keys are mapped to values. The keys can be any object with `__hash__()` and `__eq__()` methods. Called a hash in Perl.

**docstring**

A string literal which appears as the first expression in a class, function or module. While ignored when the suite is executed, it is recognized by the compiler and put into the `__doc__` attribute of the enclosing class, function or module. Since it is available via introspection, it is the canonical place for documentation of the object.

**duck-typing**

A programming style which does not look at an object’s type to determine if it has the right interface; instead, the method or attribute is simply called or used (“If it looks like a duck and quacks like a duck, it must be a duck.”) By emphasizing interfaces rather than specific types, well-designed code improves its flexibility by allowing polymorphic substitution. Duck-typing avoids tests using `type()` or `isinstance()`. (Note, however, that duck-typing can be complemented with *abstract base classes.*) Instead, it typically employs `hasattr()` tests or *EAFP* programming.

**EAFP**

Easier to ask for forgiveness than permission. This common Python coding style assumes the existence of valid keys or attributes and catches exceptions if the assumption proves false. This clean and fast style is characterized by the presence of many `try` and `except` statements. The technique contrasts with the *LBYL* style common to many other languages such as C.

**expression**
A piece of syntax which can be evaluated to some value. In other words, an expression is an accumulation of expression elements like literals, names, attribute access, operators or function calls which all return a value. In contrast to many other languages, not all language constructs are expressions. There are also statements which cannot be used as expressions, such as if. Assignments are also statements, not expressions.

extension module
A module written in C or C++, using Python’s C API to interact with the core and with user code.

file object
An object exposing a file-oriented API (with methods such as read() or write()) to an underlying resource. Depending on the way it was created, a file object can mediate access to a real on-disk file or to another type of storage or communication device (for example standard input/output, in-memory buffers, sockets, pipes, etc.). File objects are also called file-like objects or streams.

There are actually three categories of file objects: raw binary files, buffered binary files and text files. Their interfaces are defined in the io module. The canonical way to create a file object is by using the open() function.

file-like object
A synonym for file object.

finder
An object that tries to find the loader for a module. It must implement either a method named find_loader() or a method named find_module(). See PEP 302 and PEP 420 for details and importlib.abc.Finder for an abstract base class.

floor division
Mathematical division that rounds down to nearest integer. The floor division operator is `//`. For example, the expression `11 // 4` evaluates to 2 in contrast to the 2.75 returned by float true division. Note that `(-11) // 4` is -3 because that is rounded downward. See PEP 238.

**function**

A series of statements which returns some value to a caller. It can also be passed zero or more arguments which may be used in the execution of the body. See also parameter, method, and the Function definitions section.

**function annotation**

An arbitrary metadata value associated with a function parameter or return value. Its syntax is explained in section Function definitions. Annotations may be accessed via the `__annotations__` special attribute of a function object.

Python itself does not assign any particular meaning to function annotations. They are intended to be interpreted by third-party libraries or tools. See PEP 3107, which describes some of their potential uses.

**__future__**

A pseudo-module which programmers can use to enable new language features which are not compatible with the current interpreter.

By importing the `__future__` module and evaluating its variables, you can see when a new feature was first added to the language and when it becomes the default:

```python
>>> import __future__
>>> __future__.division
```
garbage collection
The process of freeing memory when it is not used anymore. Python performs garbage collection via reference counting and a cyclic garbage collector that is able to detect and break reference cycles.

generator
A function which returns an iterator. It looks like a normal function except that it contains yield statements for producing a series a values usable in a for-loop or that can be retrieved one at a time with the next() function. Each yield temporarily suspends processing, remembering the location execution state (including local variables and pending try-statements). When the generator resumes, it picks-up where it left-off (in contrast to functions which start fresh on every invocation).

generator expression
An expression that returns an iterator. It looks like a normal expression followed by a for expression defining a loop variable, range, and an optional if expression. The combined expression generates values for an enclosing function:

```python
>>> sum(i*i for i in range(10))  # sum of squares 0, 1, 4, ... 81
285
```

generic function
A function composed of multiple functions implementing the same operation for different types. Which implementation should be used during a call is determined by the dispatch algorithm.

See also the single dispatch glossary entry, the
functools.singledispatch() decorator, and PEP 443.

GIL
See *global interpreter lock*.

global interpreter lock
The mechanism used by the *CPython* interpreter to assure that only one thread executes Python *bytecode* at a time. This simplifies the CPython implementation by making the object model (including critical built-in types such as *dict*) implicitly safe against concurrent access. Locking the entire interpreter makes it easier for the interpreter to be multi-threaded, at the expense of much of the parallelism afforded by multi-processor machines.

However, some extension modules, either standard or third-party, are designed so as to release the GIL when doing computationally-intensive tasks such as compression or hashing. Also, the GIL is always released when doing I/O.

Past efforts to create a “free-threaded” interpreter (one which locks shared data at a much finer granularity) have not been successful because performance suffered in the common single-processor case. It is believed that overcoming this performance issue would make the implementation much more complicated and therefore costlier to maintain.

hashable
An object is *hashable* if it has a hash value which never changes during its lifetime (it needs a __hash__() method), and can be compared to other objects (it needs an __eq__() method). Hashable objects which compare equal must have the same hash value.
Hashability makes an object usable as a dictionary key and a set member, because these data structures use the hash value internally.

All of Python’s immutable built-in objects are hashable, while no mutable containers (such as lists or dictionaries) are. Objects which are instances of user-defined classes are hashable by default; they all compare unequal (except with themselves), and their hash value is their \texttt{id()}.

\textbf{IDLE}

An Integrated Development Environment for Python. IDLE is a basic editor and interpreter environment which ships with the standard distribution of Python.

\textbf{immutable}

An object with a fixed value. Immutable objects include numbers, strings and tuples. Such an object cannot be altered. A new object has to be created if a different value has to be stored. They play an important role in places where a constant hash value is needed, for example as a key in a dictionary.

\textbf{import path}

A list of locations (or \textit{path entries}) that are searched by the \textit{path based finder} for modules to import. During import, this list of locations usually comes from \texttt{sys.path}, but for subpackages it may also come from the parent package’s \texttt{__path__} attribute.

\textbf{importing}

The process by which Python code in one module is made available to Python code in another module.

\textbf{importer}

An object that both finds and loads a module; both a \textit{finder} and \textit{loader} object.
**interactive**

Python has an interactive interpreter which means you can enter statements and expressions at the interpreter prompt, immediately execute them and see their results. Just launch `python` with no arguments (possibly by selecting it from your computer’s main menu). It is a very powerful way to test out new ideas or inspect modules and packages (remember `help(x)`).

**interpreted**

Python is an interpreted language, as opposed to a compiled one, though the distinction can be blurry because of the presence of the bytecode compiler. This means that source files can be run directly without explicitly creating an executable which is then run. Interpreted languages typically have a shorter development/debug cycle than compiled ones, though their programs generally also run more slowly. See also *interactive*.

**iterable**

An object capable of returning its members one at a time. Examples of iterables include all sequence types (such as `list`, `str`, and `tuple`) and some non-sequence types like `dict`, `file objects`, and objects of any classes you define with an `_iter_()` or `__getitem__()` method. Iterables can be used in a `for` loop and in many other places where a sequence is needed (`zip()`, `map()`, ...). When an iterable object is passed as an argument to the built-in function `iter()`, it returns an iterator for the object. This iterator is good for one pass over the set of values. When using iterables, it is usually not necessary to call `iter()` or deal with iterator objects yourself. The `for` statement does that automatically for you, creating a temporary unnamed variable to hold the iterator for the duration of the loop. See also *iterator*, *sequence*, and *generator*.

**iterator**

An object representing a stream of data. Repeated calls to the
iterator's __next__() method (or passing it to the built-in function \texttt{next()}) return successive items in the stream. When no more data are available a \texttt{StopIteration} exception is raised instead. At this point, the iterator object is exhausted and any further calls to its __next__() method just raise \texttt{StopIteration} again. Iterators are required to have an __iter__() method that returns the iterator object itself so every iterator is also iterable and may be used in most places where other iterables are accepted. One notable exception is code which attempts multiple iteration passes. A container object (such as a \texttt{list}) produces a fresh new iterator each time you pass it to the \texttt{iter()} function or use it in a \texttt{for} loop. Attempting this with an iterator will just return the same exhausted iterator object used in the previous iteration pass, making it appear like an empty container.

More information can be found in \textit{Iterator Types}.

\textbf{key function}

A key function or collation function is a callable that returns a value used for sorting or ordering. For example, \texttt{locale.strxfrm()} is used to produce a sort key that is aware of locale specific sort conventions.

A number of tools in Python accept key functions to control how elements are ordered or grouped. They include \texttt{min()}, \texttt{max()}, \texttt{sorted()}, \texttt{list.sort()}, \texttt{heapq.nsmallest()}, \texttt{heapq.nlargest()}, and \texttt{itertools.groupby()}.

There are several ways to create a key function. For example, the \texttt{str.lower()} method can serve as a key function for case insensitive sorts. Alternatively, an ad-hoc key function can be built from a \texttt{lambda} expression such as \texttt{lambda r: (r[0], r[2])}. 
Also, the `operator` module provides three key function constructors: `attrgetter()`, `itemgetter()`, and `methodcaller()`. See the *Sorting HOW TO* for examples of how to create and use key functions.

**keyword argument**

See `argument`.

**lambda**

An anonymous inline function consisting of a single `expression` which is evaluated when the function is called. The syntax to create a lambda function is `lambda [arguments]: expression`

**LBYL**

Look before you leap. This coding style explicitly tests for pre-conditions before making calls or lookups. This style contrasts with the *EAFP* approach and is characterized by the presence of many `if` statements.

In a multi-threaded environment, the LBYL approach can risk introducing a race condition between “the looking” and “the leaping”. For example, the code, `if key in mapping: return mapping[key]` can fail if another thread removes `key` from `mapping` after the test, but before the lookup. This issue can be solved with locks or by using the EAFP approach.

**list**

A built-in Python `sequence`. Despite its name it is more akin to an array in other languages than to a linked list since access to elements are O(1).

**list comprehension**

A compact way to process all or part of the elements in a sequence and return a list with the results. `result =`
['{:04x}'.format(x) for x in range(256) if x % 2 == 0] generates a list of strings containing even hex numbers (0x..) in the range from 0 to 255. The if clause is optional. If omitted, all elements in range(256) are processed.

**loader**

An object that loads a module. It must define a method named load_module(). A loader is typically returned by a finder. See PEP 302 for details and importlib.abc.Loader for an abstract base class.

**mapping**

A container object that supports arbitrary key lookups and implements the methods specified in the Mapping or MutableMapping abstract base classes. Examples include dict, collections.defaultdict, collections.OrderedDict and collections.Counter.

**meta path finder**

A finder returned by a search of sys.meta_path. Meta path finders are related to, but different from path entry finders.

**metaclass**

The class of a class. Class definitions create a class name, a class dictionary, and a list of base classes. The metaclass is responsible for taking those three arguments and creating the class. Most object oriented programming languages provide a default implementation. What makes Python special is that it is possible to create custom metaclasses. Most users never need this tool, but when the need arises, metaclasses can provide powerful, elegant solutions. They have been used for logging attribute access, adding thread-safety, tracking object creation, implementing singletons, and many other tasks.

More information can be found in Customizing class creation.
method
A function which is defined inside a class body. If called as an attribute of an instance of that class, the method will get the instance object as its first argument (which is usually called self). See function and nested scope.

method resolution order
Method Resolution Order is the order in which base classes are searched for a member during lookup. See The Python 2.3 Method Resolution Order.

module
An object that serves as an organizational unit of Python code. Modules have a namespace containing arbitrary Python objects. Modules are loaded into Python by the process of importing.

See also package.

module spec
A namespace containing the import-related information used to load a module.

MRO
See method resolution order.

mutable
Mutable objects can change their value but keep their id(). See also immutable.

named tuple
Any tuple-like class whose indexable elements are also accessible using named attributes (for example, time.localtime() returns a tuple-like object where the year is accessible either with an index such as t[0] or with a named attribute like t.tm_year).

A named tuple can be a built-in type such as

A named tuple can be a built-in type such as
time.struct_time, or it can be created with a regular class definition. A full featured named tuple can also be created with the factory function collections.namedtuple(). The latter approach automatically provides extra features such as a self-documenting representation like Employee(name='jones', title='programmer').

namespace
The place where a variable is stored. Namespaces are implemented as dictionaries. There are the local, global and built-in namespaces as well as nested namespaces in objects (in methods). Namespaces support modularity by preventing naming conflicts. For instance, the functions builtins.open and os.open() are distinguished by their namespaces. Namespaces also aid readability and maintainability by making it clear which module implements a function. For instance, writing random.seed() or itertools.islice() makes it clear that those functions are implemented by the random and itertools modules, respectively.

namespace package
A PEP 420 package which serves only as a container for subpackages. Namespace packages may have no physical representation, and specifically are not like a regular package because they have no __init__.py file.

See also module.

nested scope
The ability to refer to a variable in an enclosing definition. For instance, a function defined inside another function can refer to variables in the outer function. Note that nested scopes by default work only for reference and not for assignment. Local variables
both read and write in the innermost scope. Likewise, global variables read and write to the global namespace. The nonlocal allows writing to outer scopes.

new-style class
Old name for the flavor of classes now used for all class objects. In earlier Python versions, only new-style classes could use Python’s newer, versatile features like __slots__, descriptors, properties, __getattribute__(), class methods, and static methods.

object
Any data with state (attributes or value) and defined behavior (methods). Also the ultimate base class of any new-style class.

package
A Python module which can contain submodules or recursively, subpackages. Technically, a package is a Python module with an __path__ attribute.

See also regular package and namespace package.

parameter
A named entity in a function (or method) definition that specifies an argument (or in some cases, arguments) that the function can accept. There are five kinds of parameter:

- positional-or-keyword: specifies an argument that can be passed either positionally or as a keyword argument. This is the default kind of parameter, for example foo and bar in the following:

  ```python
  def func(foo, bar=None): ...
  ```

- positional-only: specifies an argument that can be supplied only by position. Python has no syntax for defining positional-
only parameters. However, some built-in functions have positional-only parameters (e.g. abs( )).

- **keyword-only**: specifies an argument that can be supplied only by keyword. Keyword-only parameters can be defined by including a single var-positional parameter or bare * in the parameter list of the function definition before them, for example kw_only1 and kw_only2 in the following:

```python
def func(arg, *, kw_only1, kw_only2): ...
```

- **var-positional**: specifies that an arbitrary sequence of positional arguments can be provided (in addition to any positional arguments already accepted by other parameters). Such a parameter can be defined by prepending the parameter name with *, for example args in the following:

```python
def func(*args, **kwargs): ...
```

- **var-keyword**: specifies that arbitrarily many keyword arguments can be provided (in addition to any keyword arguments already accepted by other parameters). Such a parameter can be defined by prepending the parameter name with **, for example kwargs in the example above.

Parameters can specify both optional and required arguments, as well as default values for some optional arguments.

See also the argument glossary entry, the FAQ question on the difference between arguments and parameters, the inspect.Parameter class, the Function definitions section, and PEP 362.
**path entry**
A single location on the *import path* which the *path based finder* consults to find modules for importing.

**path entry finder**
A *finder* returned by a callable on `sys.path_hooks` (i.e. a *path entry hook*) which knows how to locate modules given a *path entry*.

**path entry hook**
A callable on the `sys.path_hook` list which returns a *path entry finder* if it knows how to find modules on a specific *path entry*.

**path based finder**
One of the default *meta path finders* which searches an *import path* for modules.

**portion**
A set of files in a single directory (possibly stored in a zip file) that contribute to a namespace package, as defined in PEP 420.

**positional argument**
See *argument*.

**provisional API**
A provisional API is one which has been deliberately excluded from the standard library's backwards compatibility guarantees. While major changes to such interfaces are not expected, as long as they are marked provisional, backwards incompatible changes (up to and including removal of the interface) may occur if deemed necessary by core developers. Such changes will not be made gratuitously – they will occur only if serious fundamental flaws are uncovered that were missed prior to the inclusion of the API.

Even for provisional APIs, backwards incompatible changes are seen as a “solution of last resort” - every attempt will still be made to find a backwards compatible resolution to any identified
problems.

This process allows the standard library to continue to evolve over time, without locking in problematic design errors for extended periods of time. See PEP 411 for more details.

**provisional package**

See provisional API.

**Python 3000**

Nickname for the Python 3.x release line (coined long ago when the release of version 3 was something in the distant future.) This is also abbreviated “Py3k”.

**Pythonic**

An idea or piece of code which closely follows the most common idioms of the Python language, rather than implementing code using concepts common to other languages. For example, a common idiom in Python is to loop over all elements of an iterable using a `for` statement. Many other languages don't have this type of construct, so people unfamiliar with Python sometimes use a numerical counter instead:

```python
for i in range(len(food)):
    print(food[i])
```

As opposed to the cleaner, Pythonic method:

```python
for piece in food:
    print(piece)
```

**qualified name**

A dotted name showing the “path” from a module's global scope to a class, function or method defined in that module, as defined in
PEP 3155. For top-level functions and classes, the qualified name is the same as the object’s name:

```python
>>> class C:
...     class D:
...         def meth(self):
...             pass
...
>>> C.__qualname__
'C'
>>> C.D.__qualname__
'C.D'
>>> C.D.meth.__qualname__
'C.D.meth'
```

When used to refer to modules, the *fully qualified name* means the entire dotted path to the module, including any parent packages, e.g. `email.mime.text`:

```python
>>> import email.mime.text
>>> email.mime.text.__name__
'email.mime.text'
```

**reference count**

The number of references to an object. When the reference count of an object drops to zero, it is deallocated. Reference counting is generally not visible to Python code, but it is a key element of the CPython implementation. The `sys` module defines a `getrefcount()` function that programmers can call to return the reference count for a particular object.

**regular package**

A traditional *package*, such as a directory containing an `__init__.py` file.
See also namespace package.

__slots__
A declaration inside a class that saves memory by pre-declaring space for instance attributes and eliminating instance dictionaries. Though popular, the technique is somewhat tricky to get right and is best reserved for rare cases where there are large numbers of instances in a memory-critical application.

sequence
An iterable which supports efficient element access using integer indices via the __getitem__() special method and defines a __len__() method that returns the length of the sequence. Some built-in sequence types are list, str, tuple, and bytes. Note that dict also supports __getitem__() and __len__(), but is considered a mapping rather than a sequence because the lookups use arbitrary immutable keys rather than integers.

The collections.abc.Sequence abstract base class defines a much richer interface that goes beyond just __getitem__() and __len__(), adding count(), index(), __contains__(), and __reversed__(). Types that implement this expanded interface can be registered explicitly using register().

single dispatch
A form of generic function dispatch where the implementation is chosen based on the type of a single argument.

slice
An object usually containing a portion of a sequence. A slice is created using the subscript notation, [] with colons between numbers when several are given, such as in variable_name[1:3:5]. The bracket (subscript) notation uses slice objects internally.
special method
A method that is called implicitly by Python to execute a certain operation on a type, such as addition. Such methods have names starting and ending with double underscores. Special methods are documented in *Special method names*.

statement
A statement is part of a suite (a “block” of code). A statement is either an *expression* or one of several constructs with a keyword, such as *if*, *while* or *for*.

struct sequence
A tuple with named elements. Struct sequences expose an interface similar to *named tuple* in that elements can either be accessed either by index or as an attribute. However, they do not have any of the named tuple methods like _make() or _asdict(). Examples of struct sequences include `sys.float_info` and the return value of `os.stat()`.

text file
A *file object* able to read and write *str* objects. Often, a text file actually accesses a byte-oriented datastream and handles the text encoding automatically.

See also: A *binary file* reads and write *bytes* objects.

triple-quoted string
A string which is bound by three instances of either a quotation mark ("), or an apostrophe ('). While they don’t provide any functionality not available with single-quoted strings, they are useful for a number of reasons. They allow you to include unescaped single and double quotes within a string and they can span multiple lines without the use of the continuation character, making them especially useful when writing docstrings.
**type**

The type of a Python object determines what kind of object it is; every object has a type. An object's type is accessible as its \_\_class\_ attribute or can be retrieved with \texttt{type(obj)}.

**universal newlines**

A manner of interpreting text streams in which all of the following are recognized as ending a line: the Unix end-of-line convention `\n', the Windows convention `\r\n', and the old Macintosh convention `\r'. See PEP 278 and PEP 3116, as well as \texttt{str.splitlines()} for an additional use.

**view**

The objects returned from \texttt{dict.keys()}, \texttt{dict.values()}, and \texttt{dict.items()} are called dictionary views. They are lazy sequences that will see changes in the underlying dictionary. To force the dictionary view to become a full list use \texttt{list(dictview)}. See \texttt{Dictionary view objects}.

**virtual machine**

A computer defined entirely in software. Python's virtual machine executes the \textit{bytecode} emitted by the bytecode compiler.

**Zen of Python**

Listing of Python design principles and philosophies that are helpful in understanding and using the language. The listing can be found by typing "\texttt{import this}" at the interactive prompt.
About these documents

These documents are generated from reStructuredText sources by Sphinx, a document processor specifically written for the Python documentation.

Development of the documentation and its toolchain is an entirely volunteer effort, just like Python itself. If you want to contribute, please take a look at the Reporting Bugs page for information on how to do so. New volunteers are always welcome!

Many thanks go to:

- Fred L. Drake, Jr., the creator of the original Python documentation toolset and writer of much of the content;
- the Docutils project for creating reStructuredText and the Docutils suite;
- Fredrik Lundh for his Alternative Python Reference project from which Sphinx got many good ideas.
Contributors to the Python Documentation

Many people have contributed to the Python language, the Python standard library, and the Python documentation. See Misc/ACKS in the Python source distribution for a partial list of contributors.

It is only with the input and contributions of the Python community that Python has such wonderful documentation – Thank You!
Reporting Bugs

Python is a mature programming language which has established a reputation for stability. In order to maintain this reputation, the developers would like to know of any deficiencies you find in Python.
Documentation bugs

If you find a bug in this documentation or would like to propose an improvement, please submit a bug report on the tracker. If you have a suggestion how to fix it, include that as well.

If you’re short on time, you can also email your bug report to docs@python.org. ‘docs@’ is a mailing list run by volunteers; your request will be noticed, though it may take a while to be processed.

See also: Documentation bugs on the Python issue tracker
Using the Python issue tracker

Bug reports for Python itself should be submitted via the Python Bug Tracker (http://bugs.python.org/). The bug tracker offers a Web form which allows pertinent information to be entered and submitted to the developers.

The first step in filing a report is to determine whether the problem has already been reported. The advantage in doing so, aside from saving the developers time, is that you learn what has been done to fix it; it may be that the problem has already been fixed for the next release, or additional information is needed (in which case you are welcome to provide it if you can!). To do this, search the bug database using the search box on the top of the page.

If the problem you’re reporting is not already in the bug tracker, go back to the Python Bug Tracker and log in. If you don’t already have a tracker account, select the “Register” link or, if you use OpenID, one of the OpenID provider logos in the sidebar. It is not possible to submit a bug report anonymously.

Being now logged in, you can submit a bug. Select the “Create New” link in the sidebar to open the bug reporting form.

The submission form has a number of fields. For the “Title” field, enter a very short description of the problem; less than ten words is good. In the “Type” field, select the type of your problem; also select the “Component” and “Versions” to which the bug relates.

In the “Comment” field, describe the problem in detail, including what you expected to happen and what did happen. Be sure to include whether any extension modules were involved, and what hardware
and software platform you were using (including version information as appropriate).

Each bug report will be assigned to a developer who will determine what needs to be done to correct the problem. You will receive an update each time action is taken on the bug.

See also:

**How to Report Bugs Effectively**
Article which goes into some detail about how to create a useful bug report. This describes what kind of information is useful and why it is useful.

**Bug Writing Guidelines**
Information about writing a good bug report. Some of this is specific to the Mozilla project, but describes general good practices.
Getting started contributing to Python yourself

Beyond just reporting bugs that you find, you are also welcome to submit patches to fix them. You can find more information on how to get started patching Python in the Python Developer’s Guide. If you have questions, the core-mentorship mailing list is a friendly place to get answers to any and all questions pertaining to the process of fixing issues in Python.

History and License
History of the software

Python was created in the early 1990s by Guido van Rossum at Stichting Mathematisch Centrum (CWI, see http://www.cwi.nl/) in the Netherlands as a successor of a language called ABC. Guido remains Python’s principal author, although it includes many contributions from others.

In 1995, Guido continued his work on Python at the Corporation for National Research Initiatives (CNRI, see http://www.cnri.reston.va.us/) in Reston, Virginia where he released several versions of the software.

In May 2000, Guido and the Python core development team moved to BeOpen.com to form the BeOpen PythonLabs team. In October of the same year, the PythonLabs team moved to Digital Creations (now Zope Corporation; see http://www.zope.com/). In 2001, the Python Software Foundation (PSF, see http://www.python.org/psf/) was formed, a non-profit organization created specifically to own Python-related Intellectual Property. Zope Corporation is a sponsoring member of the PSF.

All Python releases are Open Source (see http://www.opensource.org/ for the Open Source Definition). Historically, most, but not all, Python releases have also been GPL-compatible; the table below summarizes the various releases.

**Note:** GPL-compatible doesn’t mean that we’re distributing Python under the GPL. All Python licenses, unlike the GPL, let you distribute a modified version without making your changes open source. The GPL-compatible licenses make it possible to combine Python with other software that is released under the GPL; the others don’t.

Thanks to the many outside volunteers who have worked under Guido’s direction to make these releases possible.
Terms and conditions for accessing or otherwise using Python

PSF LICENSE AGREEMENT FOR PYTHON 3.4.0

1. This LICENSE AGREEMENT is between the Python Software Foundation ("PSF"), and the Individual or Organization ("Licensee") accessing and otherwise using Python 3.4.0 software in source or binary form and its associated documentation.

2. Subject to the terms and conditions of this License Agreement, PSF hereby grants Licensee a nonexclusive, royalty-free, worldwide license to reproduce, analyze, test, perform and/or display publicly, prepare derivative works, distribute, and otherwise use Python 3.4.0 alone or in any derivative version, provided, however, that PSF’s License Agreement and PSF’s notice of copyright, i.e., “Copyright © 2001-2014 Python Software Foundation; All Rights Reserved” are retained in Python 3.4.0 alone or in any derivative version prepared by Licensee.

3. In the event Licensee prepares a derivative work that is based on or incorporates Python 3.4.0 or any part thereof, and wants to make the derivative work available to others as provided herein, then Licensee hereby agrees to include in any such work a brief summary of the changes made to Python 3.4.0.

4. PSF is making Python 3.4.0 available to Licensee on an “AS IS” basis. PSF MAKES NO REPRESENTATIONS OR WARRANTIES, EXPRESS OR IMPLIED. BY WAY OF EXAMPLE, BUT NOT LIMITATION, PSF MAKES NO AND DISCLAIMS ANY REPRESENTATION OR WARRANTY OF MERCHANTABILITY OR FITNESS FOR ANY PARTICULAR PURPOSE OR THAT THE USE OF PYTHON 3.4.0 WILL NOT INFRINGE ANY THIRD PARTY RIGHTS.

5. PSF SHALL NOT BE LIABLE TO LICENSEE OR ANY OTHER USERS OF PYTHON 3.4.0 FOR ANY INCIDENTAL, SPECIAL,
OR CONSEQUENTIAL DAMAGES OR LOSS AS A RESULT OF MODIFYING, DISTRIBUTING, OR OTHERWISE USING PYTHON 3.4.0, OR ANY DERIVATIVE THEREOF, EVEN IF ADVISED OF THE POSSIBILITY THEREOF.

6. This License Agreement will automatically terminate upon a material breach of its terms and conditions.

7. Nothing in this License Agreement shall be deemed to create any relationship of agency, partnership, or joint venture between PSF and Licensee. This License Agreement does not grant permission to use PSF trademarks or trade name in a trademark sense to endorse or promote products or services of Licensee, or any third party.

8. By copying, installing or otherwise using Python 3.4.0, Licensee agrees to be bound by the terms and conditions of this License Agreement.

BEOPEN.COM LICENSE AGREEMENT FOR PYTHON 2.0

BEOPEN PYTHON OPEN SOURCE LICENSE AGREEMENT

VERSION 1

1. This LICENSE AGREEMENT is between BeOpen.com (“BeOpen”), having an office at 160 Saratoga Avenue, Santa Clara, CA 95051, and the Individual or Organization (“Licensee”) accessing and otherwise using this software in source or binary form and its associated documentation (“the Software”).

2. Subject to the terms and conditions of this BeOpen Python License Agreement, BeOpen hereby grants Licensee a non-exclusive, royalty-free, world-wide license to reproduce, analyze, test, perform and/or display publicly, prepare derivative works, distribute, and otherwise use the Software alone or in any derivative version, provided, however, that the BeOpen Python License is retained in the Software, alone or in any derivative version prepared by Licensee.
3. BeOpen is making the Software available to Licensee on an “AS IS” basis. BEOPEN MAKES NO REPRESENTATIONS OR WARRANTIES, EXPRESS OR IMPLIED. BY WAY OF EXAMPLE, BUT NOT LIMITATION, BEOPEN MAKES NO AND DISCLAIMS ANY REPRESENTATION OR WARRANTY OF MERCHANTABILITY OR FITNESS FOR ANY PARTICULAR PURPOSE OR THAT THE USE OF THE SOFTWARE WILL NOT INFRINGE ANY THIRD PARTY RIGHTS.

4. BEOPEN SHALL NOT BE LIABLE TO LICENSEE OR ANY OTHER USERS OF THE SOFTWARE FOR ANY INCIDENTAL, SPECIAL, OR CONSEQUENTIAL DAMAGES OR LOSS AS A RESULT OF USING, MODIFYING OR DISTRIBUTING THE SOFTWARE, OR ANY DERIVATIVE THEREOF, EVEN IF ADVISED OF THE POSSIBILITY THEREOF.

5. This License Agreement will automatically terminate upon a material breach of its terms and conditions.

6. This License Agreement shall be governed by and interpreted in all respects by the law of the State of California, excluding conflict of law provisions. Nothing in this License Agreement shall be deemed to create any relationship of agency, partnership, or joint venture between BeOpen and Licensee. This License Agreement does not grant permission to use BeOpen trademarks or trade names in a trademark sense to endorse or promote products or services of Licensee, or any third party. As an exception, the “BeOpen Python” logos available at http://www.pythonlabs.com/logos.html may be used according to the permissions granted on that web page.

7. By copying, installing or otherwise using the software, Licensee agrees to be bound by the terms and conditions of this License Agreement.

CNRI LICENSE AGREEMENT FOR PYTHON 1.6.1

1. This LICENSE AGREEMENT is between the Corporation for
National Research Initiatives, having an office at 1895 Preston White Drive, Reston, VA 20191 (“CNRI”), and the Individual or Organization (“Licensee”) accessing and otherwise using Python 1.6.1 software in source or binary form and its associated documentation.

2. Subject to the terms and conditions of this License Agreement, CNRI hereby grants Licensee a nonexclusive, royalty-free, worldwide license to reproduce, analyze, test, perform and/or display publicly, prepare derivative works, distribute, and otherwise use Python 1.6.1 alone or in any derivative version, provided, however, that CNRI’s License Agreement and CNRI’s notice of copyright, i.e., “Copyright © 1995-2001 Corporation for National Research Initiatives; All Rights Reserved” are retained in Python 1.6.1 alone or in any derivative version prepared by Licensee. Alternately, in lieu of CNRI’s License Agreement, Licensee may substitute the following text (omitting the quotes): “Python 1.6.1 is made available subject to the terms and conditions in CNRI’s License Agreement. This Agreement together with Python 1.6.1 may be located on the Internet using the following unique, persistent identifier (known as a handle): 1895.22/1013. This Agreement may also be obtained from a proxy server on the Internet using the following URL: http://hdl.handle.net/1895.22/1013.”

3. In the event Licensee prepares a derivative work that is based on or incorporates Python 1.6.1 or any part thereof, and wants to make the derivative work available to others as provided herein, then Licensee hereby agrees to include in any such work a brief summary of the changes made to Python 1.6.1.

4. CNRI is making Python 1.6.1 available to Licensee on an “AS IS” basis. CNRI MAKES NO REPRESENTATIONS OR WARRANTIES, EXPRESS OR IMPLIED. BY WAY OF EXAMPLE, BUT NOT LIMITATION, CNRI MAKES NO AND DISCLAIMS ANY REPRESENTATION OR WARRANTY OF MERCHANTABILITY OR FITNESS FOR ANY PARTICULAR PURPOSE OR THAT THE
USE OF PYTHON 1.6.1 WILL NOT INFRINGE ANY THIRD PARTY RIGHTS.

5. CNRI SHALL NOT BE LIABLE TO LICENSEE OR ANY OTHER USERS OF PYTHON 1.6.1 FOR ANY INCIDENTAL, SPECIAL, OR CONSEQUENTIAL DAMAGES OR LOSS AS A RESULT OF MODIFYING, DISTRIBUTING, OR OTHERWISE USING PYTHON 1.6.1, OR ANY DERIVATIVE THEREOF, EVEN IF ADVISED OF THE POSSIBILITY THEREOF.

6. This License Agreement will automatically terminate upon a material breach of its terms and conditions.

7. This License Agreement shall be governed by the federal intellectual property law of the United States, including without limitation the federal copyright law, and, to the extent such U.S. federal law does not apply, by the law of the Commonwealth of Virginia, excluding Virginia’s conflict of law provisions. Notwithstanding the foregoing, with regard to derivative works based on Python 1.6.1 that incorporate non-separable material that was previously distributed under the GNU General Public License (GPL), the law of the Commonwealth of Virginia shall govern this License Agreement only as to issues arising under or with respect to Paragraphs 4, 5, and 7 of this License Agreement. Nothing in this License Agreement shall be deemed to create any relationship of agency, partnership, or joint venture between CNRI and Licensee. This License Agreement does not grant permission to use CNRI trademarks or trade name in a trademark sense to endorse or promote products or services of Licensee, or any third party.

8. By clicking on the “ACCEPT” button where indicated, or by copying, installing or otherwise using Python 1.6.1, Licensee agrees to be bound by the terms and conditions of this License Agreement.

Modified by Jack Jansen, CWI, July 1995:
- Use binascii module to do the actual line-by-line conversion between ascii and binary. This results in a 1000-fold speedup. The C version is still 5 times faster, though.
- Arguments more compliant with Python standard

XML Remote Procedure Calls

The xmlrpc.client module contains the following notice:
The XML-RPC client interface is

</MIT License>

Original location:  
https://github.com/majek/csiphash/

Solution inspired by code from:
strtod and dtoa

The file Python/dtoa.c, which supplies C functions dtoa and strtod for conversion of C doubles to and from strings, is derived from the file of the same name by David M. Gay, currently available from http://www.netlib.org/fp/. The original file, as retrieved on March 16, 2009, contains the following copyright and licensing notice:

OPENSSL
The modules `hashlib`, `posix`, `ssl`, `crypt` use the OpenSSL library for added performance if made available by the operating system. Additionally, the Windows installers for Python include a copy of the OpenSSL libraries, so we include a copy of the OpenSSL license here:

**LICENSE ISSUES**

The OpenSSL toolkit stays under a dual license, i.e. both the OpenSSL License and the original SSLeay license apply to the toolkit. See below for the actual license texts. Actually both licenses are BSD-style Open Source licenses. In case of any license issues related to OpenSSL please contact openssl-core@openssl.org.

**OpenSSL License**

What’s New in Python

The “What’s New in Python” series of essays takes tours through the most important changes between major Python versions. They are a “must read” for anyone wishing to stay up-to-date after a new release.

- What’s New In Python 3.4
  - Summary – Release Highlights
  - New Features
  - New Modules
  - Improved Modules
  - CPython Implementation Changes
  - Deprecated
  - Removed
  - Porting to Python 3.4

- What’s New In Python 3.3
  - Summary – Release highlights
  - PEP 405: Virtual Environments
  - PEP 420: Implicit Namespace Packages
  - PEP 3118: New memoryview implementation and buffer protocol documentation
  - PEP 393: Flexible String Representation
  - PEP 397: Python Launcher for Windows
  - PEP 3151: Reworking the OS and IO exception hierarchy
  - PEP 380: Syntax for Delegating to a Subgenerator
  - PEP 409: Suppressing exception context
  - PEP 414: Explicit Unicode literals
  - PEP 3155: Qualified name for classes and functions
  - PEP 412: Key-Sharing Dictionary
  - PEP 362: Function Signature Object
  - PEP 421: Adding sys.implementation
  - Using importlib as the Implementation of Import
  - Other Language Changes
A Finer-Grained Import Lock
Builtin functions and types
New Modules
Improved Modules
Optimizations
Build and C API Changes
Deprecated
Porting to Python 3.3

What’s New In Python 3.2
- PEP 384: Defining a Stable ABI
- PEP 389: Argparse Command Line Parsing Module
- PEP 391: Dictionary Based Configuration for Logging
- PEP 3148: The concurrent.futures module
- PEP 3147: PYC Repository Directories
- PEP 3149: ABI Version Tagged .so Files
- PEP 3333: Python Web Server Gateway Interface v1.0.1

Other Language Changes
- New, Improved, and Deprecated Modules
- Multi-threading
- Optimizations
- Unicode
- Codecs
- Documentation
- IDLE
- Code Repository
- Build and C API Changes
- Porting to Python 3.2

What’s New In Python 3.1
- PEP 372: Ordered Dictionaries
- PEP 378: Format Specifier for Thousands Separator
- Other Language Changes
- New, Improved, and Deprecated Modules
- Optimizations
- IDLE
• Build and C API Changes
• Porting to Python 3.1

• What's New In Python 3.0
  • Common Stumbling Blocks
  • Overview Of Syntax Changes
  • Changes Already Present In Python 2.6
  • Library Changes
  • **PEP 3101**: A New Approach To String Formatting
  • Changes To Exceptions
  • Miscellaneous Other Changes
  • Build and C API Changes
  • Performance
  • Porting To Python 3.0

• What’s New in Python 2.7
  • The Future for Python 2.x
  • Python 3.1 Features
  • PEP 372: Adding an Ordered Dictionary to collections
  • PEP 378: Format Specifier for Thousands Separator
  • PEP 389: The argparse Module for Parsing Command Lines
  • PEP 391: Dictionary-Based Configuration For Logging
  • PEP 3106: Dictionary Views
  • PEP 3137: The memoryview Object
  • Other Language Changes
  • New and Improved Modules
  • Build and C API Changes
  • Other Changes and Fixes
  • Porting to Python 2.7
  • Acknowledgements

• What’s New in Python 2.6
  • Python 3.0
  • Changes to the Development Process
  • PEP 343: The ‘with’ statement
  • PEP 366: Explicit Relative Imports From a Main Module
  • PEP 370: Per-user site-packages Directory
• PEP 371: The multiprocessing Package
• PEP 3101: Advanced String Formatting
• PEP 3105: print As a Function
• PEP 3110: Exception-Handling Changes
• PEP 3112: Byte Literals
• PEP 3116: New I/O Library
• PEP 3118: Revised Buffer Protocol
• PEP 3119: Abstract Base Classes
• PEP 3127: Integer Literal Support and Syntax
• PEP 3129: Class Decorators
• PEP 3141: A Type Hierarchy for Numbers

Other Language Changes
• New, Improved, and Removed Modules
• Deprecations and Removals
• Build and C API Changes
• Porting to Python 2.6
• Acknowledgements

• What’s New in Python 2.5
  • PEP 308: Conditional Expressions
  • PEP 309: Partial Function Application
  • PEP 314: Metadata for Python Software Packages v1.1
  • PEP 328: Absolute and Relative Imports
  • PEP 338: Executing Modules as Scripts
  • PEP 341: Unified try/except/finally
  • PEP 342: New Generator Features
  • PEP 343: The ’with’ statement
  • PEP 352: Exceptions as New-Style Classes
  • PEP 353: Using ssize_t as the index type
  • PEP 357: The ‘__index__’ method

Other Language Changes
• New, Improved, and Removed Modules
• Build and C API Changes
• Porting to Python 2.5
• Acknowledgements
• What's New in Python 2.4
  ○ PEP 218: Built-In Set Objects
  ○ PEP 237: Unifying Long Integers and Integers
  ○ PEP 289: Generator Expressions
  ○ PEP 292: Simpler String Substitutions
  ○ PEP 318: Decorators for Functions and Methods
  ○ PEP 322: Reverse Iteration
  ○ PEP 324: New subprocess Module
  ○ PEP 327: Decimal Data Type
  ○ PEP 328: Multi-line Imports
  ○ PEP 331: Locale-Independent Float/String Conversions
  ○ Other Language Changes
  ○ New, Improved, and Deprecated Modules
  ○ Build and C API Changes
  ○ Porting to Python 2.4
  ○ Acknowledgements

• What's New in Python 2.3
  ○ PEP 218: A Standard Set Datatype
  ○ PEP 255: Simple Generators
  ○ PEP 263: Source Code Encodings
  ○ PEP 273: Importing Modules from ZIP Archives
  ○ PEP 277: Unicode file name support for Windows NT
  ○ PEP 278: Universal Newline Support
  ○ PEP 279: enumerate()
  ○ PEP 282: The logging Package
  ○ PEP 285: A Boolean Type
  ○ PEP 293: Codec Error Handling Callbacks
  ○ PEP 301: Package Index and Metadata for Distutils
  ○ PEP 302: New Import Hooks
  ○ PEP 305: Comma-separated Files
  ○ PEP 307: Pickle Enhancements
  ○ Extended Slices
  ○ Other Language Changes
  ○ New, Improved, and Deprecated Modules
- Pymalloc: A Specialized Object Allocator
- Build and C API Changes
- Other Changes and Fixes
- Porting to Python 2.3
- Acknowledgements

- What's New in Python 2.2

The Python Tutorial

Python is an easy to learn, powerful programming language. It has efficient high-level data structures and a simple but effective approach to object-oriented programming. Python’s elegant syntax and dynamic typing, together with its interpreted nature, make it an ideal language for scripting and rapid application development in many areas on most platforms.

The Python interpreter and the extensive standard library are freely available in source or binary form for all major platforms from the Python Web site, http://www.python.org/, and may be freely distributed. The same site also contains distributions of and pointers to many free third party Python modules, programs and tools, and additional documentation.

The Python interpreter is easily extended with new functions and data types implemented in C or C++ (or other languages callable from C). Python is also suitable as an extension language for customizable applications.

This tutorial introduces the reader informally to the basic concepts and features of the Python language and system. It helps to have a Python interpreter handy for hands-on experience, but all examples are self-contained, so the tutorial can be read off-line as well.

For a description of standard objects and modules, see *The Python Standard Library*. *The Python Language Reference* gives a more formal definition of the language. To write extensions in C or C++, read *Extending and Embedding the Python Interpreter* and *Python/C API Reference Manual*. There are also several books covering Python in depth.
This tutorial does not attempt to be comprehensive and cover every single feature, or even every commonly used feature. Instead, it introduces many of Python's most noteworthy features, and will give you a good idea of the language's flavor and style. After reading it, you will be able to read and write Python modules and programs, and you will be ready to learn more about the various Python library modules described in *The Python Standard Library*.

The *Glossary* is also worth going through.

- 1. Whetting Your Appetite
- 2. Using the Python Interpreter
  - 2.1. Invoking the Interpreter
    - 2.1.1. Argument Passing
    - 2.1.2. Interactive Mode
  - 2.2. The Interpreter and Its Environment
    - 2.2.1. Error Handling
    - 2.2.2. Executable Python Scripts
    - 2.2.3. Source Code Encoding
    - 2.2.4. The Interactive Startup File
    - 2.2.5. The Customization Modules
- 3. An Informal Introduction to Python
  - 3.1. Using Python as a Calculator
    - 3.1.1. Numbers
    - 3.1.2. Strings
    - 3.1.3. Lists
  - 3.2. First Steps Towards Programming
- 4. More Control Flow Tools
  - 4.1. if Statements
  - 4.2. for Statements
  - 4.3. The *range()* Function
  - 4.4. break and continue Statements, and else Clauses on Loops
- 4.5. pass Statements
- 4.6. Defining Functions
- 4.7. More on Defining Functions
  - 4.7.1. Default Argument Values
  - 4.7.2. Keyword Arguments
  - 4.7.3. Arbitrary Argument Lists
  - 4.7.4. Unpacking Argument Lists
  - 4.7.5. Lambda Expressions
  - 4.7.6. Documentation Strings
  - 4.7.7. Function Annotations
- 4.8. Intermezzo: Coding Style

The Python Standard Library

While *The Python Language Reference* describes the exact syntax and semantics of the Python language, this library reference manual describes the standard library that is distributed with Python. It also describes some of the optional components that are commonly included in Python distributions.

Python’s standard library is very extensive, offering a wide range of facilities as indicated by the long table of contents listed below. The library contains built-in modules (written in C) that provide access to system functionality such as file I/O that would otherwise be inaccessible to Python programmers, as well as modules written in Python that provide standardized solutions for many problems that occur in everyday programming. Some of these modules are explicitly designed to encourage and enhance the portability of Python programs by abstracting away platform-specifics into platform-neutral APIs.

The Python installers for the Windows platform usually includes the entire standard library and often also include many additional components. For Unix-like operating systems Python is normally provided as a collection of packages, so it may be necessary to use the packaging tools provided with the operating system to obtain some or all of the optional components.

In addition to the standard library, there is a growing collection of several thousand components (from individual programs and modules to packages and entire application development frameworks), available from the Python Package Index.

- 1. Introduction
2. Built-in Functions
3. Built-in Constants
   - 3.1. Constants added by the site module
4. Built-in Types
   - 4.1. Truth Value Testing
   - 4.2. Boolean Operations — and, or, not
   - 4.3. Comparisons
   - 4.4. Numeric Types — int, float, complex
   - 4.5. Iterator Types
   - 4.6. Sequence Types — list, tuple, range
   - 4.7. Text Sequence Type — str
   - 4.8. Binary Sequence Types — bytes, bytearray, memoryview
   - 4.9. Set Types — set, frozenset
   - 4.10. Mapping Types — dict
   - 4.11. Context Manager Types
   - 4.12. Other Built-in Types
   - 4.13. Special Attributes
5. Built-in Exceptions
   - 5.1. Base classes
   - 5.2. Concrete exceptions
   - 5.3. Warnings
   - 5.4. Exception hierarchy
6. Text Processing Services
   - 6.1. string — Common string operations
   - 6.2. re — Regular expression operations
   - 6.3. difflib — Helpers for computing deltas
   - 6.4. textwrap — Text wrapping and filling
   - 6.5. unicodedata — Unicode Database
   - 6.6. stringprep — Internet String Preparation
   - 6.7. readline — GNU readline interface
   - 6.8. rlcompleter — Completion function for GNU readline
7. Binary Data Services
8. Data Types
- 8.1. datetime — Basic date and time types
- 8.2. calendar — General calendar-related functions
- 8.3. collections — Container datatypes
- 8.4. collections.abc — Abstract Base Classes for Containers
- 8.5. heapq — Heap queue algorithm
- 8.6. bisect — Array bisection algorithm
- 8.7. array — Efficient arrays of numeric values
- 8.8. weakref — Weak references
- 8.9. types — Dynamic type creation and names for built-in types
- 8.10. copy — Shallow and deep copy operations
- 8.11. pprint — Data pretty printer
- 8.12. reprlib — Alternate repr() implementation
- 8.13. enum — Support for enumerations

9. Numeric and Mathematical Modules
- 9.1. numbers — Numeric abstract base classes
- 9.2. math — Mathematical functions
- 9.3. cmath — Mathematical functions for complex numbers
- 9.4. decimal — Decimal fixed point and floating point arithmetic
- 9.5. fractions — Rational numbers
- 9.6. random — Generate pseudo-random numbers
- 9.7. statistics — Mathematical statistics functions

10. Functional Programming Modules
- 10.1. itertools — Functions creating iterators for efficient looping
- 10.2. functools — Higher-order functions and operations on callable objects
10.3. operator — Standard operators as functions

11. File and Directory Access
   - 11.1. pathlib — Object-oriented filesystem paths
   - 11.2. os.path — Common pathname manipulations
   - 11.3. fileinput — Iterate over lines from multiple input streams
   - 11.4. stat — Interpreting stat() results
   - 11.5. filecmp — File and Directory Comparisons
   - 11.6. tempfile — Generate temporary files and directories
   - 11.7. glob — Unix style pathname pattern expansion
   - 11.8. fnmatch — Unix filename pattern matching
   - 11.9. linecache — Random access to text lines
   - 11.10. shutil — High-level file operations
   - 11.11. macpath — Mac OS 9 path manipulation functions

12. Data Persistence
   - 12.1. pickle — Python object serialization
   - 12.2. copyreg — Register pickle support functions
   - 12.3. shelve — Python object persistence
   - 12.4. marshal — Internal Python object serialization
   - 12.5. dbm — Interfaces to Unix “databases”
   - 12.6. sqlite3 — DB-API 2.0 interface for SQLite databases

13. Data Compression and Archiving
   - 13.1. zlib — Compression compatible with gzip
   - 13.2. gzip — Support for gzip files
   - 13.3. bz2 — Support for bzip2 compression
   - 13.4. lzma — Compression using the LZMA algorithm
   - 13.5. zipfile — Work with ZIP archives
   - 13.6. tarfile — Read and write tar archive files

14. File Formats
   - 14.1. csv — CSV File Reading and Writing
   - 14.2. configparser — Configuration file parser
   - 14.3. netrc — netrc file processing
14.4. xdrlib — Encode and decode XDR data
14.5. plistlib — Generate and parse Mac OS X .plist files

15. Cryptographic Services
15.1. hashlib — Secure hashes and message digests
15.2. hmac — Keyed-Hashing for Message Authentication

16. Generic Operating System Services
16.1. os — Miscellaneous operating system interfaces
16.2. io — Core tools for working with streams
16.3. time — Time access and conversions
16.4. argparse — Parser for command-line options, arguments and sub-commands
16.5. optparse — Parser for command line options
16.6. getopt — C-style parser for command line options
16.7. logging — Logging facility for Python
16.8. logging.config — Logging configuration
16.9. logging.handlers — Logging handlers
16.10. getpass — Portable password input
16.11. curses — Terminal handling for character-cell displays
16.12. curses.textpad — Text input widget for curses programs
16.13. curses.ascii — Utilities for ASCII characters
16.14. curses.panel — A panel stack extension for curses
16.15. platform — Access to underlying platform's identifying data
16.16. errno — Standard errno system symbols
16.17. ctypes — A foreign function library for Python

17. Concurrent Execution
17.1. threading — Thread-based parallelism
17.2. multiprocessing — Process-based parallelism
17.3. The concurrent package
- 17.4. concurrent.futures — Launching parallel tasks
- 17.5. subprocess — Subprocess management
- 17.6. sched — Event scheduler
- 17.7. queue — A synchronized queue class
- 17.8. dummy_threading — Drop-in replacement for the threading module
- 17.9. _thread — Low-level threading API
- 17.10. _dummy_thread — Drop-in replacement for the _thread module

- 18. Interprocess Communication and Networking
  - 18.1. socket — Low-level networking interface
  - 18.2. ssl — TLS/SSL wrapper for socket objects
  - 18.3. select — Waiting for I/O completion
  - 18.4. selectors — High-level I/O multiplexing
  - 18.5. asyncio — Asynchronous I/O, event loop, coroutines and tasks
  - 18.6. asyncore — Asynchronous socket handler
  - 18.7. asynchat — Asynchronous socket command/response handler
  - 18.8. signal — Set handlers for asynchronous events
  - 18.9. mmap — Memory-mapped file support

- 19. Internet Data Handling
  - 19.1. email — An email and MIME handling package
  - 19.2. json — JSON encoder and decoder
  - 19.3. mailcap — Mailcap file handling
  - 19.4. mailbox — Manipulate mailboxes in various formats
  - 19.5. mimetypes — Map filenames to MIME types
  - 19.6. base64 — Base16, Base32, Base64, Base85 Data Encodings
  - 19.7. binhex — Encode and decode binhex4 files
  - 19.8. binascii — Convert between binary and ASCII
  - 19.9. quopri — Encode and decode MIME quoted-printable
data

- 19.10. uu — Encode and decode uuencode files

20. Structured Markup Processing Tools
- 20.1. html — HyperText Markup Language support
- 20.2. html.parser — Simple HTML and XHTML parser
- 20.3. html.entities — Definitions of HTML general entities
- 20.4. XML Processing Modules
- 20.5. xml.etree.ElementTree — The ElementTree XML API
- 20.6. xml.dom — The Document Object Model API
- 20.7. xml.dom.minidom — Minimal DOM implementation
- 20.8. xml.dom.pulldom — Support for building partial DOM trees
- 20.9. xml.sax — Support for SAX2 parsers
- 20.10. xml.sax.handler — Base classes for SAX handlers
- 20.11. xml.sax.saxutils — SAX Utilities
- 20.12. xml.sax.xmlreader — Interface for XML parsers
- 20.13. xml.parsers.expat — Fast XML parsing using Expat

21. Internet Protocols and Support
- 21.1. webbrowser — Convenient Web-browser controller
- 21.2. cgi — Common Gateway Interface support
- 21.3. cgitb — Traceback manager for CGI scripts
- 21.4. wsgiref — WSGI Utilities and Reference Implementation
- 21.5. urllib — URL handling modules
- 21.6. urllib.request — Extensible library for opening URLs
- 21.7. urllib.response — Response classes used by urllib
- 21.8. urllib.parse — Parse URLs into components
- 21.9. `urllib.error` — Exception classes raised by `urllib.request`
- 21.10. `urllib.robotparser` — Parser for robots.txt
- 21.11. `http` — HTTP modules
- 21.13. `ftplib` — FTP protocol client
- 21.14. `poplib` — POP3 protocol client
- 21.15. `imaplib` — IMAP4 protocol client
- 21.16. `nntplib` — NNTP protocol client
- 21.17. `smtplib` — SMTP protocol client
- 21.18. `smtpd` — SMTP Server
- 21.19. `telnetlib` — Telnet client
- 21.20. `uuid` — UUID objects according to RFC 4122
- 21.21. `socketserver` — A framework for network servers
- 21.22. `http.server` — HTTP servers
- 21.23. `http.cookies` — HTTP state management
- 21.24. `http.cookiejar` — Cookie handling for HTTP clients
- 21.25. `xmlrpc` — XMLRPC server and client modules
- 21.26. `xmlrpc.client` — XML-RPC client access
- 21.27. `xmlrpc.server` — Basic XML-RPC servers
- 21.28. `ipaddress` — IPv4/IPv6 manipulation library

- 22. Multimedia Services
  - 22.1. `audioop` — Manipulate raw audio data
  - 22.2. `aifc` — Read and write AIFF and AIFC files
  - 22.3. `sunau` — Read and write Sun AU files
  - 22.4. `wave` — Read and write WAV files
  - 22.5. `chunk` — Read IFF chunked data
  - 22.6. `colorsys` — Conversions between color systems
  - 22.7. `imghdr` — Determine the type of an image
  - 22.8. `sndhdr` — Determine type of sound file
  - 22.9. `ossaudiodev` — Access to OSS-compatible audio
• 23. Internationalization
  ○ 23.1. gettext — Multilingual internationalization services
  ○ 23.2. locale — Internationalization services

• 24. Program Frameworks
  ○ 24.1. turtle — Turtle graphics
  ○ 24.2. cmd — Support for line-oriented command interpreters
  ○ 24.3. shlex — Simple lexical analysis

• 25. Graphical User Interfaces with Tk
  ○ 25.1. tkinter — Python interface to Tcl/Tk
  ○ 25.2. tkinter.ttk — Tk themed widgets
  ○ 25.3. tkinter.tix — Extension widgets for Tk
  ○ 25.4. tkinter.scrolledtext — Scrolled Text Widget
  ○ 25.5. IDLE
  ○ 25.6. Other Graphical User Interface Packages

• 26. Development Tools
  ○ 26.1. pydoc — Documentation generator and online help system
  ○ 26.2. doctest — Test interactive Python examples
  ○ 26.3. unittest — Unit testing framework
  ○ 26.4. unittest.mock — mock object library
  ○ 26.5. unittest.mock — getting started
  ○ 26.6. 2to3 - Automated Python 2 to 3 code translation
  ○ 26.7. test — Regression tests package for Python
  ○ 26.8. test.support — Utilities for the Python test suite

• 27. Debugging and Profiling
  ○ 27.1. bdb — Debugger framework
  ○ 27.2. faulthandler — Dump the Python traceback
  ○ 27.3. pdb — The Python Debugger
  ○ 27.4. The Python Profilers
  ○ 27.5. timeit — Measure execution time of small code snippets
  ○ 27.6. trace — Trace or track Python statement execution
- 27.7. tracemalloc — Trace memory allocations
- 27.8. Examples
- 27.9. API

28. Software Packaging and Distribution
- 28.1. distutils — Building and installing Python modules
- 28.2. ensurepip — Bootstrapping the pip installer
- 28.3. venv — Creation of virtual environments

29. Python Runtime Services
- 29.1. sys — System-specific parameters and functions
- 29.2. sysconfig — Provide access to Python’s configuration information
- 29.3. builtins — Built-in objects
- 29.4. __main__ — Top-level script environment
- 29.5. warnings — Warning control
- 29.6. contextlib — Utilities for with-statement contexts
- 29.7. abc — Abstract Base Classes
- 29.8. atexit — Exit handlers
- 29.9. traceback — Print or retrieve a stack traceback
- 29.10. __future__ — Future statement definitions
- 29.11. gc — Garbage Collector interface
- 29.12. inspect — Inspect live objects
- 29.13. site — Site-specific configuration hook
- 29.14. fpectl — Floating point exception control

30. Custom Python Interpreters
- 30.1. code — Interpreter base classes
- 30.2. codeop — Compile Python code

31. Importing Modules
- 31.1. imp — Access the import internals
- 31.2. zipimport — Import modules from Zip archives
- 31.3. pkgutil — Package extension utility
- 31.4. modulefinder — Find modules used by a script
- 31.5. runpy — Locating and executing Python modules
31.6. importlib – The implementation of import

32. Python Language Services
   32.1. parser — Access Python parse trees
   32.2. ast — Abstract Syntax Trees
   32.3. symtable — Access to the compiler's symbol tables
   32.4. symbol — Constants used with Python parse trees
   32.5. token — Constants used with Python parse trees
   32.6. keyword — Testing for Python keywords
   32.7. tokenize — Tokenizer for Python source
   32.8. tabnanny — Detection of ambiguous indentation
   32.9. pyclbr — Python class browser support
   32.10. py_compile — Compile Python source files
   32.11. compileall — Byte-compile Python libraries
   32.12. dis — Disassembler for Python bytecode
   32.13. pickletools — Tools for pickle developers

33. Miscellaneous Services
   33.1. formatter — Generic output formatting

34. MS Windows Specific Services
   34.1. msilib — Read and write Microsoft Installer files
   34.2. msvcrt – Useful routines from the MS VC++ runtime
   34.3. winreg — Windows registry access
   34.4. winsound — Sound-playing interface for Windows

35. Unix Specific Services
   35.1. posix — The most common POSIX system calls
   35.2. pwd — The password database
   35.3. spwd — The shadow password database
   35.4. grp — The group database
   35.5. crypt — Function to check Unix passwords
   35.6. termios — POSIX style tty control
   35.7. tty — Terminal control functions
   35.8. pty — Pseudo-terminal utilities
   35.9. fcntl — The fcntl and ioctl system calls
- 35.10. pipes — Interface to shell pipelines
- 35.11. resource — Resource usage information
- 35.12. nis — Interface to Sun's NIS (Yellow Pages)
- 35.13. syslog — Unix syslog library routines

- 36. Undocumented Modules
  - 36.1. Platform specific modules
The Python Language Reference

This reference manual describes the syntax and “core semantics” of the language. It is terse, but attempts to be exact and complete. The semantics of non-essential built-in object types and of the built-in functions and modules are described in The Python Standard Library. For an informal introduction to the language, see The Python Tutorial. For C or C++ programmers, two additional manuals exist: Extending and Embedding the Python Interpreter describes the high-level picture of how to write a Python extension module, and the Python/C API Reference Manual describes the interfaces available to C/C++ programmers in detail.

- 1. Introduction
  - 1.1. Alternate Implementations
  - 1.2. Notation
- 2. Lexical analysis
  - 2.1. Line structure
  - 2.2. Other tokens
  - 2.3. Identifiers and keywords
  - 2.4. Literals
  - 2.5. Operators

  - 7.8. The raise statement
  - 7.9. The break statement
  - 7.10. The continue statement
7.11. The import statement
7.12. The global statement
7.13. The nonlocal statement

8. Compound statements
  8.1. The if statement
  8.2. The while statement
  8.3. The for statement
  8.4. The try statement
  8.5. The with statement
  8.6. Function definitions
  8.7. Class definitions

9. Top-level components
  9.1. Complete Python programs
  9.2. File input
  9.3. Interactive input
  9.4. Expression input

10. Full Grammar specification
Python Setup and Usage

This part of the documentation is devoted to general information on the setup of the Python environment on different platforms, the invocation of the interpreter and things that make working with Python easier.

- **1. Command line and environment**
  - 1.1. Command line
    - 1.1.1. Interface options
    - 1.1.2. Generic options
    - 1.1.3. Miscellaneous options
    - 1.1.4. Options you shouldn’t use
  - 1.2. Environment variables
    - 1.2.1. Debug-mode variables
- **2. Using Python on Unix platforms**
  - 2.1. Getting and installing the latest version of Python
    - 2.1.1. On Linux
    - 2.1.2. On FreeBSD and OpenBSD
    - 2.1.3. On OpenSolaris
  - 2.2. Building Python
  - 2.3. Python-related paths and files
  - 2.4. Miscellaneous
  - 2.5. Editors
- **3. Using Python on Windows**
  - 3.1. Installing Python
  - 3.2. Alternative bundles
  - 3.3. Configuring Python
    - 3.3.1. Excursus: Setting environment variables
    - 3.3.2. Finding the Python executable
    - 3.3.3. Finding modules
    - 3.3.4. Executing scripts
    - 3.3.5. Executing scripts without the Python launcher
3.4. Python Launcher for Windows
   - 3.4.1. Getting started
     - 3.4.1.1. From the command-line
     - 3.4.1.2. From a script
     - 3.4.1.3. From file associations
   - 3.4.2. Shebang Lines
   - 3.4.3. Arguments in shebang lines
   - 3.4.4. Customization
     - 3.4.4.1. Customization via INI files
     - 3.4.4.2. Customizing default Python versions
   - 3.4.5. Diagnostics

3.5. Additional modules
   - 3.5.1. PyWin32
   - 3.5.2. cx_Freeze
   - 3.5.3. WConio

3.6. Compiling Python on Windows

3.7. Other resources

4. Using Python on a Macintosh
   - 4.1. Getting and Installing MacPython
     - 4.1.1. How to run a Python script
     - 4.1.2. Running scripts with a GUI
     - 4.1.3. Configuration
   - 4.2. The IDE
   - 4.3. Installing Additional Python Packages
   - 4.4. GUI Programming on the Mac
   - 4.5. Distributing Python Applications on the Mac
   - 4.6. Other Resources

5. Additional Tools and Scripts
   - 5.1. pyvenv - Creating virtual environments
Python HOWTOs

Python HOWTOs are documents that cover a single, specific topic, and attempt to cover it fairly completely. Modelled on the Linux Documentation Project’s HOWTO collection, this collection is an effort to foster documentation that’s more detailed than the Python Library Reference.

Currently, the HOWTOs are:

- Porting Python 2 Code to Python 3
- Porting Extension Modules to Python 3
- Curses Programming with Python
- Descriptor HowTo Guide
- Functional Programming HOWTO
- Logging HOWTO
- Logging Cookbook
- Regular Expression HOWTO
- Socket Programming HOWTO
- Sorting HOW TO
- Unicode HOWTO
- HOWTO Fetch Internet Resources Using The urllib Package
- HOWTO Use Python in the web
- Argparse Tutorial
- An introduction to the ipaddress module
- Argument Clinic How-To
Installing Python Modules

Email: distutils-sig@python.org

As a popular open source development project, Python has an active supporting community of contributors and users that also make their software available for other Python developers to use under open source license terms.

This allows Python users to share and collaborate effectively, benefiting from the solutions others have already created to common (and sometimes even rare!) problems, as well as potentially contributing their own solutions to the common pool.

This guide covers the installation part of the process. For a guide to creating and sharing your own Python projects, refer to the distribution guide.

Note: For corporate and other institutional users, be aware that many organisations have their own policies around using and contributing to open source software. Please take such policies into account when making use of the distribution and installation tools provided with Python.
Key terms

- **pip** is the preferred installer program. Starting with Python 3.4, it is included by default with the Python binary installers.
- A virtual environment is a semi-isolated Python environment that allows packages to be installed for use by a particular application, rather than being installed system wide.
- **pyvenv** is the standard tool for creating virtual environments, and has been part of Python since Python 3.3. Starting with Python 3.4, it defaults to installing **pip** into all created virtual environments.
- The **Python Package Index** is a public repository of open source licensed packages made available for use by other Python users.
- The **Python Packaging Authority** are the group of developers and documentation authors responsible for the maintenance and evolution of the standard packaging tools and the associated metadata and file format standards. They maintain a variety of tools, documentation and issue trackers on both **GitHub** and **BitBucket**.
- **distutils** is the original build and distribution system first added to the Python standard library in 1998. While direct use of **distutils** is being phased out, it still laid the foundation for the current packaging and distribution infrastructure, and it not only remains part of the standard library, but its name lives on in other ways (such as the name of the mailing list used to coordinate Python packaging standards development).
Basic usage

The standard packaging tools are all designed to be used from the command line. For Windows users, the examples below assume that the option to adjust the system PATH environment variable was selected when installing Python. For Linux users, the command to install into the system version of Python 3 is likely to be pip3 rather than pip.

The following command will install the latest version of a module and its dependencies from the Python Package Index:

```
pip install SomePackage
```

It’s also possible to specify an exact or minimum version directly on the command line:

```
pip install SomePackage==1.0.4      # specific version  
pip install 'SomePackage>=1.0.4'   # minimum version
```

Normally, if a suitable module is already installed, attempting to install it again will have no effect. Upgrading existing modules must be requested explicitly:

```
pip install --upgrade SomePackage
```

More information and resources regarding pip and its capabilities can be found in the Python Packaging User Guide.

pyenv has its own documentation at pyenv - Creating virtual environments. Installing into an active virtual environment uses the commands shown above.
See also: Python Packaging User Guide: Installing Python packages
How do I ...?

These are quick answers or links for some common tasks.

... install pip in versions of Python prior to Python 3.4?

Python only started bundling pip with Python 3.4. For earlier versions, pip needs to be “bootstrapped” as described in the Python Packaging User Guide.

See also: Python Packaging User Guide: Installing the Tools

... install packages just for the current user?

Passing the --user option to pip install will install a package just for the current user, rather than for all users of the system.

... install scientific Python packages?

A number of scientific Python packages have complex binary dependencies, and aren’t currently easy to install using pip directly. At this point in time, it will often be easier for users to install these packages by other means rather than attempting to install them with pip.

See also: Python Packaging User Guide: Installing Scientific Packages

... work with multiple versions of Python installed
in parallel?

On Linux, Mac OS X and other POSIX systems, use the versioned Python commands in combination with the `-m` switch to run the appropriate copy of `pip`:

```
python2    -m pip install SomePackage  # default Python 2
python2.7  -m pip install SomePackage  # specifically Python 2.7
python3    -m pip install SomePackage  # default Python 3
python3.4  -m pip install SomePackage  # specifically Python 3.4
```

(appropriately versioned `pip` commands may also be available)

On Windows, use the `py` Python launcher in combination with the `-m` switch:

```
p y -2    -m pip install SomePackage  # default Python 2
py -2.7   -m pip install SomePackage  # specifically Python 2.7
py -3     -m pip install SomePackage  # default Python 3
py -3.4   -m pip install SomePackage  # specifically Python 3.4
```
Common installation issues

Installing into the system Python on Linux

On Linux systems, a Python installation will typically be included as part of the distribution. Installing into this Python installation requires root access to the system, and may interfere with the operation of the system package manager and other components of the system if a component is unexpectedly upgraded using `pip`.

On such systems, it is often better to use a virtual environment or a per-user installation when installing packages with `pip`.

Installing binary extensions

Python has typically relied heavily on source based distribution, with end users being expected to compile extension modules from source as part of the installation process.

With the introduction of support for the binary `wheel` format, and the ability to publish wheels for at least Windows and Mac OS X through the Python Package Index, this problem is expected to diminish over time, as users are more regularly able to install pre-built extensions rather than needing to build them themselves.

Some of the solutions for installing scientific software that is not yet available as pre-built `wheel` files may also help with obtaining other binary extensions without needing to build them locally.

Distributing Python Modules

Email: distutils-sig@python.org

As a popular open source development project, Python has an active supporting community of contributors and users that also make their software available for other Python developers to use under open source license terms.

This allows Python users to share and collaborate effectively, benefiting from the solutions others have already created to common (and sometimes even rare!) problems, as well as potentially contributing their own solutions to the common pool.

This guide covers the distribution part of the process. For a guide to installing other Python projects, refer to the installation guide.

Note: For corporate and other institutional users, be aware that many organisations have their own policies around using and contributing to open source software. Please take such policies into account when making use of the distribution and installation tools provided with Python.
Key terms

- the **Python Package Index** is a public repository of open source licensed packages made available for use by other Python users.
- the **Python Packaging Authority** are the group of developers and documentation authors responsible for the maintenance and evolution of the standard packaging tools and the associated metadata and file format standards. They maintain a variety of tools, documentation and issue trackers on both GitHub and BitBucket.
- **distutils** is the original build and distribution system first added to the Python standard library in 1998. While direct use of distutils is being phased out, it still laid the foundation for the current packaging and distribution infrastructure, and it not only remains part of the standard library, but its name lives on in other ways (such as the name of the mailing list used to coordinate Python packaging standards development).
Open source licensing and collaboration

In most parts of the world, software is automatically covered by copyright. This means that other developers require explicit permission to copy, use, modify and redistribute the software.

Open source licensing is a way of explicitly granting such permission in a relatively consistent way, allowing developers to share and collaborate efficiently by making common solutions to various problems freely available. This leaves many developers free to spend more time focusing on the problems that are relatively unique to their specific situation.

The distribution tools provided with Python are designed to make it reasonably straightforward for developers to make their own contributions back to that common pool of software if they choose to do so.

The same distribution tools can also be used to distribute software within an organisation, regardless of whether that software is published as open source software or not.
Installing the tools

The standard library does not include build tools that support modern Python packaging standards, as the core development team has found that it is important to have standard tools that work consistently, even on older versions of Python.

The currently recommended build and distribution tools can be installed using `pip`:

```
pip install setuptools wheel twine
```
Reading the guide

The Python Packaging User Guide covers the various key steps and elements involved in creating a project

- Project structure
- Building and packaging the project
- Uploading the project to the Python Package Index
How do I...?

These are quick answers or links for some common tasks.

... choose a name for my project?

This isn't an easy topic, but here are a few tips:

- check the Python Package Index to see if the name is already in use
- check popular hosting sites like GitHub, BitBucket, etc to see if there is already a project with that name
- check what comes up in a web search for the name you're considering
- avoid particularly common words, especially ones with multiple meanings, as they can make it difficult for users to find your software when searching for it

... create and distribute binary extensions?

This is actually quite a complex topic, with a variety of alternatives available depending on exactly what you're aiming to achieve. See the Python Packaging User Guide for more information and recommendations.

Extending and Embedding the Python Interpreter

This document describes how to write modules in C or C++ to extend the Python interpreter with new modules. Those modules can not only define new functions but also new object types and their methods. The document also describes how to embed the Python interpreter in another application, for use as an extension language. Finally, it shows how to compile and link extension modules so that they can be loaded dynamically (at run time) into the interpreter, if the underlying operating system supports this feature.

This document assumes basic knowledge about Python. For an informal introduction to the language, see *The Python Tutorial*. *The Python Language Reference* gives a more formal definition of the language. *The Python Standard Library* documents the existing object types, functions and modules (both built-in and written in Python) that give the language its wide application range.

For a detailed description of the whole Python/C API, see the separate *Python/C API Reference Manual*. 
Recommended third party tools

This guide only covers the basic tools for creating extensions provided as part of this version of CPython. Third party tools like Cython, cffi, SWIG and Numba offer both simpler and more sophisticated approaches to creating C and C++ extensions for Python.

See also:

Python Packaging User Guide: Binary Extensions
The Python Packaging User Guide not only covers several available tools that simplify the creation of binary extensions, but also discusses the various reasons why creating an extension module may be desirable in the first place.
Creating extensions without third party tools

This section of the guide covers creating C and C++ extensions without assistance from third party tools. It is intended primarily for creators of those tools, rather than being a recommended way to create your own C extensions.

- **1. Extending Python with C or C++**
  - 1.1. A Simple Example
  - 1.2. Intermezzo: Errors and Exceptions
  - 1.3. Back to the Example
  - 1.4. The Module’s Method Table and Initialization Function
  - 1.5. Compilation and Linkage
  - 1.6. Calling Python Functions from C
  - 1.7. Extracting Parameters in Extension Functions
  - 1.8. Keyword Parameters for Extension Functions
  - 1.9. Building Arbitrary Values
  - 1.10. Reference Counts
  - 1.11. Writing Extensions in C++
  - 1.12. Providing a C API for an Extension Module

- **2. Defining New Types**
  - 2.1. The Basics
  - 2.2. Type Methods

- **3. Building C and C++ Extensions with distutils**
  - 3.1. Distributing your extension modules

- **4. Building C and C++ Extensions on Windows**
  - 4.1. A Cookbook Approach
  - 4.2. Differences Between Unix and Windows
  - 4.3. Using DLLs in Practice
Embedding the CPython runtime in a larger application

Sometimes, rather than creating an extension that runs inside the Python interpreter as the main application, it is desirable to instead embed the CPython runtime inside a larger application. This section covers some of the details involved in doing that successfully.

- **1. Embedding Python in Another Application**
  - 1.1. Very High Level Embedding
  - 1.2. Beyond Very High Level Embedding: An overview
  - 1.3. Pure Embedding
  - 1.4. Extending Embedded Python
  - 1.5. Embedding Python in C++
  - 1.6. Compiling and Linking under Unix-like systems
Python/C API Reference Manual

This manual documents the API used by C and C++ programmers who want to write extension modules or embed Python. It is a companion to *Extending and Embedding the Python Interpreter*, which describes the general principles of extension writing but does not document the API functions in detail.

- **Introduction**
  - Include Files
  - Objects, Types and Reference Counts
  - Exceptions
  - Embedding Python
  - Debugging Builds
- **Stable Application Binary Interface**
- **The Very High Level Layer**
- **Reference Counting**
- **Exception Handling**
  - Exception Objects
  - Unicode Exception Objects
  - Recursion Control
  - Standard Exceptions
- **Utilities**
  - Operating System Utilities
  - System Functions
  - Process Control
  - Importing Modules
  - Data marshalling support
  - Parsing arguments and building values
  - String conversion and formatting
  - Reflection
  - Codec registry and support functions
- **Abstract Objects Layer**
  - Object Protocol
  - Number Protocol
  - Sequence Protocol
  - Mapping Protocol
  - Iterator Protocol
  - Buffer Protocol
  - Old Buffer Protocol
- **Concrete Objects Layer**
  - Fundamental Objects
  - Numeric Objects
  - Sequence Objects
  - Container Objects
  - Function Objects
  - Other Objects
- **Initialization, Finalization, and Threads**
  - Initializing and finalizing the interpreter
  - Process-wide parameters
  - Thread State and the Global Interpreter Lock
  - Sub-interpreter support
  - Asynchronous Notifications
  - Profiling and Tracing
  - Advanced Debugger Support
- **Memory Management**
  - Overview
  - Raw Memory Interface
  - Memory Interface
  - Customize Memory Allocators
  - Customize PyObject Arena Allocator
  - Examples
- **Object Implementation Support**
  - Allocating Objects on the Heap
  - Common Object Structures
  - Type Objects
- Number Object Structures
- Mapping Object Structures
- Sequence Object Structures
- Buffer Object Structures

- The Python Tutorial
  - 1. Whetting Your Appetite
  - 2. Using the Python Interpreter
    - 2.1. Invoking the Interpreter
      - 2.1.1. Argument Passing
      - 2.1.2. Interactive Mode
    - 2.2. The Interpreter and Its Environment
      - 2.2.1. Error Handling
      - 2.2.2. Executable Python Scripts
      - 2.2.3. Source Code Encoding
      - 2.2.4. The Interactive Startup File
      - 2.2.5. The Customization Modules
  - 3. An Informal Introduction to Python
3.1. Using Python as a Calculator
   - 3.1.1. Numbers
   - 3.1.2. Strings
   - 3.1.3. Lists

3.2. First Steps Towards Programming

4. More Control Flow Tools
   - 4.1. if Statements
   - 4.2. for Statements
   - 4.3. The range() Function
   - 4.4. break and continue Statements, and else Clauses on Loops
   - 4.5. pass Statements
   - 4.6. Defining Functions
   - 4.7. More on Defining Functions
     - 4.7.1. Default Argument Values
     - 4.7.2. Keyword Arguments
     - 4.7.3. Arbitrary Argument Lists
     - 4.7.4. Unpacking Argument Lists
     - 4.7.5. Lambda Expressions
     - 4.7.6. Documentation Strings
     - 4.7.7. Function Annotations
   - 4.8. Intermezzo: Coding Style

5. Data Structures
   - 5.1. More on Lists
     - 5.1.1. Using Lists as Stacks
     - 5.1.2. Using Lists as Queues
     - 5.1.3. List Comprehensions
     - 5.1.4. Nested List Comprehensions
   - 5.2. The del statement
   - 5.3. Tuples and Sequences
   - 5.4. Sets
   - 5.5. Dictionaries
   - 5.6. Looping Techniques
   - 5.7. More on Conditions
- 5.8. Comparing Sequences and Other Types
- 6. Modules
  - 6.1. More on Modules
    - 6.1.1. Executing modules as scripts
    - 6.1.2. The Module Search Path
    - 6.1.3. “Compiled” Python files
  - 6.2. Standard Modules
  - 6.3. The dir() Function
  - 6.4. Packages
    - 6.4.1. Importing * From a Package
    - 6.4.2. Intra-package References
    - 6.4.3. Packages in Multiple Directories
- 7. Input and Output
  - 7.1. Fancier Output Formatting
    - 7.1.1. Old string formatting
  - 7.2. Reading and Writing Files
    - 7.2.1. Methods of File Objects
    - 7.2.2. Saving structured data with json
- 8. Errors and Exceptions
  - 8.1. Syntax Errors
  - 8.2. Exceptions
  - 8.3. Handling Exceptions
  - 8.4. Raising Exceptions
  - 8.5. User-defined Exceptions
  - 8.6. Defining Clean-up Actions
  - 8.7. Predefined Clean-up Actions
- 9. Classes
  - 9.1. A Word About Names and Objects
  - 9.2. Python Scopes and Namespaces
    - 9.2.1. Scopes and Namespaces Example
  - 9.3. A First Look at Classes
    - 9.3.1. Class Definition Syntax
    - 9.3.2. Class Objects
    - 9.3.3. Instance Objects
- 9.3.4. Method Objects
- 9.4. Random Remarks
- 9.5. Inheritance
  - 9.5.1. Multiple Inheritance
- 9.6. Private Variables
- 9.7. Odds and Ends
- 9.8. Exceptions Are Classes Too
- 9.9. Iterators
- 9.10. Generators
- 9.11. Generator Expressions

- 10. Brief Tour of the Standard Library
  - 10.1. Operating System Interface
  - 10.2. File Wildcards
  - 10.3. Command Line Arguments
  - 10.4. Error Output Redirection and Program Termination
  - 10.5. String Pattern Matching
  - 10.6. Mathematics
  - 10.7. Internet Access
  - 10.8. Dates and Times
  - 10.9. Data Compression
  - 10.10. Performance Measurement
  - 10.11. Quality Control
  - 10.12. Batteries Included

- 11. Brief Tour of the Standard Library – Part II
  - 11.1. Output Formatting
  - 11.2. Templating
  - 11.3. Working with Binary Data Record Layouts
  - 11.4. Multi-threading
  - 11.5. Logging
  - 11.6. Weak References
  - 11.7. Tools for Working with Lists
  - 11.8. Decimal Floating Point Arithmetic

- 12. What Now?
- 13. Interactive Input Editing and History Substitution
13.1. Tab Completion and History Editing
13.2. Alternatives to the Interactive Interpreter
14. Floating Point Arithmetic: Issues and Limitations
   14.1. Representation Error

- Python Setup and Usage
  - 1. Command line and environment
    - 1.1. Command line
      - 1.1.1. Interface options
      - 1.1.2. Generic options
      - 1.1.3. Miscellaneous options
      - 1.1.4. Options you shouldn’t use
    - 1.2. Environment variables
      - 1.2.1. Debug-mode variables
  - 2. Using Python on Unix platforms
    - 2.1. Getting and installing the latest version of Python
      - 2.1.1. On Linux
      - 2.1.2. On FreeBSD and OpenBSD
      - 2.1.3. On OpenSolaris
    - 2.2. Building Python
    - 2.3. Python-related paths and files
    - 2.4. Miscellaneous
    - 2.5. Editors
  - 3. Using Python on Windows
    - 3.1. Installing Python
    - 3.2. Alternative bundles
    - 3.3. Configuring Python
      - 3.3.1. Excursus: Setting environment variables
      - 3.3.2. Finding the Python executable
      - 3.3.3. Finding modules
      - 3.3.4. Executing scripts
      - 3.3.5. Executing scripts without the Python launcher
    - 3.4. Python Launcher for Windows
      - 3.4.1. Getting started
        - 3.4.1.1. From the command-line
- 3.4.1.2. From a script
- 3.4.1.3. From file associations
- 3.4.2. Shebang Lines
- 3.4.3. Arguments in shebang lines
- 3.4.4. Customization
  - 3.4.4.1. Customization via INI files
  - 3.4.4.2. Customizing default Python versions
- 3.4.5. Diagnostics
- 3.5. Additional modules
  - 3.5.1. PyWin32
  - 3.5.2. cx_Freeze
  - 3.5.3. WConio
- 3.6. Compiling Python on Windows
- 3.7. Other resources
- 4. Using Python on a Macintosh
  - 4.1. Getting and Installing MacPython
    - 4.1.1. How to run a Python script
    - 4.1.2. Running scripts with a GUI
    - 4.1.3. Configuration
  - 4.2. The IDE
  - 4.3. Installing Additional Python Packages
  - 4.4. GUI Programming on the Mac
  - 4.5. Distributing Python Applications on the Mac
  - 4.6. Other Resources
- 5. Additional Tools and Scripts
  - 5.1. pyvenv - Creating virtual environments

- The Python Language Reference
  - 1. Introduction
    - 1.1. Alternate Implementations
    - 1.2. Notation
  - 2. Lexical analysis
    - 2.1. Line structure
      - 2.1.1. Logical lines
      - 2.1.2. Physical lines
2.1.3. Comments
2.1.4. Encoding declarations
2.1.5. Explicit line joining
2.1.6. Implicit line joining
2.1.7. Blank lines
2.1.8. Indentation
2.1.9. Whitespace between tokens
2.2. Other tokens
2.3. Identifiers and keywords
  2.3.1. Keywords
  2.3.2. Reserved classes of identifiers
2.4. Literals
  2.4.1. String and Bytes literals
  2.4.2. String literal concatenation
  2.4.3. Numeric literals
  2.4.4. Integer literals
  2.4.5. Floating point literals
  2.4.6. Imaginary literals
2.5. Operators
2.6. Delimiters
3. Data model
  3.1. Objects, values and types
  3.2. The standard type hierarchy
  3.3. Special method names
    3.3.1. Basic customization
    3.3.2. Customizing attribute access
      3.3.2.1. Implementing Descriptors
      3.3.2.2. Invoking Descriptors
      3.3.2.3. __slots__
        3.3.2.3.1. Notes on using __slots__
    3.3.3. Customizing class creation
      3.3.3.1. Determining the appropriate metaclass
      3.3.3.2. Preparing the class namespace
      3.3.3.3. Executing the class body
- 3.3.3.4. Creating the class object
- 3.3.3.5. Metaclass example
- 3.3.4. Customizing instance and subclass checks
- 3.3.5. Emulating callable objects
- 3.3.6. Emulating container types
- 3.3.7. Emulating numeric types
- 3.3.8. With Statement Context Managers
- 3.3.9. Special method lookup

- 4. Execution model
  - 4.1. Naming and binding
    - 4.1.1. Interaction with dynamic features
  - 4.2. Exceptions

- 5. The import system
  - 5.1. importlib
  - 5.2. Packages
    - 5.2.1. Regular packages
    - 5.2.2. Namespace packages
  - 5.3. Searching
    - 5.3.1. The module cache
    - 5.3.2. Finders and loaders
    - 5.3.3. Import hooks
    - 5.3.4. The meta path
  - 5.4. Loading
    - 5.4.1. Loaders
    - 5.4.2. Module spec
    - 5.4.3. Import-related module attributes
    - 5.4.4. module.__path__
    - 5.4.5. Module reprs
  - 5.5. The Path Based Finder
    - 5.5.1. Path entry finders
    - 5.5.2. Path entry finder protocol
  - 5.6. Replacing the standard import system
  - 5.7. Open issues
  - 5.8. References
6. Expressions
   • 6.1. Arithmetic conversions
   • 6.2. Atoms
      • 6.2.1. Identifiers (Names)
      • 6.2.2. Literals
      • 6.2.3. Parenthesized forms
      • 6.2.4. Displays for lists, sets and dictionaries
      • 6.2.5. List displays
      • 6.2.6. Set displays
      • 6.2.7. Dictionary displays
      • 6.2.8. Generator expressions
      • 6.2.9. Yield expressions
         • 6.2.9.1. Generator-iterator methods
         • 6.2.9.2. Examples
   • 6.3. Primaries
      • 6.3.1. Attribute references
      • 6.3.2. Subscriptions
      • 6.3.3. Slicings
      • 6.3.4. Calls
   • 6.4. The power operator
   • 6.5. Unary arithmetic and bitwise operations
   • 6.6. Binary arithmetic operations
   • 6.7. Shifting operations
   • 6.8. Binary bitwise operations
   • 6.9. Comparisons
   • 6.10. Boolean operations
   • 6.11. Conditional expressions
   • 6.12. Lambdas
   • 6.13. Expression lists
   • 6.14. Evaluation order
   • 6.15. Operator precedence

7. Simple statements
   • 7.1. Expression statements
   • 7.2. Assignment statements
7.2.1. Augmented assignment statements
7.3. The assert statement
7.4. The pass statement
7.5. The del statement
7.6. The return statement
7.7. The yield statement
7.8. The raise statement
7.9. The break statement
7.10. The continue statement
7.11. The import statement
  7.11.1. Future statements
7.12. The global statement
7.13. The nonlocal statement
8. Compound statements
  8.1. The if statement
  8.2. The while statement
  8.3. The for statement
  8.4. The try statement
  8.5. The with statement
  8.6. Function definitions
  8.7. Class definitions
9. Top-level components
  9.1. Complete Python programs
  9.2. File input
  9.3. Interactive input
  9.4. Expression input
10. Full Grammar specification
The Python Standard Library
  1. Introduction
  2. Built-in Functions
  3. Built-in Constants
    3.1. Constants added by the site module
  4. Built-in Types
4.1. Truth Value Testing
4.2. Boolean Operations — and, or, not
4.3. Comparisons
4.4. Numeric Types — int, float, complex
  4.4.1. Bitwise Operations on Integer Types
  4.4.2. Additional Methods on Integer Types
  4.4.3. Additional Methods on Float
  4.4.4. Hashing of numeric types
4.5. Iterator Types
  4.5.1. Generator Types
4.6. Sequence Types — list, tuple, range
  4.6.1. Common Sequence Operations
  4.6.2. Immutable Sequence Types
  4.6.3. Mutable Sequence Types
  4.6.4. Lists
  4.6.5. Tuples
  4.6.6. Ranges
4.7. Text Sequence Type — str
  4.7.1. String Methods
  4.7.2. printf-style String Formatting
4.8. Binary Sequence Types — bytes, bytearray, memoryview
  4.8.1. Bytes
  4.8.2. Bytearray Objects
  4.8.3. Bytes and Bytearray Operations
  4.8.4. Memory Views
4.9. Set Types — set, frozenset
4.10. Mapping Types — dict
  4.10.1. Dictionary view objects
4.11. Context Manager Types
4.12. Other Built-in Types
  4.12.1. Modules
  4.12.2. Classes and Class Instances
  4.12.3. Functions
4.12.4. Methods
4.12.5. Code Objects
4.12.6. Type Objects
4.12.7. The Null Object
4.12.8. The Ellipsis Object
4.12.9. The NotImplemented Object
4.12.10. Boolean Values
4.12.11. Internal Objects

4.13. Special Attributes

5. Built-in Exceptions
5.1. Base classes
5.2. Concrete exceptions
  5.2.1. OS exceptions
5.3. Warnings
5.4. Exception hierarchy

6. Text Processing Services
  6.1. string — Common string operations
    6.1.1. String constants
    6.1.2. String Formatting
    6.1.3. Format String Syntax
      6.1.3.1. Format Specification Mini-Language
      6.1.3.2. Format examples
    6.1.4. Template strings
    6.1.5. Helper functions
  6.2. re — Regular expression operations
    6.2.1. Regular Expression Syntax
    6.2.2. Module Contents
    6.2.3. Regular Expression Objects
    6.2.4. Match Objects
    6.2.5. Regular Expression Examples
      6.2.5.1. Checking for a Pair
      6.2.5.2. Simulating scanf()
      6.2.5.3. search() vs. match()
      6.2.5.4. Making a Phonebook
- 6.2.5.5. Text Munging
- 6.2.5.6. Finding all Adverbs
- 6.2.5.7. Finding all Adverbs and their Positions
- 6.2.5.8. Raw String Notation
- 6.2.5.9. Writing a Tokenizer

- 6.3. difflib — Helpers for computing deltas
  - 6.3.1. SequenceMatcher Objects
  - 6.3.2. SequenceMatcher Examples
  - 6.3.3. Differ Objects
  - 6.3.4. Differ Example
  - 6.3.5. A command-line interface to difflib

- 6.4. textwrap — Text wrapping and filling
- 6.5. unicodedata — Unicode Database
- 6.6. stringprep — Internet String Preparation
- 6.7. readline — GNU readline interface
  - 6.7.1. Example
- 6.8. rlcompleter — Completion function for GNU readline
  - 6.8.1. Completer Objects

- 7. Binary Data Services
  - 7.1. struct — Interpret bytes as packed binary data
    - 7.1.1. Functions and Exceptions
    - 7.1.2. Format Strings
      - 7.1.2.1. Byte Order, Size, and Alignment
      - 7.1.2.2. Format Characters
      - 7.1.2.3. Examples
    - 7.1.3. Classes
  - 7.2. codecs — Codec registry and base classes
    - 7.2.1. Codec Base Classes
      - 7.2.1.1. Codec Objects
      - 7.2.1.2. IncrementalEncoder Objects
      - 7.2.1.3. IncrementalDecoder Objects
      - 7.2.1.4. StreamWriter Objects
      - 7.2.1.5. StreamReader Objects
7.2.1.6. StreamReaderWriter Objects
7.2.1.7. StreamRecoder Objects

7.2.2. Encodings and Unicode
7.2.3. Standard Encodings
7.2.4. Python Specific Encodings
    7.2.4.1. Text Encodings
    7.2.4.2. Binary Transforms
    7.2.4.3. Text Transforms
7.2.5. encodings.idna — Internationalized Domain Names in Applications
7.2.6. encodings.mbc — Windows ANSI codepage
7.2.7. encodings.utf_8_sig — UTF-8 codec with BOM signature

8. Data Types
8.1. datetime — Basic date and time types
    8.1.1. Available Types
    8.1.2. timedelta Objects
    8.1.3. date Objects
    8.1.4. datetime Objects
    8.1.5. time Objects
    8.1.6. tzinfo Objects
    8.1.7. timezone Objects
    8.1.8. strftime() and strptime() Behavior
8.2. calendar — General calendar-related functions
8.3. collections — Container datatypes
    8.3.1. ChainMap objects
        8.3.1.1. ChainMap Examples and Recipes
    8.3.2. Counter objects
    8.3.3. deque objects
        8.3.3.1. deque Recipes
    8.3.4. defaultdict objects
        8.3.4.1. defaultdict Examples
- 8.12. `reprlib` — Alternate `repr()` implementation
  - 8.12.1. Repr Objects
  - 8.12.2. Subclassing Repr Objects
- 8.13. `enum` — Support for enumerations
  - 8.13.1. Module Contents
  - 8.13.2. Creating an Enum
  - 8.13.3. Programmatic access to enumeration members and their attributes
  - 8.13.4. Duplicating enum members and values
  - 8.13.5. Ensuring unique enumeration values
  - 8.13.6. Iteration
  - 8.13.7. Comparisons
  - 8.13.8. Allowed members and attributes of enumerations
  - 8.13.9. Restricted subclassing of enumerations
  - 8.13.10. Pickling
  - 8.13.11. Functional API
  - 8.13.12. Derived Enumerations
    - 8.13.12.1. `IntEnum`
    - 8.13.12.2. Others
  - 8.13.13. Interesting examples
    - 8.13.13.1. `AutoNumber`
    - 8.13.13.2. `OrderedEnum`
    - 8.13.13.3. `DuplicateFreeEnum`
    - 8.13.13.4. `Planet`
  - 8.13.14. How are Enums different?
    - 8.13.14.2. Enum Members (aka instances)
    - 8.13.14.3. Finer Points
- 9. Numeric and Mathematical Modules
  - 9.1. `numbers` — Numeric abstract base classes
    - 9.1.1. The numeric tower
    - 9.1.2. Notes for type implementors
      - 9.1.2.1. Adding More Numeric ABCs
- 9.1.2.2. Implementing the arithmetic operations
- 9.2. math — Mathematical functions
  - 9.2.1. Number-theoretic and representation functions
  - 9.2.2. Power and logarithmic functions
  - 9.2.3. Trigonometric functions
  - 9.2.4. Angular conversion
  - 9.2.5. Hyperbolic functions
  - 9.2.6. Special functions
  - 9.2.7. Constants
- 9.3. cmath — Mathematical functions for complex numbers
  - 9.3.1. Conversions to and from polar coordinates
  - 9.3.2. Power and logarithmic functions
  - 9.3.3. Trigonometric functions
  - 9.3.4. Hyperbolic functions
  - 9.3.5. Classification functions
  - 9.3.6. Constants
- 9.4. decimal — Decimal fixed point and floating point arithmetic
  - 9.4.1. Quick-start Tutorial
  - 9.4.2. Decimal objects
    - 9.4.2.1. Logical operands
  - 9.4.3. Context objects
  - 9.4.4. Constants
  - 9.4.5. Rounding modes
  - 9.4.6. Signals
  - 9.4.7. Floating Point Notes
    - 9.4.7.1. Mitigating round-off error with increased precision
    - 9.4.7.2. Special values
  - 9.4.8. Working with threads
  - 9.4.9. Recipes
  - 9.4.10. Decimal FAQ
- 9.5. fractions — Rational numbers
- 9.6. random — Generate pseudo-random numbers
  - 9.6.1. Notes on Reproducibility
  - 9.6.2. Examples and Recipes
- 9.7. statistics — Mathematical statistics functions
  - 9.7.1. Averages and measures of central location
  - 9.7.2. Measures of spread
  - 9.7.3. Function details
  - 9.7.4. Exceptions
- 10. Functional Programming Modules
  - 10.1. itertools — Functions creating iterators for efficient looping
    - 10.1.1. Itertool functions
    - 10.1.2. Itertools Recipes
  - 10.2. functools — Higher-order functions and operations on callable objects
    - 10.2.1. partial Objects
  - 10.3. operator — Standard operators as functions
    - 10.3.1. Mapping Operators to Functions
    - 10.3.2. Inplace Operators
- 11. File and Directory Access
  - 11.1. pathlib — Object-oriented filesystem paths
    - 11.1.1. Basic use
    - 11.1.2. Pure paths
      - 11.1.2.1. General properties
      - 11.1.2.2. Operators
      - 11.1.2.3. Accessing individual parts
      - 11.1.2.4. Methods and properties
    - 11.1.3. Concrete paths
      - 11.1.3.1. Methods
  - 11.2. os.path — Common pathname manipulations
  - 11.3. fileinput — Iterate over lines from multiple input streams
- 11.4. stat — Interpreting stat() results
- 11.5. filecmp — File and Directory Comparisons
  - 11.5.1. The dircmp class
- 11.6. tempfile — Generate temporary files and directories
  - 11.6.1. Examples
- 11.7. glob — Unix style pathname pattern expansion
- 11.8. fnmatch — Unix filename pattern matching
- 11.9. linecache — Random access to text lines
- 11.10. shutil — High-level file operations
  - 11.10.1. Directory and files operations
    - 11.10.1.1. copytree example
  - 11.10.2. Archiving operations
    - 11.10.2.1. Archiving example
  - 11.10.3. Querying the size of the output terminal
- 11.11. macpath — Mac OS 9 path manipulation functions
- 12. Data Persistence
  - 12.1. pickle — Python object serialization
    - 12.1.1. Relationship to other Python modules
      - 12.1.1.1. Comparison with marshal
      - 12.1.1.2. Comparison with json
    - 12.1.2. Data stream format
    - 12.1.3. Module Interface
    - 12.1.4. What can be pickled and unpickled?
    - 12.1.5. Pickling Class Instances
      - 12.1.5.1. Persistence of External Objects
      - 12.1.5.2. Dispatch Tables
      - 12.1.5.3. Handling Stateful Objects
    - 12.1.6. Restricting Globals
    - 12.1.7. Performance
    - 12.1.8. Examples
  - 12.2. copyreg — Register pickle support functions
- 12.2.1. Example
- 12.3. `shelve` — Python object persistence
  - 12.3.1. Restrictions
  - 12.3.2. Example
- 12.4. `marshal` — Internal Python object serialization
- 12.5. `dbm` — Interfaces to Unix “databases”
  - 12.5.1. `dbm.gnu` — GNU’s reinterpretation of `dbm`
  - 12.5.2. `dbm.ndbm` — Interface based on `ndbm`
  - 12.5.3. `dbm.dumb` — Portable DBM implementation
- 12.6. `sqlite3` — DB-API 2.0 interface for SQLite databases
  - 12.6.1. Module functions and constants
  - 12.6.2. Connection Objects
  - 12.6.3. Cursor Objects
  - 12.6.4. Row Objects
  - 12.6.5. SQLite and Python types
    - 12.6.5.1. Introduction
    - 12.6.5.2. Using adapters to store additional Python types in SQLite databases
      - 12.6.5.2.1. Letting your object adapt itself
      - 12.6.5.2.2. Registering an adapter callable
    - 12.6.5.3. Converting SQLite values to custom Python types
    - 12.6.5.4. Default adapters and converters
  - 12.6.6. Controlling Transactions
  - 12.6.7. Using `sqlite3` efficiently
    - 12.6.7.1. Using shortcut methods
    - 12.6.7.2. Accessing columns by name instead of by index
    - 12.6.7.3. Using the connection as a context manager
  - 12.6.8. Common issues
    - 12.6.8.1. Multithreading
- 13. Data Compression and Archiving
13.1. **zlib** — Compression compatible with **gzip**
13.2. **gzip** — Support for **gzip** files
   - 13.2.1. Examples of usage
13.3. **bz2** — Support for **bzip2** compression
   - 13.3.1. (De)compression of files
   - 13.3.2. Incremental (de)compression
   - 13.3.3. One-shot (de)compression
13.4. **lzma** — Compression using the LZMA algorithm
   - 13.4.1. Reading and writing compressed files
   - 13.4.2. Compressing and decompressing data in memory
   - 13.4.3. Miscellaneous
   - 13.4.4. Specifying custom filter chains
   - 13.4.5. Examples
13.5. **zipfile** — Work with ZIP archives
   - 13.5.1. ZipFile Objects
   - 13.5.2. PyZipFile Objects
   - 13.5.3. ZipInfo Objects
13.6. **tarfile** — Read and write tar archive files
   - 13.6.1. TarFile Objects
   - 13.6.2. TarInfo Objects
   - 13.6.3. Command Line Interface
     - 13.6.3.1. Command line options
   - 13.6.4. Examples
   - 13.6.5. Supported tar formats
   - 13.6.6. Unicode issues

14. **File Formats**
   - 14.1. **csv** — CSV File Reading and Writing
     - 14.1.1. Module Contents
     - 14.1.2. Dialects and Formatting Parameters
     - 14.1.3. Reader Objects
     - 14.1.4. Writer Objects
     - 14.1.5. Examples
   - 14.2. **configparser** — Configuration file parser
14.2.1. Quick Start
14.2.2. Supported Datatypes
14.2.3. Fallback Values
14.2.4. Supported INI File Structure
14.2.5. Interpolation of values
14.2.6. Mapping Protocol Access
14.2.7. Customizing Parser Behaviour
14.2.8. Legacy API Examples
14.2.9. ConfigParser Objects
14.2.10. RawConfigParser Objects
14.2.11. Exceptions

14.3. netrc — netrc file processing
  14.3.1. netrc Objects

14.4. xdrlib — Encode and decode XDR data
  14.4.1. Packer Objects
  14.4.2. Unpacker Objects
  14.4.3. Exceptions

14.5. plistlib — Generate and parse Mac OS X .plist files
  14.5.1. Examples

15. Cryptographic Services
  15.1. hashlib — Secure hashes and message digests
    15.1.1. Hash algorithms
    15.1.2. Key Derivation Function
  15.2. hmac — Keyed-Hashing for Message Authentication

16. Generic Operating System Services
  16.1. os — Miscellaneous operating system interfaces
    16.1.1. File Names, Command Line Arguments, and Environment Variables
    16.1.2. Process Parameters
    16.1.3. File Object Creation
    16.1.4. File Descriptor Operations
      16.1.4.1. Querying the size of a terminal
- 16.1.4.2. Inheritance of File Descriptors
- 16.1.5. Files and Directories
  - 16.1.5.1. Linux extended attributes
- 16.1.6. Process Management
- 16.1.7. Interface to the scheduler
- 16.1.8. Miscellaneous System Information
- 16.1.9. Miscellaneous Functions
- 16.2. io — Core tools for working with streams
  - 16.2.1. Overview
    - 16.2.1.1. Text I/O
    - 16.2.1.2. Binary I/O
    - 16.2.1.3. Raw I/O
  - 16.2.2. High-level Module Interface
    - 16.2.2.1. In-memory streams
  - 16.2.3. Class hierarchy
    - 16.2.3.1. I/O Base Classes
    - 16.2.3.2. Raw File I/O
    - 16.2.3.3. Buffered Streams
    - 16.2.3.4. Text I/O
  - 16.2.4. Performance
    - 16.2.4.1. Binary I/O
    - 16.2.4.2. Text I/O
    - 16.2.4.3. Multi-threading
    - 16.2.4.4. Reentrancy
- 16.3. time — Time access and conversions
- 16.4. argparse — Parser for command-line options, arguments and sub-commands
  - 16.4.1. Example
    - 16.4.1.1. Creating a parser
    - 16.4.1.2. Adding arguments
    - 16.4.1.3. Parsing arguments
  - 16.4.2. ArgumentParser objects
    - 16.4.2.1. prog
    - 16.4.2.2. usage
- 16.4.2.3. description
- 16.4.2.4. epilog
- 16.4.2.5. parents
- 16.4.2.6. formatter_class
- 16.4.2.7. prefix_chars
- 16.4.2.8. fromfile_prefix_chars
- 16.4.2.9. argument_default
- 16.4.2.10. conflict_handler
- 16.4.2.11. add_help

- 16.4.3. The add_argument() method
  - 16.4.3.1. name or flags
  - 16.4.3.2. action
  - 16.4.3.3. nargs
  - 16.4.3.4. const
  - 16.4.3.5. default
  - 16.4.3.6. type
  - 16.4.3.7. choices
  - 16.4.3.8. required
  - 16.4.3.9. help
  - 16.4.3.10. metavar
  - 16.4.3.11. dest

- 16.4.4. The parse_args() method
  - 16.4.4.1. Option value syntax
  - 16.4.4.2. Invalid arguments
  - 16.4.4.3. Arguments containing -
  - 16.4.4.4. Argument abbreviations (prefix matching)
  - 16.4.4.5. Beyond sys.argv
  - 16.4.4.6. The Namespace object

- 16.4.5. Other utilities
  - 16.4.5.1. Sub-commands
  - 16.4.5.2. FileType objects
  - 16.4.5.3. Argument groups
  - 16.4.5.4. Mutual exclusion
- 16.4.5.5. Parser defaults
- 16.4.5.6. Printing help
- 16.4.5.7. Partial parsing
- 16.4.5.8. Customizing file parsing
- 16.4.5.9.Exiting methods

- 16.4.6. Upgrading optparse code

- 16.5. **optparse** — Parser for command line options

  - 16.5.1. Background
    - 16.5.1.1. Terminology
    - 16.5.1.2. What are options for?
    - 16.5.1.3. What are positional arguments for?

  - 16.5.2. Tutorial
    - 16.5.2.1. Understanding option actions
    - 16.5.2.2. The store action
    - 16.5.2.3. Handling boolean (flag) options
    - 16.5.2.4. Other actions
    - 16.5.2.5. Default values
    - 16.5.2.6. Generating help
      - 16.5.2.6.1. Grouping Options
    - 16.5.2.7. Printing a version string
    - 16.5.2.8. How optparse handles errors
    - 16.5.2.9. Putting it all together

  - 16.5.3. Reference Guide
    - 16.5.3.1. Creating the parser
    - 16.5.3.2. Populating the parser
    - 16.5.3.3. Defining options
    - 16.5.3.4. Option attributes
    - 16.5.3.5. Standard option actions
    - 16.5.3.6. Standard option types
    - 16.5.3.7. Parsing arguments
    - 16.5.3.8. Querying and manipulating your option parser
    - 16.5.3.9. Conflicts between options
    - 16.5.3.10. Cleanup
16.5.3.11. Other methods

16.5.4. Option Callbacks
- 16.5.4.1. Defining a callback option
- 16.5.4.2. How callbacks are called
- 16.5.4.3. Raising errors in a callback
- 16.5.4.4. Callback example 1: trivial callback
- 16.5.4.5. Callback example 2: check option order
- 16.5.4.6. Callback example 3: check option order (generalized)
- 16.5.4.7. Callback example 4: check arbitrary condition
- 16.5.4.8. Callback example 5: fixed arguments
- 16.5.4.9. Callback example 6: variable arguments

16.5.5. Extending optparse
- 16.5.5.1. Adding new types
- 16.5.5.2. Adding new actions

16.6. getopt — C-style parser for command line options

16.7. logging — Logging facility for Python
- 16.7.1. Logger Objects
- 16.7.2. Logging Levels
- 16.7.3. Handler Objects
- 16.7.4. Formatter Objects
- 16.7.5. Filter Objects
- 16.7.6. LogRecord Objects
- 16.7.7. LogRecord attributes
- 16.7.8. LoggerAdapter Objects
- 16.7.9. Thread Safety
- 16.7.10. Module-Level Functions
- 16.7.11. Module-Level Attributes
- 16.7.12. Integration with the warnings module

16.8. logging.config — Logging configuration
16.8.1. Configuration functions
16.8.2. Configuration dictionary schema
  16.8.2.1. Dictionary Schema Details
  16.8.2.2. Incremental Configuration
  16.8.2.3. Object connections
  16.8.2.4. User-defined objects
  16.8.2.5. Access to external objects
  16.8.2.6. Access to internal objects
  16.8.2.7. Import resolution and custom importers
16.8.3. Configuration file format
16.9. logging.handlers — Logging handlers
  16.9.1. StreamHandler
  16.9.2. FileHandler
  16.9.3. NullHandler
  16.9.4. WatchedFileHandler
  16.9.5. BaseRotatingHandler
  16.9.6. RotatingFileHandler
  16.9.7. TimedRotatingFileHandler
  16.9.8. SocketHandler
  16.9.9. DatagramHandler
  16.9.10. SysLogHandler
  16.9.11. NTEventLogHandler
  16.9.12. SMTPHandler
  16.9.13. MemoryHandler
  16.9.14. HTTPHandler
  16.9.15. QueueHandler
  16.9.16. QueueListener
16.10. getpass — Portable password input
16.11. curses — Terminal handling for character-cell displays
  16.11.1. Functions
  16.11.2. Window Objects
  16.11.3. Constants
- 16.12. **curses.textpad** — Text input widget for curses programs
  - 16.12.1.Textbox objects
- 16.13. **curses.ascii** — Utilities for ASCII characters
- 16.14. **curses.panel** — A panel stack extension for curses
  - 16.14.1. Functions
  - 16.14.2. Panel Objects
- 16.15. **platform** — Access to underlying platform's identifying data
  - 16.15.1. Cross Platform
  - 16.15.2. Java Platform
  - 16.15.3. Windows Platform
    - 16.15.3.1. Win95/98 specific
  - 16.15.4. Mac OS Platform
  - 16.15.5. Unix Platforms
- 16.16. **errno** — Standard errno system symbols
- 16.17. **ctypes** — A foreign function library for Python
  - 16.17.1. ctypes tutorial
    - 16.17.1.1. Loading dynamic link libraries
    - 16.17.1.2. Accessing functions from loaded dlls
    - 16.17.1.3. Calling functions
    - 16.17.1.4. Fundamental data types
    - 16.17.1.5. Calling functions, continued
    - 16.17.1.6. Calling functions with your own custom data types
    - 16.17.1.7. Specifying the required argument types (function prototypes)
    - 16.17.1.8. Return types
    - 16.17.1.9. Passing pointers (or: passing parameters by reference)
    - 16.17.1.10. Structures and unions
    - 16.17.1.11. Structure/union alignment and byte order
- 16.17.1.12. Bit fields in structures and unions
- 16.17.1.13. Arrays
- 16.17.1.14. Pointers
- 16.17.1.15. Type conversions
- 16.17.1.16. Incomplete Types
- 16.17.1.17. Callback functions
- 16.17.1.18. Accessing values exported from dlls
- 16.17.1.19. Surprises
- 16.17.1.20. Variable-sized data types

- 16.17.2. ctypes reference
  - 16.17.2.1. Finding shared libraries
  - 16.17.2.2. Loading shared libraries
  - 16.17.2.3. Foreign functions
  - 16.17.2.4. Function prototypes
  - 16.17.2.5. Utility functions
  - 16.17.2.6. Data types
  - 16.17.2.7. Fundamental data types
  - 16.17.2.8. Structured data types
  - 16.17.2.9. Arrays and pointers

- 17. Concurrent Execution
  - 17.1. threading — Thread-based parallelism
    - 17.1.1. Thread-Local Data
    - 17.1.2. Thread Objects
    - 17.1.3. Lock Objects
    - 17.1.4. RLock Objects
    - 17.1.5. Condition Objects
    - 17.1.6. Semaphore Objects
      - 17.1.6.1. Semaphore Example
    - 17.1.7. Event Objects
    - 17.1.8. Timer Objects
    - 17.1.9. Barrier Objects
    - 17.1.10. Using locks, conditions, and semaphores in the with statement
  - 17.2. multiprocessing — Process-based parallelism
17.2.1. Introduction
- 17.2.1.1. The Process class
- 17.2.1.2. Contexts and start methods
- 17.2.1.3. Exchanging objects between processes
- 17.2.1.4. Synchronization between processes
- 17.2.1.5. Sharing state between processes
- 17.2.1.6. Using a pool of workers

- 17.2.2.12. Logging
- 17.2.2.13. The multiprocessing.dummy module

17.2.3. Programming guidelines
- 17.2.3.1. All start methods
- 17.2.3.2. The spawn and forkserver start
methods

- 17.2.4. Examples
- 17.3. The concurrent package
- 17.4. concurrent.futures — Launching parallel tasks
  - 17.4.1. Executor Objects
  - 17.4.2. ThreadPoolExecutor
    - 17.4.2.1. ThreadPoolExecutor Example
  - 17.4.3. ProcessPoolExecutor
    - 17.4.3.1. ProcessPoolExecutor Example
  - 17.4.4. Future Objects
  - 17.4.5. Module Functions
  - 17.4.6. Exception classes
- 17.5. subprocess — Subprocess management
  - 17.5.1. Using the subprocess Module
    - 17.5.1.1. Frequently Used Arguments
    - 17.5.1.2. Popen Constructor
    - 17.5.1.3. Exceptions
    - 17.5.1.4. Security
  - 17.5.2. Popen Objects
  - 17.5.3. Windows Popen Helpers
    - 17.5.3.1. Constants
  - 17.5.4. Replacing Older Functions with the subprocess Module
    - 17.5.4.1. Replacing /bin/sh shell backquote
    - 17.5.4.2. Replacing shell pipeline
    - 17.5.4.3. Replacing os.system()
    - 17.5.4.4. Replacing the os.spawn family
    - 17.5.4.5. Replacing os.popen(), os.popen2(), os.popen3()
    - 17.5.4.6. Replacing functions from the popen2 module
  - 17.5.5. Legacy Shell Invocation Functions
- 17.5.6. Notes
  - 17.5.6.1. Converting an argument sequence to a string on Windows
- 17.6. sched — Event scheduler
  - 17.6.1. Scheduler Objects
- 17.7. queue — A synchronized queue class
  - 17.7.1. Queue Objects
- 17.8. dummy_threading — Drop-in replacement for the threading module
- 17.9. _thread — Low-level threading API
- 17.10. _dummy_thread — Drop-in replacement for the _thread module
- 18. Interprocess Communication and Networking
  - 18.1. socket — Low-level networking interface
    - 18.1.1. Socket families
    - 18.1.2. Module contents
      - 18.1.2.1. Exceptions
      - 18.1.2.2. Constants
      - 18.1.2.3. Functions
        - 18.1.2.3.1. Creating sockets
        - 18.1.2.3.2. Other functions
    - 18.1.3. Socket Objects
    - 18.1.4. Notes on socket timeouts
      - 18.1.4.1. Timeouts and the connect method
      - 18.1.4.2. Timeouts and the accept method
    - 18.1.5. Example
  - 18.2. ssl — TLS/SSL wrapper for socket objects
    - 18.2.1. Functions, Constants, and Exceptions
      - 18.2.1.1. Socket creation
      - 18.2.1.2. Context creation
      - 18.2.1.3. Random generation
      - 18.2.1.4. Certificate handling
      - 18.2.1.5. Constants
- 18.2.2. SSL Sockets
- 18.2.3. SSL Contexts
- 18.2.4. Certificates
  - 18.2.4.1. Certificate chains
  - 18.2.4.2. CA certificates
  - 18.2.4.3. Combined key and certificate
  - 18.2.4.4. Self-signed certificates
- 18.2.5. Examples
  - 18.2.5.1. Testing for SSL support
  - 18.2.5.2. Client-side operation
  - 18.2.5.3. Server-side operation
- 18.2.6. Notes on non-blocking sockets
- 18.2.7. Security considerations
  - 18.2.7.1. Verifying certificates
  - 18.2.7.2. Protocol versions
  - 18.2.7.3. Cipher selection
  - 18.2.7.4. Multi-processing
- 18.3. select — Waiting for I/O completion
  - 18.3.1. /dev/poll Polling Objects
  - 18.3.2. Edge and Level Trigger Polling (epoll) Objects
  - 18.3.3. Polling Objects
  - 18.3.4. Kqueue Objects
  - 18.3.5. Kevent Objects
- 18.4. selectors – High-level I/O multiplexing
  - 18.4.1. Introduction
  - 18.4.2. Classes
  - 18.4.3. Examples
- 18.5. asyncio – Asynchronous I/O, event loop, coroutines and tasks
  - 18.5.1. Event loops
    - 18.5.1.1. Event loop policies and the default policy
    - 18.5.1.2. Event loop functions
- 18.5.1.3. Event loop policy interface
- 18.5.1.4. Access to the global loop policy
- 18.5.1.5. Run an event loop
- 18.5.1.6. Calls
- 18.5.1.7. Delayed calls
- 18.5.1.8. Creating connections
- 18.5.1.9. Creating listening connections
- 18.5.1.10. Watch file descriptors
- 18.5.1.11. Low-level socket operations
- 18.5.1.12. Resolve host name
- 18.5.1.13. Running subprocesses
- 18.5.1.14. UNIX signals
- 18.5.1.15. Executor
- 18.5.1.16. Error Handling API
- 18.5.1.17. Debug mode
- 18.5.1.18. Server
- 18.5.1.19. Handle
- 18.5.1.20. Example: Hello World (callback)
- 18.5.1.21. Example: Set signal handlers for SIGINT and SIGTERM

- 18.5.2. Tasks and coroutines
  - 18.5.2.1. Coroutines
    - 18.5.2.1.1. Example: “Hello World” coroutine
    - 18.5.2.1.2. Example: Chain coroutines
  - 18.5.2.2. InvalidStateError
  - 18.5.2.3. Future
    - 18.5.2.3.1. Example: Future with run_until_complete()
    - 18.5.2.3.2. Example: Future with run_forever()
  - 18.5.2.4. Task
    - 18.5.2.4.1. Example: Parallel execution of tasks
- 18.5.2.5. Task functions
- 18.5.3. Transports and protocols (low-level API)
  - 18.5.3.1. Transports
    - 18.5.3.1.1. BaseTransport
    - 18.5.3.1.2. ReadTransport
    - 18.5.3.1.3. WriteTransport
    - 18.5.3.1.4. DatagramTransport
    - 18.5.3.1.5. BaseSubprocessTransport
  - 18.5.3.2. Protocols
    - 18.5.3.2.1. Protocol classes
    - 18.5.3.2.2. Connection callbacks
    - 18.5.3.2.3. Streaming protocols
    - 18.5.3.2.4. Datagram protocols
    - 18.5.3.2.5. Flow control callbacks
    - 18.5.3.2.6. Coroutines and protocols
  - 18.5.3.3. Protocol example: TCP echo server and client
    - 18.5.3.3.1. Echo client
    - 18.5.3.3.2. Echo server
- 18.5.4. Streams (high-level API)
  - 18.5.4.1. Stream functions
  - 18.5.4.2. StreamReader
  - 18.5.4.3. StreamWriter
  - 18.5.4.4. StreamReaderProtocol
  - 18.5.4.5. IncompleteReadError
  - 18.5.4.6. Example
- 18.5.5. Subprocess
  - 18.5.5.1. Create a subprocess
  - 18.5.5.2. Constants
  - 18.5.5.3. Process
  - 18.5.5.4. Example
- 18.5.6. Synchronization primitives
  - 18.5.6.1. Locks
    - 18.5.6.1.1. Lock
- 18.5.6.1.2. Event
- 18.5.6.1.3. Condition
- 18.5.6.2. Semaphores
  - 18.5.6.2.1. Semaphore
  - 18.5.6.2.2. BoundedSemaphore
- 18.5.6.3. Queues
  - 18.5.6.3.1. Queue
  - 18.5.6.3.2. PriorityQueue
  - 18.5.6.3.3. LifoQueue
  - 18.5.6.3.4. JoinableQueue
  - 18.5.6.3.5. Exceptions
- 18.5.7. Develop with asyncio
  - 18.5.7.1. Concurrency and multithreading
  - 18.5.7.2. Handle blocking functions correctly
  - 18.5.7.3. Logging
  - 18.5.7.4. Detect coroutine objects never scheduled
  - 18.5.7.5. Detect exceptions not consumed
  - 18.5.7.6. Chain coroutines correctly
- 18.6. asyncore — Asynchronous socket handler
  - 18.6.1. asyncore Example basic HTTP client
  - 18.6.2. asyncore Example basic echo server
- 18.7. asynchat — Asynchronous socket command/response handler
  - 18.7.1. asynchat - Auxiliary Classes
  - 18.7.2. asynchat Example
- 18.8. signal — Set handlers for asynchronous events
  - 18.8.1. General rules
    - 18.8.1.1. Execution of Python signal handlers
    - 18.8.1.2. Signals and threads
  - 18.8.2. Module contents
  - 18.8.3. Example
- 18.9. mmap — Memory-mapped file support
- 19. Internet Data Handling
19.1. email — An email and MIME handling package
   19.1.1. email.message: Representing an email message
   19.1.2. email.parser: Parsing email messages
      19.1.2.1. FeedParser API
      19.1.2.2. Parser class API
      19.1.2.3. Additional notes
   19.1.3. email.generator: Generating MIME documents
   19.1.4. email.policy: Policy Objects
   19.1.5. email.headerregistry: Custom Header Objects
   19.1.6. email.contentmanager: Managing MIME Content
      19.1.6.1. Content Manager Instances
   19.1.7. email.mime: Creating email and MIME objects from scratch
   19.1.8. email.header: Internationalized headers
   19.1.9. email.charset: Representing character sets
   19.1.10. email.encoders: Encoders
   19.1.11. email.errors: Exception and Defect classes
   19.1.12. email.utils: Miscellaneous utilities
   19.1.13. email.iterators: Iterators
   19.1.14. email: Examples
      19.1.14.1. Examples using the Provisional API
   19.1.15. Package History
   19.1.16. Differences from mimelib

19.2. json — JSON encoder and decoder
   19.2.1. Basic Usage
   19.2.2. Encoders and Decoders
   19.2.3. Standard Compliance
19.2.3.1. Character Encodings
19.2.3.2. Top-level Non-Object, Non-Array Values
19.2.3.3. Infinite and NaN Number Values
19.2.3.4. Repeated Names Within an Object

19.3. mailcap — Mailcap file handling
19.4. mailbox — Manipulate mailboxes in various formats
  19.4.1. Mailbox objects
    19.4.1.1. Maildir
    19.4.1.2. mbox
    19.4.1.3. MH
    19.4.1.4. Babyl
    19.4.1.5. MMDF
  19.4.2. Message objects
    19.4.2.1. MaildirMessage
    19.4.2.2. mboxMessage
    19.4.2.3. MHMessage
    19.4.2.4. BabylMessage
    19.4.2.5. MMDFMessage
  19.4.3. Exceptions
  19.4.4. Examples
19.5. mimetypes — Map filenames to MIME types
  19.5.1. MimeTypes Objects
19.6. base64 — Base16, Base32, Base64, Base85 Data Encodings
19.7. binhex — Encode and decode binhex4 files
  19.7.1. Notes
19.8. binascii — Convert between binary and ASCII
19.9. quopri — Encode and decode MIME quoted-printable data
19.10. uu — Encode and decode uuencode files

20. Structured Markup Processing Tools
- 20.1. html — HyperText Markup Language support
- 20.2. html.parser — Simple HTML and XHTML parser
  - 20.2.1. Example HTML Parser Application
  - 20.2.2. HTMLParser Methods
  - 20.2.3. Examples
- 20.3. html.entities — Definitions of HTML general entities
- 20.4. XML Processing Modules
  - 20.4.1. XML vulnerabilities
  - 20.4.2. The defusedxml and defusedexpat Packages
- 20.5. xml.etree.ElementTree — The ElementTree XML API
  - 20.5.1. Tutorial
    - 20.5.1.1. XML tree and elements
    - 20.5.1.2. Parsing XML
    - 20.5.1.3. Pull API for non-blocking parsing
    - 20.5.1.4. Finding interesting elements
    - 20.5.1.5. Modifying an XML File
    - 20.5.1.6. Building XML documents
    - 20.5.1.7. Additional resources
  - 20.5.2. XPath support
    - 20.5.2.1. Example
    - 20.5.2.2. Supported XPath syntax
  - 20.5.3. Reference
    - 20.5.3.1. Functions
    - 20.5.3.2. Element Objects
    - 20.5.3.3. ElementTree Objects
    - 20.5.3.4. QName Objects
    - 20.5.3.5. TreeBuilder Objects
    - 20.5.3.6. XMLParser Objects
    - 20.5.3.7. XMLPullParser Objects
    - 20.5.3.8. Exceptions
20.6. `xml.dom` — The Document Object Model API
- 20.6.1. Module Contents
- 20.6.2. Objects in the DOM
  - 20.6.2.1. `DOMImplementation` Objects
  - 20.6.2.2. `Node` Objects
  - 20.6.2.3. `NodeList` Objects
  - 20.6.2.4. `DocumentType` Objects
  - 20.6.2.5. `Document` Objects
  - 20.6.2.6. `Element` Objects
  - 20.6.2.7. `Attr` Objects
  - 20.6.2.8. `NamedNodeMap` Objects
  - 20.6.2.9. `Comment` Objects
  - 20.6.2.10. `Text` and `CDATASection` Objects
  - 20.6.2.11. `ProcessingInstruction` Objects
  - 20.6.2.12. Exceptions
- 20.6.3. Conformance
  - 20.6.3.1. Type Mapping
  - 20.6.3.2. Accessor Methods

20.7. `xml.dom.minidom` — Minimal DOM implementation
- 20.7.1. `DOM` Objects
- 20.7.2. `DOM` Example
- 20.7.3. `minidom` and the DOM standard

20.8. `xml.dom.pulldom` — Support for building partial DOM trees
- 20.8.1. `DOMEventStream` Objects

20.9. `xml.sax` — Support for SAX2 parsers
- 20.9.1. `SAXException` Objects

20.10. `xml.sax.handler` — Base classes for SAX handlers
- 20.10.1. `ContentHandler` Objects
- 20.10.2. `DTDHandler` Objects
- 20.10.3. `EntityResolver` Objects
- 20.10.4. `ErrorHandler` Objects
- 20.11. *xml.sax.saxutils* — SAX Utilities
- 20.12. *xml.sax.xmlreader* — Interface for XML parsers
  - 20.12.1. XMLReader Objects
  - 20.12.2. IncrementalParser Objects
  - 20.12.3. Locator Objects
  - 20.12.4. InputSource Objects
  - 20.12.5. The Attributes Interface
  - 20.12.6. The AttributesNS Interface
  - 20.13.1. XMLParser Objects
  - 20.13.2. ExpatError Exceptions
  - 20.13.3. Example
  - 20.13.4. Content Model Descriptions
  - 20.13.5. Expat error constants
- 21. Internet Protocols and Support
  - 21.1. *webbrowser* — Convenient Web-browser controller
    - 21.1.1. Browser Controller Objects
  - 21.2. *cgi* — Common Gateway Interface support
    - 21.2.1. Introduction
    - 21.2.2. Using the cgi module
    - 21.2.3. Higher Level Interface
    - 21.2.4. Functions
    - 21.2.5. Caring about security
    - 21.2.6. Installing your CGI script on a Unix system
    - 21.2.7. Testing your CGI script
    - 21.2.8. Debugging CGI scripts
    - 21.2.9. Common problems and solutions
- 21.3. *cgitb* — Traceback manager for CGI scripts
- 21.4. *wsgiref* — WSGI Utilities and Reference Implementation
- 21.4.1. wsgiref.util – WSGI environment utilities
- 21.4.2. wsgiref.headers – WSGI response header tools
- 21.4.3. wsgiref.simple_server – a simple WSGI HTTP server
- 21.4.4. wsgiref.validate — WSGI conformance checker
- 21.4.5. wsgiref.handlers – server/gateway base classes
- 21.4.6. Examples
- 21.5. urllib — URL handling modules
- 21.6. urllib.request — Extensible library for opening URLs
  - 21.6.1. Request Objects
  - 21.6.2. OpenerDirector Objects
  - 21.6.3. BaseHandler Objects
  - 21.6.4. HTTPRedirectHandler Objects
  - 21.6.5. HTTPCookieProcessor Objects
  - 21.6.6. ProxyHandler Objects
  - 21.6.7. HTTPPasswordMgr Objects
  - 21.6.8. AbstractBasicAuthHandler Objects
  - 21.6.9. HTTPBasicAuthHandler Objects
  - 21.6.10. ProxyBasicAuthHandler Objects
  - 21.6.11. AbstractDigestAuthHandler Objects
  - 21.6.12. HTTPDigestAuthHandler Objects
  - 21.6.13. ProxyDigestAuthHandler Objects
  - 21.6.14. HTTPHandler Objects
  - 21.6.15. HTTPSHandler Objects
  - 21.6.16. FileHandler Objects
  - 21.6.17. DataHandler Objects
  - 21.6.18. FTPHandler Objects
  - 21.6.19. CacheFTPHandler Objects
  - 21.6.20. UnknownHandler Objects
- 21.6.21. HTTPErrorProcessor Objects
- 21.6.22. Examples
- 21.6.23. Legacy interface
- 21.6.24. urllib.request Restrictions
- 21.7. urllib.response — Response classes used by urllib
- 21.8. urllib.parse — Parse URLs into components
  - 21.8.1. URL Parsing
  - 21.8.2. Parsing ASCII Encoded Bytes
  - 21.8.3. Structured Parse Results
  - 21.8.4. URL Quoting
- 21.9. urllib.error — Exception classes raised by urllib.request
- 21.10. urllib.robotparser — Parser for robots.txt
- 21.11. http — HTTP modules
  - 21.12.1. HTTPConnection Objects
  - 21.12.2. HTTPResponse Objects
  - 21.12.3. Examples
  - 21.12.4. HTTPMessage Objects
- 21.13. ftplib — FTP protocol client
  - 21.13.1. FTP Objects
  - 21.13.2. FTP_TLS Objects
- 21.14. poplib — POP3 protocol client
  - 21.14.1. POP3 Objects
  - 21.14.2. POP3 Example
- 21.15. imaplib — IMAP4 protocol client
  - 21.15.1. IMAP4 Objects
  - 21.15.2. IMAP4 Example
- 21.16. nntplib — NNTP protocol client
  - 21.16.1. NNTP Objects
    - 21.16.1.1. Attributes
    - 21.16.1.2. Methods
- 21.16.2. Utility functions
- 21.17. smtplib — SMTP protocol client
  - 21.17.1. SMTP Objects
  - 21.17.2. SMTP Example
- 21.18. smtpd — SMTP Server
  - 21.18.1. SMTPServer Objects
  - 21.18.2. DebuggingServer Objects
  - 21.18.3. PureProxy Objects
  - 21.18.4. MailmanProxy Objects
  - 21.18.5. SMTPChannel Objects
- 21.19. telnetlib — Telnet client
  - 21.19.1. Telnet Objects
  - 21.19.2. Telnet Example
- 21.20. uuid — UUID objects according to RFC 4122
  - 21.20.1. Example
- 21.21. socketserver — A framework for network servers
  - 21.21.1. Server Creation Notes
  - 21.21.2. Server Objects
  - 21.21.3. RequestHandler Objects
  - 21.21.4. Examples
    - 21.21.4.1. socketserver.TCPServer Example
    - 21.21.4.2. socketserver.UDPServer Example
    - 21.21.4.3. Asynchronous Mixins
- 21.22. http.server — HTTP servers
- 21.23. http.cookies — HTTP state management
  - 21.23.1. Cookie Objects
  - 21.23.2. Morsel Objects
  - 21.23.3. Example
- 21.24. http.cookiejar — Cookie handling for HTTP clients
21.24.2. FileCookieJar subclasses and co-operation with web browsers
21.24.3. CookiePolicy Objects
21.24.4. DefaultCookiePolicy Objects
21.24.5. Cookie Objects
21.24.6. Examples

21.25. xmlrpc — XMLRPC server and client modules
21.26. xmlrpc.client — XML-RPC client access
   21.26.2. DateTime Objects
   21.26.3. Binary Objects
   21.26.4. Fault Objects
   21.26.5. ProtocolError Objects
   21.26.6. MultiCall Objects
   21.26.7. Convenience Functions
   21.26.9. Example of Client and Server Usage

21.27. xmlrpc.server — Basic XML-RPC servers
   21.27.1. SimpleXMLRPCServer Objects
      21.27.1.1. SimpleXMLRPCServer Example
   21.27.2. CGIXMLRPCRequestHandler
   21.27.3. Documenting XMLRPC server
   21.27.4. DocXMLRPCServer Objects
   21.27.5. DocCGIXMLRPCRequestHandler

21.28. ipaddress — IPv4/IPv6 manipulation library
   21.28.1. Convenience factory functions
   21.28.2. IP Addresses
      21.28.2.1. Address objects
      21.28.2.2. Conversion to Strings and Integers
      21.28.2.3. Operators
         21.28.2.3.1. Comparison operators
         21.28.2.3.2. Arithmetic operators
   21.28.3. IP Network definitions
- 21.28.3.1. Prefix, net mask and host mask
- 21.28.3.2. Network objects
- 21.28.3.3. Operators
  - 21.28.3.3.1. Logical operators
  - 21.28.3.3.2. Iteration
  - 21.28.3.3.3. Networks as containers of addresses
- 21.28.4. Interface objects
- 21.28.5. Other Module Level Functions
- 21.28.6. Custom Exceptions

- 22. Multimedia Services
  - 22.1. audioop — Manipulate raw audio data
  - 22.2. aifc — Read and write AIFF and AIFC files
  - 22.3. sunau — Read and write Sun AU files
    - 22.3.1. AU_read Objects
    - 22.3.2. AU_write Objects
  - 22.4. wave — Read and write WAV files
    - 22.4.1. Wave_read Objects
    - 22.4.2. Wave_write Objects
  - 22.5. chunk — Read IFF chunked data
  - 22.6. colorsys — Conversions between color systems
  - 22.7. imghdr — Determine the type of an image
  - 22.8. sndhdr — Determine type of sound file
  - 22.9. ossaudiodev — Access to OSS-compatible audio devices
    - 22.9.1. Audio Device Objects
    - 22.9.2. Mixer Device Objects

- 23. Internationalization
  - 23.1. gettext — Multilingual internationalization services
    - 23.1.1. GNU gettext API
    - 23.1.2. Class-based API
      - 23.1.2.1. The NullTranslations class
- 23.1.2.2. The GNUTranslations class
- 23.1.2.3. Solaris message catalog support
- 23.1.2.4. The Catalog constructor
- 23.1.3. Internationalizing your programs and modules
  - 23.1.3.1. Localizing your module
  - 23.1.3.2. Localizing your application
  - 23.1.3.3. Changing languages on the fly
  - 23.1.3.4. Deferred translations
- 23.1.4. Acknowledgements
- 23.2. locale — Internationalization services
  - 23.2.1. Background, details, hints, tips and caveats
  - 23.2.2. For extension writers and programs that embed Python
  - 23.2.3. Access to message catalogs
- 24. Program Frameworks
  - 24.1. turtle — Turtle graphics
    - 24.1.1. Introduction
    - 24.1.2. Overview of available Turtle and Screen methods
      - 24.1.2.1. Turtle methods
      - 24.1.2.2. Methods of TurtleScreen/Screen
    - 24.1.3. Methods of RawTurtle/Turtle and corresponding functions
      - 24.1.3.1. Turtle motion
      - 24.1.3.2. Tell Turtle's state
      - 24.1.3.3. Settings for measurement
      - 24.1.3.4. Pen control
        - 24.1.3.4.1. Drawing state
        - 24.1.3.4.2. Color control
        - 24.1.3.4.3. Filling
        - 24.1.3.4.4. More drawing control
    - 24.1.3.5. Turtle state
      - 24.1.3.5.1. Visibility
• 24.1.3.5.2. Appearance
• 24.1.3.6. Using events
• 24.1.3.7. Special Turtle methods
• 24.1.3.8. Compound shapes

    - 26.3.9.2. setUpModule and tearDownModule
  - 26.3.10. Signal Handling
- 26.4. unittest.mock — mock object library
26.4.1. Quick Guide
26.4.2. The Mock Class
  26.4.2.1. Calling
  26.4.2.2. Deleting Attributes
  26.4.2.3. Mock names and the name attribute
  26.4.2.4. Attaching Mocks as Attributes
26.4.3. The patchers
  26.4.3.1. patch
  26.4.3.2. patch.object
  26.4.3.3. patch.dict
  26.4.3.4. patch.multiple
  26.4.3.5. patch methods: start and stop
  26.4.3.6. TEST_PREFIX
  26.4.3.7. Nesting Patch Decorators
  26.4.3.8. Where to patch
  26.4.3.9. Patching Descriptors and Proxy Objects
26.4.4. MagicMock and magic method support
  26.4.4.1. Mocking Magic Methods
  26.4.4.2. Magic Mock
26.4.5. Helpers
  26.4.5.1. sentinel
  26.4.5.2. DEFAULT
  26.4.5.3. call
  26.4.5.4. create_autospec
  26.4.5.5. ANY
  26.4.5.6. FILTER_DIR
  26.4.5.7. mock_open
  26.4.5.8. Autospeccing
26.5. unittest.mock — getting started
  26.5.1. Using Mock
    26.5.1.1. Mock Patching Methods
    26.5.1.2. Mock for Method Calls on an Object
    26.5.1.3. Mocking Classes
- 26.5.1.4. Naming your mocks
- 26.5.1.5. Tracking all Calls
- 26.5.1.6. Setting Return Values and Attributes
- 26.5.1.7. Raising exceptions with mocks
- 26.5.1.8. Side effect functions and iterables
- 26.5.1.9. Creating a Mock from an Existing Object
- 26.5.2. Patch Decorators
- 26.5.3. Further Examples
  - 26.5.3.1. Mocking chained calls
  - 26.5.3.2. Partial mocking
  - 26.5.3.3. Mocking a Generator Method
  - 26.5.3.4. Applying the same patch to every test method
  - 26.5.3.5. Mocking Unbound Methods
  - 26.5.3.6. Checking multiple calls with mock
  - 26.5.3.7. Coping with mutable arguments
  - 26.5.3.8. Nesting Patches
  - 26.5.3.9. Mocking a dictionary with MagicMock
  - 26.5.3.10. Mock subclasses and their attributes
  - 26.5.3.11. Mocking imports with patch.dict
  - 26.5.3.12. Tracking order of calls and less verbose call assertions
  - 26.5.3.13. More complex argument matching
- 26.6. 2to3 - Automated Python 2 to 3 code translation
  - 26.6.1. Using 2to3
  - 26.6.2. Fixers
  - 26.6.3. lib2to3 - 2to3’s library
- 26.7. test — Regression tests package for Python
  - 26.7.1. Writing Unit Tests for the test package
  - 26.7.2. Running tests using the command-line interface
- 26.8. test.support — Utilities for the Python test suite
27. Debugging and Profiling
   - 27.1. bdb — Debugger framework
   - 27.2. faulthandler — Dump the Python traceback
     - 27.2.1. Dump the traceback
     - 27.2.2. Fault handler state
     - 27.2.3. Dump the tracebacks after a timeout
     - 27.2.4. Dump the traceback on a user signal
     - 27.2.5. File descriptor issue
     - 27.2.6. Example
   - 27.3. pdb — The Python Debugger
     - 27.3.1. Debugger Commands
   - 27.4. The Python Profilers
     - 27.4.1. Introduction to the profilers
     - 27.4.2. Instant User’s Manual
     - 27.4.3. profile and cProfile Module Reference
     - 27.4.4. The Stats Class
     - 27.4.5. What Is Deterministic Profiling?
     - 27.4.6. Limitations
     - 27.4.7. Calibration
     - 27.4.8. Using a custom timer
   - 27.5. timeit — Measure execution time of small code snippets
     - 27.5.1. Basic Examples
     - 27.5.2. Python Interface
     - 27.5.3. Command-Line Interface
     - 27.5.4. Examples
   - 27.6. trace — Trace or track Python statement execution
     - 27.6.1. Command-Line Usage
       - 27.6.1.1. Main options
       - 27.6.1.2. Modifiers
       - 27.6.1.3. Filters
     - 27.6.2. Programmatic Interface
   - 27.7. tracemalloc — Trace memory allocations
27.8. Examples
- 27.8.1. Display the top 10
- 27.8.2. Compute differences
- 27.8.3. Get the traceback of a memory block
- 27.8.4. Pretty top

27.9. API
- 27.9.1. Functions
- 27.9.2. Filter
- 27.9.3. Frame
- 27.9.4. Snapshot
- 27.9.5. Statistic
- 27.9.6. StatisticDiff
- 27.9.7. Trace
- 27.9.8. Traceback

28. Software Packaging and Distribution
- 28.1. distutils — Building and installing Python modules
- 28.2. ensurepip — Bootstrapping the pip installer
  - 28.2.1. Command line interface
  - 28.2.2. Module API
- 28.3. venv — Creation of virtual environments
  - 28.3.1. Creating virtual environments
  - 28.3.2. API
  - 28.3.3. An example of extending EnvBuilder

29. Python Runtime Services
- 29.1. sys — System-specific parameters and functions
- 29.2. sysconfig — Provide access to Python's configuration information
  - 29.2.1. Configuration variables
  - 29.2.2. Installation paths
  - 29.2.3. Other functions
  - 29.2.4. Using sysconfig as a script
- 29.3. builtins — Built-in objects
- 29.4. __main__ — Top-level script environment
- 29.5. warnings — Warning control
  - 29.5.1. Warning Categories
  - 29.5.2. The Warnings Filter
    - 29.5.2.1. Default Warning Filters
  - 29.5.3. Temporarily Suppressing Warnings
  - 29.5.4. Testing Warnings
  - 29.5.5. Updating Code For New Versions of Python
  - 29.5.6. Available Functions
  - 29.5.7. Available Context Managers
- 29.6. contextlib — Utilities for with-statement contexts
  - 29.6.1. Utilities
  - 29.6.2. Examples and Recipes
    - 29.6.2.1. Supporting a variable number of context managers
    - 29.6.2.2. Simplifying support for single optional context managers
    - 29.6.2.3. Catching exceptions from __enter__ methods
    - 29.6.2.4. Cleaning up in an __enter__ implementation
    - 29.6.2.5. Replacing any use of try-finally and flag variables
    - 29.6.2.6. Using a context manager as a function decorator
  - 29.6.3. Single use, reusable and reentrant context managers
    - 29.6.3.1. Reentrant context managers
    - 29.6.3.2. Reusable context managers
- 29.7. abc — Abstract Base Classes
- 29.8. atexit — Exit handlers
  - 29.8.1. atexit Example
- 29.9. traceback — Print or retrieve a stack traceback
  - 29.9.1. Traceback Examples
- 29.10. __future__ — Future statement definitions
- 29.11. gc — Garbage Collector interface
- 29.12. inspect — Inspect live objects
  - 29.12.1. Types and members
  - 29.12.2. Retrieving source code
  - 29.12.3. Introspecting callables with the Signature object
  - 29.12.4. Classes and functions
  - 29.12.5. The interpreter stack
  - 29.12.6. Fetching attributes statically
  - 29.12.7. Current State of a Generator
  - 29.12.8. Command Line Interface
- 29.13. site — Site-specific configuration hook
  - 29.13.1. Readline configuration
  - 29.13.2. Module contents
- 29.14. fpectl — Floating point exception control
  - 29.14.1. Example
  - 29.14.2. Limitations and other considerations

- 30. Custom Python Interpreters
  - 30.1. code — Interpreter base classes
    - 30.1.1. Interactive Interpreter Objects
    - 30.1.2. Interactive Console Objects
  - 30.2. codeop — Compile Python code

- 31. Importing Modules
  - 31.1. imp — Access the import internals
    - 31.1.1. Examples
  - 31.2. zipimport — Import modules from Zip archives
    - 31.2.1. zipimporter Objects
    - 31.2.2. Examples
  - 31.3. pkgutil — Package extension utility
  - 31.4. modulefinder — Find modules used by a script
- 31.4.1. Example usage of ModuleFinder
- 31.5. runpy — Locating and executing Python modules
- 31.6. importlib – The implementation of import
  - 31.6.1. Introduction
  - 31.6.2. Functions
  - 31.6.3. importlib.abc – Abstract base classes related to import
  - 31.6.4. importlib.machinery – Importers and path hooks
  - 31.6.5. importlib.util – Utility code for importers
- 32. Python Language Services
  - 32.1. parser — Access Python parse trees
    - 32.1.1. Creating ST Objects
    - 32.1.2. Converting ST Objects
    - 32.1.3. Queries on ST Objects
    - 32.1.4. Exceptions and Error Handling
    - 32.1.5. ST Objects
    - 32.1.6. Example: Emulation of compile()
  - 32.2. ast — Abstract Syntax Trees
    - 32.2.1. Node classes
    - 32.2.2. Abstract Grammar
    - 32.2.3. ast Helpers
  - 32.3. symtable — Access to the compiler's symbol tables
    - 32.3.1. Generating Symbol Tables
    - 32.3.2. Examining Symbol Tables
  - 32.4. symbol — Constants used with Python parse trees
  - 32.5. token — Constants used with Python parse trees
  - 32.6. keyword — Testing for Python keywords
  - 32.7. tokenize — Tokenizer for Python source
    - 32.7.1. Tokenizing Input
32.7.2. Command-Line Usage
32.7.3. Examples
32.8. tabnanny — Detection of ambiguous indentation
32.9. pyc1br — Python class browser support
   32.9.1. Class Objects
   32.9.2. Function Objects
32.10. py_compile — Compile Python source files
32.11. compileall — Byte-compile Python libraries
   32.11.1. Command-line use
   32.11.2. Public functions
32.12. dis — Disassembler for Python bytecode
   32.12.1. Bytecode analysis
   32.12.2. Analysis functions
   32.12.3. Python Bytecode Instructions
   32.12.4. Opcode collections
32.13. pickletools — Tools for pickle developers
   32.13.1. Command line usage
      32.13.1.1. Command line options
   32.13.2. Programmatic Interface
33. Miscellaneous Services
   33.1. formatter — Generic output formatting
      33.1.1. The Formatter Interface
      33.1.2. Formatter Implementations
      33.1.3. The Writer Interface
      33.1.4. Writer Implementations
34. MS Windows Specific Services
   34.1. msilib — Read and write Microsoft Installer files
      34.1.1. Database Objects
      34.1.2. View Objects
      34.1.3. Summary Information Objects
      34.1.4. Record Objects
      34.1.5. Errors
      34.1.6. CAB Objects
      34.1.7. Directory Objects
34.1.8. Features
34.1.9. GUI classes
34.1.10. Precomputed tables
34.2. msvcrt – Useful routines from the MS VC++ runtime
   34.2.1. File Operations
   34.2.2. Console I/O
   34.2.3. Other Functions
34.3. winreg – Windows registry access
   34.3.1. Functions
   34.3.2. Constants
      34.3.2.1. HKEY_* Constants
      34.3.2.2. Access Rights
         34.3.2.2.1. 64-bit Specific
      34.3.2.3. Value Types
   34.3.3. Registry Handle Objects
34.4. winsound — Sound-playing interface for Windows
35. Unix Specific Services
   35.1. posix — The most common POSIX system calls
      35.1.1. Large File Support
      35.1.2. Notable Module Contents
   35.2. pwd — The password database
   35.3. spwd — The shadow password database
   35.4. grp — The group database
   35.5. crypt — Function to check Unix passwords
      35.5.1. Hashing Methods
      35.5.2. Module Attributes
      35.5.3. Module Functions
      35.5.4. Examples
   35.6. termios — POSIX style tty control
      35.6.1. Example
   35.7. tty — Terminal control functions
   35.8. pty — Pseudo-terminal utilities
- 35.8.1. Example
- 35.9. `fcntl` — The `fcntl` and `ioctl` system calls
- 35.10. `pipes` — Interface to shell pipelines
  - 35.10.1. Template Objects
- 35.11. `resource` — Resource usage information
  - 35.11.1. Resource Limits
  - 35.11.2. Resource Usage
- 35.12. `nis` — Interface to Sun's NIS (Yellow Pages)
- 35.13. `syslog` — Unix syslog library routines
  - 35.13.1. Examples
    - 35.13.1.1. Simple example
- 36. Undocumented Modules
  - 36.1. Platform specific modules
- **Extending and Embedding the Python Interpreter**

10. API Reference
10.1. distutils.core — Core Distutils functionality

The distutils.core module is the only module that needs to be installed to use the Distutils. It provides the setup() (which is called from the setup script). Indirectly provides the distutils.dist.Distribution and distutils.cmd.Command class.

distutils.core.setup(arguments)

The basic do-everything function that does most everything you could ever ask for from a Distutils method.

The setup function takes a large number of arguments. These are laid out in the following table.

<table>
<thead>
<tr>
<th>argument name</th>
<th>value</th>
<th>type</th>
</tr>
</thead>
<tbody>
<tr>
<td>name</td>
<td>The name of the package</td>
<td>a string</td>
</tr>
<tr>
<td>version</td>
<td>The version number of the package; see distutils.version</td>
<td>a string</td>
</tr>
<tr>
<td>description</td>
<td>A single line describing the package</td>
<td>a string</td>
</tr>
<tr>
<td>long_description</td>
<td>Longer description of the package</td>
<td>a string</td>
</tr>
<tr>
<td>author</td>
<td>The name of the package author</td>
<td>a string</td>
</tr>
<tr>
<td>author_email</td>
<td>The email address of the package author</td>
<td>a string</td>
</tr>
<tr>
<td><strong>maintainer</strong></td>
<td>The name of the current maintainer, if different from the author. Note that if the maintainer is provided, distutils will use it as the author in PKG-INFO</td>
<td>a string</td>
</tr>
<tr>
<td><strong>maintainer_email</strong></td>
<td>The email address of the current maintainer, if different from the author</td>
<td>a string</td>
</tr>
<tr>
<td><strong>url</strong></td>
<td>A URL for the package (homepage)</td>
<td>a string</td>
</tr>
<tr>
<td><strong>download_url</strong></td>
<td>A URL to download the package</td>
<td>a string</td>
</tr>
<tr>
<td><strong>packages</strong></td>
<td>A list of Python packages that distutils will manipulate</td>
<td>a list of strings</td>
</tr>
<tr>
<td><strong>py_modules</strong></td>
<td>A list of Python modules that distutils will manipulate</td>
<td>a list of strings</td>
</tr>
<tr>
<td><strong>scripts</strong></td>
<td>A list of standalone script files to be built and installed</td>
<td>a list of strings</td>
</tr>
<tr>
<td><strong>ext_modules</strong></td>
<td>A list of Python extensions to be built</td>
<td>a list of instances of <code>distutils.core.Extension</code></td>
</tr>
<tr>
<td><strong>classifiers</strong></td>
<td>A list of categories for the package</td>
<td>a list of strings; valid listed on PyPI.</td>
</tr>
<tr>
<td><strong>distclass</strong></td>
<td>the Distribution class to use</td>
<td>a subclass of <code>distutils.core.Distribution</code></td>
</tr>
<tr>
<td></td>
<td>The name of the setup.py script -</td>
<td></td>
</tr>
</tbody>
</table>
**script_name**
defaults to `sys.argv[0]`  a string

**script_args**
Arguments to supply to the setup script  a list of strings

**options**
default options for the setup script  a dictionary

**license**
The license for the package  a string

**keywords**
Descriptive meta-data, see PEP 314  a list of strings or a comma-separated string

**platforms**
a list of strings or a comma-separated string

**cmdclass**
A mapping of command names to `Command` subclasses  a dictionary

**data_files**
A list of data files to install  a list

**package_dir**
A mapping of package to directory names  a dictionary

```python
distutils.core.run_setup(script_name[, script_args=None, stop_after='run'])
```

Run a setup script in a somewhat controlled environment, and return the distutils.dist.Distribution instance that drives things. This is useful if you need to find out the distribution metadata (passed as keyword args from `script` to `setup()`), or the contents of the config files or command-line.

`script_name` is a file that will be read and run with `exec()`. `sys.argv[0]` will be replaced with `script` for the duration of the
call. `script_args` is a list of strings; if supplied, `sys.argv[1:]` will be replaced by `script_args` for the duration of the call.

`stop_after` tells `setup()` when to stop processing; possible values:

<table>
<thead>
<tr>
<th>value</th>
<th>description</th>
</tr>
</thead>
<tbody>
<tr>
<td><code>init</code></td>
<td>Stop after the <code>Distribution</code> instance has been created and populated with the keyword arguments to <code>setup()</code></td>
</tr>
<tr>
<td><code>config</code></td>
<td>Stop after config files have been parsed (and their data stored in the <code>Distribution</code> instance)</td>
</tr>
<tr>
<td><code>commandline</code></td>
<td>Stop after the command-line (sys.argv[1:] or <code>script_args</code>) have been parsed (and the data stored in the <code>Distribution</code> instance.)</td>
</tr>
<tr>
<td><code>run</code></td>
<td>Stop after all commands have been run (the same as if <code>setup()</code> had been called in the usual way). This is the default value.</td>
</tr>
</tbody>
</table>

In addition, the `distutils.core` module exposed a number of classes that live elsewhere.

- Extension from `distutils.extension`
- `Command` from `distutils.cmd`
- Distribution from `distutils.dist`

A short description of each of these follows, but see the relevant module for the full reference.

**class distutils.core.Extension**

The Extension class describes a single C or C++ extension module in a setup script. It accepts the following keyword arguments in its constructor:
<table>
<thead>
<tr>
<th>argument name</th>
<th>value</th>
<th>type</th>
</tr>
</thead>
<tbody>
<tr>
<td><strong>name</strong></td>
<td>the full name of the extension, including any packages — ie. <em>not</em> a filename or pathname, but Python dotted name</td>
<td>a string</td>
</tr>
<tr>
<td><strong>sources</strong></td>
<td>list of source filenames, relative to the distribution root (where the setup script lives), in Unix form (slash-separated) for portability. Source files may be C, C++, SWIG (.i), platform-specific resource files, or whatever else is recognized by the <strong>build_ext</strong> command as source for a Python extension.</td>
<td>a list of strings</td>
</tr>
<tr>
<td><strong>include_dirs</strong></td>
<td>list of directories to search for C/C++ header files (in Unix form for portability)</td>
<td>a list of strings</td>
</tr>
<tr>
<td><strong>define_macros</strong></td>
<td>list of macros to define; each macro is defined using a 2-tuple ((name, value)), where value is either the string to define it to or None to define it without a particular value (equivalent of #define F00 in</td>
<td>a list of tuples</td>
</tr>
<tr>
<td>Variable</td>
<td>Description</td>
<td>Type</td>
</tr>
<tr>
<td>------------------------------</td>
<td>-----------------------------------------------------------------------------</td>
<td>-------------------------------</td>
</tr>
<tr>
<td><code>source</code></td>
<td>source or <code>-DFOO</code> on Unix C compiler command line</td>
<td></td>
</tr>
<tr>
<td><code>undef_macros</code></td>
<td>list of macros to undefine explicitly</td>
<td>a list of strings</td>
</tr>
<tr>
<td><code>library_dirs</code></td>
<td>list of directories to search for C/C++ libraries at link time</td>
<td>a list of strings</td>
</tr>
<tr>
<td><code>libraries</code></td>
<td>list of library names (not filenames or paths) to link against</td>
<td>a list of strings</td>
</tr>
<tr>
<td><code>runtime_library_dirs</code></td>
<td>list of directories to search for C/C++ libraries at run time (for shared extensions, this is when the extension is loaded)</td>
<td>a list of strings</td>
</tr>
<tr>
<td><code>extra_objects</code></td>
<td>list of extra files to link with (e.g. object files not implied by ‘sources’, static library that must be explicitly specified, binary resource files, etc.)</td>
<td>a list of strings</td>
</tr>
<tr>
<td><code>extra_compile_args</code></td>
<td>any extra platform- and compiler-specific information to use when compiling the source files in ‘sources’. For platforms and compilers where a command line makes sense, this is typically a list of command-line arguments</td>
<td>a list of strings</td>
</tr>
<tr>
<td><strong>Argument</strong></td>
<td>Description</td>
<td>Type</td>
</tr>
<tr>
<td>-----------------------</td>
<td>-----------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------</td>
<td>---------------------------</td>
</tr>
<tr>
<td><strong>extra_link_args</strong></td>
<td>any extra platform- and compiler-specific information to use when linking object files together to create the extension (or to create a new static Python interpreter). Similar interpretation as for 'extra_compile_args'.</td>
<td>a list of strings</td>
</tr>
<tr>
<td><strong>export_symbols</strong></td>
<td>list of symbols to be exported from a shared extension. Not used on all platforms, and not generally necessary for Python extensions, which typically export exactly one symbol: <code>init + extension_name</code>.</td>
<td>a list of strings</td>
</tr>
<tr>
<td><strong>depends</strong></td>
<td>list of files that the extension depends on</td>
<td>a list of strings</td>
</tr>
<tr>
<td><strong>language</strong></td>
<td>extension language (i.e. 'c', 'c++', 'objc'). Will be detected from the source extensions if not provided.</td>
<td>a string</td>
</tr>
<tr>
<td><strong>optional</strong></td>
<td>specifies that a build failure in the extension should not abort the build process, but</td>
<td>a boolean</td>
</tr>
</tbody>
</table>
class distutils.core.Distribution

A Distribution describes how to build, install and package up a Python software package.

See the setup() function for a list of keyword arguments accepted by the Distribution constructor. setup() creates a Distribution instance.

class distutils.core.Command

A Command class (or rather, an instance of one of its subclasses) implement a single distutils command.
10.2. distutils.ccompiler — CCompiler base class

This module provides the abstract base class for the CCompiler classes. A CCompiler instance can be used for all the compile and link steps needed to build a single project. Methods are provided to set options for the compiler — macro definitions, include directories, link path, libraries and the like.

This module provides the following functions.

- `gen_lib_options(compiler, library_dirs, runtime_library_dirs, libraries)`
  Generate linker options for searching library directories and linking with specific libraries. `libraries` and `library_dirs` are, respectively, lists of library names (not filenames!) and search directories. Returns a list of command-line options suitable for use with some compiler (depending on the two format strings passed in).

- `gen_preprocess_options(macros, include_dirs)`
  Generate C pre-processor options (`-D`, `-U`, `-I`) as used by at least two types of compilers: the typical Unix compiler and Visual C++. `macros` is the usual thing, a list of 1- or 2-tuples, where `(name,)` means undefine `-U` macro `name`, and `(name, value)` means define `-D` macro `name` to `value`. `include_dirs` is just a list of directory names to be added to the header file search path `-I`. Returns a list of command-line options suitable for either Unix compilers or Visual C++.

- `get_default_compiler(osname,`
Determine the default compiler to use for the given platform.

`osname` should be one of the standard Python OS names (i.e. the ones returned by `os.name`) and `platform` the common value returned by `sys.platform` for the platform in question.

The default values are `os.name` and `sys.platform` in case the parameters are not given.

distutils.ccompiler.**new_compiler**(plat=None, compiler=None, verbose=0, dry_run=0, force=0)

Factory function to generate an instance of some CCompiler subclass for the supplied platform/compiler combination. `plat` defaults to `os.name` (e.g. `'posix'`, `'nt'`), and `compiler` defaults to the default compiler for that platform. Currently only `'posix'` and `'nt'` are supported, and the default compilers are “traditional Unix interface” (UnixCCompiler class) and Visual C++ (MSVCCCompiler class). Note that it’s perfectly possible to ask for a Unix compiler object under Windows, and a Microsoft compiler object under Unix—if you supply a value for `compiler`, `plat` is ignored.

distutils.ccompiler.**show_compilers**()

Print list of available compilers (used by the `--help-compiler` options to `build`, `build_ext`, `build_clib`).

class distutils.ccompiler.**CCompiler**([verbose=0, dry_run=0, force=0])

The abstract base class `CCompiler` defines the interface that must be implemented by real compiler classes. The class also has some utility methods used by several compiler classes.
The basic idea behind a compiler abstraction class is that each instance can be used for all the compile/link steps in building a single project. Thus, attributes common to all of those compile and link steps — include directories, macros to define, libraries to link against, etc. — are attributes of the compiler instance. To allow for variability in how individual files are treated, most of those attributes may be varied on a per-compilation or per-link basis.

The constructor for each subclass creates an instance of the Compiler object. Flags are *verbose* (show verbose output), *dry_run* (don’t actually execute the steps) and *force* (rebuild everything, regardless of dependencies). All of these flags default to 0 (off). Note that you probably don’t want to instantiate `CCompiler` or one of its subclasses directly - use the distutils.CCompiler.new_compiler() factory function instead.

The following methods allow you to manually alter compiler options for the instance of the Compiler class.

**add_include_dir(dir)**

Add `dir` to the list of directories that will be searched for header files. The compiler is instructed to search directories in the order in which they are supplied by successive calls to `add_include_dir()`.

**set_include_dirs(dirs)**

Set the list of directories that will be searched to `dirs` (a list of strings). Overrides any preceding calls to `add_include_dir()`. Subsequent calls to `add_include_dir()` add to the list passed to `set_include_dirs()`. This does not affect any list of
standard include directories that the compiler may search by default.

**add_library**(*libname*)

Add *libname* to the list of libraries that will be included in all links driven by this compiler object. Note that *libname* should *not* be the name of a file containing a library, but the name of the library itself: the actual filename will be inferred by the linker, the compiler, or the compiler class (depending on the platform).

The linker will be instructed to link against libraries in the order they were supplied to **add_library()** and/or **set_libraries()**. It is perfectly valid to duplicate library names; the linker will be instructed to link against libraries as many times as they are mentioned.

**set_libraries**(*libnames*)

Set the list of libraries to be included in all links driven by this compiler object to *libnames* (a list of strings). This does not affect any standard system libraries that the linker may include by default.

**add_library_dir**(*dir*)

Add *dir* to the list of directories that will be searched for libraries specified to **add_library()** and **set_libraries()**. The linker will be instructed to search for libraries in the order they are supplied to **add_library_dir()** and/or **set_library_dirs()**.

**set_library_dirs**(*dirs*)

Set the list of library search directories to *dirs* (a list of strings). This does not affect any standard library search path that the
linker may search by default.

**add_runtime_library_dir(dir)**
Add dir to the list of directories that will be searched for shared libraries at runtime.

**set_runtime_library_dirs(dirs)**
Set the list of directories to search for shared libraries at runtime to dirs (a list of strings). This does not affect any standard search path that the runtime linker may search by default.

**define_macro(name[, value=None])**
Define a preprocessor macro for all compilations driven by this compiler object. The optional parameter value should be a string; if it is not supplied, then the macro will be defined without an explicit value and the exact outcome depends on the compiler used.

**undefine_macro(name)**
Undefine a preprocessor macro for all compilations driven by this compiler object. If the same macro is defined by define_macro() and undefined by undefine_macro() the last call takes precedence (including multiple redefinitions or undefinitions). If the macro is redefined/undefined on a per-compilation basis (i.e. in the call to compile()), then that takes precedence.

**add_link_object(object)**
Add object to the list of object files (or analogues, such as explicitly named library files or the output of “resource compilers”) to be included in every link driven by this compiler

object.

**set_link_objects(objects)**

Set the list of object files (or analogues) to be included in every link to `objects`. This does not affect any standard object files that the linker may include by default (such as system libraries).

The following methods implement methods for autodetection of compiler options, providing some functionality similar to GNU autoconf.

**detect_language(sources)**

Detect the language of a given file, or list of files. Uses the instance attributes `language_map` (a dictionary), and `language_order` (a list) to do the job.

**find_library_file(dirs, lib[, debug=0])**

Search the specified list of directories for a static or shared library file `lib` and return the full path to that file. If `debug` is true, look for a debugging version (if that makes sense on the current platform). Return `None` if `lib` wasn’t found in any of the specified directories.

**has_function(funcname[, includes=None, include_dirs=None, libraries=None, library_dirs=None])**

Return a boolean indicating whether `funcname` is supported on the current platform. The optional arguments can be used to augment the compilation environment by providing additional include files and paths and libraries and paths.

**library_dir_option(dir)**

Return the compiler option to add `dir` to the list of directories
searched for libraries.

**library_option**(lib)

Return the compiler option to add `dir` to the list of libraries linked into the shared library or executable.

**runtime_library_dir_option**(dir)

Return the compiler option to add `dir` to the list of directories searched for runtime libraries.

**set_executables**(**args**)

Define the executables (and options for them) that will be run to perform the various stages of compilation. The exact set of executables that may be specified here depends on the compiler class (via the `executables` class attribute), but most will have:

<table>
<thead>
<tr>
<th>attribute</th>
<th>description</th>
</tr>
</thead>
<tbody>
<tr>
<td><em>compiler</em></td>
<td>the C/C++ compiler</td>
</tr>
<tr>
<td><em>linker_so</em></td>
<td>linker used to create shared objects and libraries</td>
</tr>
<tr>
<td><em>linker_exe</em></td>
<td>linker used to create binary executables</td>
</tr>
<tr>
<td><em>archiver</em></td>
<td>static library creator</td>
</tr>
</tbody>
</table>

On platforms with a command-line (Unix, DOS/Windows), each of these is a string that will be split into executable name and (optional) list of arguments. (Splitting the string is done similarly to how Unix shells operate: words are delimited by spaces, but quotes and backslashes can override this. See `distutils.util.split_quoted()`.)

The following methods invoke stages in the build process.
`compile(sources[, output_dir=None, macros=None, include_dirs=None, debug=0, extra_preargs=None, extra_postargs=None, depends=None])`

Compile one or more source files. Generates object files (e.g. transforms a .c file to a .o file.)

`sources` must be a list of filenames, most likely C/C++ files, but in reality anything that can be handled by a particular compiler and compiler class (eg. MSVCCompiler can handle resource files in `sources`). Return a list of object filenames, one per source filename in `sources`. Depending on the implementation, not all source files will necessarily be compiled, but all corresponding object filenames will be returned.

If `output_dir` is given, object files will be put under it, while retaining their original path component. That is, foo/bar.c normally compiles to foo/bar.o (for a Unix implementation); if `output_dir` is `build`, then it would compile to build/foo/bar.o.

`macros`, if given, must be a list of macro definitions. A macro definition is either a (name, value) 2-tuple or a (name,) 1-tuple. The former defines a macro; if the value is None, the macro is defined without an explicit value. The 1-tuple case undefines a macro. Later definitions/redefinitions/undefinitions take precedence.

`include_dirs`, if given, must be a list of strings, the directories to add to the default include file search path for this compilation only.

`debug` is a boolean; if true, the compiler will be instructed to
output debug symbols in (or alongside) the object file(s).

`extra_preargs` and `extra_postargs` are implementation-dependent. On platforms that have the notion of a command-line (e.g. Unix, DOS/Windows), they are most likely lists of strings: extra command-line arguments to prepend/append to the compiler command line. On other platforms, consult the implementation class documentation. In any event, they are intended as an escape hatch for those occasions when the abstract compiler framework doesn’t cut the mustard.

`depends`, if given, is a list of filenames that all targets depend on. If a source file is older than any file in depends, then the source file will be recompiled. This supports dependency tracking, but only at a coarse granularity.

Raises CompileError on failure.

```python
create_static_lib(objects, output_libname[, output_dir=None, debug=0, target_lang=None])
```

Link a bunch of stuff together to create a static library file. The “bunch of stuff” consists of the list of object files supplied as `objects`, the extra object files supplied to `add_link_object()` and/or `set_link_objects()`, the libraries supplied to `add_library()` and/or `set_libraries()`, and the libraries supplied as `libraries` (if any).

`output_libname` should be a library name, not a filename; the filename will be inferred from the library name. `output_dir` is the directory where the library file will be put.

`debug` is a boolean; if true, debugging information will be included in the library (note that on most platforms, it is the
compile step where this matters: the debug flag is included here just for consistency).

*target_lang* is the target language for which the given objects are being compiled. This allows specific linkage time treatment of certain languages.

Raises LibError on failure.

```python
link(target_desc, objects, output_filename[, output_dir=None, libraries=None, library_dirs=None, runtime_library_dirs=None, export_symbols=None, debug=0, extra_preargs=None, extra_postargs=None, build_temp=None, target_lang=None])
```

Link a bunch of stuff together to create an executable or shared library file.

The “bunch of stuff” consists of the list of object files supplied as *objects*. *output_filename* should be a filename. If *output_dir* is supplied, *output_filename* is relative to it (i.e. *output_filename* can provide directory components if needed).

*libraries* is a list of libraries to link against. These are library names, not filenames, since they’re translated into filenames in a platform-specific way (eg. *foo* becomes *libfoo.a* on Unix and *foo.lib* on DOS/Windows). However, they can include a directory component, which means the linker will look in that specific directory rather than searching all the normal locations.

*library_dirs*, if supplied, should be a list of directories to search for libraries that were specified as bare library names (ie. no directory component). These are on top of the system default and those supplied to add_library_dir() and/or set_library_dirs(). *runtime_library_dirs* is a list of
directories that will be embedded into the shared library and used to search for other shared libraries that *it* depends on at run-time. (This may only be relevant on Unix.)

*export_symbols* is a list of symbols that the shared library will export. (This appears to be relevant only on Windows.)

*debug* is as for *compile()* and *create_static_lib()*, with the slight distinction that it actually matters on most platforms (as opposed to *create_static_lib()* which includes a *debug* flag mostly for form's sake).

*extra_preargs* and *extra_postargs* are as for *compile()* (except of course that they supply command-line arguments for the particular linker being used).

*target_lang* is the target language for which the given objects are being compiled. This allows specific linkage time treatment of certain languages.

Raises *LinkError* on failure.

**link_executable**(*objects*, *output_progname*[*,
  *output_dir=None*, *libraries=None*, *library_dirs=None*, *runtime_library_dirs=None*, *debug=0*, *extra_preargs=None*,
  *extra_postargs=None*, *target_lang=None]*)

Link an executable. *output_progname* is the name of the file executable, while *objects* are a list of object filenames to link in. Other arguments are as for the *link()* method.

**link_shared_lib**(*objects*, *output_libname*[*,
  *output_dir=None*, *libraries=None*, *library_dirs=None*, *runtime_library_dirs=None*, *debug=0*,
  *export_symbols=None*, *extra_preargs=None*,
  *extra_postargs=None*, *target_lang=None]*)
Link a shared library. *output_libname* is the name of the output library, while *objects* is a list of object filenames to link in. Other arguments are as for the *link()* method.

```python
link_shared_object(objects, output_filename[, output_dir=None, libraries=None, library_dirs=None, runtime_library_dirs=None, export_symbols=None, debug=0, extra_preargs=None, extra_postargs=None, build_temp=None, target_lang=None])
```

Link a shared object. *output_filename* is the name of the shared object that will be created, while *objects* is a list of object filenames to link in. Other arguments are as for the *link()* method.

```python
preprocess(source[, output_file=None, macros=None, include_dirs=None, extra_preargs=None, extra_postargs=None])
```

Preprocess a single C/C++ source file, named in *source*. Output will be written to file named *output_file*, or *stdout* if *output_file* not supplied. *macros* is a list of macro definitions as for *compile()* , which will augment the macros set with *define_macro()* and *undefine_macro()* . *include_dirs* is a list of directory names that will be added to the default list, in the same way as *add_include_dir()* .

Raises *PreprocessError* on failure.

The following utility methods are defined by the *CCompiler* class, for use by the various concrete subclasses.
executable_filename(basename[, strip_dir=0,
output_dir=''])

Returns the filename of the executable for the given basename. Typically for non-Windows platforms this is the same as the basename, while Windows will get a .exe added.

library_filename(libname[, lib_type='static', strip_dir=0,
output_dir=''])

Returns the filename for the given library name on the current platform. On Unix a library with lib_type of 'static' will typically be of the form liblibname.a, while a lib_type of 'dynamic' will be of the form liblibname.so.

object_filenames(source_filenames[, strip_dir=0,
output_dir=''])

Returns the name of the object files for the given source files. source_filenames should be a list of filenames.

shared_object_filename(basename[, strip_dir=0,
output_dir=''])

Returns the name of a shared object file for the given file name basename.

execute(func, args[, msg=None, level=1])

Invokes distutils.util.execute(). This method invokes a Python function func with the given arguments args, after logging and taking into account the dry_run flag.

spawn(cmd)

Invokes distutils.util.spawn(). This invokes an
external process to run the given command.

**mkpath**(name[, mode=511])
Invokes distutils.dir_util.mkpath(). This creates a directory and any missing ancestor directories.

**move_file**(src, dst)
Invokes distutils.file_util.move_file(). Renames src to dst.

**announce**(msg[, level=1])
Write a message using distutils.log.debug().

**warn**(msg)
Write a warning message msg to standard error.

**debug_print**(msg)
If the debug flag is set on this CCompiler instance, print msg to standard output, otherwise do nothing.
This module provides the UnixCCompiler class, a subclass of CCompiler that handles the typical Unix-style command-line C compiler:

- macros defined with `-Dname[=value]`
- macros undefined with `-Uname`
- include search directories specified with `-Idir`
- libraries specified with `-l` or `-llib`
- library search directories specified with `-Ldir`
- compile handled by `cc` (or similar) executable with `-c` option: compiles `.c` to `.o`
- link static library handled by `ar` command (possibly with `ranlib`)
- link shared library handled by `cc -shared`
10.4. **distutils.msvccompiler** — Microsoft Compiler

This module provides MSVCCompiler, an implementation of the abstract CCompiler class for Microsoft Visual Studio. Typically, extension modules need to be compiled with the same compiler that was used to compile Python. For Python 2.3 and earlier, the compiler was Visual Studio 6. For Python 2.4 and 2.5, the compiler is Visual Studio .NET 2003. The AMD64 and Itanium binaries are created using the Platform SDK.

MSVCCompiler will normally choose the right compiler, linker etc. on its own. To override this choice, the environment variables `DISTUTILS_USE_SDK` and `MSSdk` must be both set. `MSSdk` indicates that the current environment has been setup by the SDK’s `SetEnv.Cmd` script, or that the environment variables had been registered when the SDK was installed; `DISTUTILS_USE_SDK` indicates that the distutils user has made an explicit choice to override the compiler selection by MSVCCompiler.
10.5. `dist utils.bcppcompiler` — Borland Compiler

This module provides BorlandCCompiler, an subclass of the abstract CCompiler class for the Borland C++ compiler.
10.6. distutils.cygwincompiler — Cygwin Compiler

This module provides the CygwinCCompiler class, a subclass of UnixCCompiler that handles the Cygwin port of the GNU C compiler to Windows. It also contains the Mingw32CCompiler class which handles the mingw32 port of GCC (same as cygwin in no-cygwin mode).
This module provides a few functions for creating archive files, such as tarballs or zipfiles.

```
10.7. distutils.archive_util —
Archiving utilities

distutils.archive_util.make_archive(base_name,
format[, root_dir=None, base_dir=None, verbose=0, dry_run=0])

Create an archive file (eg. zip or tar). base_name is the name of the file to create, minus any format-specific extension; format is the archive format: one of zip, tar, ztar, or gztar. root_dir is a directory that will be the root directory of the archive; ie. we typically chdir into root_dir before creating the archive. base_dir is the directory where we start archiving from; ie. base_dir will be the common prefix of all files and directories in the archive. root_dir and base_dir both default to the current directory. Returns the name of the archive file.

distutils.archive_util.make_tarball(base_name,
base_dir[, compress='gzip', verbose=0, dry_run=0])

'Create an (optional compressed) archive as a tar file from all files in and under base_dir. compress must be 'gzip' (the default), 'compress', 'bzip2', or None. Both tar and the compression utility named by compress must be on the default program search path, so this is probably Unix-specific. The output tar file will be named base_dir.tar, possibly plus the appropriate compression extension (.gz, .bz2 or .Z). Return the output filename.

distutils.archive_util.make_zipfile(base_name,
base_dir[, verbose=0, dry_run=0])

Create a zip file from all files in and under base_dir. The output zip file will be named base_name + .zip. Uses either the zipfile Python module (if available) or the InfoZIP zip utility (if installed and found on the default search path). If neither tool is available, raises DistutilsExecError. Returns the name of the output zip file.
10.8. **distutils.dep_util** — Dependency checking

This module provides functions for performing simple, timestamp-based dependency of files and groups of files; also, functions based entirely on such timestamp dependency analysis.

```python
import distutils.dep_util

distutils.dep_util.newer(source, target)
```

Return true if `source` exists and is more recently modified than `target`, or if `source` exists and `target` doesn't. Return false if both exist and `target` is the same age or newer than `source`. Raise DistutilsFileError if `source` does not exist.

```python
import distutils.dep_util

distutils.dep_util.newer_pairwise(sources, targets)
```

Walk two filename lists in parallel, testing if each source is newer than its corresponding target. Return a pair of lists (`sources`, `targets`) where source is newer than target, according to the semantics of `newer()`.

```python
import distutils.dep_util

distutils.dep_util.newer_group(sources, target[, missing='error'])
```

Return true if `target` is out-of-date with respect to any file listed in `sources` In other words, if `target` exists and is newer than every file in `sources`, return false; otherwise return true. `missing` controls what we do when a source file is missing; the default ("error") is to blow up with an OSError from inside os.stat(); if it is "ignore", we silently drop any missing source files; if it is "newer", any missing source files make us assume that `target` is out-of-date (this is handy in "dry-run" mode: it'll make you pretend to carry out commands that wouldn't work because inputs are
missing, but that doesn't matter because you're not actually going to run the commands).
10.9. **distutils.dir_util** — Directory tree operations

This module provides functions for operating on directories and trees of directories.

```python
distutils.dir_util.mkpath(name[, mode=0o777, verbose=0, dry_run=0])
```

Create a directory and any missing ancestor directories. If the directory already exists (or if `name` is the empty string, which means the current directory, which of course exists), then do nothing. Raise `DistutilsFileError` if unable to create some directory along the way (eg. some sub-path exists, but is a file rather than a directory). If `verbose` is true, print a one-line summary of each `mkdir` to stdout. Return the list of directories actually created.

```python
distutils.dir_util.create_tree(base_dir, files[, mode=0o777, verbose=0, dry_run=0])
```

Create all the empty directories under `base_dir` needed to put `files` there. `base_dir` is just the a name of a directory which doesn’t necessarily exist yet; `files` is a list of filenames to be interpreted relative to `base_dir`. `base_dir` + the directory portion of every file in `files` will be created if it doesn’t already exist. `mode`, `verbose` and `dry_run` flags are as for `mkpath()`.

```python
distutils.dir_util.copy_tree(src, dst[, preserve_mode=1, preserve_times=1, preserve_symlinks=0, update=0, verbose=0, dry_run=0])
```

Copy an entire directory tree `src` to a new location `dst`. Both `src` and
**dst** must be directory names. If **src** is not a directory, raise DistutilsFileError. If **dst** does not exist, it is created with **mkpath()**. The end result of the copy is that every file in **src** is copied to **dst**, and directories under **src** are recursively copied to **dst**. Return the list of files that were copied or might have been copied, using their output name. The return value is unaffected by **update** or **dry_run**: it is simply the list of all files under **src**, with the names changed to be under **dst**.

**preserve_mode** and **preserve_times** are the same as for **distutils.file_util.copy_file()**; note that they only apply to regular files, not to directories. If **preserve_symlinks** is true, symlinks will be copied as symlinks (on platforms that support them!); otherwise (the default), the destination of the symlink will be copied. **update** and **verbose** are the same as for **copy_file()**.

Files in **src** that begin with **.nfs** are skipped (more information on these files is available in answer D2 of the NFS FAQ page.

*Changed in version 3.3.1*: NFS files are ignored.

**distutils.dir_util.remove_tree**(directory[, verbose=0, dry_run=0])

Recursively remove **directory** and all files and directories underneath it. Any errors are ignored (apart from being reported to **sys.stdout** if **verbose** is true).
10.10. **distutils.file_util** — Single file operations

This module contains some utility functions for operating on individual files.

```python
distutils.file_util.copy_file(src, dst[, preserve_mode=1, preserve_times=1, update=0, link=None, verbose=0, dry_run=0])
```

Copy file `src` to `dst`. If `dst` is a directory, then `src` is copied there with the same name; otherwise, it must be a filename. (If the file exists, it will be ruthlessly clobbered.) If `preserve_mode` is true (the default), the file's mode (type and permission bits, or whatever is analogous on the current platform) is copied. If `preserve_times` is true (the default), the last-modified and last-access times are copied as well. If `update` is true, `src` will only be copied if `dst` does not exist, or if `dst` does exist but is older than `src`.

`link` allows you to make hard links (using `os.link()`) or symbolic links (using `os.symlink()`) instead of copying: set it to `'hard'` or `'sym'`; if it is `None` (the default), files are copied. Don't set `link` on systems that don't support it: `copy_file()` doesn't check if hard or symbolic linking is available. It uses `_copy_file_contents()` to copy file contents.

Return a tuple `(dest_name, copied)`: `dest_name` is the actual name of the output file, and `copied` is true if the file was copied (or would have been copied, if `dry_run` true).

```python
distutils.file_util.move_file(src, dst[, verbose, dry_run])
```
Move file src to dst. If dst is a directory, the file will be moved into it with the same name; otherwise, src is just renamed to dst. Returns the new full name of the file.

**Warning:** Handles cross-device moves on Unix using `copy_file()`. What about other systems?

distutils.file_util.write_file(filename, contents)
Create a file called filename and write contents (a sequence of strings without line terminators) to it.
10.11. distutils.util — Miscellaneous other utility functions

This module contains other assorted bits and pieces that don’t fit into any other utility module.

*distutils.util.get_platform()*

Return a string that identifies the current platform. This is used mainly to distinguish platform-specific build directories and platform-specific built distributions. Typically includes the OS name and version and the architecture (as supplied by ‘os.uname()’), although the exact information included depends on the OS; eg. for IRIX the architecture isn’t particularly important (IRIX only runs on SGI hardware), but for Linux the kernel version isn’t particularly important.

Examples of returned values:

- linux-i586
- linux-alpha
- solaris-2.6-sun4u
- irix-5.3
- irix64-6.2

For non-POSIX platforms, currently just returns sys.platform.

For Mac OS X systems the OS version reflects the minimal version on which binaries will run (that is, the value of MACOSX_DEPLOYMENT_TARGET during the build of Python), not the OS version of the current system.

For universal binary builds on Mac OS X the architecture value
reflects the universal binary status instead of the architecture of the current processor. For 32-bit universal binaries the architecture is \texttt{fat}, for 64-bit universal binaries the architecture is \texttt{fat64}, and for 4-way universal binaries the architecture is \texttt{universal}. Starting from Python 2.7 and Python 3.2 the architecture \texttt{fat3} is used for a 3-way universal build (ppc, i386, x86_64) and \texttt{intel} is used for a universal build with the i386 and x86_64 architectures.

Examples of returned values on Mac OS X:

- \texttt{macosx-10.3-ppc}
- \texttt{macosx-10.3-fat}
- \texttt{macosx-10.5-universal}
- \texttt{macosx-10.6-intel}

\texttt{distutils.util.convert\_path(pathname)}

Return ‘pathname’ as a name that will work on the native filesystem, i.e. split it on ‘/’ and put it back together again using the current directory separator. Needed because filenames in the setup script are always supplied in Unix style, and have to be converted to the local convention before we can actually use them in the filesystem. Raises \texttt{ValueError} on non-Unix-ish systems if \texttt{pathname} either starts or ends with a slash.

\texttt{distutils.util.change\_root(new\_root, pathname)}

Return \texttt{pathname} with \texttt{new\_root} prepended. If \texttt{pathname} is relative, this is equivalent to \texttt{os.path.join(new\_root, pathname)} Otherwise, it requires making \texttt{pathname} relative and then joining the two, which is tricky on DOS/Windows.

\texttt{distutils.util.check\_environ()}
Ensure that ‘os.environ’ has all the environment variables we guarantee that users can use in config files, command-line options, etc. Currently this includes:

- **HOME** - user's home directory (Unix only)
- **PLAT** - description of the current platform, including hardware and OS (see `get_platform()`)

**distutils.util.subst_vars(s, local_vars)**

Perform shell/Perl-style variable substitution on s. Every occurrence of $ followed by a name is considered a variable, and variable is substituted by the value found in the `local_vars` dictionary, or in `os.environ` if it's not in `local_vars`. `os.environ` is first checked/augmented to guarantee that it contains certain values: see `check_environ()`. Raise `ValueError` for any variables not found in either `local_vars` or `os.environ`.

Note that this is not a fully-fledged string interpolation function. A valid $variable can consist only of upper and lower case letters, numbers and an underscore. No {} or () style quoting is available.

**distutils.util.split_quoted(s)**

Split a string up according to Unix shell-like rules for quotes and backslashes. In short: words are delimited by spaces, as long as those spaces are not escaped by a backslash, or inside a quoted string. Single and double quotes are equivalent, and the quote characters can be backslash-escaped. The backslash is stripped from any two-character escape sequence, leaving only the escaped character. The quote characters are stripped from any quoted string. Returns a list of words.

**distutils.util.execute(func, args[, msg=None, verbose=0,**
**Perform some action that affects the outside world** (for instance, writing to the filesystem). Such actions are special because they are disabled by the `dry_run` flag. This method takes care of all that bureaucracy for you; all you have to do is supply the function to call and an argument tuple for it (to embody the “external action” being performed), and an optional message to print.

**distutils.util.strtobool(val)**

Convert a string representation of truth to true (1) or false (0).

True values are `y`, `yes`, `t`, `true`, `on` and `1`; false values are `n`, `no`, `f`, `false`, `off` and `0`. Raises `ValueError` if `val` is anything else.

**distutils.util.byte_compile(py_files[, optimize=0, force=0, prefix=None, base_dir=None, verbose=1, dry_run=0, direct=None])**

Byte-compile a collection of Python source files to either `.pyc` or `.pyo` files in a `__pycache__` subdirectory (see PEP 3147). `py_files` is a list of files to compile; any files that don’t end in `.py` are silently skipped. `optimize` must be one of the following:

- 0 - don’t optimize (generate `.pyc`)
- 1 - normal optimization (like `python -O`)
- 2 - extra optimization (like `python -OO`)

If `force` is true, all files are recompiled regardless of timestamps.

The source filename encoded in each `bytecode` file defaults to the filenames listed in `py_files`; you can modify these with `prefix` and `basedir`. `prefix` is a string that will be stripped off of each source filename, and `base_dir` is a directory name that will be prepended
(after prefix is stripped). You can supply either or both (or neither) of prefix and base_dir, as you wish.

If dry_run is true, doesn’t actually do anything that would affect the filesystem.

Byte-compilation is either done directly in this interpreter process with the standard py_compile module, or indirectly by writing a temporary script and executing it. Normally, you should let byte_compile() figure out to use direct compilation or not (see the source for details). The direct flag is used by the script generated in indirect mode; unless you know what you’re doing, leave it set to None.

Changed in version 3.2.3: Create .pyc or .pyo files with an import magic tag in their name, in a __pycache__ subdirectory instead of files without tag in the current directory.

distutils.util/rfc822_escape(header)
Return a version of header escaped for inclusion in an RFC 822 header, by ensuring there are 8 spaces space after each newline. Note that it does no other modification of the string.
10.12. distutils.dist — The Distribution class

This module provides the Distribution class, which represents the module distribution being built/installed/distributed.
10.13. `distutils.extension` — The Extension class

This module provides the Extension class, used to describe C/C++ extension modules in setup scripts.
10.14. `distutils.debug` — Distutils debug mode

This module provides the DEBUG flag.
10.15. `distutils.errors` — Distutils exceptions

Provides exceptions used by the Distutils modules. Note that Distutils modules may raise standard exceptions; in particular, SystemExit is usually raised for errors that are obviously the end-user’s fault (e.g. bad command-line arguments).

This module is safe to use in `from ... import *` mode; it only exports symbols whose names start with `Distutils` and end with `Error`. 
10.16. `distutils.fancy_getopt` — Wrapper around the standard getopt module

This module provides a wrapper around the standard `getopt` module that provides the following additional features:

- short and long options are tied together
- options have help strings, so `fancy_getopt()` could potentially create a complete usage summary
- options set attributes of a passed-in object
- boolean options can have “negative aliases” — eg. if `--quiet` is the “negative alias” of `--verbose`, then `--quiet` on the command line sets `verbose` to false.

```python
don't show
```
def fancy_getopt(options, negative_opt, object, args)
    Wrapper function. `options` is a list of (long_option, short_option, help_string) 3-tuples as described in the constructor for `FancyGetopt`. `negative_opt` should be a dictionary mapping option names to option names, both the key and value should be in the `options` list. `object` is an object which will be used to store values (see the `getopt()` method of the `FancyGetopt` class). `args` is the argument list. Will use `sys.argv[1:]` if you pass `None` as `args`.

```python
don't show
```
def wrap_text(text, width)
    Wraps `text` to less than `width` wide.

```python
don't show
```
class FancyGetopt([option_table=None])
```

```python
don't show
```
The option_table is a list of 3-tuples: (long_option, short_option, help_string)

If an option takes an argument, its long_option should have '=' appended; short_option should just be a single character, no ':' in any case. short_option should be None if a long_option doesn't have a corresponding short_option. All option tuples must have long options.

The FancyGetopt class provides the following methods:

FancyGetopt.getopt([args=None, object=None])
 Parse command-line options in args. Store as attributes on object.

If args is None or not supplied, uses sys.argv[1:]. If object is None or not supplied, creates a new OptionDummy instance, stores option values there, and returns a tuple (args, object). If object is supplied, it is modified in place and getopt() just returns args; in both cases, the returned args is a modified copy of the passed-in args list, which is left untouched.

FancyGetopt.get_option_order()
 Returns the list of (option, value) tuples processed by the previous run of getopt() Raises RuntimeError if getopt() hasn't been called yet.

FancyGetopt.generate_help([header=None])
 Generate help text (a list of strings, one per suggested line of output) from the option table for this FancyGetopt object.

If supplied, prints the supplied header at the top of the help.
10.17. `distutils.filelist` — The FileList class

This module provides the `FileList` class, used for poking about the filesystem and building lists of files.
10.18. `distutils.log` — Simple PEP 282-style logging
10.19. `distutils.spawn` — Spawn a sub-process

This module provides the `spawn()` function, a front-end to various platform-specific functions for launching another program in a subprocess. Also provides `find_executable()` to search the path for a given executable name.
10.20. distutils.sysconfig — System configuration information

The distutils.sysconfig module provides access to Python's low-level configuration information. The specific configuration variables available depend heavily on the platform and configuration. The specific variables depend on the build process for the specific version of Python being run; the variables are those found in the Makefile and configuration header that are installed with Python on Unix systems. The configuration header is called pyconfig.h for Python versions starting with 2.2, and config.h for earlier versions of Python.

Some additional functions are provided which perform some useful manipulations for other parts of the distutils package.

distutils.sysconfig.PREFIX
   The result of os.path.normpath(sys.prefix).

distutils.sysconfig.EXEC_PREFIX
   The result of os.path.normpath(sys.exec_prefix).

distutils.sysconfig.get_config_var(name)
   Return the value of a single variable. This is equivalent to get_config_vars().get(name).

distutils.sysconfig.get_config_vars(...)
   Return a set of variable definitions. If there are no arguments, this returns a dictionary mapping names of configuration variables to values. If arguments are provided, they should be strings, and the return value will be a sequence giving the associated values. If a
given name does not have a corresponding value, None will be included for that variable.

distutils.sysconfig.get_config_h_filename()
Return the full path name of the configuration header. For Unix, this will be the header generated by the configure script; for other platforms the header will have been supplied directly by the Python source distribution. The file is a platform-specific text file.

distutils.sysconfig.get_makefile_filename()
Return the full path name of the Makefile used to build Python. For Unix, this will be a file generated by the configure script; the meaning for other platforms will vary. The file is a platform-specific text file, if it exists. This function is only useful on POSIX platforms.

distutils.sysconfig.get_python_inc([plat_specific[, prefix]])
Return the directory for either the general or platform-dependent C include files. If plat_specific is true, the platform-dependent include directory is returned; if false or omitted, the platform-independent directory is returned. If prefix is given, it is used as either the prefix instead of PREFIX, or as the exec-prefix instead of EXEC_PREFIX if plat_specific is true.

distutils.sysconfig.get_python_lib([plat_specific[, standard_lib[, prefix]]])
Return the directory for either the general or platform-dependent library installation. If plat_specific is true, the platform-dependent include directory is returned; if false or omitted, the platform-independent directory is returned. If prefix is given, it is used as either the prefix instead of PREFIX, or as the exec-prefix instead of
\texttt{EXEC\_PREFIX} if \textit{plat\_specific} is true. If \textit{standard\_lib} is true, the directory for the standard library is returned rather than the directory for the installation of third-party extensions.

The following function is only intended for use within the \texttt{distutils} package.

\begin{verbatim}
distutils.sysconfig\texttt{.customize\_compiler}(compiler)
\end{verbatim}

Do any platform-specific customization of a \texttt{distutils.ccompiler.CCompiler} instance.

This function is only needed on Unix at this time, but should be called consistently to support forward-compatibility. It inserts the information that varies across Unix flavors and is stored in Python's \texttt{Makefile}. This information includes the selected compiler, compiler and linker options, and the extension used by the linker for shared objects.

This function is even more special-purpose, and should only be used from Python's own build procedures.

\begin{verbatim}
distutils.sysconfig\texttt{.set\_python\_build}()
\end{verbatim}

Inform the \texttt{distutils.sysconfig} module that it is being used as part of the build process for Python. This changes a lot of relative locations for files, allowing them to be located in the build area rather than in an installed Python.
10.21. distutils.text_file — The TextFile class

This module provides the TextFile class, which gives an interface to text files that (optionally) takes care of stripping comments, ignoring blank lines, and joining lines with backslashes.

```python
class distutils.text_file.TextFile([filename=None, file=None, **options])
```

This class provides a file-like object that takes care of all the things you commonly want to do when processing a text file that has some line-by-line syntax: strip comments (as long as `#` is your comment character), skip blank lines, join adjacent lines by escaping the newline (ie. backslash at end of line), strip leading and/or trailing whitespace. All of these are optional and independently controllable.

The class provides a ```warn()``` method so you can generate warning messages that report physical line number, even if the logical line in question spans multiple physical lines. Also provides ```unreadline()``` for implementing line-at-a-time lookahead.

TextFile instances are create with either `filename`, `file`, or both. ```RuntimeError``` is raised if both are ```None```. `filename` should be a string, and `file` a file object (or something that provides ```readline()``` and ```close()``` methods). It is recommended that you supply at least `filename`, so that TextFile can include it in warning messages. If `file` is not supplied, TextFile creates its own using the ```open()``` built-in function.
The options are all boolean, and affect the values returned by `readline()`

<table>
<thead>
<tr>
<th>option name</th>
<th>description</th>
<th>default</th>
</tr>
</thead>
<tbody>
<tr>
<td><code>strip_comments</code></td>
<td>strip from '#' to end-of-line, as well as any whitespace leading up to the '#'—unless it is escaped by a backslash</td>
<td>true</td>
</tr>
<tr>
<td><code>lstrip_ws</code></td>
<td>strip leading whitespace from each line before returning it</td>
<td>false</td>
</tr>
<tr>
<td><code>rstrip_ws</code></td>
<td>strip trailing whitespace (including line terminator!) from each line before returning it.</td>
<td>true</td>
</tr>
<tr>
<td><code>skip_blanks</code></td>
<td>skip lines that are empty <em>after</em> stripping comments and whitespace. (If both <code>lstrip_ws</code> and <code>rstrip_ws</code> are false, then some lines may consist of solely whitespace: these will <em>not</em> be skipped, even if <code>skip_blanks</code> is true.)</td>
<td>true</td>
</tr>
<tr>
<td><code>join_lines</code></td>
<td>if a backslash is the last non-newline character on a line after stripping comments and whitespace, join the following line to it to form one logical line; if N consecutive lines end with a backslash, then N+1 physical lines will be joined to form one logical line.</td>
<td>false</td>
</tr>
<tr>
<td><code>collapse_join</code></td>
<td>strip leading whitespace from lines that are joined to their predecessor; only matters if <code>join_lines</code> and not <code>lstrip_ws</code></td>
<td>false</td>
</tr>
</tbody>
</table>
Note that since `rstrip_ws` can strip the trailing newline, the semantics of `readline()` must differ from those of the built-in file object’s `readline()` method! In particular, `readline()` returns `None` for end-of-file: an empty string might just be a blank line (or an all-whitespace line), if `rstrip_ws` is true but `skip_blanks` is not.

`open(filename)`
Open a new file `filename`. This overrides any `file` or `filename` constructor arguments.

`close()`
Close the current file and forget everything we know about it (including the filename and the current line number).

`warn(msg[, line=None])`
Print (to stderr) a warning message tied to the current logical line in the current file. If the current logical line in the file spans multiple physical lines, the warning refers to the whole range, such as "lines 3-5". If `line` is supplied, it overrides the current line number; it may be a list or tuple to indicate a range of physical lines, or an integer for a single physical line.

`readline()`
Read and return a single logical line from the current file (or from an internal buffer if lines have previously been “unread” with `unreadline()`). If the `join_lines` option is true, this may involve reading multiple physical lines concatenated into a single string. Updates the current line number, so calling `warn()` after `readline()` emits a warning about the physical line(s) just read. Returns `None` on end-of-file, since the empty string can occur if `rstrip_ws` is true but `strip_blanks` is not.
readlines()

Read and return the list of all logical lines remaining in the current file. This updates the current line number to the last line of the file.

unreadline(line)

Push line (a string) onto an internal buffer that will be checked by future readline() calls. Handy for implementing a parser with line-at-a-time lookahead. Note that lines that are “unread” with unreadline() are not subsequently re-cleansed (whitespace stripped, or whatever) when read with readline(). If multiple calls are made to unreadline() before a call to readline(), the lines will be returned most in most recent first order.
10.22. `distutils.version` — Version number classes
10.23. **distutils.cmd** — Abstract base class for Distutils commands

This module supplies the abstract base class `Command`.

```python
class distutils.cmd.Command(dist)
```

Abstract base class for defining command classes, the “worker bees” of the Distutils. A useful analogy for command classes is to think of them as subroutines with local variables called `options`. The options are declared in `initialize_options()` and defined (given their final values) in `finalize_options()`, both of which must be defined by every command class. The distinction between the two is necessary because option values might come from the outside world (command line, config file, ...), and any options dependent on other options must be computed after these outside influences have been processed — hence `finalize_options()`. The body of the subroutine, where it does all its work based on the values of its options, is the `run()` method, which must also be implemented by every command class.

The class constructor takes a single argument `dist`, a `Distribution` instance.
10.24. Creating a new Distutils command

This section outlines the steps to create a new Distutils command.

A new command lives in a module in the `distutils.command` package. There is a sample template in that directory called `command_template`. Copy this file to a new module with the same name as the new command you’re implementing. This module should implement a class with the same name as the module (and the command). So, for instance, to create the command `peel_banana` (so that users can run `setup.py peel_banana`), you’d copy `command_template` to `distutils/command/peel_banana.py`, then edit it so that it’s implementing the class `peel_banana`, a subclass of `distutils.cmd.Command`.

Subclasses of `Command` must define the following methods.

**Command. `initialize_options()`**

Set default values for all the options that this command supports. Note that these defaults may be overridden by other commands, by the setup script, by config files, or by the command-line. Thus, this is not the place to code dependencies between options; generally, `initialize_options()` implementations are just a bunch of `self.foo = None` assignments.

**Command. `finalize_options()`**

Set final values for all the options that this command supports. This is always called as late as possible, ie. after any option assignments from the command-line or from other commands have been done. Thus, this is the place to code option dependencies: if `foo` depends on `bar`, then it is safe to set `foo` from `bar` as long as
foo still has the same value it was assigned in initialize_options().

Command.run()

A command’s raison d’etre: carry out the action it exists to perform, controlled by the options initialized in initialize_options(), customized by other commands, the setup script, the command-line, and config files, and finalized in finalize_options(). All terminal output and filesystem interaction should be done by run().

Command.sub_commands

sub_commands formalizes the notion of a “family” of commands, e.g. install as the parent with sub-commands install_lib, install_headers, etc. The parent of a family of commands defines sub_commands as a class attribute; it’s a list of 2-tuples (command_name, predicate), with command_name a string and predicate a function, a string or None. predicate is a method of the parent command that determines whether the corresponding command is applicable in the current situation. (E.g. install_headers is only applicable if we have any C header files to install.) If predicate is None, that command is always applicable.

sub_commands is usually defined at the end of a class, because predicates can be methods of the class, so they must already have been defined. The canonical example is the install command.
10.25. **distutils.command** — Individual Distutils commands
10.26. `distutils.command.bdist` — Build a binary installer
10.27. distutils.command.bdist_packager — Abstract base class for packagers
distutils.command.bdist_dumb —
Build a “dumb” installer
10.29.  
distutils.command.bdist_msi —  
Build a Microsoft Installer binary package

class distutils.command.bdist_msi.bdist_msi

Builds a Windows Installer (.msi) binary package.

In most cases, the bdist_msi installer is a better choice than the bdist_wininst installer, because it provides better support for Win64 platforms, allows administrators to perform non-interactive installations, and allows installation through group policies.
10.30. 
*distutils.command.bdist_rpm* — Build a binary distribution as a Redhat RPM and SRPM
10.31.
distutils.command.bdist_wininst
— Build a Windows installer
10.32. **distutils.command.sdist** — Build a source distribution
10.33. **distutils.command.build** — Build all files of a package
10.34.
```
```
---

```
```
---

distutils.command.build_clib —
Build any C libraries in a package
10.35.
distutils.command.build_ext —
Build any extensions in a package
10.36. distutils.command.build_py
— Build the .py/.pyc files of a package

class distutils.command.build_py. build_py

class distutils.command.build_py. build_py_2to3

Alternative implementation of build_py which also runs the 2to3
conversion library on each .py file that is going to be installed. To
use this in a setup.py file for a distribution that is designed to run
with both Python 2.x and 3.x, add:

```python
try:
    from distutils.command.build_py import build_py
except ImportError:
    from distutils.command.build_py import build_py

try:
    from distutils.command.build_py import build_py_2to3
except ImportError:
    from distutils.command.build_py import build_py

try:
    from distutils.command.build_py import build_py_2to3
except ImportError:
    from distutils.command.build_py import build_py
```

to your setup.py, and later:

```python
cmdclass = {'build_py': build_py}
```

to the invocation of setup().
10.37. 
`distutils.command.build_scripts` — Build the scripts of a package
This command removes the temporary files created by `build` and its subcommands, like intermediary compiled object files. With the `--all` option, the complete build directory will be removed.

Extension modules built *in place* will not be cleaned, as they are not in the build directory.
10.40. distutils.command.install
— Install a package
10.41. distutils.command.install_data — Install data files from a package
10.42. `distutils.command.install_headers` — Install C/C++ header files from a package
10.43.
distutils.command.install_lib — Install library files from a package
10.44.
`distutils.command.install_script` — Install script files from a package
10.45. distutils.command.register — Register a module with the Python Package Index

The `register` command registers the package with the Python Package Index. This is described in more detail in PEP 301.
10.46. `distutils.command.check` — Check the meta-data of a package

The `check` command performs some tests on the meta-data of a package. For example, it verifies that all required meta-data are provided as the arguments passed to the `setup()` function.
Installing Python Modules (Legacy version)

**Author:** Greg Ward

This document describes the Python Distribution Utilities ("Distutils") from the end-user’s point-of-view, describing how to extend the capabilities of a standard Python installation by building and installing third-party Python modules and extensions.

**Note:** This guide only covers the basic tools for installing extensions that are provided as part of this version of Python. Third party tools offer easier to use and more secure alternatives. Refer to the quick recommendations section in the Python Packaging User Guide for more information.
Introduction

Although Python’s extensive standard library covers many programming needs, there often comes a time when you need to add some new functionality to your Python installation in the form of third-party modules. This might be necessary to support your own programming, or to support an application that you want to use and that happens to be written in Python.

In the past, there has been little support for adding third-party modules to an existing Python installation. With the introduction of the Python Distribution Utilities (Distutils for short) in Python 2.0, this changed.

This document is aimed primarily at the people who need to install third-party Python modules: end-users and system administrators who just need to get some Python application running, and existing Python programmers who want to add some new goodies to their toolbox. You don’t need to know Python to read this document; there will be some brief forays into using Python’s interactive mode to explore your installation, but that’s it. If you’re looking for information on how to distribute your own Python modules so that others may use them, see the Distributing Python Modules (Legacy version) manual. Debugging the setup script may also be of interest.

Best case: trivial installation

In the best case, someone will have prepared a special version of the module distribution you want to install that is targeted specifically at your platform and is installed just like any other software on your platform. For example, the module developer might make an executable installer available for Windows users, an RPM package for
users of RPM-based Linux systems (Red Hat, SuSE, Mandrake, and many others), a Debian package for users of Debian-based Linux systems, and so forth.

In that case, you would download the installer appropriate to your platform and do the obvious thing with it: run it if it's an executable installer, `rpm --install` it if it's an RPM, etc. You don't need to run Python or a setup script, you don't need to compile anything—you might not even need to read any instructions (although it's always a good idea to do so anyway).

Of course, things will not always be that easy. You might be interested in a module distribution that doesn't have an easy-to-use installer for your platform. In that case, you'll have to start with the source distribution released by the module's author/maintainer. Installing from a source distribution is not too hard, as long as the modules are packaged in the standard way. The bulk of this document is about building and installing modules from standard source distributions.

**The new standard: Distutils**

If you download a module source distribution, you can tell pretty quickly if it was packaged and distributed in the standard way, i.e. using the Distutils. First, the distribution's name and version number will be featured prominently in the name of the downloaded archive, e.g. `foo-1.0.tar.gz` or `widget-0.9.7.zip`. Next, the archive will unpack into a similarly-named directory: `foo-1.0` or `widget-0.9.7`. Additionally, the distribution will contain a setup script `setup.py`, and a file named `README.txt` or possibly just `README`, which should explain that building and installing the module distribution is a simple matter of running one command from a terminal:
python setup.py install

For Windows, this command should be run from a command prompt window (Start ▶ Accessories):

setup.py install

If all these things are true, then you already know how to build and install the modules you’ve just downloaded: Run the command above. Unless you need to install things in a non-standard way or customize the build process, you don’t really need this manual. Or rather, the above command is everything you need to get out of this manual.
Standard Build and Install

As described in section *The new standard: Distutils*, building and installing a module distribution using the Distutils is usually one simple command to run from a terminal:

```
python setup.py install
```

**Platform variations**

You should always run the setup command from the distribution root directory, i.e. the top-level subdirectory that the module source distribution unpacks into. For example, if you’ve just downloaded a module source distribution `foo-1.0.tar.gz` onto a Unix system, the normal thing to do is:

```
gunzip -c foo-1.0.tar.gz | tar xf -   # unpacks into directory foo-1.0
cd foo-1.0
python setup.py install
```

On Windows, you’d probably download `foo-1.0.zip`. If you downloaded the archive file to `C:\Temp`, then it would unpack into `C:\Temp\foo-1.0`; you can use either a archive manipulator with a graphical user interface (such as WinZip) or a command-line tool (such as `unzip` or `pkunzip`) to unpack the archive. Then, open a command prompt window and run:

```
cd c:\Temp\foo-1.0
python setup.py install
```
Splitting the job up

Running `setup.py install` builds and installs all modules in one run. If you prefer to work incrementally—especially useful if you want to customize the build process, or if things are going wrong—you can use the setup script to do one thing at a time. This is particularly helpful when the build and install will be done by different users—for example, you might want to build a module distribution and hand it off to a system administrator for installation (or do it yourself, with super-user privileges).

For example, you can build everything in one step, and then install everything in a second step, by invoking the setup script twice:

```bash
python setup.py build
python setup.py install
```

If you do this, you will notice that running the `install` command first runs the `build` command, which—in this case—quickly notices that it has nothing to do, since everything in the build directory is up-to-date.

You may not need this ability to break things down often if all you do is install modules downloaded off the ‘net, but it’s very handy for more advanced tasks. If you get into distributing your own Python modules and extensions, you’ll run lots of individual Distutils commands on their own.

How building works

As implied above, the `build` command is responsible for putting the files to install into a build directory. By default, this is `build` under the
distribution root; if you’re excessively concerned with speed, or want to keep the source tree pristine, you can change the build directory with the `--build-base` option. For example:

```
python setup.py build --build-base=/path/to/pybuild/
```

(Or you could do this permanently with a directive in your system or personal Distutils configuration file; see section Distutils Configuration Files.) Normally, this isn't necessary.

The default layout for the build tree is as follows:

```
--- build/  --- lib/
```

or

```
--- build/  --- lib.<plat>/
  temp.<plat>/
```

where `<plat>` expands to a brief description of the current OS/hardware platform and Python version. The first form, with just a `lib` directory, is used for “pure module distributions”—that is, module distributions that include only pure Python modules. If a module distribution contains any extensions (modules written in C/C++), then the second form, with two `<plat>` directories, is used. In that case, the `temp.plat` directory holds temporary files generated by the compile/link process that don’t actually get installed. In either case, the `lib` (or `lib.plat`) directory contains all Python modules (pure Python and extensions) that will be installed.

In the future, more directories will be added to handle Python scripts, documentation, binary executables, and whatever else is needed to handle the job of installing Python modules and applications.
How installation works

After the build command runs (whether you run it explicitly, or the install command does it for you), the work of the install command is relatively simple: all it has to do is copy everything under build/lib (or build/lib.pythonX.Y/site-packages) to your chosen installation directory.

If you don't choose an installation directory—i.e., if you just run setup.py install—then the install command installs to the standard location for third-party Python modules. This location varies by platform and by how you built/installed Python itself. On Unix (and Mac OS X, which is also Unix-based), it also depends on whether the module distribution being installed is pure Python or contains extensions ("non-pure"):

<table>
<thead>
<tr>
<th>Platform</th>
<th>Standard installation location</th>
<th>Default</th>
</tr>
</thead>
<tbody>
<tr>
<td>Unix (pure)</td>
<td><code>prefix/lib/pythonX.Y/site-packages</code></td>
<td><code>/usr/local/lib/packages</code></td>
</tr>
<tr>
<td>Unix (non-pure)</td>
<td><code>exec-prefix/lib/pythonX.Y/site-packages</code></td>
<td><code>/usr/local/lib/packages</code></td>
</tr>
<tr>
<td>Windows</td>
<td><code>prefix\Lib\site-packages</code></td>
<td><code>C:\PythonXY\Lib</code></td>
</tr>
</tbody>
</table>

Notes:

1. Most Linux distributions include Python as a standard part of the system, so `prefix` and `exec-prefix` are usually both `/usr` on Linux. If you build Python yourself on Linux (or any Unix-like system), the default `prefix` and `exec-prefix` are `/usr/local`.
2. The default installation directory on Windows was `C:\Program Files\Python` under Python 1.6a1, 1.5.2, and earlier.
prefix and exec-prefix stand for the directories that Python is installed to, and where it finds its libraries at run-time. They are always the same under Windows, and very often the same under Unix and Mac OS X. You can find out what your Python installation uses for prefix and exec-prefix by running Python in interactive mode and typing a few simple commands. Under Unix, just type python at the shell prompt. Under Windows, choose Start ▶ Programs ▶ Python X.Y ▶ Python (command line). Once the interpreter is started, you type Python code at the prompt. For example, on my Linux system, I type the three Python statements shown below, and get the output as shown, to find out my prefix and exec-prefix:

```python
Python 2.4 (#26, Aug 7 2004, 17:19:02)
Type "help", "copyright", "credits" or "license" for more information.
>>> import sys
>>> sys.prefix
'/usr'
>>> sys.exec_prefix
'/usr'
```

A few other placeholders are used in this document: X.Y stands for the version of Python, for example 3.2; abiflags will be replaced by the value of sys.abiflags or the empty string for platforms which don’t define ABI flags; distname will be replaced by the name of the module distribution being installed. Dots and capitalization are important in the paths; for example, a value that uses python3.2 on UNIX will typically use Python32 on Windows.

If you don’t want to install modules to the standard location, or if you don’t have permission to write there, then you need to read about alternate installations in section Alternate Installation. If you want to customize your installation directories more heavily, see section
Custom Installation on custom installations.
Alternate Installation

Often, it is necessary or desirable to install modules to a location other than the standard location for third-party Python modules. For example, on a Unix system you might not have permission to write to the standard third-party module directory. Or you might wish to try out a module before making it a standard part of your local Python installation. This is especially true when upgrading a distribution already present: you want to make sure your existing base of scripts still works with the new version before actually upgrading.

The Distutils install command is designed to make installing module distributions to an alternate location simple and painless. The basic idea is that you supply a base directory for the installation, and the install command picks a set of directories (called an installation scheme) under this base directory in which to install files. The details differ across platforms, so read whichever of the following sections applies to you.

Note that the various alternate installation schemes are mutually exclusive: you can pass --user, or --home, or --prefix and --exec-prefix, or --install-base and --install-platbase, but you can’t mix from these groups.

Alternate installation: the user scheme

This scheme is designed to be the most convenient solution for users that don’t have write permission to the global site-packages directory or don’t want to install into it. It is enabled with a simple option:

```
python setup.py install --user
```
Files will be installed into subdirectories of `site.USER_BASE` (written as `userbase` hereafter). This scheme installs pure Python modules and extension modules in the same location (also known as `site.USER_SITE`). Here are the values for UNIX, including Mac OS X:

<table>
<thead>
<tr>
<th>Type of file</th>
<th>Installation directory</th>
</tr>
</thead>
<tbody>
<tr>
<td>modules</td>
<td><code>userbase/lib/pythonX.Y/site-packages</code></td>
</tr>
<tr>
<td>scripts</td>
<td><code>userbase/bin</code></td>
</tr>
<tr>
<td>data</td>
<td><code>userbase</code></td>
</tr>
<tr>
<td>C headers</td>
<td><code>userbase/include/pythonX.Yabiflags/distname</code></td>
</tr>
</tbody>
</table>

And here are the values used on Windows:

<table>
<thead>
<tr>
<th>Type of file</th>
<th>Installation directory</th>
</tr>
</thead>
<tbody>
<tr>
<td>modules</td>
<td><code>userbase\PythonXY\site-packages</code></td>
</tr>
<tr>
<td>scripts</td>
<td><code>userbase\Scripts</code></td>
</tr>
<tr>
<td>data</td>
<td><code>userbase</code></td>
</tr>
<tr>
<td>C headers</td>
<td><code>userbase\PythonXY\Include\distname</code></td>
</tr>
</tbody>
</table>

The advantage of using this scheme compared to the other ones described below is that the user site-packages directory is under normal conditions always included in `sys.path` (see `site` for more information), which means that there is no additional step to perform after running the `setup.py` script to finalize the installation.

The `build_ext` command also has a `--user` option to add `userbase/include` to the compiler search path for header files and
*userbase/lib* to the compiler search path for libraries as well as to the runtime search path for shared C libraries (rpath).

### Alternate installation: the home scheme

The idea behind the “home scheme” is that you build and maintain a personal stash of Python modules. This scheme’s name is derived from the idea of a “home” directory on Unix, since it’s not unusual for a Unix user to make their home directory have a layout similar to `/usr/` or `/usr/local/`. This scheme can be used by anyone, regardless of the operating system they are installing for.

Installing a new module distribution is as simple as

```
python setup.py install --home=<dir>
```

where you can supply any directory you like for the *--home* option. On Unix, lazy typists can just type a tilde (`~`); the `install` command will expand this to your home directory:

```
python setup.py install --home=~
```

To make Python find the distributions installed with this scheme, you may have to *modify Python’s search path* or edit `sitecustomize` (see `site`) to call `site.addsitedir()` or edit `sys.path`.

The *--home* option defines the installation base directory. Files are installed to the following directories under the installation base as follows:

<table>
<thead>
<tr>
<th>Type of file</th>
<th>Installation directory</th>
</tr>
</thead>
<tbody>
<tr>
<td>modules</td>
<td><em>home/lib/python</em></td>
</tr>
</tbody>
</table>
scripts | home/bin
---|---
data | home
C headers | home/include/python/distname

(Mentally replace slashes with backslashes if you’re on Windows.)

Alternate installation: Unix (the prefix scheme)

The “prefix scheme” is useful when you wish to use one Python installation to perform the build/install (i.e., to run the setup script), but install modules into the third-party module directory of a different Python installation (or something that looks like a different Python installation). If this sounds a trifle unusual, it is—that’s why the user and home schemes come before. However, there are at least two known cases where the prefix scheme will be useful.

First, consider that many Linux distributions put Python in `/usr`, rather than the more traditional `/usr/local`. This is entirely appropriate, since in those cases Python is part of “the system” rather than a local add-on. However, if you are installing Python modules from source, you probably want them to go in `/usr/local/lib/python2.X` rather than `/usr/lib/python2.X`. This can be done with

```
/usr/bin/python setup.py install --prefix=/usr/local
```

Another possibility is a network filesystem where the name used to write to a remote directory is different from the name used to read it: for example, the Python interpreter accessed as `/usr/local/bin/python` might search for modules in `/usr/local/lib/python2.X`, but those modules would have to be
installed to, say, `/mnt/@server/export/lib/python2.X`. This could be done with

```
/usr/local/bin/python setup.py install --prefix=/mnt/@server/export
```

In either case, the `--prefix` option defines the installation base, and the `--exec-prefix` option defines the platform-specific installation base, which is used for platform-specific files. (Currently, this just means non-pure module distributions, but could be expanded to C libraries, binary executables, etc.) If `--exec-prefix` is not supplied, it defaults to `--prefix`. Files are installed as follows:

<table>
<thead>
<tr>
<th>Type of file</th>
<th>Installation directory</th>
</tr>
</thead>
<tbody>
<tr>
<td>Python modules</td>
<td><code>prefix/lib/pythonX.Y/site-packages</code></td>
</tr>
<tr>
<td>extension modules</td>
<td><code>exec-prefix/lib/pythonX.Y/site-packages</code></td>
</tr>
<tr>
<td>scripts</td>
<td><code>prefix/bin</code></td>
</tr>
<tr>
<td>data</td>
<td><code>prefix</code></td>
</tr>
<tr>
<td>C headers</td>
<td><code>prefix/include/pythonX.Yabiflags/distname</code></td>
</tr>
</tbody>
</table>

There is no requirement that `--prefix` or `--exec-prefix` actually point to an alternate Python installation; if the directories listed above do not already exist, they are created at installation time.

Incidentally, the real reason the prefix scheme is important is simply that a standard Unix installation uses the prefix scheme, but with `--prefix` and `--exec-prefix` supplied by Python itself as `sys.prefix` and `sys.exec_prefix`. Thus, you might think you'll never use the prefix
scheme, but every time you run `python setup.py install` without any other options, you’re using it.

Note that installing extensions to an alternate Python installation has no effect on how those extensions are built: in particular, the Python header files (Python.h and friends) installed with the Python interpreter used to run the setup script will be used in compiling extensions. It is your responsibility to ensure that the interpreter used to run extensions installed in this way is compatible with the interpreter used to build them. The best way to do this is to ensure that the two interpreters are the same version of Python (possibly different builds, or possibly copies of the same build). (Of course, if your `--prefix` and `--exec-prefix` don’t even point to an alternate Python installation, this is immaterial.)

**Alternate installation: Windows (the prefix scheme)**

Windows has no concept of a user’s home directory, and since the standard Python installation under Windows is simpler than under Unix, the `--prefix` option has traditionally been used to install additional packages in separate locations on Windows.

```
python setup.py install --prefix="\Temp\Python"
```

to install modules to the `\Temp\Python` directory on the current drive.

The installation base is defined by the `--prefix` option; the `--exec-prefix` option is not supported under Windows, which means that pure Python modules and extension modules are installed into the same location. Files are installed as follows:
<table>
<thead>
<tr>
<th>Type of file</th>
<th>Installation directory</th>
</tr>
</thead>
<tbody>
<tr>
<td>modules</td>
<td>prefix\Lib\site-packages</td>
</tr>
<tr>
<td>scripts</td>
<td>prefix\Scripts</td>
</tr>
<tr>
<td>data</td>
<td>prefix</td>
</tr>
<tr>
<td>C headers</td>
<td>prefix\Include\distname</td>
</tr>
</tbody>
</table>
Custom Installation

Sometimes, the alternate installation schemes described in section *Alternate Installation* just don’t do what you want. You might want to tweak just one or two directories while keeping everything under the same base directory, or you might want to completely redefine the installation scheme. In either case, you’re creating a *custom installation scheme*.

To create a custom installation scheme, you start with one of the alternate schemes and override some of the installation directories used for the various types of files, using these options:

<table>
<thead>
<tr>
<th>Type of file</th>
<th>Override option</th>
</tr>
</thead>
<tbody>
<tr>
<td>Python modules</td>
<td>--install-purelib</td>
</tr>
<tr>
<td>extension modules</td>
<td>--install-platlib</td>
</tr>
<tr>
<td>all modules</td>
<td>--install-lib</td>
</tr>
<tr>
<td>scripts</td>
<td>--install-scripts</td>
</tr>
<tr>
<td>data</td>
<td>--install-data</td>
</tr>
<tr>
<td>C headers</td>
<td>--install-headers</td>
</tr>
</tbody>
</table>

These override options can be relative, absolute, or explicitly defined in terms of one of the installation base directories. (There are two installation base directories, and they are normally the same—they only differ when you use the Unix “prefix scheme” and supply different *--prefix* and *--exec-prefix* options; using *--install-lib*
will override values computed or given for --install-purelib and --install-platlib, and is recommended for schemes that don't make a difference between Python and extension modules.)

For example, say you're installing a module distribution to your home directory under Unix—but you want scripts to go in ~/scripts rather than ~/bin. As you might expect, you can override this directory with the --install-scripts option; in this case, it makes most sense to supply a relative path, which will be interpreted relative to the installation base directory (your home directory, in this case):

```
python setup.py install --home=~ --install-scripts=scripts
```

Another Unix example: suppose your Python installation was built and installed with a prefix of /usr/local/python, so under a standard installation scripts will wind up in /usr/local/python/bin. If you want them in /usr/local/bin instead, you would supply this absolute directory for the --install-scripts option:

```
python setup.py install --install-scripts=/usr/local/bin
```

(This performs an installation using the “prefix scheme,” where the prefix is whatever your Python interpreter was installed with—/usr/local/python in this case.)

If you maintain Python on Windows, you might want third-party modules to live in a subdirectory of prefix, rather than right in prefix itself. This is almost as easy as customizing the script installation directory — you just have to remember that there are two types of modules to worry about, Python and extension modules, which can conveniently be both controlled by one option:
python setup.py install --install-lib=Site

The specified installation directory is relative to prefix. Of course, you also have to ensure that this directory is in Python’s module search path, such as by putting a .pth file in a site directory (see site). See section Modifying Python’s Search Path to find out how to modify Python’s search path.

If you want to define an entire installation scheme, you just have to supply all of the installation directory options. The recommended way to do this is to supply relative paths; for example, if you want to maintain all Python module-related files under python in your home directory, and you want a separate directory for each platform that you use your home directory from, you might define the following installation scheme:

python setup.py install --home=~/
   --install-purelib=python/lib
   --install-platlib=python/lib
   --install-scripts=python/scripts
   --install-data=python/data

or, equivalently,

python setup.py install --home=/python/
   --install-purelib=lib
   --install-platlib='lib.$PLAT'
   --install-scripts=scripts
   --install-data=data

$PLAT is not (necessarily) an environment variable—it will be expanded by the Distutils as it parses your command line options, just
as it does when parsing your configuration file(s).

Obviously, specifying the entire installation scheme every time you install a new module distribution would be very tedious. Thus, you can put these options into your Distutils config file (see section Distutils Configuration Files):

```
[install]
install-base=$HOME
install-purelib=python/lib
install-platlib=python/lib.$PLAT
install-scripts=python/scripts
install-data=python/data
```

or, equivalently,

```
[install]
install-base=$HOME/python
install-purelib=lib
install-platlib=lib.$PLAT
install-scripts=scripts
install-data=data
```

Note that these two are not equivalent if you supply a different installation base directory when you run the setup script. For example,

```
python setup.py install --install-base=/tmp
```

would install pure modules to /tmp/python/lib in the first case, and to /tmp/lib in the second case. (For the second case, you probably want to supply an installation base of /tmp/python.)

You probably noticed the use of $HOME and $PLAT in the sample configuration file input. These are Distutils configuration variables,
which bear a strong resemblance to environment variables. In fact, you can use environment variables in config files on platforms that have such a notion but the Distutils additionally define a few extra variables that may not be in your environment, such as $PLAT$. (And of course, on systems that don’t have environment variables, such as Mac OS 9, the configuration variables supplied by the Distutils are the only ones you can use.) See section Distutils Configuration Files for details.

Note: When a virtual environment is activated, any options that change the installation path will be ignored from all distutils configuration files to prevent inadvertently installing projects outside of the virtual environment.

Modifying Python’s Search Path

When the Python interpreter executes an import statement, it searches for both Python code and extension modules along a search path. A default value for the path is configured into the Python binary when the interpreter is built. You can determine the path by importing the sys module and printing the value of sys.path.

```
$ python
Python 2.2 (#11, Oct 3 2002, 13:31:27) [GCC 2.96 20000731 (Red Hat Linux 7.3 2.96-112)] on linux2
Type "help", "copyright", "credits" or "license" for more information.

>>> import sys
>>> sys.path
```
The null string in `sys.path` represents the current working directory.

The expected convention for locally installed packages is to put them in the `./site-packages/` directory, but you may want to install Python modules into some arbitrary directory. For example, your site may have a convention of keeping all software related to the web server under `/www`. Add-on Python modules might then belong in `/www/python`, and in order to import them, this directory must be added to `sys.path`. There are several different ways to add the directory.

The most convenient way is to add a path configuration file to a directory that's already on Python's path, usually to the `./site-packages/` directory. Path configuration files have an extension of `.pth`, and each line must contain a single path that will be appended to `sys.path`. (Because the new paths are appended to `sys.path`, modules in the added directories will not override standard modules. This means you can't use this mechanism for installing fixed versions of standard modules.)

Paths can be absolute or relative, in which case they're relative to the directory containing the `.pth` file. See the documentation of the `site` module for more information.

A slightly less convenient way is to edit the `site.py` file in Python's standard library, and modify `sys.path`. `site.py` is automatically imported when the Python interpreter is executed, unless the `-S` switch is supplied to suppress this behaviour. So you could simply edit `site.py` and add two lines to it:

```python
import sys
sys.path.append('/www/python/')
```
However, if you reinstall the same major version of Python (perhaps when upgrading from 2.2 to 2.2.2, for example) `site.py` will be overwritten by the stock version. You’d have to remember that it was modified and save a copy before doing the installation.

There are two environment variables that can modify `sys.path`. `PYTHONHOME` sets an alternate value for the prefix of the Python installation. For example, if `PYTHONHOME` is set to `/www/python`, the search path will be set to `['', '/www/python/lib/pythonX.Y/', '/www/python/lib/pythonX.Y/plat-linux2', ...]`.

The `PYTHONPATH` variable can be set to a list of paths that will be added to the beginning of `sys.path`. For example, if `PYTHONPATH` is set to `/www/python:/opt/py`, the search path will begin with `['/www/python', '/opt/py']`. (Note that directories must exist in order to be added to `sys.path`; the `site` module removes paths that don’t exist.)

Finally, `sys.path` is just a regular Python list, so any Python application can modify it by adding or removing entries.
Distutils Configuration Files

As mentioned above, you can use Distutils configuration files to record personal or site preferences for any Distutils options. That is, any option to any command can be stored in one of two or three (depending on your platform) configuration files, which will be consulted before the command-line is parsed. This means that configuration files will override default values, and the command-line will in turn override configuration files. Furthermore, if multiple configuration files apply, values from “earlier” files are overridden by “later” files.

Location and names of config files

The names and locations of the configuration files vary slightly across platforms. On Unix and Mac OS X, the three configuration files (in the order they are processed) are:

<table>
<thead>
<tr>
<th>Type of file</th>
<th>Location and filename</th>
</tr>
</thead>
<tbody>
<tr>
<td>system</td>
<td>prefix/lib/pythonver/distutils/distutils.cfg</td>
</tr>
<tr>
<td>personal</td>
<td>$HOME/.pydistutils.cfg</td>
</tr>
<tr>
<td>local</td>
<td>setup.cfg</td>
</tr>
</tbody>
</table>

And on Windows, the configuration files are:

<table>
<thead>
<tr>
<th>Type of file</th>
<th>Location and filename</th>
<th>Notes</th>
</tr>
</thead>
<tbody>
<tr>
<td>system</td>
<td>prefix\Lib\distutils\distutils.cfg</td>
<td>(4)</td>
</tr>
<tr>
<td>personal</td>
<td>%HOME%\pydistutils.cfg</td>
<td>(5)</td>
</tr>
</tbody>
</table>
On all platforms, the “personal” file can be temporarily disabled by passing the `--no-user-cfg` option.

Notes:

1. Strictly speaking, the system-wide configuration file lives in the directory where the Distutils are installed; under Python 1.6 and later on Unix, this is as shown. For Python 1.5.2, the Distutils will normally be installed to `prefix/lib/python1.5/site-packages(distutils)`, so the system configuration file should be put there under Python 1.5.2.

2. On Unix, if the `HOME` environment variable is not defined, the user’s home directory will be determined with the `getpwuid()` function from the standard `pwd` module. This is done by the `os.path.expanduser()` function used by Distutils.

3. I.e., in the current directory (usually the location of the setup script).

4. (See also note (1).) Under Python 1.6 and later, Python's default “installation prefix” is `C:\Python`, so the system configuration file is normally `C:\Python\Lib\distutils\distutils.cfg`. Under Python 1.5.2, the default prefix was `C:\Program Files\Python`, and the Distutils were not part of the standard library—so the system configuration file would be `C:\Program Files\Python\distutils\distutils.cfg` in a standard Python 1.5.2 installation under Windows.

5. On Windows, if the `HOME` environment variable is not defined, `USERPROFILE` then `HOMEDRIVE` and `HOMEPATH` will be tried. This is done by the `os.path.expanduser()` function used by Distutils.

Syntax of config files
The Distutils configuration files all have the same syntax. The config files are grouped into sections. There is one section for each Distutils command, plus a global section for global options that affect every command. Each section consists of one option per line, specified as option=value.

For example, the following is a complete config file that just forces all commands to run quietly by default:

```
[global]
verbose=0
```

If this is installed as the system config file, it will affect all processing of any Python module distribution by any user on the current system. If it is installed as your personal config file (on systems that support them), it will affect only module distributions processed by you. And if it is used as the setup.cfg for a particular module distribution, it affects only that distribution.

You could override the default “build base” directory and make the build* commands always forcibly rebuild all files with the following:

```
[build]
build-base=blib
force=1
```

which corresponds to the command-line arguments

```
python setup.py build --build-base=blib --force
```

except that including the build command on the command-line means that command will be run. Including a particular command in config files has no such implication; it only means that if the command is run,
the options in the config file will apply. (Or if other commands that derive values from it are run, they will use the values in the config file.)

You can find out the complete list of options for any command using the \texttt{--help} option, e.g.:

\begin{verbatim}
python setup.py build --help
\end{verbatim}

and you can find out the complete list of global options by using \texttt{--help} without a command:

\begin{verbatim}
python setup.py --help
\end{verbatim}

See also the “Reference” section of the “Distributing Python Modules” manual.
Building Extensions: Tips and Tricks

Whenever possible, the Distutils try to use the configuration information made available by the Python interpreter used to run the setup.py script. For example, the same compiler and linker flags used to compile Python will also be used for compiling extensions. Usually this will work well, but in complicated situations this might be inappropriate. This section discusses how to override the usual Distutils behaviour.

Tweaking compiler/linker flags

Compiling a Python extension written in C or C++ will sometimes require specifying custom flags for the compiler and linker in order to use a particular library or produce a special kind of object code. This is especially true if the extension hasn’t been tested on your platform, or if you’re trying to cross-compile Python.

In the most general case, the extension author might have foreseen that compiling the extensions would be complicated, and provided a Setup file for you to edit. This will likely only be done if the module distribution contains many separate extension modules, or if they often require elaborate sets of compiler flags in order to work.

A Setup file, if present, is parsed in order to get a list of extensions to build. Each line in a Setup describes a single module. Lines have the following structure:

```
module ... [sourcefile ...] [cpparg ...] [library ..
```

Let's examine each of the fields in turn.
- `module` is the name of the extension module to be built, and should be a valid Python identifier. You can't just change this in order to rename a module (edits to the source code would also be needed), so this should be left alone.
- `sourcefile` is anything that's likely to be a source code file, at least judging by the filename. Filenames ending in `.c` are assumed to be written in C, filenames ending in `.C`, `.cc`, and `.c++` are assumed to be C++, and filenames ending in `.m` or `.mm` are assumed to be in Objective C.
- `cpparg` is an argument for the C preprocessor, and is anything starting with `-I`, `-D`, `-U` or `-C`.
- `library` is anything ending in `.a` or beginning with `-l` or `-L`.

If a particular platform requires a special library on your platform, you can add it by editing the `Setup` file and running `python setup.py build`. For example, if the module defined by the line

```plaintext
foo foomodule.c
```

must be linked with the math library `libm.a` on your platform, simply add `-lm` to the line:

```plaintext
foo foomodule.c -lm
```

Arbitrary switches intended for the compiler or the linker can be supplied with the `-Xcompiler arg` and `-Xlinker arg` options:

```plaintext
foo foomodule.c -Xcompiler -o32 -Xlinker -shared -lm
```

The next option after `-Xcompiler` and `-Xlinker` will be appended to the proper command line, so in the above example the compiler will be passed the `-o32` option, and the linker will be passed `-shared`. If a compiler option requires an argument, you'll have to supply multiple -
**X**compiler options; for example, to pass -x c++ the Setup file would have to contain -Xcompiler -x -Xcompiler c++.

Compiler flags can also be supplied through setting the CFLAGS environment variable. If set, the contents of CFLAGS will be added to the compiler flags specified in the Setup file.

### Using non-Microsoft compilers on Windows

**Borland/CodeGear C++**

This subsection describes the necessary steps to use Distutils with the Borland C++ compiler version 5.5. First you have to know that Borland’s object file format (OMF) is different from the format used by the Python version you can download from the Python or ActiveState Web site. (Python is built with Microsoft Visual C++, which uses COFF as the object file format.) For this reason you have to convert Python’s library `python25.lib` into the Borland format. You can do this as follows:

```bash
coff2omf python25.lib python25_bcpp.lib
```

The `coff2omf` program comes with the Borland compiler. The file `python25.lib` is in the `Libs` directory of your Python installation. If your extension uses other libraries (zlib, ...) you have to convert them too.

The converted files have to reside in the same directories as the normal libraries.

How does Distutils manage to use these libraries with their changed names? If the extension needs a library (eg. `foo`) Distutils checks first
if it finds a library with suffix _bcpp (eg. foo_bcpp.lib) and then uses this library. In the case it doesn’t find such a special library it uses the default name (foo.lib.) [1]

To let Distutils compile your extension with Borland C++ you now have to type:

```
python setup.py build --compiler=bcpp
```

If you want to use the Borland C++ compiler as the default, you could specify this in your personal or system-wide configuration file for Distutils (see section Distutils Configuration Files.)

See also:

**C++Builder Compiler**

Information about the free C++ compiler from Borland, including links to the download pages.

**Creating Python Extensions Using Borland’s Free Compiler**

Document describing how to use Borland's free command-line C++ compiler to build Python.

**GNU C / Cygwin / MinGW**

This section describes the necessary steps to use Distutils with the GNU C/C++ compilers in their Cygwin and MinGW distributions. [2]

For a Python interpreter that was built with Cygwin, everything should work without any of these following steps.

Not all extensions can be built with MinGW or Cygwin, but many can. Extensions most likely to not work are those that use C++ or depend on Microsoft Visual C extensions.
To let Distutils compile your extension with Cygwin you have to type:

```
python setup.py build --compiler=cygwin
```

and for Cygwin in no-cygwin mode [3] or for MinGW type:

```
python setup.py build --compiler=mingw32
```

If you want to use any of these options/compilers as default, you should consider writing it in your personal or system-wide configuration file for Distutils (see section Distutils Configuration Files.)

Older Versions of Python and MinGW

The following instructions only apply if you’re using a version of Python inferior to 2.4.1 with a MinGW inferior to 3.0.0 (with binutils-2.13.90-20030111-1).

These compilers require some special libraries. This task is more complex than for Borland’s C++, because there is no program to convert the library. First you have to create a list of symbols which the Python DLL exports. (You can find a good program for this task at http://sourceforge.net/projects/mingw/files/MinGW/Extension/pexports/)

```
pexports python25.dll >python25.def
```

The location of an installed python25.dll will depend on the installation options and the version and language of Windows. In a “just for me” installation, it will appear in the root of the installation directory. In a shared installation, it will be located in the system directory.

Then you can create from these information an import library for gcc.
/cygwin/bin/dlltool --dllname python25.dll --def python25.def --output-lib libpython25.a

The resulting library has to be placed in the same directory as python25.lib. (Should be the libs directory under your Python installation directory.)

If your extension uses other libraries (zlib,...) you might have to convert them too. The converted files have to reside in the same directories as the normal libraries do.

**Building Python modules on MS Windows platform with MinGW**

Information about building the required libraries for the MinGW environment.

### Footnotes

[1] This also means you could replace all existing COFF-libraries with OMF-libraries of the same name.

[3] Then you have no POSIX emulation available, but you also don't need cygwin1.dll.
Distributing Python Modules (Legacy version)

This document describes the Python Distribution Utilities ("Distutils") from the module developer’s point of view, describing how to use the Distutils to make Python modules and extensions easily available to a wider audience with very little overhead for build/release/install mechanics.

**Note:** This guide only covers the basic tools for building and distributing extensions that are provided as part of this version of Python. Third party tools offer easier to use and more secure alternatives. Refer to the quick recommendations section in the Python Packaging User Guide for more information.

- **1. An Introduction to Distutils**
  - 1.1. Concepts & Terminology
  - 1.2. A Simple Example
  - 1.3. General Python terminology
  - 1.4. Distutils-specific terminology
- **2. Writing the Setup Script**
  - 2.1. Listing whole packages
  - 2.2. Listing individual modules
  - 2.3. Describing extension modules
  - 2.4. Relationships between Distributions and Packages
  - 2.5. Installing Scripts
  - 2.6. Installing Package Data
  - 2.7. Installing Additional Files
2.8. Additional meta-data
2.9. Debugging the setup script

3. Writing the Setup Configuration File

4. Creating a Source Distribution
   4.1. Specifying the files to distribute
   4.2. Manifest-related options

5. Creating Built Distributions
   5.1. Creating RPM packages
   5.2. Creating Windows Installers
   5.3. Cross-compiling on Windows
   5.4. Vista User Access Control (UAC)

6. The Python Package Index (PyPI)
   6.1. Registering Packages
   6.2. Uploading Packages
   6.3. The .pypirc file
   6.4. PyPI package display

7. Examples
   7.1. Pure Python distribution (by module)
   7.2. Pure Python distribution (by package)
   7.3. Single extension module
   7.4. Checking a package
   7.5. Reading the metadata

8. Extending Distutils
   8.1. Integrating new commands
   8.2. Adding new distribution types

9. Command Reference
   9.1. Installing modules: the install command family
   9.2. Creating a source distribution: the sdist command

10. API Reference
    10.1. distutils.core — Core Distutils functionality
    10.2. distutils.ccompiler — CCompiler base class
    10.3. distutils.unixccompiler — Unix C Compiler
    10.4. distutils.msvccompiler — Microsoft Compiler
    10.5. distutils.bcppcompiler — Borland Compiler
10.6. distutils.cygwincompiler — Cygwin Compiler
10.7. distutils.archive_util — Archiving utilities
10.8. distutils.dep_util — Dependency checking
10.9. distutils.dir_util — Directory tree operations
10.10. distutils.file_util — Single file operations
10.11. distutils.util — Miscellaneous other utility functions
10.12. distutils.dist — The Distribution class
10.13. distutils.extension — The Extension class
10.14. distutils.debug — Distutils debug mode
10.15. distutils.errors — Distutils exceptions
10.16. distutils.fancy_getopt — Wrapper around the standard getopt module
10.17. distutils.filelist — The FileList class
10.18. distutils.log — Simple PEP 282-style logging
10.19. distutils.spawn — Spawn a sub-process
10.20. distutils.sysconfig — System configuration information
10.21. distutils.text_file — The TextFile class
10.22. distutils.version — Version number classes
10.23. distutils.cmd — Abstract base class for Distutils commands
10.24. Creating a new Distutils command
10.25. distutils.command — Individual Distutils commands
10.26. distutils.command.bdist — Build a binary installer
10.27. distutils.command.bdist_packager — Abstract base class for packagers
10.28. distutils.command.bdist_dumb — Build a “dumb” installer
10.29. distutils.command.bdist_msi — Build a
Microsoft Installer binary package

- **10.30. distutils.command.bdist_rpm** — Build a binary distribution as a Redhat RPM and SRPM
- **10.31. distutils.command.bdist_wininst** — Build a Windows installer
- **10.32. distutils.command.sdist** — Build a source distribution
- **10.33. distutils.command.build** — Build all files of a package
- **10.34. distutils.command.build_clib** — Build any C libraries in a package
- **10.35. distutils.command.build_ext** — Build any extensions in a package
- **10.36. distutils.command.build_py** — Build the .py/.pyc files of a package
- **10.37. distutils.command.build_scripts** — Build the scripts of a package
- **10.38. distutils.command.clean** — Clean a package build area
- **10.39. distutils.command.config** — Perform package configuration
- **10.40. distutils.command.install** — Install a package
- **10.41. distutils.command.install_data** — Install data files from a package
- **10.42. distutils.command.install_headers** — Install C/C++ header files from a package
- **10.43. distutils.command.install_lib** — Install library files from a package
- **10.44. distutils.command.install_scripts** — Install script files from a package
- **10.45. distutils.command.register** — Register a module with the Python Package Index
- **10.46. distutils.command.check** — Check the meta-
data of a package
8. Extending Distutils

Distutils can be extended in various ways. Most extensions take the form of new commands or replacements for existing commands. New commands may be written to support new types of platform-specific packaging, for example, while replacements for existing commands may be made to modify details of how the command operates on a package.

Most extensions of the distutils are made within `setup.py` scripts that want to modify existing commands; many simply add a few file extensions that should be copied into packages in addition to `.py` files as a convenience.

Most distutils command implementations are subclasses of the `distutils.cmd.Command` class. New commands may directly inherit from Command, while replacements often derive from Command indirectly, directly subclassing the command they are replacing. Commands are required to derive from Command.
8.1. Integrating new commands

There are different ways to integrate new command implementations into distutils. The most difficult is to lobby for the inclusion of the new features in distutils itself, and wait for (and require) a version of Python that provides that support. This is really hard for many reasons.

The most common, and possibly the most reasonable for most needs, is to include the new implementations with your setup.py script, and cause the distutils.core.setup() function use them:

```python
from distutils.command.build_py import build_py as _build_py
from distutils.core import setup

class build_py(_build_py):
    """Specialized Python source builder."""

        # implement whatever needs to be different...

    setup(cmdclass={'build_py': build_py}, ...
```

This approach is most valuable if the new implementations must be used to use a particular package, as everyone interested in the package will need to have the new command implementation.

Beginning with Python 2.4, a third option is available, intended to allow new commands to be added which can support existing setup.py scripts without requiring modifications to the Python installation. This is expected to allow third-party extensions to provide support for additional packaging systems, but the commands can be used for anything distutils commands can be used for. A new configuration
option, `command_packages` (command-line option `--command-packages`), can be used to specify additional packages to be searched for modules implementing commands. Like all distutils options, this can be specified on the command line or in a configuration file. This option can only be set in the `[global]` section of a configuration file, or before any commands on the command line. If set in a configuration file, it can be overridden from the command line; setting it to an empty string on the command line causes the default to be used. This should never be set in a configuration file provided with a package.

This new option can be used to add any number of packages to the list of packages searched for command implementations; multiple package names should be separated by commas. When not specified, the search is only performed in the `distutils.command` package. When `setup.py` is run with the option `--command-packages distcmds,buildcmds`, however, the packages `distutils.command`, distcmds, and buildcmds will be searched in that order. New commands are expected to be implemented in modules of the same name as the command by classes sharing the same name. Given the example command line option above, the command `bdist_openpkg` could be implemented by the class `distcmds.bdist_openpkg.bdist_openpkg` or `buildcmds.bdist_openpkg.bdist_openpkg`. 
8.2. Adding new distribution types

Commands that create distributions (files in the dist/ directory) need to add (command, filename) pairs to self.distribution.dist_files so that upload can upload it to PyPI. The filename in the pair contains no path information, only the name of the file itself. In dry-run mode, pairs should still be added to represent what would have been created.

Created using Sphinx 1.2.
9. Command Reference
9.1. Installing modules: the **install** command family

The install command ensures that the build commands have been run and then runs the subcommands **install_lib**, **install_data** and **install_scripts**.

9.1.1. **install_data**

This command installs all data files provided with the distribution.

9.1.2. **install_scripts**

This command installs all (Python) scripts in the distribution.
9.2. Creating a source distribution: the sdist command

The manifest template commands are:

<table>
<thead>
<tr>
<th>Command</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>include pat1 pat2 ...</td>
<td>include all files matching any of the listed patterns</td>
</tr>
<tr>
<td>exclude pat1 pat2 ...</td>
<td>exclude all files matching any of the listed patterns</td>
</tr>
<tr>
<td>recursive-include dir pat1 pat2 ...</td>
<td>include all files under <code>dir</code> matching any of the listed patterns</td>
</tr>
<tr>
<td>recursive-exclude dir pat1 pat2 ...</td>
<td>exclude all files under <code>dir</code> matching any of the listed patterns</td>
</tr>
<tr>
<td>global-include pat1 pat2 ...</td>
<td>include all files anywhere in the source tree matching — &amp; any of the listed patterns</td>
</tr>
<tr>
<td>global-exclude pat1 pat2 ...</td>
<td>exclude all files anywhere in the source tree matching — &amp; any of the listed patterns</td>
</tr>
<tr>
<td>prune dir</td>
<td>exclude all files under <code>dir</code></td>
</tr>
<tr>
<td>graft dir</td>
<td>include all files under <code>dir</code></td>
</tr>
</tbody>
</table>

The patterns here are Unix-style “glob” patterns: `*` matches any sequence of regular filename characters, `?` matches any single regular filename character, and `[range]` matches any of the characters in `range` (e.g., `a-z`, `a-zA-Z`, `a-f0-9_`). The definition of “regular filename character” is platform-specific: on Unix it is anything except slash; on Windows anything except backslash or colon.
3. Writing the Setup Configuration File

Often, it’s not possible to write down everything needed to build a distribution *a priori*: you may need to get some information from the user, or from the user’s system, in order to proceed. As long as that information is fairly simple—a list of directories to search for C header files or libraries, for example—then providing a configuration file, `setup.cfg`, for users to edit is a cheap and easy way to solicit it. Configuration files also let you provide default values for any command option, which the installer can then override either on the command-line or by editing the config file.

The setup configuration file is a useful middle-ground between the setup script—which, ideally, would be opaque to installers [1]—and the command-line to the setup script, which is outside of your control and entirely up to the installer. In fact, `setup.cfg` (and any other Distutils configuration files present on the target system) are processed after the contents of the setup script, but before the command-line. This has several useful consequences:

- installers can override some of what you put in `setup.py` by editing `setup.cfg`
- you can provide non-standard defaults for options that are not easily set in `setup.py`
- installers can override anything in `setup.cfg` using the command-line options to `setup.py`

The basic syntax of the configuration file is simple:

```
[command]
```
where command is one of the Distutils commands (e.g. `build_py`, `install`), and option is one of the options that command supports. Any number of options can be supplied for each command, and any number of command sections can be included in the file. Blank lines are ignored, as are comments, which run from a '#' character until the end of the line. Long option values can be split across multiple lines simply by indenting the continuation lines.

You can find out the list of options supported by a particular command with the universal `--help` option, e.g.

```bash
> python setup.py --help build_ext
[...]
Options for 'build_ext' command:
    --build-lib (-b) directory for compiled extensions
    --build-temp (-t) directory for temporary files
    --inplace (-i) ignore build-lib and put compiled source directory alongside your module
    --include-dirs (-I) list of directories to search
    --define (-D) C preprocessor macros to define
    --undef (-U) C preprocessor macros to undefine
    --swig-opts list of SWIG command line options
[...]
```

Note that an option spelled `--foo-bar` on the command-line is spelled `foo_bar` in configuration files.

For example, say you want your extensions to be built “in-place”—that is, you have an extension pkg.ext, and you want the compiled extension file (ext.so on Unix, say) to be put in the same source directory as your pure Python modules pkg.mod1 and pkg.mod2.
You can always use the `--inplace` option on the command-line to ensure this:

```
python setup.py build_ext --inplace
```

But this requires that you always specify the `build_ext` command explicitly, and remember to provide `--inplace`. An easier way is to “set and forget” this option, by encoding it in `setup.cfg`, the configuration file for this distribution:

```
[build_ext]
inplace=1
```

This will affect all builds of this module distribution, whether or not you explicitly specify `build_ext`. If you include `setup.cfg` in your source distribution, it will also affect end-user builds—which is probably a bad idea for this option, since always building extensions in-place would break installation of the module distribution. In certain peculiar cases, though, modules are built right in their installation directory, so this is conceivably a useful ability. (Distributing extensions that expect to be built in their installation directory is almost always a bad idea, though.)

Another example: certain commands take a lot of options that don’t change from run to run; for example, `bdist rpm` needs to know everything required to generate a “spec” file for creating an RPM distribution. Some of this information comes from the setup script, and some is automatically generated by the Distutils (such as the list of files installed). But some of it has to be supplied as options to `bdist rpm`, which would be very tedious to do on the command-line for every run. Hence, here is a snippet from the Distutils’ own `setup.cfg`:

```
[bdist_rpm]
```
release = 1
packager = Greg Ward <gward@python.net>
doc_files = CHANGES.txt
          README.txt
          USAGE.txt
doc/
examples/

Note that the `doc_files` option is simply a whitespace-separated string split across multiple lines for readability.

See also:

**Syntax of config files** in “Installing Python Modules”

More information on the configuration files is available in the manual for system administrators.

Footnotes

[1] This ideal probably won’t be achieved until auto-configuration is fully supported by the Distutils.
2. Writing the Setup Script

The setup script is the centre of all activity in building, distributing, and installing modules using the Distutils. The main purpose of the setup script is to describe your module distribution to the Distutils, so that the various commands that operate on your modules do the right thing. As we saw in section *A Simple Example* above, the setup script consists mainly of a call to setup(), and most information supplied to the Distutils by the module developer is supplied as keyword arguments to setup().

Here’s a slightly more involved example, which we’ll follow for the next couple of sections: the Distutils’ own setup script. (Keep in mind that although the Distutils are included with Python 1.6 and later, they also have an independent existence so that Python 1.5.2 users can use them to install other module distributions. The Distutils’ own setup script, shown here, is used to install the package into Python 1.5.2.)

```python
#!/usr/bin/env python

from distutils.core import setup

setup(name='Distutils',
      version='1.0',
      description='Python Distribution Utilities',
      author='Greg Ward',
      author_email='gward@python.net',
      url='http://www.python.org/sigs/distutils-sig/',
      packages=['distutils', 'distutils.command'],
)
```

There are only two differences between this and the trivial one-file
distribution presented in section *A Simple Example*: more metadata, and the specification of pure Python modules by package, rather than by module. This is important since the Distutils consist of a couple of dozen modules split into (so far) two packages; an explicit list of every module would be tedious to generate and difficult to maintain. For more information on the additional meta-data, see section *Additional meta-data*.

Note that any pathnames (files or directories) supplied in the setup script should be written using the Unix convention, i.e. slash-separated. The Distutils will take care of converting this platform-neutral representation into whatever is appropriate on your current platform before actually using the pathname. This makes your setup script portable across operating systems, which of course is one of the major goals of the Distutils. In this spirit, all pathnames in this document are slash-separated.

This, of course, only applies to pathnames given to Distutils functions. If you, for example, use standard Python functions such as `glob.glob()` or `os.listdir()` to specify files, you should be careful to write portable code instead of hardcoding path separators:

```python
glob.glob(os.path.join('mydir', 'subdir', '*.html'))
os.listdir(os.path.join('mydir', 'subdir'))
```
2.1. Listing whole packages

The *packages* option tells the Distutils to process (build, distribute, install, etc.) all pure Python modules found in each package mentioned in the *packages* list. In order to do this, of course, there has to be a correspondence between package names and directories in the filesystem. The default correspondence is the most obvious one, i.e. package *distutils* is found in the directory *distutils* relative to the distribution root. Thus, when you say `packages = ['foo']` in your setup script, you are promising that the Distutils will find a file `foo/__init__.py` (which might be spelled differently on your system, but you get the idea) relative to the directory where your setup script lives. If you break this promise, the Distutils will issue a warning but still process the broken package anyway.

If you use a different convention to lay out your source directory, that's no problem: you just have to supply the *package_dir* option to tell the Distutils about your convention. For example, say you keep all Python source under *lib*, so that modules in the “root package” (i.e., not in any package at all) are in *lib*, modules in the *foo* package are in *lib/foo*, and so forth. Then you would put

```
package_dir = {'': 'lib'}
```

in your setup script. The keys to this dictionary are package names, and an empty package name stands for the root package. The values are directory names relative to your distribution root. In this case, when you say `packages = ['foo']`, you are promising that the file *lib/foo/__init__.py* exists.

Another possible convention is to put the *foo* package right in *lib*,
the foo.bar package in lib/bar, etc. This would be written in the setup script as

```python
package_dir = {'foo': 'lib'}
```

A package: dir entry in the package_dir dictionary implicitly applies to all packages below package, so the foo.bar case is automatically handled here. In this example, having `packages = ['foo', 'foo.bar']` tells the Distutils to look for lib/__init__.py and lib/bar/__init__.py. (Keep in mind that although package_dir applies recursively, you must explicitly list all packages in packages: the Distutils will not recursively scan your source tree looking for any directory with an __init__.py file.)
2.2. Listing individual modules

For a small module distribution, you might prefer to list all modules rather than listing packages—especially the case of a single module that goes in the “root package” (i.e., no package at all). This simplest case was shown in section *A Simple Example*; here is a slightly more involved example:

```python
pymodules = ['mod1', 'pkg.mod2']
```

This describes two modules, one of them in the “root” package, the other in the pkg package. Again, the default package/directory layout implies that these two modules can be found in `mod1.py` and `pkg/mod2.py`, and that `pkg/__init__.py` exists as well. And again, you can override the package/directory correspondence using the `package_dir` option.
2.3. Describing extension modules

Just as writing Python extension modules is a bit more complicated than writing pure Python modules, describing them to the Distutils is a bit more complicated. Unlike pure modules, it’s not enough just to list modules or packages and expect the Distutils to go out and find the right files; you have to specify the extension name, source file(s), and any compile/link requirements (include directories, libraries to link with, etc.).

All of this is done through another keyword argument to setup(), the `ext_modules` option. `ext_modules` is just a list of `Extension` instances, each of which describes a single extension module. Suppose your distribution includes a single extension, called `foo` and implemented by `foo.c`. If no additional instructions to the compiler/linker are needed, describing this extension is quite simple:

```python
Extension('foo', ['foo.c'])
```

The `Extension` class can be imported from `distutils.core` along with `setup()`. Thus, the setup script for a module distribution that contains only this one extension and nothing else might be:

```python
from distutils.core import setup, Extension
setup(name='foo',
      version='1.0',
      ext_modules=[Extension('foo', ['foo.c'])],
```

The `Extension` class (actually, the underlying extension-building machinery implemented by the `build_ext` command) supports a great deal of flexibility in describing Python extensions, which is explained in
2.3.1. Extension names and packages

The first argument to the `Extension` constructor is always the name of the extension, including any package names. For example,

```python
Extension('foo', ['src/foo1.c', 'src/foo2.c'])
```

describes an extension that lives in the root package, while

```python
Extension('pkg.foo', ['src/foo1.c', 'src/foo2.c'])
```

describes the same extension in the pkg package. The source files and resulting object code are identical in both cases; the only difference is where in the filesystem (and therefore where in Python’s namespace hierarchy) the resulting extension lives.

If you have a number of extensions all in the same package (or all under the same base package), use the `ext_package` keyword argument to `setup()`. For example,

```python
setup(...,
    ext_package='pkg',
    ext_modules=[
        Extension('foo', ['foo.c']),
        Extension('subpkg.bar', ['bar.c'])
    ]
)
```

will compile `foo.c` to the extension `pkg.foo`, and `bar.c` to `pkg.subpkg.bar`.

2.3.2. Extension source files
The second argument to the `Extension` constructor is a list of source files. Since the Distutils currently only support C, C++, and Objective-C extensions, these are normally C/C++/Objective-C source files. (Be sure to use appropriate extensions to distinguish C++ source files: `.cc` and `.cpp` seem to be recognized by both Unix and Windows compilers.)

However, you can also include SWIG interface (.i) files in the list; the `build_ext` command knows how to deal with SWIG extensions: it will run SWIG on the interface file and compile the resulting C/C++ file into your extension.

This warning notwithstanding, options to SWIG can be currently passed like this:

```python
setup(...,
    ext_modules=[Extension('_foo', ['foo.i'],
        swig_opts=['-modern', ''],
        py_modules=['foo'],
    )
```

Or on the commandline like this:

```bash
> python setup.py build_ext --swig-opts="-modern -I.."
```

On some platforms, you can include non-source files that are processed by the compiler and included in your extension. Currently, this just means Windows message text (.mc) files and resource definition (.rc) files for Visual C++. These will be compiled to binary resource (.res) files and linked into the executable.

### 2.3.3. Preprocessor options
Three optional arguments to `Extension` will help if you need to specify include directories to search or preprocessor macros to define/undefine: `include_dirs`, `define_macros`, and `undef_macros`.

For example, if your extension requires header files in the `include` directory under your distribution root, use the `include_dirs` option:

```python
Extension('foo', ['foo.c'], include_dirs=['include'])
```

You can specify absolute directories there; if you know that your extension will only be built on Unix systems with X11R6 installed to `/usr`, you can get away with

```python
Extension('foo', ['foo.c'], include_dirs=['/usr/include'])
```

You should avoid this sort of non-portable usage if you plan to distribute your code: it's probably better to write C code like

```c
#include <X11/Xlib.h>
```

If you need to include header files from some other Python extension, you can take advantage of the fact that header files are installed in a consistent way by the Distutils `install_headers` command. For example, the Numerical Python header files are installed (on a standard Unix installation) to `/usr/local/include/python1.5/Numerical`. (The exact location will differ according to your platform and Python installation.) Since the Python include directory — `/usr/local/include/python1.5` in this case—is always
included in the search path when building Python extensions, the best approach is to write C code like

```
#include <Numerical/arrayobject.h>
```

If you must put the `Numerical` include directory right into your header search path, though, you can find that directory using the Distutils `distutils.sysconfig` module:

```
from distutils.sysconfig import get_python_inc
incdir = os.path.join(get_python_inc(plat_specific=1),
setup(...,
    Extension(..., include_dirs=[incdir]),
)
```

Even though this is quite portable—it will work on any Python installation, regardless of platform—it’s probably easier to just write your C code in the sensible way.

You can define and undefine pre-processor macros with the `define_macros` and `undef_macros` options. `define_macros` takes a list of `(name, value)` tuples, where name is the name of the macro to define (a string) and value is its value: either a string or `None`. (Defining a macro `F00` to `None` is the equivalent of a bare `#define F00` in your C source: with most compilers, this sets `F00` to the string `1`.) `undef_macros` is just a list of macros to undefine.

For example:

```
Extension(...,
    define_macros=[('NDEBUG', '1'),
                  ('HAVE_STRFTIME', None)],
    undef_macros=['HAVE_FOO', 'HAVE_BAR'])
```
is the equivalent of having this at the top of every C source file:

```
#define NDEBUG 1
#define HAVE_STRFTIME
#undef HAVE_FOO
#undef HAVE_BAR
```

2.3.4. Library options

You can also specify the libraries to link against when building your extension, and the directories to search for those libraries. The `libraries` option is a list of libraries to link against, `library_dirs` is a list of directories to search for libraries at link-time, and `runtime_library_dirs` is a list of directories to search for shared (dynamically loaded) libraries at run-time.

For example, if you need to link against libraries known to be in the standard library search path on target systems

```
Extension(...,
    libraries=['gdbm', 'readline'])
```

If you need to link with libraries in a non-standard location, you'll have to include the location in `library_dirs`:

```
Extension(...,
    library_dirs=['/usr/X11R6/lib'],
    libraries=['X11', 'Xt'])
```

(Again, this sort of non-portable construct should be avoided if you intend to distribute your code.)

2.3.5. Other options
There are still some other options which can be used to handle special cases.

The *optional* option is a boolean; if it is true, a build failure in the extension will not abort the build process, but instead simply not install the failing extension.

The *extra_objects* option is a list of object files to be passed to the linker. These files must not have extensions, as the default extension for the compiler is used.

*extra_compile_args* and *extra_link_args* can be used to specify additional command line options for the respective compiler and linker command lines.

*export_symbols* is only useful on Windows. It can contain a list of symbols (functions or variables) to be exported. This option is not needed when building compiled extensions: Distutils will automatically add *initmodule* to the list of exported symbols.

The *depends* option is a list of files that the extension depends on (for example header files). The build command will call the compiler on the sources to rebuild extension if any on this files has been modified since the previous build.
2.4. Relationships between Distributions and Packages

A distribution may relate to packages in three specific ways:

1. It can require packages or modules.
2. It can provide packages or modules.
3. It can obsolete packages or modules.

These relationships can be specified using keyword arguments to the `distutils.core.setup()` function.

Dependencies on other Python modules and packages can be specified by supplying the `requires` keyword argument to `setup()`. The value must be a list of strings. Each string specifies a package that is required, and optionally what versions are sufficient.

To specify that any version of a module or package is required, the string should consist entirely of the module or package name. Examples include `mymodule` and `xml.parsers.expat`.

If specific versions are required, a sequence of qualifiers can be supplied in parentheses. Each qualifier may consist of a comparison operator and a version number. The accepted comparison operators are:

```
< > == <= >= !=
```

These can be combined by using multiple qualifiers separated by commas (and optional whitespace). In this case, all of the qualifiers must be matched; a logical AND is used to combine the evaluations.
Let's look at a bunch of examples:

<table>
<thead>
<tr>
<th>Requires Expression</th>
<th>Explanation</th>
</tr>
</thead>
<tbody>
<tr>
<td>==1.0</td>
<td>Only version 1.0 is compatible</td>
</tr>
<tr>
<td>&gt;1.0, !=1.5.1, &lt;2.0</td>
<td>Any version after 1.0 and before 2.0 is compatible, except 1.5.1</td>
</tr>
</tbody>
</table>

Now that we can specify dependencies, we also need to be able to specify what we provide that other distributions can require. This is done using the `provides` keyword argument to `setup()`. The value for this keyword is a list of strings, each of which names a Python module or package, and optionally identifies the version. If the version is not specified, it is assumed to match that of the distribution.

Some examples:

<table>
<thead>
<tr>
<th>Provides Expression</th>
<th>Explanation</th>
</tr>
</thead>
<tbody>
<tr>
<td>mypkg</td>
<td>Provide mypkg, using the distribution version</td>
</tr>
<tr>
<td>mypkg (1.1)</td>
<td>Provide mypkg version 1.1, regardless of the distribution version</td>
</tr>
</tbody>
</table>

A package can declare that it obsoletes other packages using the `obsoletes` keyword argument. The value for this is similar to that of the `requires` keyword: a list of strings giving module or package specifiers. Each specifier consists of a module or package name optionally followed by one or more version qualifiers. Version qualifiers are given in parentheses after the module or package name.

The versions identified by the qualifiers are those that are obsoleted by the distribution being described. If no qualifiers are given, all
versions of the named module or package are understood to be obsoleted.
2.5. Installing Scripts

So far we have been dealing with pure and non-pure Python modules, which are usually not run by themselves but imported by scripts.

Scripts are files containing Python source code, intended to be started from the command line. Scripts don’t require Distutils to do anything very complicated. The only clever feature is that if the first line of the script starts with `#!` and contains the word “python”, the Distutils will adjust the first line to refer to the current interpreter location. By default, it is replaced with the current interpreter location. The `--executable` (or `-e`) option will allow the interpreter path to be explicitly overridden.

The `scripts` option simply is a list of files to be handled in this way. From the PyXML setup script:

```python
setup(...,
    scripts=['scripts/xmlproc_parse', 'scripts/xmlproc_val'],
)
```

*Changed in version 3.1:* All the scripts will also be added to the `MANIFEST` file if no template is provided. See *Specifying the files to distribute.*
2.6. Installing Package Data

Often, additional files need to be installed into a package. These files are often data that's closely related to the package's implementation, or text files containing documentation that might be of interest to programmers using the package. These files are called *package data*.

Package data can be added to packages using the `package_data` keyword argument to the `setup()` function. The value must be a mapping from package name to a list of relative path names that should be copied into the package. The paths are interpreted as relative to the directory containing the package (information from the `package_dir` mapping is used if appropriate); that is, the files are expected to be part of the package in the source directories. They may contain glob patterns as well.

The path names may contain directory portions; any necessary directories will be created in the installation.

For example, if a package should contain a subdirectory with several data files, the files can be arranged like this in the source tree:

```
setup.py
src/
  mypkg/
    __init__.py
    module.py
  data/
    tables.dat
    spoons.dat
    forks.dat
```

The corresponding call to `setup()` might be:
setup(...,
    packages=['mypkg'],
    package_dir={'mypkg': 'src/mypkg'},
    package_data={'mypkg': ['data/*.dat']},
)

*Changed in version 3.1:* All the files that match `package_data` will be added to the `MANIFEST` file if no template is provided. See *Specifying the files to distribute.*
2.7. Installing Additional Files

The `data_files` option can be used to specify additional files needed by the module distribution: configuration files, message catalogs, data files, anything which doesn’t fit in the previous categories.

`data_files` specifies a sequence of `(directory, files)` pairs in the following way:

```python
setup(...,
    data_files=[('bitmaps', ['bm/b1.gif', 'bm/b2.gif']),
                ('config', ['cfg/data.cfg']),
                ('/etc/init.d', ['init-script'])]
)
```

Note that you can specify the directory names where the data files will be installed, but you cannot rename the data files themselves.

Each `(directory, files)` pair in the sequence specifies the installation directory and the files to install there. If `directory` is a relative path, it is interpreted relative to the installation prefix (Python’s `sys.prefix` for pure-Python packages, `sys.exec_prefix` for packages that contain extension modules). Each file name in `files` is interpreted relative to the `setup.py` script at the top of the package source distribution. No directory information from `files` is used to determine the final location of the installed file; only the name of the file is used.

You can specify the `data_files` options as a simple sequence of files without specifying a target directory, but this is not recommended, and the `install` command will print a warning in this case. To install data files directly in the target directory, an empty string should be given as the directory.
Changed in version 3.1: All the files that match `data_files` will be added to the MANIFEST file if no template is provided. See *Specifying the files to distribute*. 
## 2.8. Additional meta-data

The setup script may include additional meta-data beyond the name and version. This information includes:

<table>
<thead>
<tr>
<th>Meta-Data</th>
<th>Description</th>
<th>Value</th>
<th>Notes</th>
</tr>
</thead>
<tbody>
<tr>
<td><code>name</code></td>
<td>name of the package</td>
<td>short string</td>
<td>(1)</td>
</tr>
<tr>
<td><code>version</code></td>
<td>version of this release</td>
<td>short string</td>
<td>(1)(2)</td>
</tr>
<tr>
<td><code>author</code></td>
<td>package author's name</td>
<td>short string</td>
<td>(3)</td>
</tr>
<tr>
<td><code>author_email</code></td>
<td>email address of the package author</td>
<td>email address</td>
<td>(3)</td>
</tr>
<tr>
<td><code>maintainer</code></td>
<td>package maintainer’s name</td>
<td>short string</td>
<td>(3)</td>
</tr>
<tr>
<td><code>maintainer_email</code></td>
<td>email address of the package maintainer</td>
<td>email address</td>
<td>(3)</td>
</tr>
<tr>
<td><code>url</code></td>
<td>home page for the package</td>
<td>URL</td>
<td>(1)</td>
</tr>
<tr>
<td><code>description</code></td>
<td>short, summary description of the package</td>
<td>short string</td>
<td></td>
</tr>
<tr>
<td><code>long_description</code></td>
<td>longer description of the package</td>
<td>long string</td>
<td>(5)</td>
</tr>
<tr>
<td><code>download_url</code></td>
<td>location where the package may be downloaded</td>
<td>URL</td>
<td>(4)</td>
</tr>
<tr>
<td><code>classifiers</code></td>
<td>a list of classifiers</td>
<td>list of strings</td>
<td>(4)</td>
</tr>
<tr>
<td>platforms</td>
<td>a list of platforms</td>
<td>list of strings</td>
<td></td>
</tr>
<tr>
<td>-----------</td>
<td>---------------------</td>
<td>----------------</td>
<td></td>
</tr>
<tr>
<td>license</td>
<td>license for the package</td>
<td>short string</td>
<td></td>
</tr>
</tbody>
</table>

Notes:

1. These fields are required.
2. It is recommended that versions take the form `major.minor[.patch[.sub]]`.
3. Either the author or the maintainer must be identified. If maintainer is provided, distutils lists it as the author in `PKG-INFO`.
4. These fields should not be used if your package is to be compatible with Python versions prior to 2.2.3 or 2.3. The list is available from the PyPI website.
5. The `long_description` field is used by PyPI when you are registering a package, to build its home page.
6. The `license` field is a text indicating the license covering the package where the license is not a selection from the “License” Trove classifiers. See the Classifier field. Notice that there's a `licence` distribution option which is deprecated but still acts as an alias for `license`.

‘short string’
A single line of text, not more than 200 characters.

‘long string’
Multiple lines of plain text in reStructuredText format (see http://docutils.sf.net/).

‘list of strings’
See below.

Encoding the version information is an art in itself. Python packages generally adhere to the version format `major.minor[.patch][sub]`. The
major number is 0 for initial, experimental releases of software. It is incremented for releases that represent major milestones in a package. The minor number is incremented when important new features are added to the package. The patch number increments when bug-fix releases are made. Additional trailing version information is sometimes used to indicate sub-releases. These are “a1,a2,...,aN” (for alpha releases, where functionality and API may change), “b1,b2,...,bN” (for beta releases, which only fix bugs) and “pr1,pr2,...,prN” (for final pre-release release testing). Some examples:

0.1.0
    the first, experimental release of a package
1.0.1a2
    the second alpha release of the first patch version of 1.0

classifiers are specified in a Python list:

```python
setup(...,
    classifiers=[
        'Development Status :: 4 - Beta',
        'Environment :: Console',
        'Environment :: Web Environment',
        'Intended Audience :: End Users/Desktop',
        'Intended Audience :: Developers',
        'Intended Audience :: System Administrators',
        'License :: OSI Approved :: Python Software Foundation License',
        'Operating System :: MacOS :: MacOS X',
        'Operating System :: Microsoft :: Windows',
        'Operating System :: POSIX',
        'Programming Language :: Python',
        'Topic :: Communications :: Email',
        'Topic :: Office/Business',
        'Topic :: Software Development :: Bug Tracking',
    ],
)```
If you wish to include classifiers in your `setup.py` file and also wish to remain backwards-compatible with Python releases prior to 2.2.3, then you can include the following code fragment in your `setup.py` before the `setup()` call.

```python
# patch distutils if it can't cope with the "classifiers" or "download_url" keywords
from sys import version
if version < '2.2.3':
    from distutils.dist import DistributionMetadata
    DistributionMetadata.classifiers = None
    DistributionMetadata.download_url = None
```
2.9. Debugging the setup script

Sometimes things go wrong, and the setup script doesn’t do what the developer wants.

Distutils catches any exceptions when running the setup script, and print a simple error message before the script is terminated. The motivation for this behaviour is to not confuse administrators who don’t know much about Python and are trying to install a package. If they get a big long traceback from deep inside the guts of Distutils, they may think the package or the Python installation is broken because they don’t read all the way down to the bottom and see that it’s a permission problem.

On the other hand, this doesn’t help the developer to find the cause of the failure. For this purpose, the DISTUTILS_DEBUG environment variable can be set to anything except an empty string, and distutils will now print detailed information about what it is doing, dump the full traceback when an exception occurs, and print the whole command line when an external program (like a C compiler) fails.
1. An Introduction to Distutils

This document covers using the Distutils to distribute your Python modules, concentrating on the role of developer/distributor: if you're looking for information on installing Python modules, you should refer to the *Installing Python Modules (Legacy version)* chapter.
1.1. Concepts & Terminology

Using the Distutils is quite simple, both for module developers and for users/administrators installing third-party modules. As a developer, your responsibilities (apart from writing solid, well-documented and well-tested code, of course!) are:

- write a setup script (*setup.py* by convention)
- (optional) write a setup configuration file
- create a source distribution
- (optional) create one or more built (binary) distributions

Each of these tasks is covered in this document.

Not all module developers have access to a multitude of platforms, so it's not always feasible to expect them to create a multitude of built distributions. It is hoped that a class of intermediaries, called *packagers*, will arise to address this need. Packagers will take source distributions released by module developers, build them on one or more platforms, and release the resulting built distributions. Thus, users on the most popular platforms will be able to install most popular Python module distributions in the most natural way for their platform, without having to run a single setup script or compile a line of code.
1.2. A Simple Example

The setup script is usually quite simple, although since it's written in Python, there are no arbitrary limits to what you can do with it, though you should be careful about putting arbitrarily expensive operations in your setup script. Unlike, say, Autoconf-style configure scripts, the setup script may be run multiple times in the course of building and installing your module distribution.

If all you want to do is distribute a module called foo, contained in a file foo.py, then your setup script can be as simple as this:

```python
from distutils.core import setup
setup(name='foo',
      version='1.0',
      py_modules=['foo'],
)
```

Some observations:

- most information that you supply to the Distutils is supplied as keyword arguments to the `setup()` function
- those keyword arguments fall into two categories: package metadata (name, version number) and information about what's in the package (a list of pure Python modules, in this case)
- modules are specified by module name, not filename (the same will hold true for packages and extensions)
- it's recommended that you supply a little more metadata, in particular your name, email address and a URL for the project (see section *Writing the Setup Script* for an example)

To create a source distribution for this module, you would create a setup script, `setup.py`, containing the above code, and run this
command from a terminal:

```
python setup.py sdist
```

For Windows, open a command prompt window (Start ➤ Accessories) and change the command to:

```
setup.py sdist
```

`sdist` will create an archive file (e.g., tarball on Unix, ZIP file on Windows) containing your setup script `setup.py`, and your module `foo.py`. The archive file will be named `foo-1.0.tar.gz` (or `.zip`), and will unpack into a directory `foo-1.0`.

If an end-user wishes to install your `foo` module, all she has to do is download `foo-1.0.tar.gz` (or `.zip`), unpack it, and—from the `foo-1.0` directory—run

```
python setup.py install
```

which will ultimately copy `foo.py` to the appropriate directory for third-party modules in their Python installation.

This simple example demonstrates some fundamental concepts of the Distutils. First, both developers and installers have the same basic user interface, i.e. the setup script. The difference is which Distutils commands they use: the `sdist` command is almost exclusively for module developers, while `install` is more often for installers (although most developers will want to install their own code occasionally).

If you want to make things really easy for your users, you can create one or more built distributions for them. For instance, if you are running on a Windows machine, and want to make things easy for
other Windows users, you can create an executable installer (the most appropriate type of built distribution for this platform) with the `bdist_wininst` command. For example:

```
python setup.py bdist_wininst
```

will create an executable installer, `foo-1.0.win32.exe`, in the current directory.

Other useful built distribution formats are RPM, implemented by the `bdist_rpm` command, Solaris `pkgtool` (`bdist_pkgtool`), and HP-UX `swinstall` (`bdist_sdux`). For example, the following command will create an RPM file called `foo-1.0.noarch.rpm`:

```
python setup.py bdist_rpm
```

(The `bdist_rpm` command uses the `rpm` executable, therefore this has to be run on an RPM-based system such as Red Hat Linux, SuSE Linux, or Mandrake Linux.)

You can find out what distribution formats are available at any time by running

```
python setup.py bdist --help-formats
```
1.3. General Python terminology

If you’re reading this document, you probably have a good idea of what modules, extensions, and so forth are. Nevertheless, just to be sure that everyone is operating from a common starting point, we offer the following glossary of common Python terms:

module
   the basic unit of code reusability in Python: a block of code imported by some other code. Three types of modules concern us here: pure Python modules, extension modules, and packages.

pure Python module
   a module written in Python and contained in a single .py file (and possibly associated .pyc and/or .pyo files). Sometimes referred to as a “pure module.”

extension module
   a module written in the low-level language of the Python implementation: C/C++ for Python, Java for Jython. Typically contained in a single dynamically loadable pre-compiled file, e.g. a shared object (.so) file for Python extensions on Unix, a DLL (given the .pyd extension) for Python extensions on Windows, or a Java class file for Jython extensions. (Note that currently, the Distutils only handles C/C++ extensions for Python.)

package
   a module that contains other modules; typically contained in a directory in the filesystem and distinguished from other directories by the presence of a file __init__.py.

root package
   the root of the hierarchy of packages. (This isn’t really a package, since it doesn’t have an __init__.py file. But we have to call it something.) The vast majority of the standard library is in the root
package, as are many small, standalone third-party modules that don't belong to a larger module collection. Unlike regular packages, modules in the root package can be found in many directories: in fact, every directory listed in \texttt{sys.path} contributes modules to the root package.
1.4. Distutils-specific terminology

The following terms apply more specifically to the domain of distributing Python modules using the Distutils:

module distribution
  a collection of Python modules distributed together as a single downloadable resource and meant to be installed en masse. Examples of some well-known module distributions are NumPy, SciPy, PIL (the Python Imaging Library), or mxBase. (This would be called a package, except that term is already taken in the Python context: a single module distribution may contain zero, one, or many Python packages.)

pure module distribution
  a module distribution that contains only pure Python modules and packages. Sometimes referred to as a “pure distribution.”

non-pure module distribution
  a module distribution that contains at least one extension module. Sometimes referred to as a “non-pure distribution.”

distribution root
  the top-level directory of your source tree (or source distribution); the directory where setup.py exists. Generally setup.py will be run from this directory.
4. Creating a Source Distribution

As shown in section *A Simple Example*, you use the `sdist` command to create a source distribution. In the simplest case,

```
python setup.py sdist
```

(assuming you haven’t specified any `sdist` options in the setup script or config file), `sdist` creates the archive of the default format for the current platform. The default format is a gzip’ed tar file (`.tar.gz`) on Unix, and ZIP file on Windows.

You can specify as many formats as you like using the `--formats` option, for example:

```
python setup.py sdist --formats=gztar,zip
```

to create a gzipped tarball and a zip file. The available formats are:

<table>
<thead>
<tr>
<th>Format</th>
<th>Description</th>
<th>Notes</th>
</tr>
</thead>
<tbody>
<tr>
<td>zip</td>
<td>zip file (.zip)</td>
<td>(1),(3)</td>
</tr>
<tr>
<td>gztar</td>
<td>gzip’ed tar file (.tar.gz)</td>
<td>(2)</td>
</tr>
<tr>
<td>bztar</td>
<td>bzip2’ed tar file (.tar.bz2)</td>
<td></td>
</tr>
<tr>
<td>ztar</td>
<td>compressed tar file (.tar.Z)</td>
<td>(4)</td>
</tr>
<tr>
<td>tar</td>
<td>tar file (.tar)</td>
<td></td>
</tr>
</tbody>
</table>

Notes:

1. default on Windows
2. default on Unix
3. requires either external `zip` utility or `zipfile` module (part of the standard Python library since Python 1.6)
4. requires the `compress` program. Notice that this format is now pending for deprecation and will be removed in the future versions of Python.

When using any `tar` format (gztar, bztar, ztar or tar), under Unix you can specify the owner and group names that will be set for each member of the archive.

For example, if you want all files of the archive to be owned by root:

```
python setup.py sdist --owner=root --group=root
```
4.1. Specifying the files to distribute

If you don’t supply an explicit list of files (or instructions on how to generate one), the `sdist` command puts a minimal default set into the source distribution:

- all Python source files implied by the `py_modules` and `packages` options
- all C source files mentioned in the `ext_modules` or `libraries` options
- scripts identified by the `scripts` option See `Installing Scripts`.
- anything that looks like a test script: `test/test*.py` (currently, the Distutils don’t do anything with test scripts except include them in source distributions, but in the future there will be a standard for testing Python module distributions)
- `README.txt` (or `README`), `setup.py` (or whatever you called your setup script), and `setup.cfg`
- all files that matches the `package_data` metadata. See `Installing Package Data`.
- all files that matches the `data_files` metadata. See `Installing Additional Files`.

Sometimes this is enough, but usually you will want to specify additional files to distribute. The typical way to do this is to write a manifest template, called `MANIFEST.in` by default. The manifest template is just a list of instructions for how to generate your manifest file, `MANIFEST`, which is the exact list of files to include in your source distribution. The `sdist` command processes this template and generates a manifest based on its instructions and what it finds in the filesystem.

If you prefer to roll your own manifest file, the format is simple: one
filename per line, regular files (or symlinks to them) only. If you do supply your own MANIFEST, you must specify everything: the default set of files described above does not apply in this case.

*Changed in version 3.1:* An existing generated MANIFEST will be regenerated without `sdist` comparing its modification time to the one of MANIFEST.in or setup.py.

*Changed in version 3.1.3:* MANIFEST files start with a comment indicating they are generated. Files without this comment are not overwritten or removed.

*Changed in version 3.2.2:* `sdist` will read a MANIFEST file if no MANIFEST.in exists, like it used to do.

The manifest template has one command per line, where each command specifies a set of files to include or exclude from the source distribution. For an example, again we turn to the Distutils' own manifest template:

```
include *.txt
recursive-include examples *.txt *.py
prune examples/sample?/build
```

The meanings should be fairly clear: include all files in the distribution root matching `*.txt`, all files anywhere under the examples directory matching `*.txt` or `*.py`, and exclude all directories matching examples/sample?/build. All of this is done *after* the standard include set, so you can exclude files from the standard set with explicit instructions in the manifest template. (Or, you can use the `--no-defaults` option to disable the standard set entirely.) There are several other commands available in the manifest template mini-language; see section *Creating a source distribution: the sdist*
command.

The order of commands in the manifest template matters: initially, we have the list of default files as described above, and each command in the template adds to or removes from that list of files. Once we have fully processed the manifest template, we remove files that should not be included in the source distribution:

- all files in the Distutils “build” tree (default build/)
- all files in directories named RCS, CVS, .svn, .hg, .git, .bzr or _darcs

Now we have our complete list of files, which is written to the manifest for future reference, and then used to build the source distribution archive(s).

You can disable the default set of included files with the --no-defaults option, and you can disable the standard exclude set with --no-prune.

Following the Distutils' own manifest template, let's trace how the sdist command builds the list of files to include in the Distutils source distribution:

1. include all Python source files in the distutils and distutils/command subdirectories (because packages corresponding to those two directories were mentioned in the packages option in the setup script—see section Writing the Setup Script)
2. include README.txt, setup.py, and setup.cfg (standard files)
3. include test/test*.py (standard files)
4. include *.txt in the distribution root (this will find README.txt a second time, but such redundancies are weeded out later)
5. include anything matching *.txt or *.py in the sub-tree under
examples,
6. exclude all files in the sub-trees starting at directories matching examples/sample/*/build—this may exclude files included by the previous two steps, so it's important that the prune command in the manifest template comes after the recursive-inlude command
7. exclude the entire build tree, and any RCS, CVS, .svn, .hg, .git, .bzr and _darcs directories

Just like in the setup script, file and directory names in the manifest template should always be slash-separated; the Distutils will take care of converting them to the standard representation on your platform. That way, the manifest template is portable across operating systems.
4.2. Manifest-related options

The normal course of operations for the `sdist` command is as follows:

- if the manifest file (MANIFEST by default) exists and the first line does not have a comment indicating it is generated from MANIFEST.in, then it is used as is, unaltered
- if the manifest file doesn't exist or has been previously automatically generated, read `MANIFEST.in` and create the manifest
- if neither MANIFEST nor MANIFEST.in exist, create a manifest with just the default file set
- use the list of files now in MANIFEST (either just generated or read in) to create the source distribution archive(s)

There are a couple of options that modify this behaviour. First, use the `--no-defaults` and `--no-prune` to disable the standard “include” and “exclude” sets.

Second, you might just want to (re)generate the manifest, but not create a source distribution:

```
python setup.py sdist --manifest-only
```

-o is a shortcut for `--manifest-only`. 
5. Creating Built Distributions

A “built distribution” is what you’re probably used to thinking of either as a “binary package” or an “installer” (depending on your background). It’s not necessarily binary, though, because it might contain only Python source code and/or byte-code; and we don’t call it a package, because that word is already spoken for in Python. (And “installer” is a term specific to the world of mainstream desktop systems.)

A built distribution is how you make life as easy as possible for installers of your module distribution: for users of RPM-based Linux systems, it’s a binary RPM; for Windows users, it’s an executable installer; for Debian-based Linux users, it’s a Debian package; and so forth. Obviously, no one person will be able to create built distributions for every platform under the sun, so the Distutils are designed to enable module developers to concentrate on their specialty—writing code and creating source distributions—while an intermediary species called packagers springs up to turn source distributions into built distributions for as many platforms as there are packagers.

Of course, the module developer could be his own packager; or the packager could be a volunteer “out there” somewhere who has access to a platform which the original developer does not; or it could be software periodically grabbing new source distributions and turning them into built distributions for as many platforms as the software has access to. Regardless of who they are, a packager uses the setup script and the bdist command family to generate built distributions.

As a simple example, if I run the following command in the Distutils source tree:
python setup.py bdist

then the Distutils builds my module distribution (the Distutils itself in this case), does a “fake” installation (also in the build directory), and creates the default type of built distribution for my platform. The default format for built distributions is a “dumb” tar file on Unix, and a simple executable installer on Windows. (That tar file is considered “dumb” because it has to be unpacked in a specific location to work.)

Thus, the above command on a Unix system creates Distutils-1.0.plat.tar.gz; unpacking this tarball from the right place installs the Distutils just as though you had downloaded the source distribution and run python setup.py install. (The “right place” is either the root of the filesystem or Python’s prefix directory, depending on the options given to the bdist_dumb command; the default is to make dumb distributions relative to prefix.)

Obviously, for pure Python distributions, this isn’t any simpler than just running python setup.py install—but for non-pure distributions, which include extensions that would need to be compiled, it can mean the difference between someone being able to use your extensions or not. And creating “smart” built distributions, such as an RPM package or an executable installer for Windows, is far more convenient for users even if your distribution doesn’t include any extensions.

The bdist command has a --formats option, similar to the sdist command, which you can use to select the types of built distribution to generate: for example,

python setup.py bdist --format=zip
would, when run on a Unix system, create `Distutils-1.0 plat.zip`—again, this archive would be unpacked from the root directory to install the Distutils.

The available formats for built distributions are:

<table>
<thead>
<tr>
<th>Format</th>
<th>Description</th>
<th>Notes</th>
</tr>
</thead>
<tbody>
<tr>
<td>gztar</td>
<td>gzipped tar file (.tar.gz)</td>
<td>(1),(3)</td>
</tr>
<tr>
<td>ztar</td>
<td>compressed tar file (.tar.Z)</td>
<td>(3)</td>
</tr>
<tr>
<td>tar</td>
<td>tar file (.tar)</td>
<td>(3)</td>
</tr>
<tr>
<td>zip</td>
<td>zip file (.zip)</td>
<td>(2),(4)</td>
</tr>
<tr>
<td>rpm</td>
<td>RPM</td>
<td>(5)</td>
</tr>
<tr>
<td>pkgtool</td>
<td>Solaris pkgtool</td>
<td></td>
</tr>
<tr>
<td>sdux</td>
<td>HP-UX swinstall</td>
<td></td>
</tr>
<tr>
<td>wininst</td>
<td>self-extracting ZIP file for Windows</td>
<td>(4)</td>
</tr>
<tr>
<td>msi</td>
<td>Microsoft Installer.</td>
<td></td>
</tr>
</tbody>
</table>

Notes:

1. default on Unix
2. default on Windows
3. requires external utilities: `tar` and possibly one of `gzip`, `bzip2`, or `compress`
4. requires either external `zip` utility or `zipfile` module (part of the standard Python library since Python 1.6)
5. requires external `rpm` utility, version 3.0.4 or better (use `rpm --version` to find out which version you have)

You don’t have to use the `bdist` command with the `--formats` option; you can also use the command that directly implements the format
you're interested in. Some of these **bdist** “sub-commands” actually generate several similar formats; for instance, the **bdist_dumb** command generates all the “dumb” archive formats (tar, ztar, gztar, and zip), and **bdist_rpm** generates both binary and source RPMs. The **bdist** sub-commands, and the formats generated by each, are:

<table>
<thead>
<tr>
<th>Command</th>
<th>Formats</th>
</tr>
</thead>
<tbody>
<tr>
<td><strong>bdist_dumb</strong></td>
<td>tar, ztar, gztar, zip</td>
</tr>
<tr>
<td><strong>bdist_rpm</strong></td>
<td>rpm, srpm</td>
</tr>
<tr>
<td><strong>bdist_wininst</strong></td>
<td>wininst</td>
</tr>
<tr>
<td><strong>bdist_msi</strong></td>
<td>msi</td>
</tr>
</tbody>
</table>

The following sections give details on the individual **bdist_** commands.
5.1. Creating RPM packages

The RPM format is used by many popular Linux distributions, including Red Hat, SuSE, and Mandrake. If one of these (or any of the other RPM-based Linux distributions) is your usual environment, creating RPM packages for other users of that same distribution is trivial. Depending on the complexity of your module distribution and differences between Linux distributions, you may also be able to create RPMs that work on different RPM-based distributions.

The usual way to create an RPM of your module distribution is to run the `bdist_rpm` command:

```
python setup.py bdist_rpm
```

or the `bdist` command with the `--format` option:

```
python setup.py bdist --formats=rpm
```

The former allows you to specify RPM-specific options; the latter allows you to easily specify multiple formats in one run. If you need to do both, you can explicitly specify multiple `bdist_*` commands and their options:

```
python setup.py bdist_rpm --packager="John Doe <jdoe@example.org>
bdist_wininst --target-version="2.0"
```

Creating RPM packages is driven by a `.spec` file, much as using the Distutils is driven by the setup script. To make your life easier, the `bdist_rpm` command normally creates a `.spec` file based on the information you supply in the setup script, on the command line, and in
any Distutils configuration files. Various options and sections in the .spec file are derived from options in the setup script as follows:

<table>
<thead>
<tr>
<th><strong>RPM .spec file option or section</strong></th>
<th><strong>Distutils setup script option</strong></th>
</tr>
</thead>
<tbody>
<tr>
<td>Name</td>
<td>name</td>
</tr>
<tr>
<td>Summary (in preamble)</td>
<td>description</td>
</tr>
<tr>
<td>Version</td>
<td>version</td>
</tr>
<tr>
<td>Vendor</td>
<td>author and author_email, or — &amp; maintainer and maintainer_email</td>
</tr>
<tr>
<td>Copyright</td>
<td>license</td>
</tr>
<tr>
<td>Url</td>
<td>url</td>
</tr>
<tr>
<td>%description (section)</td>
<td>long_description</td>
</tr>
</tbody>
</table>

Additionally, there are many options in .spec files that don’t have corresponding options in the setup script. Most of these are handled through options to the bdist_rpm command as follows:

<table>
<thead>
<tr>
<th><strong>RPM .spec file option or section</strong></th>
<th><strong>bdist_rpm option</strong></th>
<th><strong>default value</strong></th>
</tr>
</thead>
<tbody>
<tr>
<td>Release</td>
<td>release</td>
<td>“1”</td>
</tr>
<tr>
<td>Group</td>
<td>group</td>
<td>“Development/Libraries”</td>
</tr>
<tr>
<td>Vendor</td>
<td>vendor</td>
<td>(see above)</td>
</tr>
<tr>
<td>Packager</td>
<td>packager</td>
<td>(none)</td>
</tr>
<tr>
<td>Provides</td>
<td>provides</td>
<td>(none)</td>
</tr>
<tr>
<td>Requires</td>
<td>requires</td>
<td>(none)</td>
</tr>
<tr>
<td>Conflicts</td>
<td>conflicts</td>
<td>(none)</td>
</tr>
<tr>
<td>Obsoletes</td>
<td>obsoletes</td>
<td>(none)</td>
</tr>
<tr>
<td>Distribution</td>
<td>distribution_name</td>
<td>(none)</td>
</tr>
<tr>
<td>-----------------------</td>
<td>-------------------</td>
<td>--------</td>
</tr>
<tr>
<td>BuildRequires</td>
<td>build_requires</td>
<td>(none)</td>
</tr>
<tr>
<td>Icon</td>
<td>icon</td>
<td>(none)</td>
</tr>
</tbody>
</table>

Obviously, supplying even a few of these options on the command-line would be tedious and error-prone, so it’s usually best to put them in the setup configuration file, `setup.cfg`—see section *Writing the Setup Configuration File*. If you distribute or package many Python module distributions, you might want to put options that apply to all of them in your personal Distutils configuration file (`~/.pydistutils.cfg`). If you want to temporarily disable this file, you can pass the `--no-user-cfg` option to `setup.py`.

There are three steps to building a binary RPM package, all of which are handled automatically by the Distutils:

1. create a `.spec` file, which describes the package (analogous to the Distutils setup script; in fact, much of the information in the setup script winds up in the `.spec` file)
2. create the source RPM
3. create the “binary” RPM (which may or may not contain binary code, depending on whether your module distribution contains Python extensions)

Normally, RPM bundles the last two steps together; when you use the Distutils, all three steps are typically bundled together.

If you wish, you can separate these three steps. You can use the `--spec-only` option to make `bdist_rpm` just create the `.spec` file and exit; in this case, the `.spec` file will be written to the “distribution directory”—normally `dist/`, but customizable with the `--dist-dir` option. (Normally, the `.spec` file winds up deep in the “build tree,” in a
temporary directory created by `bdist_rpm`.)
5.2. Creating Windows Installers

Executable installers are the natural format for binary distributions on Windows. They display a nice graphical user interface, display some information about the module distribution to be installed taken from the metadata in the setup script, let the user select a few options, and start or cancel the installation.

Since the metadata is taken from the setup script, creating Windows installers is usually as easy as running:

```python
python setup.py bdist_wininst
```

or the `bdist` command with the `--formats` option:

```python
python setup.py bdist --formats=wininst
```

If you have a pure module distribution (only containing pure Python modules and packages), the resulting installer will be version independent and have a name like `foo-1.0.win32.exe`. These installers can even be created on Unix platforms or Mac OS X.

If you have a non-pure distribution, the extensions can only be created on a Windows platform, and will be Python version dependent. The installer filename will reflect this and now has the form `foo-1.0.win32-py2.0.exe`. You have to create a separate installer for every Python version you want to support.

The installer will try to compile pure modules into bytecode after installation on the target system in normal and optimizing mode. If you don't want this to happen for some reason, you can run the `bdist_wininst` command with the `--no-target-compile` and/or the `--no-`
target-optimize option.

By default the installer will display the cool “Python Powered” logo when it is run, but you can also supply your own 152x261 bitmap which must be a Windows .bmp file with the --bitmap option.

The installer will also display a large title on the desktop background window when it is run, which is constructed from the name of your distribution and the version number. This can be changed to another text by using the --title option.

The installer file will be written to the “distribution directory” — normally dist/, but customizable with the --dist-dir option.
5.3. Cross-compiling on Windows

Starting with Python 2.6, distutils is capable of cross-compiling between Windows platforms. In practice, this means that with the correct tools installed, you can use a 32bit version of Windows to create 64bit extensions and vice-versa.

To build for an alternate platform, specify the --plat-name option to the build command. Valid values are currently ‘win32’, ‘win-amd64’ and ‘win-ia64’. For example, on a 32bit version of Windows, you could execute:

```
python setup.py build --plat-name=win-amd64
```

to build a 64bit version of your extension. The Windows Installers also support this option, so the command:

```
python setup.py build --plat-name=win-amd64 bdist_wininst
```

would create a 64bit installation executable on your 32bit version of Windows.

To cross-compile, you must download the Python source code and cross-compile Python itself for the platform you are targetting - it is not possible from a binary installation of Python (as the .lib etc file for other platforms are not included.) In practice, this means the user of a 32 bit operating system will need to use Visual Studio 2008 to open the PCBuild/PCbuild.sln solution in the Python source tree and build the “x64” configuration of the ‘pythoncore’ project before cross-compiling extensions is possible.

Note that by default, Visual Studio 2008 does not install 64bit
compilers or tools. You may need to reexecute the Visual Studio setup process and select these tools (using Control Panel->[Add/Remove] Programs is a convenient way to check or modify your existing install.)

5.3.1. The Postinstallation script

Starting with Python 2.3, a postinstallation script can be specified with the `--install-script` option. The basename of the script must be specified, and the script filename must also be listed in the scripts argument to the setup function.

This script will be run at installation time on the target system after all the files have been copied, with `argv[1]` set to `install`, and again at uninstallation time before the files are removed with `argv[1]` set to `remove`.

The installation script runs embedded in the windows installer, every output (sys.stdout, sys.stderr) is redirected into a buffer and will be displayed in the GUI after the script has finished.

Some functions especially useful in this context are available as additional built-in functions in the installation script.

`directory_created(path)`
`file_created(path)`

These functions should be called when a directory or file is created by the postinstall script at installation time. It will register `path` with the uninstaller, so that it will be removed when the distribution is uninstalled. To be safe, directories are only removed if they are empty.

`get_special_folder_path(csidl_string)`
This function can be used to retrieve special folder locations on Windows like the Start Menu or the Desktop. It returns the full path to the folder. *csidl_string* must be one of the following strings:

```
"CSIDL_APPDATA"
"CSIDL_COMMON_STARTMENU"
"CSIDL_STARTMENU"
"CSIDL_COMMON_DESKTOPDIRECTORY"
"CSIDL_DESKTOPDIRECTORY"
"CSIDL_COMMON_STARTUP"
"CSIDL_STARTUP"
"CSIDL_COMMON_PROGRAMS"
"CSIDL_PROGRAMS"
"CSIDL_FONTS"
```

If the folder cannot be retrieved, **OSError** is raised.

Which folders are available depends on the exact Windows version, and probably also the configuration. For details refer to Microsoft's documentation of the SHGetSpecialFolderPath() function.

**create_shortcut**(target, description, filename[, arguments[, workdir[, iconpath[, iconindex]]]]])

This function creates a shortcut. *target* is the path to the program to be started by the shortcut. *description* is the description of the shortcut. *filename* is the title of the shortcut that the user will see. *arguments* specifies the command line arguments, if any. *workdir* is the working directory for the program. *iconpath* is the file containing
the icon for the shortcut, and \textit{iconindex} is the index of the icon in the file \textit{iconpath}. Again, for details consult the Microsoft documentation for the IShellLink interface.
5.4. Vista User Access Control (UAC)

Starting with Python 2.6, bdist_wininst supports a \textit{--user-access-control} option. The default is ‘none’ (meaning no UAC handling is done), and other valid values are ‘auto’ (meaning prompt for UAC elevation if Python was installed for all users) and ‘force’ (meaning always prompt for elevation).
6. The Python Package Index (PyPI)

The Python Package Index (PyPI) holds meta-data describing distributions packaged with distutils, as well as package data like distribution files if the package author wishes.

Distutils exposes two commands for submitting package data to PyPI: the register command for submitting meta-data to PyPI and the upload command for submitting distribution files. Both commands read configuration data from a special file called the .pypirc file. PyPI displays a home page for each package created from the long_description submitted by the register command.
6.1. Registering Packages

The distutils command register is used to submit your distribution’s meta-data to the index. It is invoked as follows:

```
python setup.py register
```

Distutils will respond with the following prompt:

```
running register
We need to know who you are, so please choose either
  1. use your existing login,
  2. register as a new user,
  3. have the server generate a new password for you
  4. quit
Your selection [default 1]:
```

Note: if your username and password are saved locally, you will not see this menu.

If you have not registered with PyPI, then you will need to do so now. You should choose option 2, and enter your details as required. Soon after submitting your details, you will receive an email which will be used to confirm your registration.

Once you are registered, you may choose option 1 from the menu. You will be prompted for your PyPI username and password, and register will then submit your meta-data to the index.

You may submit any number of versions of your distribution to the index. If you alter the meta-data for a particular version, you may submit it again and the index will be updated.
PyPI holds a record for each (name, version) combination submitted. The first user to submit information for a given name is designated the Owner of that name. They may submit changes through the `register` command or through the web interface. They may also designate other users as Owners or Maintainers. Maintainers may edit the package information, but not designate other Owners or Maintainers.

By default PyPI displays only the newest version of a given package. The web interface lets one change this default behavior and manually select which versions to display and hide.
6.2. Uploading Packages

The distutils command **upload** pushes the distribution files to PyPI.

The command is invoked immediately after building one or more distribution files. For example, the command

```
python setup.py sdist bdist_wininst upload
```

will cause the source distribution and the Windows installer to be uploaded to PyPI. Note that these will be uploaded even if they are built using an earlier invocation of `setup.py`, but that only distributions named on the command line for the invocation including the `upload` command are uploaded.

The **upload** command uses the username, password, and repository URL from the `$HOME/.pypirc` file (see section *The .pypirc file* for more on this file). If a **register** command was previously called in the same command, and if the password was entered in the prompt, **upload** will reuse the entered password. This is useful if you do not want to store a clear text password in the `$HOME/.pypirc` file.

You can specify another PyPI server with the **--repository=url** option:

```
python setup.py sdist bdist_wininst upload -r http://example.com
```

See section *The .pypirc file* for more on defining several servers.

You can use the **--sign** option to tell **upload** to sign each uploaded file using GPG (GNU Privacy Guard). The **gpg** program must be available for execution on the system PATH. You can also specify
which key to use for signing using the `--identity=name` option.

Other **upload** options include `--repository=url` or `--repository=section` where *url* is the url of the server and *section* the name of the section in `$HOME/.pypirc`, and `--show-response` (which displays the full response text from the PyPI server for help in debugging upload problems).
6.3. The `.pypirc` file

The format of the `.pypirc` file is as follows:

```plaintext
[distutils]
index-servers = pypi

[pypi]
repository: <repository-url>
username: <username>
password: <password>
```

The `distutils` section defines a `index-servers` variable that lists the name of all sections describing a repository.

Each section describing a repository defines three variables:

- `repository`, that defines the url of the PyPI server. Defaults to `http://www.python.org/pypi`.
- `username`, which is the registered username on the PyPI server.
- `password`, that will be used to authenticate. If omitted the user will be prompt to type it when needed.

If you want to define another server a new section can be created and listed in the `index-servers` variable:

```plaintext
[distutils]
index-servers = pypi
other
```
[pypi]
repository: <repository-url>
username: <username>
password: <password>

[other]
repository: http://example.com/pypi
username: <username>
password: <password>

**register** can then be called with the -r option to point the repository to work with:

```
python setup.py register -r http://example.com/pypi
```

For convenience, the name of the section that describes the repository may also be used:

```
python setup.py register -r other
```
6.4. PyPI package display

The `long_description` field plays a special role at PyPI. It is used by the server to display a home page for the registered package.

If you use the `reStructuredText` syntax for this field, PyPI will parse it and display an HTML output for the package home page.

The `long_description` field can be attached to a text file located in the package:

```python
from distutils.core import setup

with open('README.txt') as file:
    long_description = file.read()

setup(name='Distutils',
      long_description=long_description)
```

In that case, `README.txt` is a regular reStructuredText text file located in the root of the package besides `setup.py`.

To prevent registering broken reStructuredText content, you can use the `rst2html` program that is provided by the docutils package and check the `long_description` from the command line:

```
$ python setup.py --long-description | rst2html.py > output.html
```

docutils will display a warning if there's something wrong with your syntax. Because PyPI applies additional checks (e.g. by passing `--no-raw` to `rst2html.py` in the command above), being able to run the command above without warnings does not guarantee that PyPI
will convert the content successfully.
7. Examples

This chapter provides a number of basic examples to help get started with distutils. Additional information about using distutils can be found in the Distutils Cookbook.

See also:

Distutils Cookbook
    Collection of recipes showing how to achieve more control over distutils.
7.1. Pure Python distribution (by module)

If you’re just distributing a couple of modules, especially if they don’t live in a particular package, you can specify them individually using the `py_modules` option in the setup script.

In the simplest case, you’ll have two files to worry about: a setup script and the single module you’re distributing, `foo.py` in this example:

```
<root>/
    setup.py
    foo.py
```

(In all diagrams in this section, `<root>` will refer to the distribution root directory.) A minimal setup script to describe this situation would be:

```python
from distutils.core import setup
setup(name='foo',
      version='1.0',
      py_modules=['foo'],
)
```

Note that the name of the distribution is specified independently with the `name` option, and there’s no rule that says it has to be the same as the name of the sole module in the distribution (although that’s probably a good convention to follow). However, the distribution name is used to generate filenames, so you should stick to letters, digits, underscores, and hyphens.

Since `py_modules` is a list, you can of course specify multiple modules, e.g. if you’re distributing modules `foo` and `bar`, your setup might look like this:
and the setup script might be

```python
from distutils.core import setup
setup(name='foobar',
      version='1.0',
      py_modules=['foo', 'bar'],
)
```

You can put module source files into another directory, but if you have enough modules to do that, it's probably easier to specify modules by package rather than listing them individually.
7.2. Pure Python distribution (by package)

If you have more than a couple of modules to distribute, especially if they are in multiple packages, it's probably easier to specify whole packages rather than individual modules. This works even if your modules are not in a package; you can just tell the Distutils to process modules from the root package, and that works the same as any other package (except that you don't have to have an `__init__.py` file).

The setup script from the last example could also be written as

```python
from distutils.core import setup
setup(name='foobar',
      version='1.0',
      packages=[''],
)
```

(The empty string stands for the root package.)

If those two files are moved into a subdirectory, but remain in the root package, e.g.:

```
<root>/
    setup.py
    src/     foo.py
             bar.py
```

then you would still specify the root package, but you have to tell the Distutils where source files in the root package live:

```python
from distutils.core import setup
setup(name='foobar',
      version='1.0',
      package_dir={'' : 'src'},
```
More typically, though, you will want to distribute multiple modules in the same package (or in sub-packages). For example, if the foo and bar modules belong in package foobar, one way to layout your source tree is

```python
from distutils.core import setup
setup(name='foobar',
      version='1.0',
      packages=['foobar'],
)
```

If you want to put modules in directories not named for their package, then you need to use the `package_dir` option again. For example, if the `src` directory holds modules in the foobar package:

```python
from distutils.core import setup
setup(name='foobar',
      version='1.0',
      package_dir={'foobar': 'src'},
      packages=['foobar'],
)
```
an appropriate setup script would be

```python
from distutils.core import setup
setup(name='foobar',
      version='1.0',
      package_dir={'foobar': 'src'},
      packages=['foobar'],
)
```

Or, you might put modules from your main package right in the distribution root:

```
<root>/
  setup.py
  __init__.py
  foo.py
  bar.py
```

in which case your setup script would be

```python
from distutils.core import setup
setup(name='foobar',
      version='1.0',
      package_dir={'foobar': ''},
      packages=['foobar'],
)
```

(The empty string also stands for the current directory.)

If you have sub-packages, they must be explicitly listed in `packages`, but any entries in `package_dir` automatically extend to sub-packages. (In other words, the Distutils does *not* scan your source tree, trying to figure out which directories correspond to Python packages by looking for `__init__.py` files.) Thus, if the default layout grows a sub-package:

```python
from distutils.core import setup
setup(name='foobar',
      version='1.0',
      package_dir={'foobar': 'sub'},
      packages=['foobar', 'sub.foobar'],
)
```
then the corresponding setup script would be

```python
from distutils.core import setup
setup(name='foobar',
      version='1.0',
      packages=['foobar', 'foobar.subfoo'],
)
```

(Again, the empty string in `package_dir` stands for the current directory.)
7.3. Single extension module

Extension modules are specified using the `ext_modules` option. `package_dir` has no effect on where extension source files are found; it only affects the source for pure Python modules. The simplest case, a single extension module in a single C source file, is:

```python
<root>/
    setup.py
    foo.c
```

If the `foo` extension belongs in the root package, the setup script for this could be

```python
from distutils.core import setup
from distutils.extension import Extension
setup(name='foobar',
      version='1.0',
      ext_modules=[Extension('foo', ['foo.c'])],
)
```

If the extension actually belongs in a package, say `foopkg`, then

With exactly the same source tree layout, this extension can be put in the `foopkg` package simply by changing the name of the extension:

```python
from distutils.core import setup
from distutils.extension import Extension
setup(name='foobar',
      version='1.0',
      ext_modules=[Extension('foopkg.foo', ['foo.c'])]
)
7.4. Checking a package

The check command allows you to verify if your package meta-data meet the minimum requirements to build a distribution.

To run it, just call it using your `setup.py` script. If something is missing, the `check` command will display a warning.

Let's take an example with a simple script:

```python
from distutils.core import setup

setup(name='foobar')
```

Running the `check` command will display some warnings:

```
$ python setup.py check
running check
warning: check: missing required meta-data: version,
warning: check: missing meta-data: either (author and
    (maintainer and maintainor_email) must be supplied
```

If you use the reStructuredText syntax in the `long_description` field and `docutils` is installed you can check if the syntax is fine with the `check` command, using the `restructuredtext` option.

For example, if the `setup.py` script is changed like this:

```python
from distutils.core import setup

desc = """
My description
"""
```

This is the description of the ``foobar`` package. ""

```python
setup(name='foobar', version='1', author='tarek',
    author_email='tarek@ziade.org',
    url='http://example.com', long_description=desc)
```

Where the long description is broken, check will be able to detect it by using the docutils parser:

```
$ python setup.py check --restructuredtext
running check
warning: check: Title underline too short. (line 2)
warning: check: Could not finish the parsing.
```
7.5. Reading the metadata

The `distutils.core.setup()` function provides a command-line interface that allows you to query the metadata fields of a project through the `setup.py` script of a given project:

```
$ python setup.py --name
distribute
```

This call reads the `name` metadata by running the `distutils.core.setup()` function. Although, when a source or binary distribution is created with Distutils, the metadata fields are written in a static file called `PKG-INFO`. When a Distutils-based project is installed in Python, the `PKG-INFO` file is copied alongside the modules and packages of the distribution under `NAME-VERSION-pyX.X.egg-info`, where `NAME` is the name of the project, `VERSION` its version as defined in the Metadata, and `pyX.X` the major and minor version of Python like 2.7 or 3.2.

You can read back this static file, by using the `distutils.dist.DistributionMetadata` class and its `read_pkg_file()` method:

```
>>> from distutils.dist import DistributionMetadata
>>> metadata = DistributionMetadata()
>>> metadata.read_pkg_file(open('distribute-0.6.8-py2.7.egg-info'))
>>> metadata.name
'distribute'
>>> metadata.version
'0.6.8'
>>> metadata.description
'Easily download, build, install, upgrade, and uninstall Python packages'
```
Notice that the class can also be instanciated with a metadata file path to loads its values:

```python
>>> pkg_info_path = 'distribute-0.6.8-py2.7.egg-info'
>>> DistributionMetadata(pkg_info_path).name
'distribute'
```
